Abstract

Bipolar disorder (BD) impacts over 40 million people around the world, often manifesting in early adulthood and substantially impacting the quality of life and functioning of individuals. Although early interventions are associated with a better prognosis, the early detection of BD is challenging given the high degree of similarity with other psychiatric conditions, including major depressive disorder, which corroborates the high rates of misdiagnosis. Further, BD has a chronic, relapsing course, and the majority of patients will go on to experience mood relapses despite pharmacological treatment. Digital technologies present promising results to augment early detection of symptoms and enhance BD treatment. In this editorial, we will discuss current findings on the use of digital technologies in the field of BD, while debating the challenges associated with their implementation in clinical practice and the future directions.

KEYWORDS

bipolar disorder; digital phenotyping; machine learning; mobile health interventions; mobile health; mHealth; apps

Introduction

Bipolar disorder (BD) is a chronic and recurrent mental illness that affects 2.4% of the worldwide population [1]. BD usually manifests in early adulthood, with the median age at onset found to be 33 years of age and a peak age at onset of 19.5 years of age [2]. BD presents a profound negative impact on individuals' lives with high rates of disability [3]. According to the Global Burden of Disease Study (2019), BD is the 12th leading cause of years lived with disability among young adults aged between 15 to 24 years [4].

Digital health technologies have been studied in the context of BD and are showing promising results in the early detection of the disorder [5,6] and depressive or manic episodes among individuals with the disorder [7], as well as the promotion of a better prognosis [8,9]. To understand this progress, we will review 3 promising and innovative areas of work (Figure 1). In this editorial, we will discuss the role of (1) machine learning techniques, (2) digital phenotyping, and (3) mobile health (mHealth) apps to enhance BD care. Additionally, the challenges and future directions for the implementation of digital health technologies in BD will be considered.

Figure 1. Digital tools for BD: key developments and future directions. BD: bipolar disorder; ML: machine learning.

Early Detection of BD and Reducing Misdiagnosis: Insights From Machine Learning Studies

A potential contributor to the disease burden in BD is the delay in obtaining an accurate diagnosis, which consequently delays the appropriate management and treatment of the disorder. A recent systematic review showed that the median delay in help seeking was 3.5 years, the median delay in diagnosis was 6.7 years, and the median duration of untreated BD was 5.9 years [10]. Another recent study found that the rate of misdiagnosis in BD was 76.8%, and most of those cases received a misdiagnosis of major depressive disorder (MDD) [11]. Despite the similarities in the clinical presentation of a depressive episode in MDD and BD, the treatment strategies recommended for each disorder are different, with antidepressants being the main pharmacological strategy in MDD [12] and mood stabilizers being recommended for BD [13]. Thus, having strategies for the early detection of BD is crucial to reduce the misdiagnosis rates and to provide the proper treatment early in the course of the disorder. In this section, we will be describing some machine learning studies aimed at (1) predicting mood disorder misdiagnosis, (2) predicting BD onset, and (3) differentiating BD from unipolar disorder. Finally, we will discuss the challenges of translating these findings into clinical practice.

A scoping review aimed at investigating the use of machine learning techniques for the detection of BD found that the majority of the studies used classification models (eg, random forest), included a sample size of fewer than 300 individuals, and included clinical data in the model [5]. The potential of new machine learning methods to better understand factors associated with misdiagnosis was exemplified in a recent study that reported a misdiagnosis rate of 50.97% [14]. In this study, any mismatch between the self-reported diagnosis and the clinical interview diagnosis was considered a misdiagnosis. The investigators used machine learning techniques to identify the

predictors of misdiagnosis, and the mean accuracy of the predictive model was 70% [14]. This study showed that more severe depressive symptoms and unstable self-image were the strongest predictors of mood disorder misdiagnosis among the 1045 variables evaluated [14]. These results may be explained by the fact that patients usually seek treatment when they are severely depressed and that they may be underreporting hypomanic symptoms during a severe depressive episode. Consequently, they might be misdiagnosed with major depression instead of receiving the correct diagnosis of BD.

Another recent study highlights how a correct diagnosis may be made earlier. The clinical predictors of BD were described in a large birth cohort study, including 3748 subjects assessed at birth and 11, 15, 18, and 22 years of age [6]. The study used machine learning techniques and showed that the presence of suicide risk, generalized anxiety disorder, parental physical abuse, and financial problems at 18 years of age were the strongest predictors for a BD diagnosis at 22 years of age, with a balanced accuracy of 75% [6]. Additionally, the high-risk subgroup of BD showed a high frequency of drug use and depressive symptoms [6].

Several machine learning studies used digital phenotyping to classify BD and unipolar disorder [15,16]. In one study, daily smartphone-based self-assessments of mood and same-time passively collected smartphone data on smartphone usage were assessed for 6 months [15]. The main findings indicate that patients with BD, in an euthymic state, had a lower number of incoming phone calls per day compared to patients with unipolar depression also experiencing euthymia. In addition, during depressive states, patients with BD had a lower number of incoming and outgoing phone calls per day as compared with patients with unipolar depression [15]. BD was classified with an area under the curve (AUC) of 0.84 (overall; when mood state was not taken into consideration), 0.86 (during a depressive state), and 0.87 (during a euthymic state) in this study. However, when applying the leave-one-out cross-validation approach, the AUC for all models reduced (AUC=0.48 for the overall model, AUC=0.42 for the depressive state model, and AUC=0.46 for

the euthymic state model), indicating that changes in combined smartphone-based data were highly individual [15]. Another digital phenotyping study using the mindLAMP app to collect geolocation, accelerometer, and screen/state reported an AUC of 0.62 for classifying patients with MDD or Bipolar I/II disorders [16].

The differing results noted above are common in machine learning research, especially where the underlying data and technology differ between studies. A task force discussing the scientific literature related to machine learning and big data-based studies showed that machine learning studies have included a variety of data to predict BD, including neuroimaging, genetics, electroencephalogram, neurophysiological data, blood biomarkers, text, facial expressions, speech, and ecological momentary assessments [17]. The task force emphasized that some limitations should be addressed to allow these findings to be translated to clinical practice, in particular the lack of external validation of the predictive models [17].

Digital Phenotyping to Detect Mood Symptoms and Mood Episodes in BD

The development of digital phenotyping is quickly evolving and expanding in the field of BD. Digital phenotyping involves collecting data (eg, location, activity, sleep, speech patterns), typically from smartphones, to monitor behavior, cognition, and mood [18]. Digital phenotyping may help facilitate the early detection of potentially problematic mood changes, therefore facilitating early intervention. Before digital phenotyping can be applied in usual care for BD, we must develop an understanding of which of the multitude of digital data collected by smartphones and wearable sensors can reliably and validly detect early warning signs of mood episodes. Importantly, while several studies have shown that digital phenotyping is a promising technique, it faces several challenges that need to be robustly addressed [19], which will be discussed in this section.

A systematic review describing the evidence about the use of portable digital tools for detecting BD, mood states, and mood symptoms found 62 studies assessing it in terms of four main areas: (1) smartphone apps designed to collect active (eg, mood self-assessments) or passive (eg, recording geolocation, step counts, call and text logs, sleep, etc) data; (2) wearable sensors for the monitoring of electrocardiography and actigraphy; (3) audio-visual recordings for the analysis of speech or facial expressions and upper body movements; and (4) multimodal tools, combining 2 or more of the above [7]. Two-thirds of the studies included applied machine learning approaches to classify BD versus healthy controls, to identify mood states, or to predict the severity of symptoms. They achieved mixed results, yielding fair to excellent classification performances, with accuracy globally ranging from 60% to 97% [7]. A recent review assessing the application of digital tools for major depressive episodes described the following digital phenotype for BD: (1) speech alterations during a depressive episode, including decreased speech pause and reduced fundamental frequency, while these speech features were increased during a hypomanic episode; (2) irrespective of the mood state, heart rate variability

was reduced, but the change in heart rate variability in the interepisodic phases remained unclear, and (3) an electrodermal hypoactivity in a depressive episode was reported, which increased when patients were euthymic [20].

Regarding the challenges related to digital phenotyping, it is important to note that any data collected using digital devices is prone to bias and needs to be standardized to ensure accuracy not only across populations but also across different devices. Moreover, concerns relating to privacy, ethics, data security, and consent must be addressed. User comfort in sharing data differs depending on the data type (eg, users are more comfortable sharing health data than personal data such as location, communication logs, and social activity) and the recipient (eg, users have greater comfort sharing data directly with clinicians than having this entered into their electronic health record), and this may impact willingness to use digital phenotyping platforms [21]. As user engagement is essential for the success of any digital phenotyping tools [22], it is necessary to account for discrepancies in access, equity, and distribution of resources. Finally, more in-depth longitudinal studies are required to ascertain the relationship between biomarkers and long-term outcomes of health and well-being.

Smartphone-Based Interventions for BD

Psychosocial therapies and education in self-management strategies can improve outcomes in BD [23] and are recommended complements to pharmacological interventions in guidelines for BD treatment. However, access to these forms of care remains suboptimal, with less than 50% of individuals in treatment for BD receiving therapy with a psychologist, social worker, or self-help support group [24]. Smartphone apps have the potential to provide psychoeducation and facilitate several of the core components of psychosocial therapies (eg, self-monitoring, detecting and responding to mood episodes, stabilizing daily routines, improving emotion regulation, encouraging medication adherence, etc) [25]. Encouragingly, individuals with BD report high levels of access to smartphones and a willingness to receive psychosocial interventions via apps [26,27]. Several app-facilitated interventions have been developed and evaluated for BD, variously integrating self-monitoring, psychoeducation, cognitive-behavior therapy, and skills training, and targeting both symptoms and patient-valued outcomes such as functioning and quality of life [9]. However, evidence for their feasibility and efficacy is still preliminary, and interventions are yet to fully leverage the capabilities of apps for intervention personalization.

Two recent systematic reviews and meta-analyses investigated the role of smartphone-based interventions to improve clinical outcomes in BD and found conflicting results [8,9]. Liu et al [8] included 10 studies in their systematic review (7 randomized controlled trials and 3 single-arm trials) and concluded that smartphone-based interventions were effective in reducing manic and depressive symptoms in between-group (compared to controls) and within-group (comparing symptoms from baseline to postintervention in the intervention group). Anmella et al [9] included 13 studies in their qualitative synthesis of the findings and 5 studies in their meta-analysis. The meta-analyses

comparing the pre-post change in depressive and (hypo)manic symptom severity, functioning, quality of life, and perceived stress between smartphone interventions and controls did not reach statistical significance for any outcome assessed [9]. The potential explanation for the conflicting findings is that the eligibility criteria were different between both studies. The most important difference is the fact that Liu et al [8] included not only smartphone-based apps but also phone calls from specialists to facilitate therapy and website interventions in the intervention group, while Anmella et al [9] excluded interventions not delivered through smartphones (eg, exclusive of phone calls, phone messaging, only SMS text messaging, or computer-delivered interventions) from the intervention group. Another difference between both studies is that Liu et al [8] did not restrict the inclusion criteria to individuals with BD and included a few studies that recruited a more heterogeneous population (eg, serious mental illness, mood disorders), while Anmella et al [9] only included studies where the participants were diagnosed with BD.

Given the heterogeneity of BD both between and within individuals, effective psychotherapy involves appropriately tailoring intervention content and delivery to the challenges and goals of a specific individual at a specific time. However, apps are yet to fully capitalize on the potential of smartphones to personalize intervention delivery in response to changes in clinical state. One app program, SIMPLE, personalizes content using ecological momentary assessment to identify potential prodromal mood changes and adapts the delivery of psychoeducation messages in response [28,29]. To advance our understanding of how to tailor just-in-time adaptive interventions for BD, microrandomized trials can be used to evaluate the immediate impact of diverse types of intervention prompts. For example, an evaluation of mobile acceptance and commitment therapy used this trial design to evaluate different categories of intervention and found that awareness-focused prompts paradoxically increased symptoms [30]. Beyond the clinical utility of personalization, this feature is also highly prioritized by individuals with BD themselves [31], who have expressed a desire for apps that make meaningful use of their data to customize intervention delivery and facilitate proactive support.

Improving the Dissemination and Uptake of Apps for BD

Although research-led studies have developed and evaluated mobile apps for BD, the dissemination and uptake of these apps in real-world contexts must be considered to reach the target population and maximize their impact. A recent web-based survey investigating the use of mobile apps to support mood and sleep self-management among individuals with BD found that 41.6% of participants reported using a self-management app related to mood and/or sleep [32]. The most nominated app for mood monitoring was Daylio, and the most reported app for sleep monitoring was Fitbit. Since these apps are designed to support the public with well-being concerns, this raises questions about why apps specifically designed for BD are not reaching this population. Two possibilities emerge: (1) apps designed for BD are not sufficiently acceptable or engaging in the eyes

of the target audience and (2) individuals with BD may not be adequately supported to select the app that is best suited to their needs. To facilitate research-led apps reaching and impacting users with BD, we must consider their ability to create and sustain user engagement. Further, we must consider effective dissemination pathways, targeting both patients and the health care providers involved in the provision of care to people with BD (eg, clinicians, nurses, allied health professionals, and case managers).

Poor engagement is endemic to mental health apps in general, extending beyond just those aimed at BD [33], with most users of publicly available apps disengaging within 30 days. Specific to BD, a systematic review showed that adherence data in research trials was infrequently reported; of the 13 studies providing engagement data, the activity rate ranged from 58% to 91% [34]. The failure to consider the needs and goals of the targeted population likely contributes to startlingly poor levels of uptake and adherence. Involving users in the design of apps can help ensure their design, content, and feature selection are relevant, acceptable, and engaging. However, a recent review investigated the level of user involvement in the design of self-monitoring apps for BD [35] and found that 36% of the apps did not mention user involvement in the design, while 9% reported low, 36% reported medium, and 18% reported high user involvement. This review highlights the importance of including an appropriate sample size capable of adequately capturing users' needs so that technology can be better designed. Finally, it is recommended that users are involved early in the design process, and their involvement should not be limited solely to the design but also to all aspects of the research, ensuring end-to-end involvement. Case studies of apps using a co-design framework include the quality of life-focused LiveWell and PolarUs apps, both of which consulted people with BD throughout development [36,37]. Figure 2 depicts 2 screens from the PolarUs app: on the home screen (left image), users are prompted to engage in quality of life, sleep, and mood self-monitoring, and are provided with relevant resources [37]. Users can review their self-monitoring data over time (right image). Individuals with BD provided input into the app design (including icons, color scheme, and layout), navigation, features, and content.

Looking ahead, as more apps for BD are developed and made available to the public, patients with BD and health care providers will likely require support to navigate the digital health landscape, as research-led apps will compete for attention with commercial offerings that may have limitations in their privacy protections and efficacy [38]. Educational interventions to enhance digital health literacy may help individuals with BD to select the appropriate apps for their self-management goals. While in general, levels of digital health literacy are comparable for people with BD to the general population, a study found that individuals with BD who are younger, have completed less education, or are less familiar with mental health apps may require extra support to safely and productively navigate web-based health resources [39]. Recent steps have been taken to address the needs of these groups: a brief, informational video describing strategies to select safe, effective, and engaging mental health apps for BD was created [40], incorporating the

perspectives of people with lived experience in the script and design. A still image from this video is presented in Figure 3 [40]. This resource was later expanded upon to create a web-based module [41], depicted in Figure 4, which contains additional information and resources to support people in evaluating app privacy policies, inclusion of evidence-based strategies for BD, and motivational techniques. Other resources like mindapps.org can help facilitate informed decision-making about mental health apps [38].

Health care providers are an important source of information and advice on smartphone apps, yet a web survey found that only 48.8% of health care providers reported discussing or

recommending health apps to patients with BD [42]. Most of the apps recommended were related to core symptoms of BD, including mood and sleep. Among the health care providers who did not discuss health apps with patients with BD (51.2%), the predominant reason mentioned was the lack of familiarity with credible and suitable apps tailored for BD. The resources discussed above are also appropriate for use by clinicians wishing to learn more about appropriate and effective apps for BD [38,41]. These findings emphasize the importance of providing training aimed at increasing clinician self-efficacy in using mobile apps with patients, a strategy that should be considered by researchers developing new mHealth tools.

Conclusion

The evidence available to date indicates that digital technologies may help in the early detection of BD and mood episodes, as well as in enhancing treatment, improving health outcomes and consequently promoting a better prognosis for individuals with BD. However, there are important limitations that need to be addressed before these technologies can be translated to clinical practice, including the following: (1) external validation of the machine learning models developed to date, (2) need for

well-designed prospective cohort studies to validate findings about digital phenotyping and early detection of BD and mood symptoms, (3) involvement of individuals with lived experience in the development of mobile apps, and (4) dissemination of the available technology among health care providers and directly to people with BD. Finally, adequately powered randomized controlled trials are still needed to evaluate the efficacy of mental health apps for BD. Additionally, there is a need to advance our understanding of how to tailor app-based interventions based on the valuable insights generated by digital phenotyping.

Abstract

Background: Information regarding opioid use disorder (OUD) status and severity is important for patient care. Clinical notes provide valuable information for detecting and characterizing problematic opioid use, necessitating development of natural language processing (NLP) tools, which in turn requires reliably labeled OUD-relevant text and understanding of documentation patterns.

Objective: To inform automated NLP methods, we aimed to develop and evaluate an annotation schema for characterizing OUD and its severity, and to document patterns of OUD-relevant information within clinical notes of heterogeneous patient cohorts.

Methods: We developed an annotation schema to characterize OUD severity based on criteria from the *Diagnostic and Statistical Manual of Mental Disorders, 5th edition*. In total, 2 annotators reviewed clinical notes from key encounters of 100 adult patients with varied evidence of OUD, including patients with and those without chronic pain, with and without medication treatment for OUD, and a control group. We completed annotations at the sentence level. We calculated severity scores based on annotation of note text with 18 classes aligned with criteria for OUD severity and determined positive predictive values for OUD severity.

Results: The annotation schema contained 27 classes. We annotated 1436 sentences from 82 patients; notes of 18 patients (11 of whom were controls) contained no relevant information. Interannotator agreement was above 70% for 11 of 15 batches of reviewed notes. Severity scores for control group patients were all 0. Among noncontrol patients, the mean severity score was 5.1 (SD 3.2), indicating moderate OUD, and the positive predictive value for detecting moderate or severe OUD was 0.71. Progress notes and notes from emergency department and outpatient settings contained the most and greatest diversity of information. Substance misuse and psychiatric classes were most prevalent and highly correlated across note types with high co-occurrence across patients.

Conclusions: Implementation of the annotation schema demonstrated strong potential for inferring OUD severity based on key information in a small set of clinical notes and highlighting where such information is documented. These advancements will facilitate NLP tool development to improve OUD prevention, diagnosis, and treatment.

Introduction

Background

Opioid use disorder (OUD), the problematic pattern of opioid use leading to clinically significant distress or impairment, has remained a significant public health burden for over 2 decades in the United States [1]. In 2021, over 9000 opioid-related overdose deaths involved heroin and nearly 17,000 involved a prescription opioid [2]. In 2021, overdose deaths involving any opioid exceeded 80,000, with 88% involving synthetic opioids like fentanyl. In addition to this significant loss of life, approximately 2.7 million people were diagnosed with OUD in 2021 [3], with the economic cost of the US opioid epidemic estimated to be over US \$1 trillion in 2017 [4].

OUD is a *Diagnostic and Statistical Manual of Mental Disorders, 5th edition* (DSM-5) clinical diagnosis with varying levels of severity (mild to severe) based on 11 diagnostic criteria endorsed for a given patient. Criteria include items that assess physiological and behavioral symptoms, as well as harmful health and social consequences of opioid use. Access to patients' OUD status and severity is valuable to patient care. For example, a clinician might use such information to inform their approach for helping manage a patient's pain (eg, whether to use opioid analgesics or the dose required). Information about OUD severity aids in clinical decision-making regarding appropriate treatment [5], such as determining whether a patient should be referred for psychotherapy versus an inpatient or outpatient treatment facility. OUD severity has also been proposed for use in measurement-based care to track indicators of disease and improved outcomes [6]. For these reasons, accurately identifying OUD status and severity holds crucial importance to the development of patient care strategies and clinical outcome prediction.

Detecting and Characterizing OUD in Electronic Health Records

Electronic health records (EHRs) include discrete fields containing information such as diagnostic labels or medication orders, as well as fields that contain free text from clinical notes, encounters, and laboratory testing. Numerous algorithms using diagnostic codes have been designed to address problematic opioid use, including identification of patients at risk for prescription opioid misuse [7], OUD prediction [8], nonmedical opioid use detection [9,10], identification of OUD [11], characterization of problematic opioid use [12], and overdose risk prediction [13]. However, the success of such algorithms is limited when diagnostic codes are minimally applied to patient charts. Information about substance use disorders may be missing from EHRs due to a variety of factors, including disjointed care across hospitals, lack of specialty diagnostic expertise, or stigma of a given diagnosis. Thus, OUD can be challenging to isolate within a patient's medical record [14,15]. Furthermore, most algorithms have been developed in the context of research focusing on patients with prescription opioid

misuse or chronic pain. Patients with chronic pain with opioid prescriptions are at increased risk for opioid misuse [16,17], but only focusing on such populations may exclude patient populations with illicit opioid use or otherwise outside of chronic pain treatment. Previous research indicates clinical notes provide a source of rich information that could improve efforts to identify and characterize OUD [12,18,19].

Importance of Annotation for Developing and Evaluating Natural Language Processing Tools

Natural language processing (NLP) tools have the potential to improve OUD detection and severity characterization, but many NLP frameworks require high quality data with reliably labeled OUD-related information. Common workflows for generating such a data set entail developing a schema (eg, containing classes [entities and events] and attributes [qualifiers]) representing OUD-related information, creating a codebook of instruction for the annotation process, conducting an agreement study to assess schema reliability, and facilitating consensus review of disagreements to generate a reference standard for benchmarking the NLP system [20]. Prior to these steps, it is imperative to understand how and where relevant information is documented in EHRs to inform data extraction and subsequent automation. Generally, this step is not well described in the scientific literature, nor are the documentation patterns of such information well characterized in studies. This step can be critical to informing intelligent search of EHRs and limiting the note types necessary for operationalizing the algorithm, thereby reducing computational effort and potentially improving accuracy. Although prior studies have used NLP to identify problematic opioid use from EHRs [21-26], few have described an annotation process and none have reported documentation patterns for OUD-relevant information within clinical notes.

Study Objectives

Our long-term goal is to develop an automated NLP method to identify OUD arising from prescription or illicit opioid use and characterize the severity of such use that can be used for future EHR-based studies to drive informatics solutions to improve the prevention, diagnosis, and treatment of OUD through clinical care. Toward this goal, we developed an annotation schema to characterize severity and documented patterns of OUD-relevant information. Using clinical notes of varying type and across encounter settings from a large integrated health system, we annotated OUD symptoms and other relevant information, comparing several heterogeneous cohorts—including patients with chronic pain, OUD diagnoses, and receiving medication treatment for OUD—to explore the following questions:

- How accurately can OUD severity be inferred from text from a small number of targeted clinical notes per patient?
- Where and how do clinical teams document OUD-related information, in terms of clinical note types and encounter settings?

- How is OUD-related information documented over time relative to an opioid- or OUD-specific health care encounter?
- What is the frequency of OUD-related concepts and their co-occurrence in clinical notes?

This information, along with the annotation schema developed and described in this study, may be useful in future development of NLP methods to identify and characterize the severity of OUD.

Methods

Study Design

We developed an annotation schema to identify patients with OUD stemming from either prescription or illicit opioid use and characterize OUD severity based on DSM-5 criteria. We applied the schema to deidentified clinical notes from patients with varying evidence of OUD and a comparison group with minimal exposure to opioid analgesics.

Ethical Considerations

The Geisinger Institutional Review Board and University of Pennsylvania reviewed and approved the protocol for this study (2021-0113).

Study Population

We obtained clinical notes from EHRs of 100 adult patients from Geisinger, a large integrated health system that serves a largely rural area of central and northeast Pennsylvania. We used stratified random sampling to select 20 individuals from each of 5 mutually exclusive groups, stratifying by sex and age categories (18-29, 30-39, 40-49, 50-59, and 60 years and older) to ensure diversity and equal representation in the data set. Study groups were selected from preexisting data sets used in prior studies [11,27,28] to represent various methods of identifying patients with likely or diagnosed OUD from EHRs and a control group (Textbox 1). Further, 2 groups represented chronic pain patients with (at least mild) OUD confirmed through chart review [27] and patient report as to whether their opioid use began with an opioid analgesic prescription (group CP-RX) or not (group CP-nonRX). In total, 2 groups had at least one OUD diagnostic code, but differed as to whether they had an order for medication treatment of OUD such as buprenorphine (group OUD-TX) or not (group OUD-DX). The control group had a single opioid analgesic order in their EHR. Diagnoses and orders used to define study groups occurred within this study's period of January 2012 to March 2020.

Textbox 1. Inclusion and exclusion criteria for each study group.

CP-RX

- Inclusion criteria:
 - Chronic pain: chronic pain was defined as having at least two opioid analgesic prescriptions for nonprogressive musculoskeletal pain.
 - Opioid use disorder (OUD; mild, moderate, or severe) confirmed through chart review.
 - Opioid use began with opioid analgesic prescription. Based on self-report in a survey question.
- Exclusion criteria:
 - Non-European ancestry: individuals with non-European ancestry were excluded because this study's sample was originally assembled for a genetic study.

CP-nonRX

- Inclusion criteria:
 - Chronic pain.
 - OUD (mild, moderate, or severe) confirmed through chart review.
 - Opioid use did not begin with opioid analgesic prescription. Based on self-report in a survey question.
- Exclusion criteria:
 - Non-European ancestry: individuals with non-European ancestry were excluded because this study's sample was originally assembled for a genetic study.

OUD-DX

- Inclusion criteria:
 - At least one diagnosis code for OUD. International Classification of Disease codes used to define OUD were based on Jennings et al [29].
- Exclusion criteria:
 - Chronic pain.
 - Order for medications for OUD including buprenorphine, buprenorphine-naloxone, and naltrexone. Geisinger providers did not prescribe methadone for OUD treatment.

OUD-TX

- Inclusion criteria:
 - At least one diagnosis code for OUD.
 - Order for medications for OUD.
- Exclusion criteria:
 - Chronic pain.

Control

- Inclusion criteria:
 - In total, 1 opioid analgesic order.
- Exclusion criteria:
 - Chronic pain.
 - Diagnosis code for OUD.
 - Order for medications for OUD.

Data Collection

We obtained notes from inpatient, outpatient, and emergency department (ED) encounters. In total, 11 note types were obtained, selected based on clinician input: outpatient clinic notes, progress notes, ancillary progress notes, history and progress (H&P) notes, discharge summaries, ED notes, ED provider notes, ED triage notes, ED support staff notes, communication notes, and lactation notes. We obtained notes for 3 encounter dates per patient: an index date representing either the first observed OUD diagnosis (for OUD-DX and OUD-TX groups and some patients in the CP-RX and CP-nonRX groups) or the most recent opioid analgesic order (for some patients in the CP-RX and CP-nonRX groups and all patients in the control group) and the encounters immediately prior to and following the index date. Multiple notes per patient were obtained for some encounter dates. Notes were deidentified using Philter [30].

Annotation Schema Development and Procedures

Schema development was based upon pilot work [18]. We revised the pilot schema to map classes onto DSM-5 criteria for characterizing OUD severity and to clarify or eliminate ambiguous concepts. We leveraged the extensible Human Oracle Suite of Tools, an open-source text tool [31] to annotate notes. In total, 2 authors (MNP and PJF) separately reviewed and annotated notes across 15 batches (batched by note type). Annotation was completed at the sentence level, assigning full sentences to one or more relevant classes. After each batch, the 2 reviewers adjudicated discordances through discussion, with other study team members providing input when discordances remained unresolved. We varied the note type annotated in consecutive batches to ensure portability of the schema across note types.

Severity Score

We calculated a severity score for each patient based on annotations in their notes. Scores used 18 of the annotation

schema classes, which mapped onto the DSM-5 criteria for characterizing OUD severity (Multimedia Appendix 1). The “crosswalk” between classes and DSM-5 criteria was based on a systematic chart review process developed by Palumbo et al [27] and adapted by Poulsen et al [11]. Scores ranged from 0 to 11. Severity was categorized based on DSM-5 guidelines (0-1=no OUD; 2-3=mild OUD; 4-5=moderate OUD; >6=severe OUD).

We calculated positive predictive values (PPVs) for detecting moderate or severe OUD among patients with annotations for the 4 study groups with likely or diagnosed OUD, and again for patients categorized into 2 groups based on their index encounter reason (OUD diagnosis or opioid analgesic order). PPVs were calculated as the number of patients with a severity score >4 divided by the total number of patients with annotations. We did not calculate PPVs separately for severity category (mild, moderate, and severe), as there was insufficient information in EHRs on which to base such a comparison. We also calculated PPVs among the full sample of patients (regardless of whether they had annotations), a more conservative quantification of the severity score’s validity that accounts for the lack of OUD-relevant information observed in the reviewed notes.

Results

Annotation of Clinical Notes

The annotation schema contained 27 classes, 12 of which included attributes (Figure 1; Multimedia Appendix 2). Interannotator agreement (IAA) for the 2 reviewers ranged from 20% to 100% across the 15 batches of reviewed notes but was above 70% for all except 4 batches (Figure 2). Lower IAA occurred with less frequently annotated classes and for classes with an attribute denoting a historic concept (eg, *psychiatric condition current vs historic*; IAA results not shown by class).

Figure 1. Annotation schema for characterizing OUD severity from clinical note text. OUD: opioid use disorder.

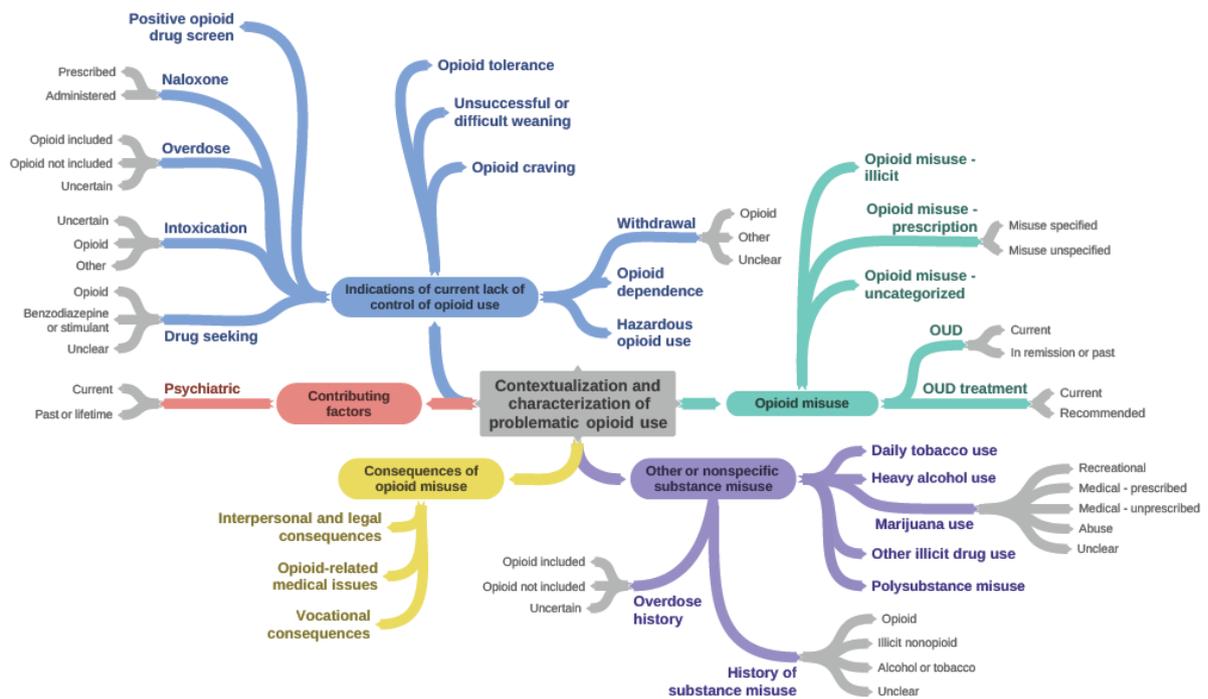

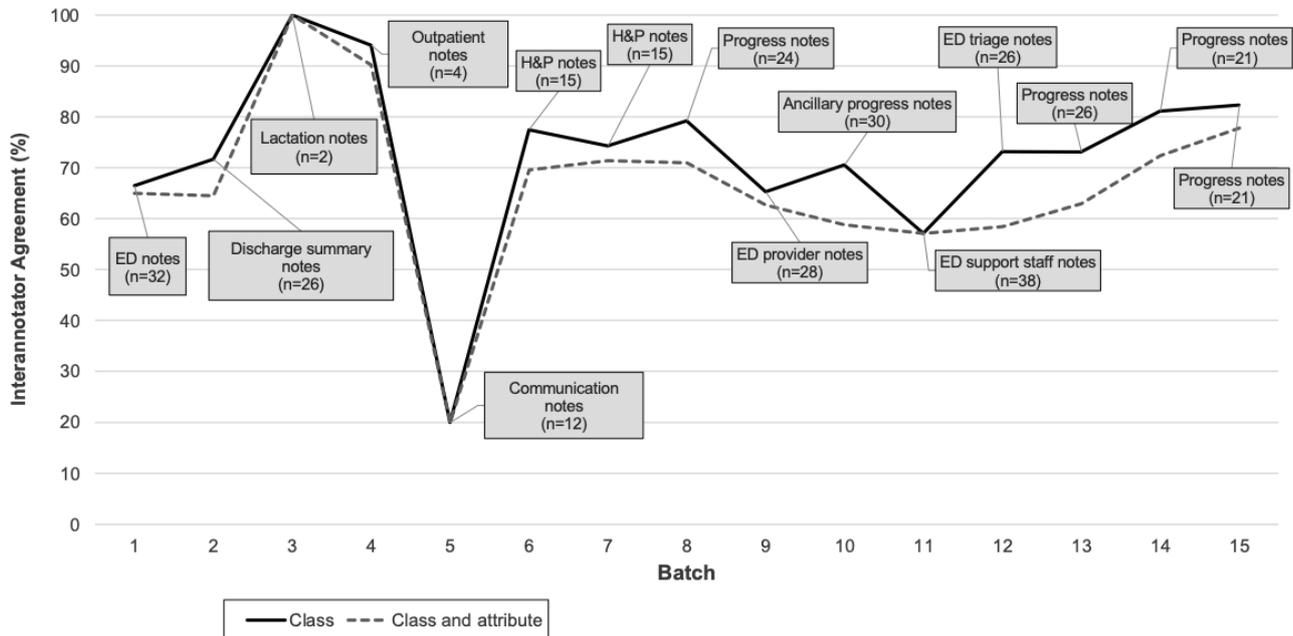

Figure 2. Interannotator agreement across batches of notes with note type and number of notes reviewed per batch. Each batch was a different note type. ED: emergency department; H&P: history and progress.

From the 100 sampled patients and 320 associated notes, we annotated 1436 sentences within 186 notes from 82 patients over 15 batches. The remaining notes did not yield any annotations (ie, they did not contain text relevant to the classification schema). Most patients without annotations were controls (11/18, 61%) and most had an index encounter based on an opioid analgesic order (16/18, 89%). They also had fewer

notes available (mean 1.8, SD 1.1) and no notes were from the inpatient setting.

Among the 4 noncontrol groups, 73 patients had annotations (Table 1). OUD-TX was the only group in which all 20 sampled patients had at least one note with text relevant for annotation and the group accounted for the largest proportion of annotations.

Table 1. Counts of patients, notes, and annotated sentences for each study group.

Study group	Count of patients with annotations, n (%)	Index encounter ^a		Count of notes with annotations, n (%)	Count of annotated sentences, n (%)
		None, n (%)	OUD ^b diagnosis, n (%)		
CP-RX	16 (20)	8 (50)	8 (50)	29 (16)	170 (12)
CP-nonRX	18 (22)	14 (78)	4 (22)	32 (18)	277 (19)

ODD-TX	20 (24)	20 (100)	0 (0)	61 (34)	602 (42)
Control	9 (11)	0 (0)	9 (100)	14 (8)	24 (2)

^aReason for selecting index encounter, either a diagnosis of OUD or an order for an opioid analgesic.

^bOUD: opioid use disorder.

Can Severity of Problematic Opioid Use Be Inferred From a Limited Number of Clinical Notes?

We used annotated classes to calculate severity scores for the 82 patients with annotations. All control group patients had a score of 0. The mean severity score among the 73 patients in noncontrol groups was 5.1 (SD 3.2). The majority (48/73, 66%) had a score >6 (indicating severe OUD), 4 of 73 (5%) had a

score of 4-5 (indicating moderate OUD), 2 of 73 (3%) had a score of 2 (indicating mild OUD), and 19 of 73 (26%) had a score of 0-1 (indicating no OUD). Severity scores were highest for the OUD-TX group and lowest for the CP-RX group (Table 2). The mean severity score among these 73 patients was 6.0 (SD 2.7) for those whose index encounter was selected based on an OUD diagnosis and 0.6 (1.7) for those with an index encounter based on an opioid analgesic order.

Table 2. Average OUD^a scores among 82 patients with annotated sentences.

Study group or index encounter reason ^b	Mean (SD) OUD score	Count of patients by OUD severity				PPVs ^c for moderate or severe OUD	
		None, n (%)	Mild, n (%)	Moderate, n (%)	Severe, n (%)	Patients with annotations	All sampled patients
CP-RX	3.4 (3.4)	8 (50)	0 (0)	1 (6)	7 (44)	0.50	0.40
CP-nonRX	4.5 (3.9)	7 (39)	0 (0)	1 (6)	10 (56)	0.61	0.55
ODD-DX	5.2 (2.5)	3 (16)	1 (5)	1 (5)	14 (74)	0.79	0.75
ODD-TX	6.8 (2.2)	1 (5)	1 (5)	1 (5)	17 (85)	0.90	0.90
Control	0.0 (0.0)	9 (100)	0 (0)	0 (0)	0 (0)	N/A ^d	N/A
OUD diagnosis	6.0 (2.7)	8 (13)	2 (3)	4 (7)	47 (77)	0.84	0.81
Opioid analgesic order	0.6 (1.7)	11 (92)	0 (0)	0 (0)	1 (1)	0.08	0.03

^aOUD: opioid use disorder.

^bReason for selecting index encounter, either an OUD diagnosis or an order for an opioid analgesic.

^cPPV: positive predictive value.

^dN/A: not applicable.

The PPV for detecting moderate or severe OUD among the 73 noncontrol group patients with annotations was 0.71. PPVs were highest for OUD-TX group at 0.90 (Table 2). At 0.84, the PPV for detecting moderate or severe OUD using the notes of patients whose index encounter was selected based on an OUD diagnosis was higher than patients whose index encounter was based on an opioid analgesic order (PPV=0.08).

The mean number of notes per patient that were reviewed and annotated differed slightly by degree of severity (Table 3), but these differences were not statistically significant (1-way ANOVA for mean number of notes reviewed: $F_{3,78}=0.60$; $P=.62$;

for mean number of notes annotated: $F_{3,56}=1.46$; $P=.24$). We observed no consistent patterns in the frequency of note types or encounter types by severity.

History of substance misuse was among the most prevalent classes across severity groups and was present in 56-126 (17%-38%) of the 332 notes (Table 3). For those with “no OUD,” the classes *psychiatric condition* and *daily tobacco use* were also common. The class *OUD treatment* automatically led to a classification of “severe OUD” and was present in 36 (16%) of the 226 notes among patients scored as “severe OUD.”

Table 3. Note characteristics by OUD^a severity among 100 sampled study patients with 332 notes.

Where Is OUD-Relevant Information Found in Clinical Notes and How Is it Documented Over Time?

Progress notes, the most common note type in the sample, had the largest total number of annotations, was among the highest yielding note types with an average of 9.3 annotations per note (SD 10.4), had the greatest diversity of classes represented, and was the only note type in which we observed the class *OUD*

(signifying a definitive OUD diagnosis; Figure 3; Table 4). However, progress notes had a lower proportion of notes with annotations compared to other note types. H&P notes had the largest proportion of notes with annotations, followed by discharge summaries, ED provider notes, and ED notes (Table 4). These 4 note types also represented a large diversity of classes.

Figure 3. Heatmap of class frequencies by note type. ED: emergency department; H&P: history and progress; OUD: opioid use disorder.

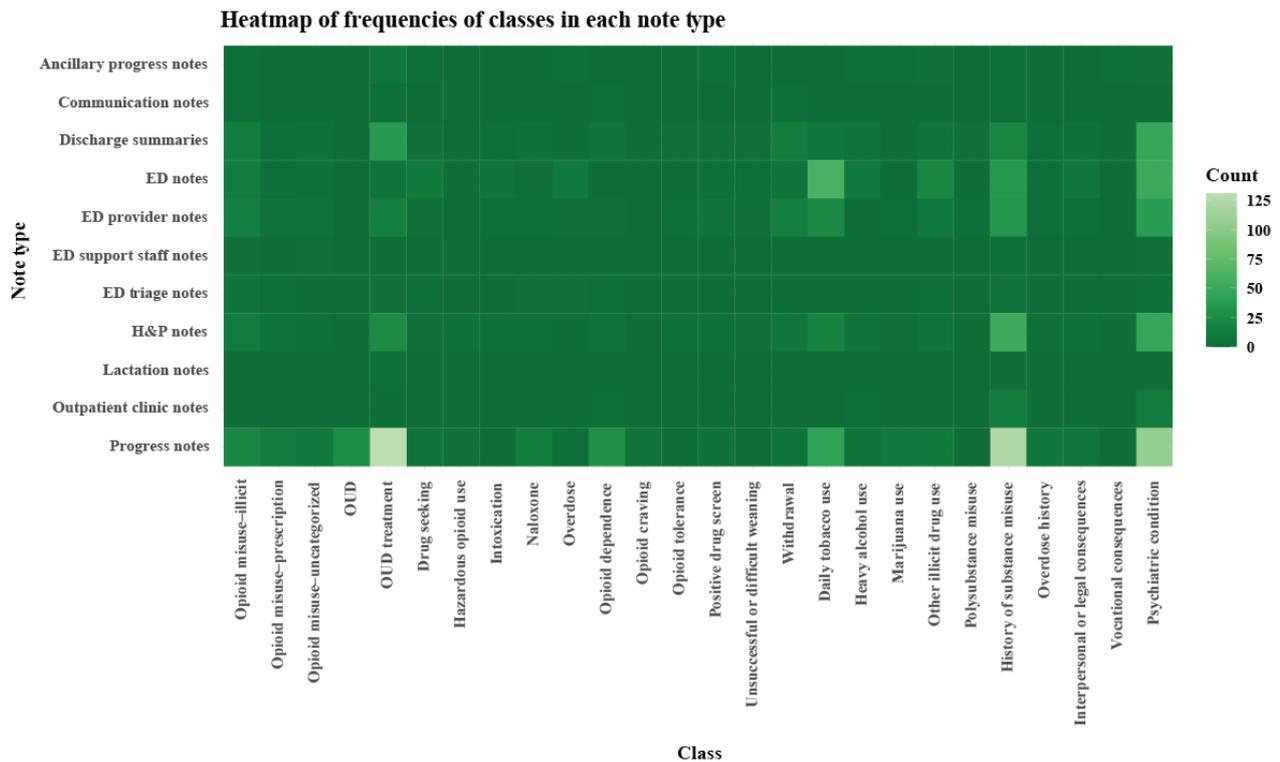

Table 4. Count of notes and annotated sentences by note type among the 1436 annotated sentences.

Note type	Number of notes	Number of notes with annotated sentences, n (%)	Counts of notes with annotated sentences by encounter setting (percentage of total)				Number of annotated sentences, n (%)	Mean (SD) number of annotated sentences per note

^aED: emergency department.

^bIPT: inpatient.

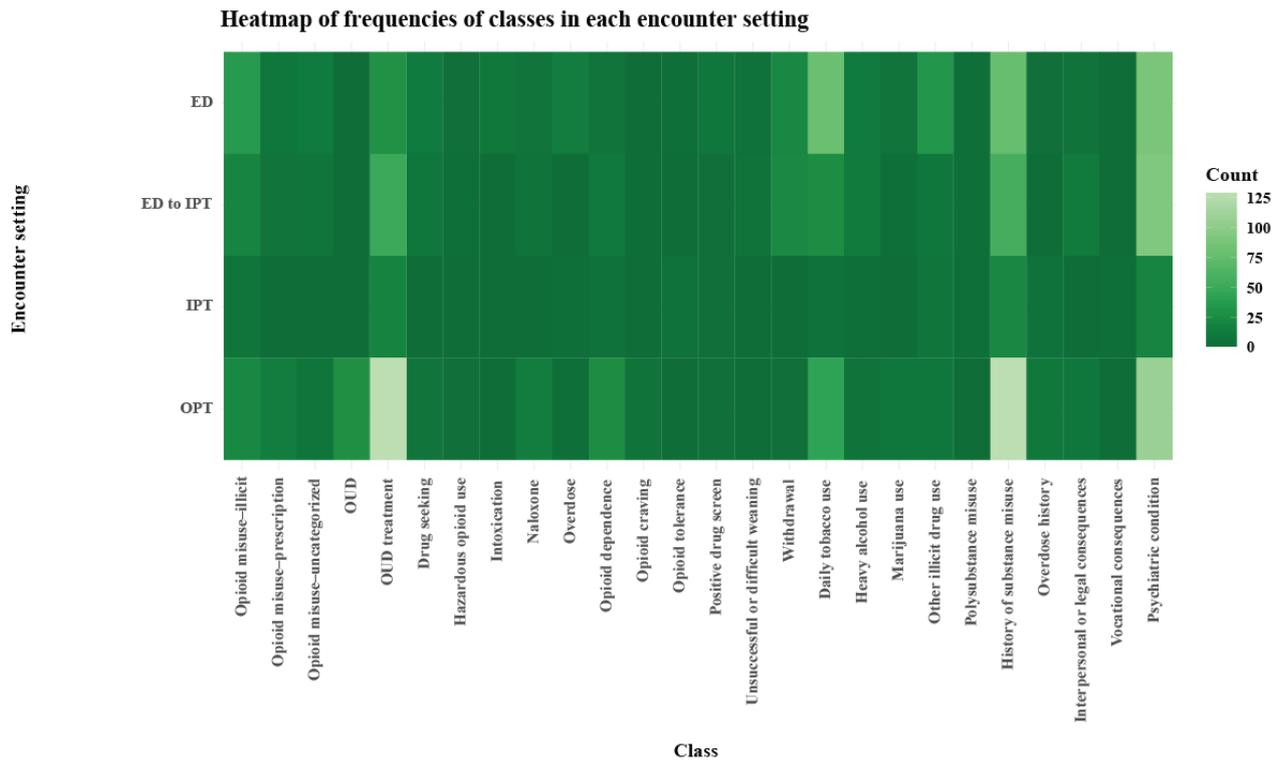

^cOPT: outpatient.

^dH&P: history and progress.

^eN/A: not applicable.

Regarding encounter type, compared to the inpatient setting, notes from ED and outpatient settings had the highest proportions of notes with annotations and a high diversity of classes represented (Figure 4).

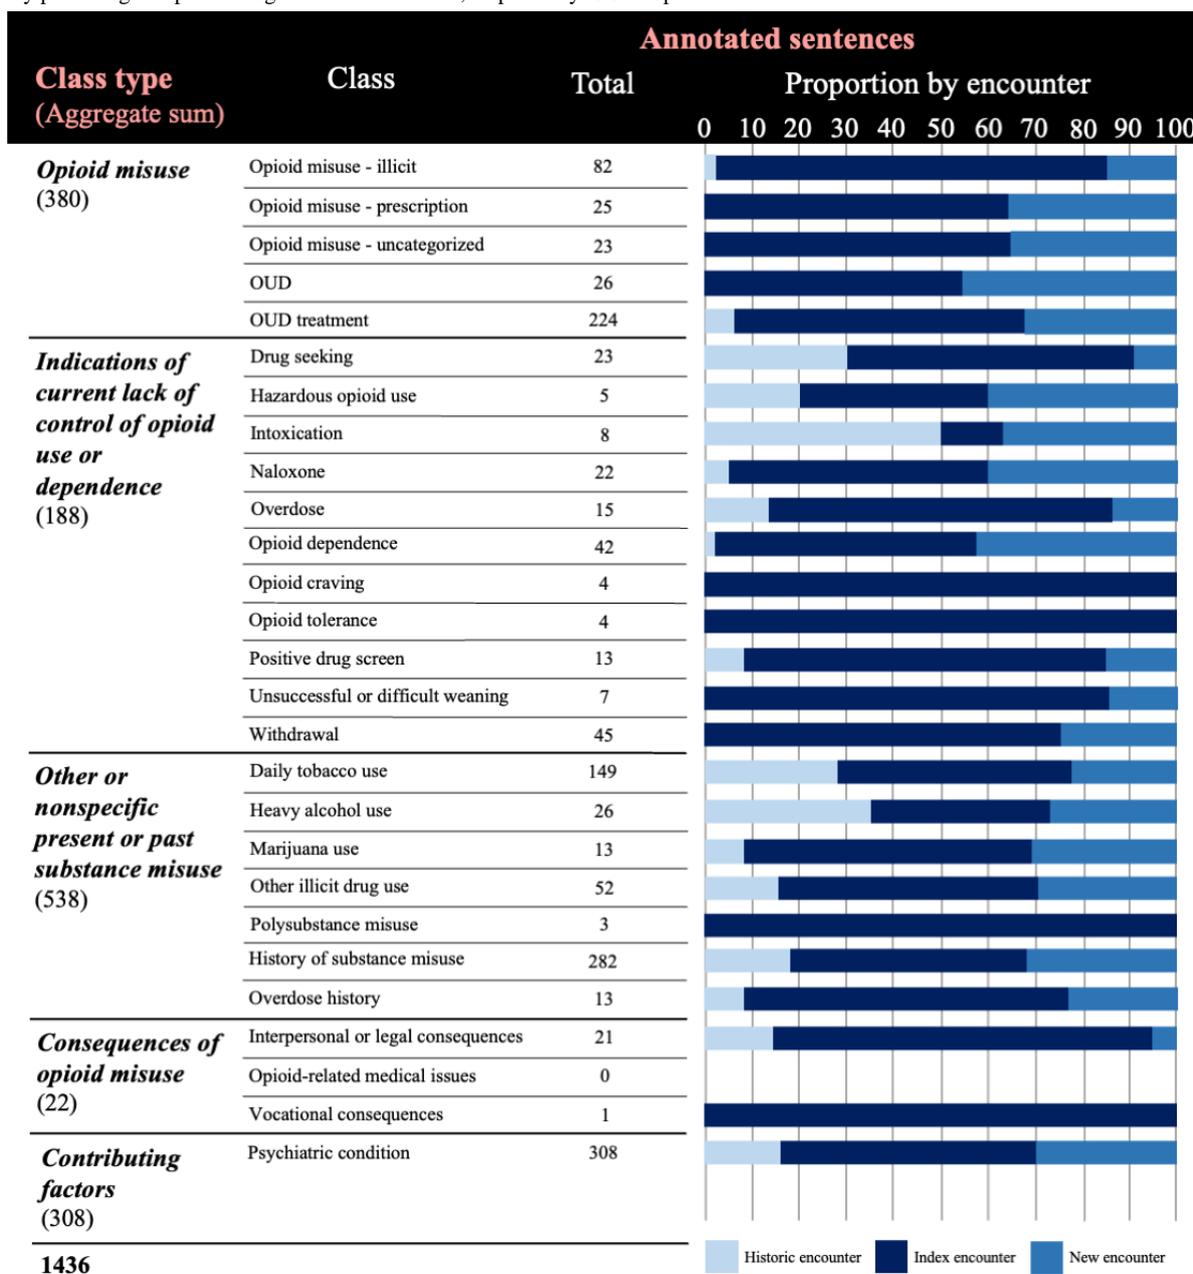

Figure 4. Heatmap of class frequencies by encounter setting. ED: emergency department; IPT: inpatient; OPT: outpatient; OUD: opioid use disorder.

Some classes appeared across varied note types, such as *OUD treatment*, *daily tobacco use*, *history of substance misuse*, and *psychiatric condition*, whereas others tended to only appear in a particular note type (eg, *OUD*, *naloxone*, *opioid craving*, and *overdose history* in progress notes; *drug seeking* in ED notes).

The largest proportion of annotations was observed at the index encounter for all classes except *intoxication* (Figure 5). The classes *opioid craving*, *opioid tolerance*, *polysubstance misuse*, and *vocational consequences* were only observed at the index encounter. Annotations were more common in “new” versus “historic” encounters, and several classes were only observed in “new” encounters and not “historic” encounters.

Figure 5. Count of total annotated sentences by class and proportion by encounter order among the 1436 annotated sentences. Note selection was centered around an index encounter, during which a patient first met group inclusion criteria. “Historic” and “new” refer to notes from encounters immediately preceding and proceeding the index encounter, respectively. OUD: opioid use disorder.

Which OUD-Related Concepts Are Most Common in Clinical Notes?

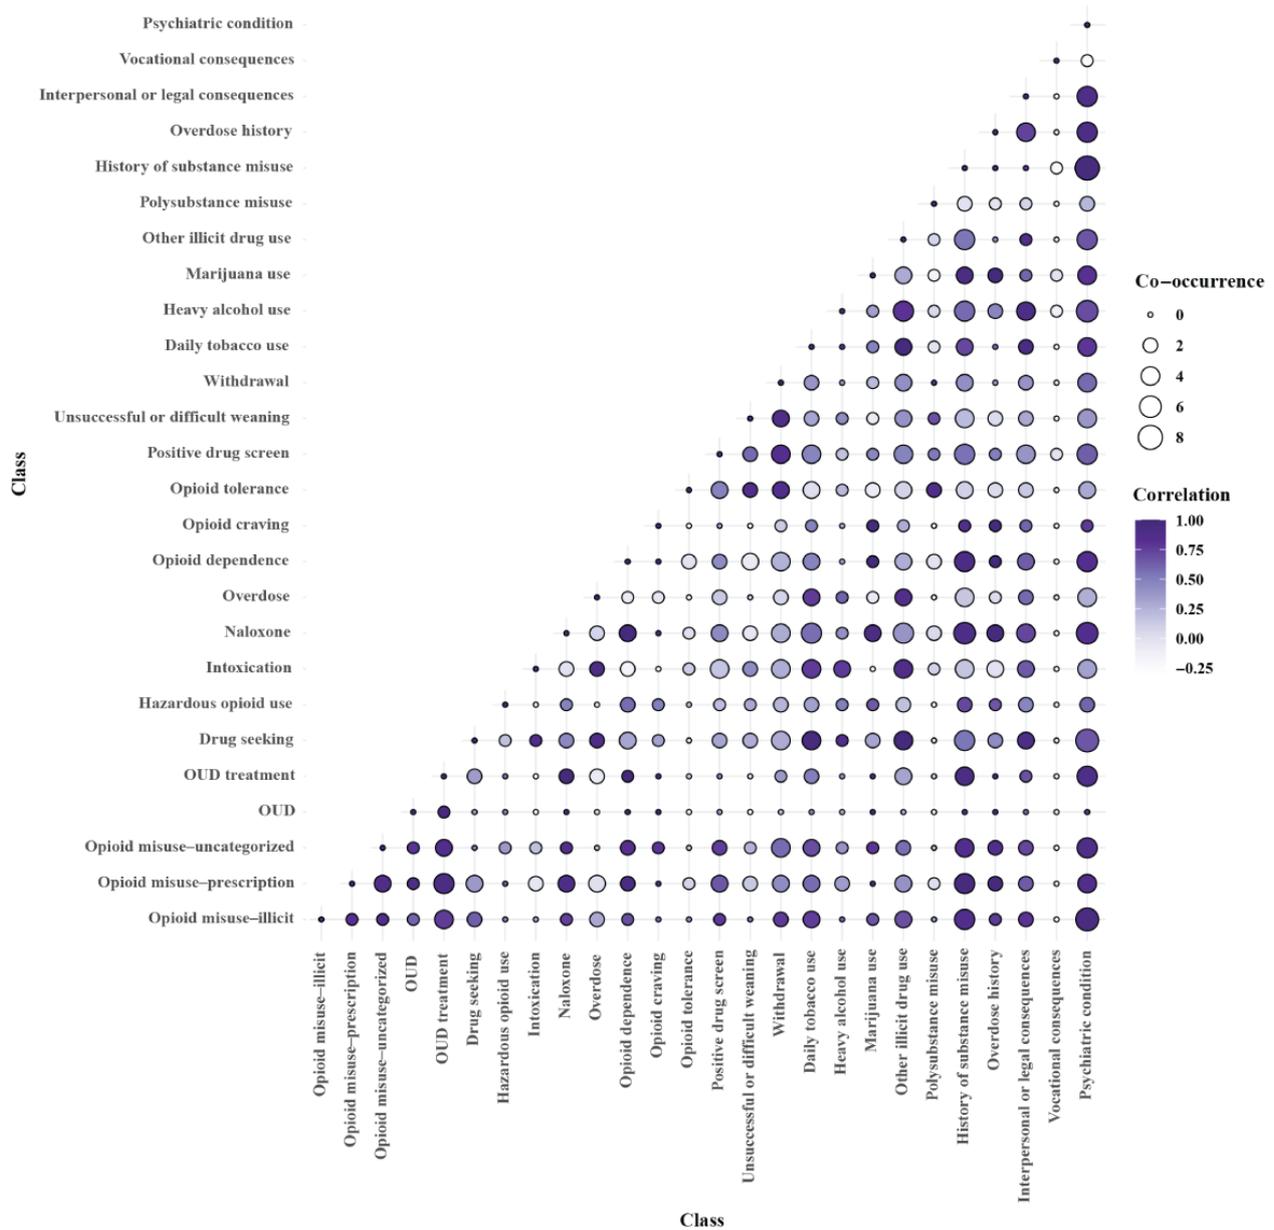

The largest number of annotations involved classes representing substance use not specific to opioids, with the most common classes being *history of substance misuse* and *daily tobacco use* (Figure 5). Except for the class *overdose history*, none of these classes contributed to the OUD severity score. Classes representing opioid misuse had the second largest number of annotations, with *OID treatment* being the most common. *Psychiatric condition*, representing a contributing factor to OUD, was also commonly observed. Few annotations with classes representing consequences of opioid misuse occurred; this category included some of the least common classes

including *vocational consequences* and *opioid-related medical issues*. Several of the least commonly assigned classes represented current lack of control of opioid use.

Which OUD-Related Concepts Are Found Together in Clinical Notes?

Several class pairs had highly correlated frequency distributions across note types, indicating similar documentation frequency (Figure 6). *Psychiatric condition*, *history of substance misuse*, *opioid misuse-illicit*, and *opioid misuse-prescription* were highly correlated with many other classes. Conversely, classes with the lowest correlations in their frequency distribution with other classes included *opioid tolerance*, *vocational consequences*, and *polysubstance misuse*.

Figure 6. Correlation between and co-occurrence of classes. Color depicts correlations between distributions of class pairs documented across note types, demonstrating how similarly 2 given classes are observed across the 11 note types. High correlation indicates classes are documented with similar frequency distributions across note types; conversely, low correlation indicates classes have different frequency distributions across notes. Bubble sizes depict class frequency co-occurrence at the patient level, showing how frequently 2 given classes are experienced across patients. Higher frequency ranges indicate 2 class pairs are more frequently experienced together by a given patient; conversely lower frequency ranges indicate 2 class pairs are less frequently experienced together. OUD: opioid use disorder.

When evaluated across patients, the classes *psychiatric condition* and *history of substance misuse* also had high frequency of co-occurrence with other classes, as did *other illicit drug use* (Figure 6). Classes with the lowest frequency of co-occurrence with other classes included *opioid tolerance*, *opioid craving*, *vocational consequences*, and *OUD*.

Discussion

Principal Results

Through development and evaluation of an annotation schema to characterize OUD severity and documentation of patterns of OUD-relevant information, this study illustrated severity can

be inferred from a limited number of clinical notes. Severity, determined by capturing features associated with DSM-5 OUD severity criteria, followed the expected range of scores, with the highest severity observed for patients receiving OUD treatment and the lowest among those with prescriptions for chronic pain. While severity was determined using a range of note types, we found the most relevant information in outpatient notes typically used for acute care and within a subset of note types. The prevalence of schema classes varied widely, providing information regarding the concepts most useful for developing NLP tools.

Inferring Severity of Problematic Opioid Use

To our knowledge, this is the first study to develop an annotation schema to characterize OUD severity. Most patients received a severity score indicating severe OUD or no OUD. The paucity of scores indicating mild or moderate OUD may be explained by our approach to mapping classes to DSM-5 criteria, the selection of study cohorts, and the limited number of notes reviewed. The “crosswalk” of classes and DSM-5 criteria was based on prior work that included clinician input [11,27], but down weighting specific classes could be justified in future uses and would yield lower severity scores. Additionally, the resulting PPVs for moderate or severe OUD aligned with expectations for this study’s cohorts. Control group individuals all had a severity score of 0, evidence of the specificity of our approach. The OUD-TX group’s PPV of 0.90 is consistent with successful EHR-based algorithms for other conditions [32]. This was expected since these individuals received medication treatment for OUD, which, if documented in the notes we reviewed, would yield a score indicative of severe OUD. The OUD-DX group also had a high PPV, which is unsurprising given their OUD diagnosis. OUD is often underdiagnosed [14,15]; thus, the existence of an OUD diagnosis would be expected to indicate a true disorder, with signs and symptoms likely documented. That said, prior studies have found International Classification of Diseases codes are insufficient for accurately identifying OUD [11,12,14], which may explain why the PPV for OUD-DX was somewhat lower than the OUD-TX group. Both chronic pain groups had moderate PPVs and individuals in these groups were more likely to have a score indicating no OUD. This is likely explained by the index encounter reason—half of the CP-RX group and nearly a quarter of the CP-nonRX group were selected based on an opioid analgesic order. Most individuals whose index encounter was based on an opioid analgesic order had a score indicative of “no OUD.” Although these 2 cohorts had OUD confirmed through a chart review process in prior studies [27,28], the confirmation was only for mild OUD. It is also probable that given the limited number of notes reviewed for this study, additional notes may have yielded information indicative of OUD, which may have occurred later than the 3 selected encounter dates. Based on these findings, we believe that using a limited number of notes is likely sufficient for characterizing OUD severity only in the presence of other confirming information, such as an OUD diagnosis or a medication order for OUD treatment.

Documentation Patterns of Information Relevant to OUD in Clinical Notes

To inform development of NLP methods, we explored documentation patterns of OUD-related information. We observed the most relevant information—as reflected by the proportion of notes with annotated sentences—were in ambulatory and outpatient settings, as opposed to the inpatient setting. This suggests clinical notes from ED and outpatient settings may yield more relevant information regarding OUD; however, we do not recommend excluding notes from the inpatient setting given that our pilot work demonstrated the ubiquity of OUD-relevant information in hospital discharge summaries [18]. Regarding note type, H&P notes, discharge summaries, ED provider notes, and ED notes yielded the most

information pertaining to OUD, and the most diverse information. Finally, relevant information was most often found within notes from the index encounter and the following encounter, demonstrating the importance of selecting notes in reference to relevant structured EHR information and suggesting the sensitivity of OUD severity scores may improve with review of additional notes following the index encounter. The index encounter was defined based on an OUD diagnostic code or the patient’s most recent opioid analgesic order; having such a meaningful anchor may be particularly important for characterizing severity with limited notes. To optimize efficiency, future studies of OUD should consider focusing on the notes likely to yield the most relevant information. However, our findings should be considered preliminary, as we did not surveil all notes, opting for those surrounding the index encounter. Documentation patterns were also likely influenced by the reason for the encounter (eg, whether related to pain management versus medication treatment for OUD). Thus, findings may differ with a review of a patient’s full history of clinical notes.

Opioid misuse, nonopioid substance abuse, and psychiatric classes were the most common annotations in our cohort. The prevalence of opioid misuse classes is not unexpected given that 4 of 5 groups had confirmed OUD. Relatedly, substance use disorders and psychiatric disorders tend to be comorbid with OUD [33]. That said, *history of substance misuse* and *psychiatric condition* were also the most common classes among individuals characterized as having no OUD based on severity criteria. Although nonopioid substance use disorders and psychiatric disorders are risk factors for OUD, they are also commonly comorbid with one another [33]. Indeed, genetic predispositions for substance use disorders, including OUD, and psychiatric disorders can be shared via genetic pleiotropy [34]. The high prevalence and co-occurrence of substance use disorders and psychiatric disorders was also observed across note types and patients. Taken together, these results highlight the importance of substance use and psychiatric classes for developing OUD-related NLP tools.

Absence of certain concepts is also informative for NLP tool development. Consistent with previous work [18,27], some classes relevant to OUD severity were rarely observed, including those representing consequences of opioid misuse and lack of control of opioid use. Reviewing a larger set of notes in an expanded patient sample could yield more frequent documentation of some classes, but some classes may represent concepts not traditionally recorded by clinicians (eg, *vocational consequences*). Documentation by clinicians of additional concepts such as the vocational, social, legal, and medical consequences patients face due to opioid use could be useful for patient care, particularly given the potential utility of such information in characterizing OUD severity. Future work to develop NLP frameworks related to OUD should consider that information captured in clinical notes may change over time with secular changes that occur in the drug landscape, clinical practices and documentation, and patients’ care-seeking behaviors.

Limitations

This study used clinical notes from an integrated health system, allowing for review of multiple note types across encounter settings. Findings may be different in health systems in which information is not integrated across settings; for example, opioid analgesic orders may be missing and OUD treatment siloed. Although we evaluated cohorts with varying evidence of opioid misuse, inclusion of other patient cohorts may yield different findings. In particular, because the cohorts were originally assembled for a genomic study, the CP-RX and CP-nonRX study groups included individuals only of European ancestry, limiting the generalizability of findings to other racial groups. Replication studies are necessary to understand whether study findings generalize to other settings and patient populations.

Conclusions

Understanding how and where OUD-relevant information is captured in EHRs is essential to informing development of NLP

tools to identify and characterize the severity of OUD. We developed an annotation schema to determine OUD severity and highlighted document patterns of OUD-relevant information in clinical notes, which may be informative for future NLP frameworks related to OUD. Findings suggest OUD-relevant information is more prevalent in a subset of note types in ambulatory and outpatient settings—particularly H&P notes, discharge summaries, ED provider notes, and ED notes—and that certain information relevant to OUD may only be captured in certain note types or may be infrequently documented. Furthermore, when reviewing a limited number of notes, having a meaningful anchor such as an OUD diagnostic code or recent opioid analgesic order is important for characterizing OUD severity. Findings also demonstrate the potential for inferring severity of OUD from key information contained in a limited number of clinical notes, paving the way for development of informatics solutions to improve the prevention, diagnosis, and treatment of OUD through clinical care.

Abstract

Background: People with alcohol and substance use disorders (SUDs) often have underlying difficulties in regulating emotions. Although dialectical behavioral therapy is effective for SUDs, it is often difficult to access. Self-guided, internet-delivered dialectical behavioral therapy (iDBT) allows for expanded availability, but few studies have rigorously evaluated it in individuals with SUDs.

Objective: This study examines the feasibility, acceptability, and potential efficacy of an iDBT intervention in treatment-seeking adults with SUDs. We hypothesized that iDBT would be feasible, credible, acceptable, and engaging to people with SUDs. We also hypothesized that the immediate versus delayed iDBT group would show comparatively greater improvements and that both groups would show significant improvements over time.

Methods: A 12-week, single-blinded, parallel-arm, randomized controlled trial was implemented, with assessments at baseline and at 4 (acute), 8, and 12 weeks (follow-up). A total of 72 community adults aged 18 to 64 years were randomized. The immediate group (n=38) received access to iDBT at baseline, and the delayed group (n=34) received access after 4 weeks. The intervention (*Pocket Skills 2.0*) was a self-guided iDBT via a website, with immediate access to all content, additional text and email reminders, and additional support meetings as requested. Our primary outcome was substance dependence, with secondary outcomes pertaining to feasibility, clinical outcomes, functional disability, and emotion dysregulation, among other measures. All outcomes were assessed using self-report questionnaires.

Results: iDBT was perceived as a credible and acceptable treatment. In terms of feasibility, 94% (68/72) of the participants started iDBT, 13% (9/68) were early dropouts, 35% (24/68) used it for the recommended 8 days in the first month, and 50% (34/68) were still active 4 weeks later. On average, the participants used iDBT for 2 hours and 24 minutes across 10 separate days. In the acute period, no greater benefit was found for the immediate group on substance dependence, although we did find lower depression ($b=-2.46$; $P=.02$) and anxiety ($b=-2.22$; $P=.02$). At follow-up, there were greater benefits in terms of reduced alcohol ($b=-2.00$; $P=.02$) and nonalcoholic substance ($b=-3.74$; $P=.01$) consumption in the immediate access group. Both groups demonstrated improvements in substance dependence in the acute ($b=-1.73$; $P<.001$) and follow-up period ($b=-2.09$; $P<.001$). At follow-up, both groups reported reduced depression, anxiety, suicidal behaviors, emotional dysregulation, and functional disability.

Conclusions: iDBT is a feasible and acceptable intervention for patients with SUDs, although methods for improving engagement are warranted. Although results did not support efficacy for the primary outcome at 4 weeks, findings support reductions in substance dependence and other mental health concerns at 12 weeks. Notwithstanding the limitations of this study, the results suggest the potential value of iDBT in the treatment of SUDs and other mental health conditions.

Trial Registration: ClinicalTrials.gov NCT05094440; <https://clinicaltrials.gov/show/NCT05094440>

Introduction

Background

Alcohol and substance use disorders (SUDs) are the leading causes of death and disability worldwide [1,2]. These conditions are often chronic, leading to elevated risks of co-occurring medical and mental health conditions, involvement with the criminal justice system, and loss of workplace productivity [1-4]. In 2019, the past-year use of alcohol, cannabis, tobacco, and illicit substances was 77%, 21%, 14%, and 3.6%, respectively, in Canadians [5]. Increased consumption during the COVID-19 pandemic in Canada and around the world has been linked to greater substance-related harms and concurrent mental health symptoms, such as depression, anxiety, and hopelessness [6]. Various evidence-based psychological treatments are available for SUDs; however, the availability and demand for these services come at a time when internet and mobile delivery formats are being promoted in care pathways [7]. These formats hold considerable public health promise in reducing the burden associated with SUDs. For example, a recent systematic review highlighted that existing mobile interventions were effective and rated as acceptable by people with SUDs [8].

Psychological Treatments for SUDs

Although pharmacological treatments exist for some substances (eg, alcohol and opioids), they have mixed evidence in treating other SUDs (eg, cannabis and stimulants [9]). Thus, psychological treatments remain a necessary therapeutic avenue for SUDs and may be particularly promising for those with multiple substance use concerns. Although psychological treatments vary greatly in their approach and theoretical framework, they tend to produce moderate effect size reductions in substance dependence [10,11]. To date, the greatest evidence supports cognitive behavioral and motivational enhancement approaches for treating SUDs.

SUDs rarely occur in isolation and often co-occur with depressive, anxiety, bipolar, and traumatic stressor disorders [12]. Psychological treatments are well suited to treat multiple conditions simultaneously when they incorporate a transdiagnostic focus or approach. There is growing consensus that people with SUDs, regardless of a specific substance, report higher difficulties in regulating their emotions compared with control samples and often use alcohol or other substances to cope with negative emotions [13]. More broadly, difficulties in emotion regulation appear to be a transdiagnostic risk factor

underlying not only the development and course of SUDs but also depressive, anxiety, bipolar, and traumatic stressor disorders [14,15]. They also represent a promising treatment target, as emotion regulation skills tend to improve during psychological treatments for SUDs, along with more general improvements in self-efficacy and coping [16,17]. One psychological intervention that may be of substantial interest is dialectical behavior therapy (DBT), which was developed to treat individuals with high emotion dysregulation and includes comprehensive skills training in the domains of mindfulness, distress tolerance, emotion regulation, and interpersonal effectiveness.

DBT is a third-wave psychological intervention designed for patients with complex and severe behavioral, emotional, and interpersonal dysfunction [18,19]. DBT was first developed and found to be effective for severe clinical presentations related to suicidal behavior, nonsuicidal self-injury, and borderline personality disorder in adolescents and adults (refer to the study by Neacsiu et al [20] for review). Over time, DBT was reconceptualized as a transdiagnostic intervention appropriate for other mental health conditions and now includes specific content relevant to SUDs as well as other addictive behaviors [16,21,22]. Nevertheless, outpatient programs offering DBT are often safeguarded for those with acute suicide risk and behavioral problems. Importantly, although DBT was originally developed as a year-long multimodal intervention, evidence suggests that relatively brief formats focusing on DBT skills training (eg, 8-32 wk) are effective in treating SUDs, either as a primary condition or a co-occurring presentation in numerous clinical trials [16,22-24]. Despite these promising results, further research is needed to support the potential benefits of digital formats of DBT skills training, particularly within inclusive samples that reflect those seeking support for SUD.

Internet-Delivered DBT

Another way to increase the availability of DBT is through internet and mobile delivery formats. Thus far, research on internet-delivered DBT (iDBT) has been promising. In a review of 11 studies, iDBT was feasible and effective, although these results were based on small sample sizes, and few studies adopted a more rigorous methodology (eg, randomized controlled trials [RCTs] [25]). Various methods have been used, such as therapist-led sessions delivered via web-based videoconferencing [26], asynchronous material delivered via email [27], self-guided stand-alone websites [28,29], and therapist-guided programs [30]. Studies that evaluated potential efficacy suggested that iDBT was at least as effective as control

conditions (waitlist or face-to-face) and was accepted by users. However, web-based delivery is not without harm or adverse events. One large-scale trial comparing integrated care management and skills training (ie, 4 self-guided DBT skills) for those with suicidal ideation found that the latter condition led to an increased risk of self-harm [31]. A discussion of the study suggested that it faced, among other issues, an implementation failure [32]. Thus, these and other considerations should be incorporated in future work.

In a seminal study, Wilks et al [30] evaluated therapist-guided iDBT in a sample of participants who are suicidal and alcohol dependent in a completely remote manner. This 8-week waitlist-controlled RCT delivered video trainings on mindfulness (2 wk), addiction (2 wk), emotion regulation (3 wk), and distress tolerance (1 wk) using an e-learning web-based platform along with handouts and worksheets delivered via email. The content was developed in collaboration with the developer of DBT. The intervention produced significant reductions in suicidal ideation, alcohol consumption, and emotion dysregulation. Although the treatment was deemed safe and acceptable to participants, there was substantial dropout, and technical issues were reported as a barrier to adherence [33]. Nevertheless, those who remained in the study reported that it was useful.

Following this work, a more advanced iDBT intervention called *Pocket Skills* (version 1.0) was created to overcome the accessibility and engagement issues encountered previously [34]. It is available through an internet browser on any device (ie, computer, tablet, or smartphone) and offers an interactive experience by using a chatbot along with embedded video lessons and practice. *Pocket Skills* 1.0 was evaluated in a single-arm trial as an adjunct intervention in individuals with a range of mental disorders completing in-person DBT for 4 weeks. The results of the study were promising, with both quantitative and qualitative evidence for its feasibility, acceptability, and potential use as an adjunct. We developed this study based on these 2 previous studies.

Current Study

This study aims to evaluate version 2.0 of *Pocket Skills* and advance the literature in several ways. First, the current investigation evaluates *Pocket Skills* 2.0, which includes some of the content from version 1.0, as well as revised and novel materials that have not yet been evaluated. Second, the delivery of iDBT in this study was predominantly self-guided, with limited therapist guidance compared with the previous trial that used iDBT intervention as a therapeutic adjunct [34]. Third, this investigation represented a more controlled study of *Pocket Skills* 2.0 as a stand-alone treatment in a sample of treatment-seeking adults with SUDs who were not receiving any other forms of psychological treatments. Finally, this investigation randomized participants to immediate versus delayed access to advance the previous single-arm study. A 12-week single-blinded parallel-arm waitlist-controlled RCT was initiated, with participants randomized to receive immediate access to the intervention or delayed access after 4 weeks. The 4-week intervention and follow-up periods are in line with previous implementations of self-guided digital mental health interventions [35-37]. These studies have found that attrition

rates start to increase steadily after 4 weeks and especially after 7 to 8 weeks (eg, >50%).

Specifically, we hypothesized that greater than 50% of participants would start the intervention (H1a); not drop out early (H1b); engage with the intervention at a recommended dose of twice a week (or 8 d) in the first 4 weeks (H1c); and would still be using the intervention after 4 weeks (H1d). We also hypothesized that participants would rate the intervention as credible and acceptable on established measures (H1e). Second, we hypothesized that (H2a) participants in the immediate versus delayed iDBT group would show significantly greater improvements in our primary outcome of substance use dependence at the acute (week 4) and follow-up periods (week 12) in the form of an interaction effect (group×time). In addition, we hypothesized (H2b) significantly greater improvements for the immediate versus delayed iDBT group for our secondary outcomes (ie, depression, anxiety, emotion dysregulation, suicidality, functional disability, dispositional mindfulness, DBT skills, risky behaviors, and frequency of alcohol and substance use). Third, we hypothesized that iDBT would (H3) produce significant main effect improvements in both groups in the acute (week 4) and follow-up phases (week 12) of the intervention for all outcome measures.

Methods

Study Design

A 2-arm, single-blinded, parallel-group, preregistered RCT design was implemented, comparing individuals who received iDBT immediately with those who were first wait-listed for 4 weeks and then offered the intervention (delayed iDBT group). Assessments were completed at baseline and at 4 weeks, with additional follow-ups at 8 and 12 weeks. A CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) checklist was completed with more detailed information on the study design ([Multimedia Appendix 1](#)).

Ethical Considerations

All study procedures were approved by the Centre for Addiction and Mental Health research ethics board (#016/2021), and this research complied with the Declaration of Helsinki of 1975, as revised in 2000. Data is stored in a de-identified format to safeguard participant information.

Participants and Recruitment

Enrollment ran from August 2022 to March 2023, and all follow-ups were completed by June 2023. Participants were recruited from psychiatric hospital clinician referrals, waitlists, and research registries and from the surrounding community through several methods of advertisement (eg, hospital and other websites, social media posts, private DBT clinics, and local community organizations). All advertisements sought individuals who wanted to reduce their alcohol or substance use and specifically stated that they would be offered an internet-delivered intervention.

All prospective participants were initially informed about the study and were prescreened for eligibility over the phone.

Inclusion criteria were as follows: (1) aged 18 to 65 years; (2) fluent in English; (3) understanding and willingness to comply with study requirements; (4) referred to addictions programming at our hospital or seeking treatment from the community, but not currently receiving any CBT or DBT intervention (support groups and psychiatric services were allowed); (5) alcohol or SUD in the past year; (6) use of alcohol or substance in the past month; (7) access to the internet (and assumed literacy); and (8) at least contemplation levels of wanting to reduce alcohol or substance use on the Contemplation Ladder measure [38]. Exclusion criteria included (1) any known practical factors that would preclude participation, (2) acute psychiatric (ie, suicidality, psychotic disorder) or medical condition (ie, acute intoxication or withdrawal) requiring medical attention, and (3) participation in another psychological intervention or treatment study. We did not exclude participants based on whether they were taking psychotropic medications or not.

Registration

The trial was registered with the ClinicalTrials.gov database (NCT05094440) on October 14, 2021. A revised registration was published on September 6, 2022, in line with changes to our protocol between our pilot study and this study. In this study, our analysis focused on the measures included in registration. One modification of the registered protocol was made, that is, the addition of a DBT skills measure at all time points to permit the evaluation of how this intervention was linked to changes in this key treatment target. Feasibility, acceptability, and engagement metrics were decided a priori for study implementation and were included in our study-specific protocol.

Randomization and Blinding

Participants were randomized to immediate or delayed iDBT using a blinded envelope system to ensure allocation concealment, with 3 randomization blocks (4, 6, and 8 participants). The randomization procedure was blinded to the participants and the experimenter who ran all baseline sessions (ARD). Thus, neither party knew which group the participant would be allocated to until after the informed consent and baseline procedures were completed. None of the participants withdrew immediately following randomization. The experimenters were not blinded to the procedures following the baseline session, including the follow-up assessments and contact. All follow-up assessments were conducted remotely and consisted solely of self-report measures.

Procedure

Eligible participants attended a 45-minute baseline session via a videoconference, where they provided informed consent (electronically), completed a demographic questionnaire and semistructured diagnostic interview, and were randomized into either immediate or delayed access groups. At the end of the baseline session, those randomized to the immediate group were provided the iDBT website URL and an invitation code and completed the sign-in procedure (15 min) with the experimenter during the videoconference call. Those randomized to the delayed access group were scheduled for an additional

appointment in 4 weeks, where they met with the experimenter again and completed the sign-in procedure (15 min). Thus, although the time spent with the experimenter was approximately the same, the delayed group met with the experimenter via videoconference twice. Each participant was sent a guide to the intervention via email, with a suggested 8-week protocol.

Follow-up questionnaires, completed via REDCap (Research Electronic Data Capture; Vanderbilt University), were automatically distributed via email or text every 4 weeks. Text and email reminders for the follow-up questionnaires were sent daily for up to 4 days until completed, starting 2 days before each assessment was due. To support engagement, additional text messages were sent to consenting participants (56/72, 78%) twice a week for the first 4 weeks following the start of iDBT in both groups (following this point, reminders were discontinued). These text messages contained a link to a short REDCap survey that encouraged use, queried whether participants wanted a follow-up call, and reported any technical issues. Participants could request additional calls or meetings with the experimenter (via REDCap survey or email) to troubleshoot or clarify different components of the website; however, <10 of these calls or meetings took place throughout the study. Participants were compensated up to CAD \$70 (US \$45.5) for the completion of these procedures (CAD \$10 [US \$6.5] for baseline and CAD \$20 [US \$13] each for the 4-, 8-, and 12-week assessments). On average, participants were compensated CAD \$59 (US \$38.35), including those who did not collect their final payment.

Intervention

Pocket Skills 2.0 is an iDBT intervention developed by author CRW in collaboration with Microsoft Research and Dr Marsha Linehan; it is built upon the most recent DBT manual available [18]. It uses a web-based portal built on the Microsoft Azure platform that is compatible with any internet browser in addition to the Android and iOS mobile operating systems. This iDBT intervention incorporates lessons following the core modules of DBT as well as a specific module focused on addiction (Table 1 provides more details, and Figure 1 provides the screenshots). Within each module, participants selected a specific skill and were presented with a brief video featuring Dr Linehan introducing the skill and its uses. A practice session then ensues with the rule-based chatbot, which allows for feedback through both open-ended text input and a closed selection of responses. The chatbot guides users on how to select skills to use in different situations that may arise as well as the ability to gain points and unlock additional content, which increases user engagement. After logging in for the first time, participants were prompted to complete an introductory module in which they entered a nickname and set personal goals. Following the completion of this module, participants were able to enter any of the 5 DBT modules offered freely, without the need to unlock any content. The procedure in which iDBT was delivered in this study differs from that in previous studies (refer to Multimedia Appendix 2 [30,34] for a comparison).

Table 1. List of skills covered within the Pocket Skills 2.0 internet-delivered dialectical behavior therapy (DBT) intervention.

Module	DBT skills	Brief training description
Mindfulness	Introduction to mindfulness; wise mind; observing, describing, and participating; and nonjudgment, one-mindfully, and effectively	Introduces the foundational skills to develop nonjudgmental awareness of the present and practice mindfulness with skillful effectiveness.
Emotion regulation	Introduction to emotion regulation; understanding emotions; check the facts, opposite action, and problem-solving; accumulating positives and pleasant events; and building mastery and coping ahead	Teaches the functions of emotions, how to describe them, and skills to reduce the frequency and quantity of unwanted emotions. Also teaches skills to build resilience against future negative emotions.
Distress tolerance	Introduction to distress tolerance; TIP ^a , distraction (ACCEPTS ^b), and self-soothe; pros and cons; and Help Me Cope!	Teaches skills to weather crises and intense negative emotions, manage experiential changes, and produce emotional and cognitive change. Help Me Cope! helps the user pick a coping strategy based on a few contextual questions.
Interpersonal effectiveness	Introduction to interpersonal effectiveness; DEARMAN ^c , GIVE ^d , and FAST ^e ; and Dime Game	Teaches skills to navigate interpersonal situations and needs more effectively. Dime Game helps the user evaluate a situation for how firmly to make a request or say no.
Addiction	Introduction to addiction; pros and cons (addiction context); dialectical abstinence and clear mind; and community reinforcement and burning bridges	Helps learners find a middle path between sobriety and unrestrained substance use. Helps learners develop a clear mind and other strategies to stop or reduce problematic substance use.

^aTIP: temperature, intense exercise, and paced breathing.

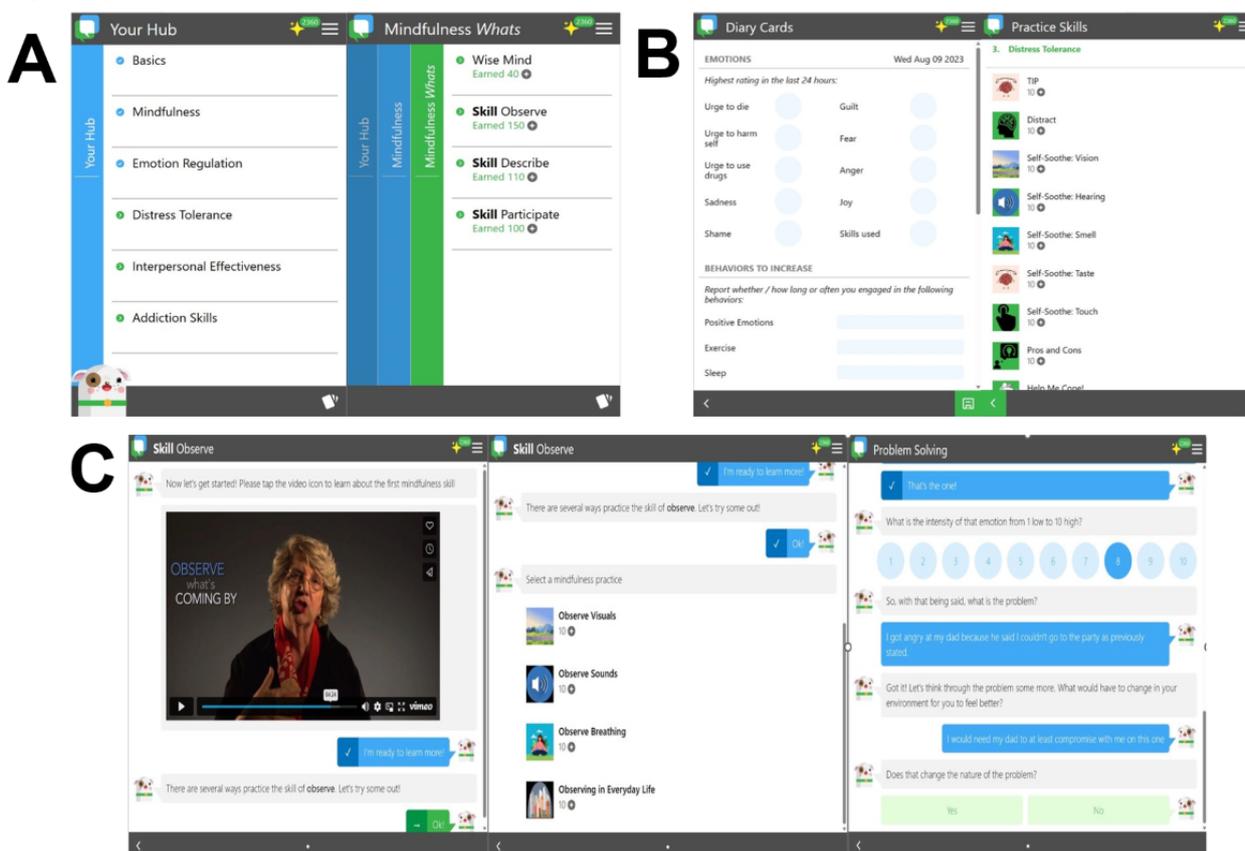

^bACCEPTS: activities, contributing, comparisons, emotions, pushing away, thoughts, and sensations.

^cDEARMAN: describe, express, assert, reinforce, be mindful, appear confident, and negotiate.

^dGIVE: be gentle, act interested, validate, and use an easy manner.

^eFAST: be fair, no apologies, stick to values, and be truthful.

Figure 1. Screenshots depicting different features of the Pocket Skills 2.0 internet-delivered dialectical behavior therapy intervention: (A) displays the main Your Hub page, with the next screen showing the submenu selection within the Mindfulness module; (B) shows the optional Diary Card page to input various skills training targets, with the next screen showing the Practice skills page with quicker access to skills training without lessons; and (C) shows the initial portion of the Mindfulness Observe skill lesson, with an embedded video featuring Dr Linehan. The second screen shows the chatbot initializing an interactive skills training exercise, and the third screen shows the types of open- and closed-ended response options along with an example Likert-type rating scale.

Measures

Diagnostic Interviews

The Diagnostic Assessment and Research Tool version 4.0 [39] was used to assess depressive, anxiety, bipolar, obsessive-compulsive, trauma and stressor, alcohol, and SUDs according to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth edition* [40]. We also screened the presence of psychotic disorders. All interviews were completed by the first author, who is a licensed clinical psychologist.

Feasibility and Credibility Measures

For feasibility, we calculated the proportion of randomized participants who started the intervention (by signing in on the first day of access). Of those who started the intervention, we calculated the proportion that (1) dropped out of the intervention after starting (indicated by not logging in after the first day), (2) recorded at least 1 activity after 4 weeks, and (3) completed a recommended dose of using the intervention twice per week for the first month (8 d total). Next, we administered the 6-item Credibility and Expectancy Scale [41] at baseline to assess whether participants had favorable opinions of the intervention and its potential effectiveness before starting treatment. In line with previous work [42], the first 3 items were used to evaluate credibility (using a 9-point Likert scale), whereas a single item (item 4) was used to evaluate expectancy of clinical improvement (using an 11-point Likert scale ranging from 0% to 100%).

Acceptability and Engagement Measures

We used the 6-item Treatment Acceptability Questionnaire [43], which was administered at weeks 4, 8, and 12 to assess ratings of acceptability, perceived effectiveness, and trustworthiness using a 7-point Likert scale. In this analysis, we used only the week 4 and 12 scores. From the intervention source, we examined several metrics tied to engagement or use: the total amount of time spent on the website, the number of interactions with the website (eg, clicks, page views, and text inputs), unique days of log-in, and days of use spread. We then recalculated these metrics for the first 4 weeks, consistent with the acute period of the intervention.

Primary Outcome

The Substance Dependence Scale [44] is a 5-item self-report scale used to assess the severity of alcohol or substance dependence at the baseline and follow-up assessments. Higher scores indicated a higher level of substance dependence. Participants were first asked to indicate which class of substance (including alcohol) they were experiencing the most difficulties abstaining from, even if they reported no use in the past month. The ω reliability coefficient in this study was 0.95. All primary and secondary outcome measures were administered at each assessment point.

Secondary Outcomes

The Patient Health Questionnaire, Depression subscale [45], is a 9-item self-report measure used to assess depressive symptoms over the past 2 weeks, with excellent internal reliability and clinical utility in predicting depression. The ω reliability coefficient was 0.93.

The Generalized Anxiety Disorder-7 Scale [46] is a 7-item self-report measure used to assess generalized anxiety symptoms over the past 2 weeks, with excellent internal reliability and clinical utility in predicting generalized anxiety disorder. The ω reliability coefficient was 0.95.

The Suicidal Behaviors Questionnaire-Revised [47] is a 4-item measure of suicidal thoughts and attempts as well as future intent over the past month, with evidence for its reliability and clinical utility. The total score ranges from 3 to 18, with scores ≥ 8 indicating significant suicidal risk within clinical samples. The ω reliability coefficient was 0.87.

The World Health Organization Disability Assessment Schedule 2.0 [48] is a 12-item self-report measure assessing functional disability over the past month in several domains (cognition, mobility, self-care, and getting along with others). Higher scores indicate greater functional disability. The ω reliability coefficient was 0.94.

The Difficulties in Emotion Regulation Scale, Short Form [49], is a 16-item self-report measure with excellent internal consistency, assessing emotion dysregulation based on a 6-facet model first described by Gratz and Roemer [50]. Higher scores suggest greater emotion dysregulation difficulties. The ω reliability coefficient was 0.83.

The Mindful Attention Awareness Scale [51] is a 15-item self-report measure of dispositional mindfulness in the form of open or receptive awareness and attention to what is taking place in the present over the past month. Higher scores, which were summed and then averaged, reflected higher levels of dispositional mindfulness. Owing to an administrative error, the anchors were reversed when presented to participants for the entire duration of the study. Therefore, we reversed all scores to ensure a standard interpretation as above. The ω reliability coefficient was 0.94.

The DBT Ways of Coping Checklist [52] is a 59-item self-report measure that assesses the frequency of maladaptive and adaptive skills used to manage difficult situations over the past month, with good internal consistency and test-retest reliability. In this study, we only used the 38-item adaptive skills subscale, which includes skillful behaviors often learned in DBT without using DBT-specific language. The ω reliability coefficient was 0.80.

The National Institutes of Drug Abuse–modified Alcohol, Smoking, and Substance Involvement Screening Test is an adaptation of the original measure [53] used to assess alcohol, smoking, and substance use involvement. This measure was used to assess tobacco, cannabis, cocaine, amphetamine-type stimulants, inhalants, sedatives or sleeping pills, hallucinogens, and opioids. Each class of substance was rated for frequency over the past month using an ordinal scale: 0=never; 1=once or twice; 2=3 or 4 times; 3=5, 6, or 7 times; 4=2 or 3 times a week; 5=4 or 5 times a week; and 6=daily or almost daily. The ω reliability coefficient was 0.23, likely because of the heterogeneity and range of substances used in our sample.

The Daily Drinking Questionnaire [54] was used to assess the frequency of alcohol use on each day of a typical week. Participants were asked how many standard drinks they had consumed on a typical Monday in the past month, with separate

questions for each day of the week. Responses were recoded into an ordinal scale: 0=none, 1=1 to 2 standard drinks, 2=3 to 4 standard drinks, 3=5 to 7 standard drinks, 4=8 to 10 standard drinks, 5=11 to 14 standard drinks; and 6= \geq 15 standard drinks. The ω reliability coefficient was 0.96.

The Risky, Impulsive, and Self-Destructive Questionnaire [55] is an inventory of 38 risky, impulsive, and self-destructive behaviors that sometimes cause problems for people. For brevity and to avoid overlap with other measures, we only used the 4-item *risky sexual behavior* subscale and the 4-item *reckless behavior* subscale. We recoded the frequency of responses, which were evaluated over the past month, into an ordinal scale: 1=none, 2=once or twice, 3=3 to 4 times, 4=5 to 6 times, 5=7 to 9 times, and 6= \geq 10 times. The ω reliability coefficient was 0.86.

Statistical Analysis

Overview

No outcome measure data were missing from the baseline, and participants returned at least partially completed follow-up questionnaires at rates of 94% (68/72; week 4), 78% (56/72; week 8), and 81% (58/72; week 12). At follow-up, scores for outcome measures were only used if there were <10% of items missing, and we treated outcome measures with no data as missing. The frequency of nonalcoholic substance use, standard alcoholic drinks per day, and risky impulsive behaviors was first recoded using ordinal values to approximately equate each scale with respect to their frequency of occurrence. For each measure, we took the average of each ordinal item score and then rounded the average value to the nearest one to serve as the dependent variable. This rounding was required as an ordinal regression relies on categorizing each value of the ordinal dependent variable as a factor variable. There are several ways to analyze ordinal variables, and this procedure was supported by our biostatistical consultation team.

Descriptive statistics were used to evaluate treatment feasibility, acceptability, and engagement data. Chi-square test, Fisher exact test, and 2-tailed *t* test analyses were used to evaluate baseline differences. Engagement data consisted of time stamped logs of each interaction (ie, clicks, page views, and text inputs) with the website, organized hierarchically within persons, with a total of 39,884 observations. To capture the time spent on iDBT, we ordered the data in Excel (Microsoft Corporation) according to time within persons and calculated a difference score (delta time) between rows. This difference score assessed the time between one meaningful interaction and the next. We then applied a filter to remove any difference scores >30 minutes to account for participants taking breaks or not returning to the app until the next day, capturing 93% of the data. A 10-minute filter captured 92% of the data; however, we wanted to account for playing video content, which could run up to 10 minutes, and the potential of practicing skills live, while remaining on 1 of the web pages. Once the filter was applied, we also calculated the number (and spread) of dates the app was used as well as the number of observations per person, which we called the meaningful interactions calculation. Sensitivity analyses were then performed by examining the same metrics over the first 4 weeks and the time spent on each iDBT module.

All other statistics were run in the statistical program R (version 4.2.1; R Foundation for Statistical Computing). To evaluate the internal consistency of our measures over time, we calculated the between-person ω reliability coefficient [56] statistic using the *omegaSEM* function from the *MultilevelTools* package (version 0.1.1). To characterize changes over time for our continuous variables, we ran a series of linear mixed models with the *lme4* package (version 1.1-26 [57]), with each primary and secondary outcome serving as a dependent variable in separate models. To characterize changes over time for our ordinal variables, we ran additional linear mixed cumulative link models using the *ordinal* package (version 2022.11-16) with separate models for each outcome. As per recommendations, we adjusted each model by incorporating the baseline dependent variable value for each person irrespective of whether the difference was significant between groups [58].

All models included a random intercept for a person and relied on restricted maximum likelihood estimation. We omitted any random slope effects throughout the analyses because all our independent variables were level-2 grouping variables.

Each primary and secondary outcome variable was assessed with models containing an interaction effect (group \times time, as factor variables) and main effects only (group+time, as factor variables) along with a continuous covariate controlling for the baseline assessment of each outcome per person. The final model chosen for interpretation was the better fitting model based on lower Akaike information criterion and Bayes information criterion values. Therefore, if the model fit was improved by the inclusion of the interaction term, we report that model; otherwise, we removed the interaction term and report the model with the main effects only. All model comparisons were evaluated using maximum likelihood estimation with the *lmerTest* (version 3.1-3 [59]) package, which uses the Satterthwaite *df* method. To further reduce the number of statistical tests reported, we also opted to interpret only the week 4 and week 12 contrasts against baseline as these were the most pertinent time points to address our hypotheses. Our α significance level was $P=.05$, and all statistical tests were 2 tailed. The outputs of each final statistical model are provided in [Multimedia Appendix 2](#) for full transparency.

Power

To achieve at least a medium effect size reduction in substance dependence, as suggested by Wilks et al [30], we would require a minimum sample of 60 as per G*Power (version 3.1.9.7; Cohen $f=0.15$; 2 groups; 4 measurements over 12 wk; power=0.95; $\alpha=.05$; and correlation between measures of at least 0.70) [60]. With an expected attrition rate of approximately 20%, we aimed to recruit approximately 72 to 75 individuals in total.

Results

Hypothesis 1: Feasibility and Acceptability

Participant Enrollment and Demographic Characteristics

Initially, 116 individuals were assessed for eligibility, and 72 participants aged 18 to 64 years completed all baseline procedures and were randomized. Demographic and clinical characteristics of the sample are presented in [Table 2](#); these characteristics did not differ between groups, suggesting that the randomization procedure was successful. Of the 72 participants, 9 (13%) met the full threshold criteria for >1 SUD. The primary nonalcohol substance disorder across the sample was cannabis (22/72, 31%); nicotine (10/72, 14%); stimulants (7/72, 10%); and sedative, hypnotic, or anxiolytic (1/72, 1%). None of the participants had a current opioid use disorder.

Participants met the criteria for a median of 3 psychiatric diagnoses overall (mean 3.30, SD 1.69; range 1-7).

At baseline, 46% (33/72) of the participants reported taking psychotropic medications in the past month, 22% (16/72) of the participants reported seeing a psychiatrist in the past month, and 8% (6/72) of the participants reported attending a community resource (eg, Alcoholics Anonymous and peer support group) in the past month. These rates did not increase when the participants reported the same services at each follow-up. As we did not restrict new options for care following baseline, 4 participants reported having access to outpatient programming at week 4, but only 2 reported this at both weeks 8 and 12. [Figure 2](#) summarizes the study flow of participants in a CONSORT (Consolidated Standards of Reporting Trials) diagram.

^dParticipants could select multiple options.

^eSH or A: sedative, hypnotic, or anxiolytic.

Figure 2. CONSORT (Consolidated Standards of Reporting Trials) diagram depicting the participant flow through the study. iDBT: internet-delivered dialectical behavior therapy.

Feasibility and Credibility

Moreover, 94% (68/72) of the randomized participants started the intervention. Three participants in the delayed iDBT group did not attend the follow-up session and never connected to the intervention following attempts to reschedule and instructions provided via email. One additional participant withdrew from the delayed group owing to technical issues and being unable to sign in and therefore did not access the intervention. One participant asked to withdraw from the immediate group because of lack of time to spend on the intervention. In addition, 87% (59/68) of those who started iDBT used it for longer than the initial sign-in day (early dropouts: 9/68, 13%), 50% (34/68) recorded at least 1 iDBT activity after 4 weeks, and 35% (24/68) used it according to the recommended dose of 8 days within the first month. Finally, 63% (43/68) of the participants used it for at least 1 hour in total.

Perceptions of intervention credibility at baseline were positive (mean 74%, SD 16%; range 44%-100%). Participants thought it was logical and it was likely to raise their quality of functioning, and they were confident in recommending it to

another person. Participants also estimated a mean 58% (SD 21%; range 10%-90%) improvement in symptoms.

Acceptability and Engagement

Treatment acceptability was similar in the immediate iDBT group (mean 36.7, SD 3.8) compared with the delayed iDBT group (mean 35.9, SD 5.3) at week 12; there was no difference between groups ($t_{56}=0.66$; $P=.51$). A summary of the engagement metrics is provided in Table 3. On average, participants used the app for 2 hours and 24 minutes over the course of 43 days during the study, with 10 unique sign-in days. Participants also recorded an average of 543 meaningful interactions with the website. A breakdown of engagement by module is also provided in Table 3. All metrics tended to be higher on average in the immediate versus delayed iDBT group, consistent with the waitlist control design. Metrics improved further after removing 9 dropout participants who did not use the app after the first day. These individuals appeared to abide closer to the recommendation of using the resource for 8 days within the first month.

^mDBT-WCCCL: Dialectical Behavior Therapy Ways of Coping Checklist.

Primary Outcome

Contrary to our hypotheses, we did not find any significant group \times time interactions for the severity of substance dependence at week 4 or week 12.

Secondary Outcomes

Consistent with the hypotheses, the results supported greater benefits for the immediate versus delayed iDBT group for several secondary outcomes. At week 4, there were significant group \times time interactions for depression and anxiety, where the immediate access group reported fewer depressive ($b=-2.46$; SE 1.05; 95% CI -4.51 to -0.40; $P=.02$) and anxiety symptoms ($b=-2.22$; SE 0.96; 95% CI -4.09 to -0.34; $P=.02$) compared with the delayed iDBT group. At week 12, there were significant group \times time interactions for standard alcoholic drinks per day ($b=-2.00$; SE 0.83; 95% CI -3.64 to -0.36; $P=.02$) and nonalcoholic substance use ($b=-3.74$; SE 1.47; 95% CI -6.63 to -0.85; $P=.01$), where the immediate group had lower frequencies of both over the course of the study compared with the delayed group. Contrary to the expectations, there were no significant group \times time interactions for all other outcomes: emotion dysregulation, suicidality, DBT skills acquisition,

dispositional mindfulness, functional disability, and risky impulsive behaviors.

Hypothesis 3: Did iDBT Produce Improvements Regardless of Group?

Primary Outcome

There were significant main effects of time at week 4 ($b=-1.73$; SE 0.34; 95% CI -2.40 to -1.07; $P<.001$) and week 12 ($b=-2.09$; SE 0.36; 95% CI -2.80 to -1.39; $P<.001$), indicating a significant decrease in substance dependence for both groups, with no differences between groups ($P=.25$).

Secondary Outcomes

There were several findings supporting the benefits of the intervention in the follow-up phase of the study (no other significant main effects emerged at week 4). At week 12, there were significant main effects of time for depression ($b=-2.95$; SE 0.79; 95% CI -4.50 to -1.39; $P<.001$), anxiety ($b=-1.57$; SE 0.73; 95% CI -2.99 to -0.14; $P=.03$), suicidality ($b=-0.70$; SE 0.24; 95% CI -1.12 to -0.28; $P=.001$), emotion dysregulation ($b=-6.56$; SE 1.20; 95% CI -8.90 to -4.21; $P<.001$), functional disability ($b=-3.64$; SE 0.77; 95% CI -5.15 to -2.14; $P<.001$), dispositional mindfulness ($b=0.44$; SE 0.09;

95% CI 0.27-0.62; $P < .001$), and DBT skill acquisition ($b = 0.14$; $SE = 0.05$; 95% CI 0.04-0.23; $P = .005$), indicating that both groups saw significant improvements from baseline over the study duration, with no differences between groups (all $P > .25$). There were no main effects of time for risky impulsive behaviors and no difference between groups ($P > .23$).

Discussion

Summary

This study is unique in that it delivered high-quality iDBT in a self-guided format that participants could use through any internet browser on a computer, tablet, or smartphone. Here, we evaluated the feasibility, acceptability, and potential efficacy of iDBT in a sample of treatment-seeking individuals with SUDs often presenting with additional mental health symptoms. In this study, *Pocket Skills* 2.0 garnered some meaningful support as a potential intervention for those with SUDs and other mental health concerns. We also discuss some caveats and limitations in the following sections.

Feasibility and Acceptability

The intervention was deemed credible and potentially helpful by participants. In terms of treatment initiation, we found that 94% of the randomized participants started *Pocket Skills* compared with 98% in a previous remote iDBT intervention study [30]. For reference, 88% of the participants started the intervention in the study by van Spijker et al [28] and only 39% of the participants started self-guided iDBT in the study by Simon et al [31]. In this study, not initiating iDBT was mostly because of participants not attending a follow-up session after 4 weeks of being on the waitlist, and in 1 case, owing to technical issues. Thus, the feasibility of deploying iDBT remains high with few technical compatibility issues. These results support the feasibility of adapting DBT for delivery in internet-delivered formats in this context [25,30,34].

Of those who started iDBT, 13% (9/68) were early dropouts, defined as those who did not attempt the intervention after the first day of use, and 50% (34/68) continued to use the app after 4 weeks. Comparatively, Wilks et al [30] recorded a dropout rate of 19%, although different dropout criteria were used (eg, stopped attempting or completing the intervention for 3 weeks in a row). This study differs in that our participants had unrestricted access to all content, whereas the previous study used a week-to-week module approach; thus, we had different definitions of dropout by virtue of study design. There was an overall dropout rate of approximately 10% in the intervention arm in the study by van Spijker et al [28], whereas <9% went beyond the introduction section in the study by Simon et al [31,32]. The rate can also be compared with internet-based psychological treatments more broadly (31%), in-person delivered DBT for different clinical conditions (28%), and in-person psychological treatments for SUDs (30%) [63-65]. Although definitions of dropout vary across trials, this study provides some promise regarding the potential uptake and adherence to iDBT by individuals with SUDs. An analysis of the predictors of dropout from the 2018 study [30] indicated that technological barriers and low perceptions of usefulness emerged as significant [33]. Although we focused on the current

hypotheses, we intend to examine predictors of treatment outcomes (including dropout) in future research.

The time spent on the iDBT intervention varied widely. Only 35% (24/68) of the participants completed the recommended dose of spending 8 days in the first 4 weeks, which improved to 41% (24/59) when early dropouts were omitted. These findings can be contextualized by the limited support and self-guided nature of the intervention. Comparatively, 42% of the participants in the study by Wilks et al [30] completed half of the iDBT content in the same time frame (1 month), which included considerably more support, such as daily reminders, homework assignments, and phone calls regarding suicide risk. Approximately half of the participants in the intervention arm completed ≥ 3 of 6 sessions in the study by van Spijker et al [28], and a similar proportion finished a 15-session course of DBT delivered by email [27]. While we did offer text message reminders to facilitate encouragement, few participants asked for additional meetings or followed our suggested guide. However, even with limited support, a sizeable proportion of participants used the app over several days within the first month, totaling >1 hour of use. These findings suggest potential benefits of additional meetings or coaching sessions, which may improve adherence and engagement to the intervention and improve clinical outcomes overall.

There were relatively high ratings for the content, suitability, and trustworthiness of *Pocket Skills* using an established measure of treatment acceptability, extending 2 earlier studies [30,34]. Participants recorded most of their engagement within the first 4 weeks of the intervention and in that time, averaged 2 hours of interaction. In a previous 4-week trial of an earlier version of *Pocket Skills*, which was conducted in patients concurrently completing in-person DBT, participants used the app for 14 out of 28 days and spent 2.25 hours on the app during that time [34]. This equated to approximately 4 minutes of activity per person per day. Given that our study was largely self-guided without additional support or check-ins, this newer version of *Pocket Skills* saw comparative engagement with respect to total time. One self-guided skills training intervention reported 10.5 hours of use on average or approximately 15 minutes per day over 6 weeks [28]. Examining iDBT as an adjunct to in-person (or videoconference) DBT to improve engagement even further may be warranted.

Potential Efficacy

With regard to our second hypothesis evaluating the waitlist control design of the study, we found little evidence that the immediate iDBT group benefited more in the acute period of 4 weeks. We did not find a difference between groups in our primary outcome at this time point, where we expected it. We found interactions at week 4 for 2 secondary outcomes (ie, depression and anxiety) in favor of the hypothesis. We found additional interactions during the follow-up period (week 12) for decreased standard alcoholic drinks per day and overall substance use frequency in favor of the immediate iDBT group. Notably, we originally planned a 16-week trial with an equal immediate and waitlist period of 8 weeks. However, in a pilot study, we found attrition and lack of engagement to be greater than in this study, which contributed to the revised study design.

Most studies on app- and internet-based interventions use one month as an acute test of the intervention with another month as a follow-up assessment period owing to increasing attrition after 7 to 8 weeks [35-37].

Our third hypothesis regarding overall improvement was more consistently supported, with favorable improvements in our primary and secondary outcome measures in both groups by week 12. There were medium to large effect size improvements in our primary outcome of substance dependence, both in the acute (week 4) and follow-up phase, consistent with the literature supporting in-person DBT for alcohol use disorders and SUDs [16,21-24]. There were many medium to large effect size improvements to our secondary outcomes by week 12, including depression, anxiety, suicidal behavior, emotion dysregulation, and functional disability and these effects did not differ significantly by group once accounting for baseline differences. These findings are consistent with in-person DBT improvements in suicidal behavior, depression, anxiety, and emotion dysregulation [23,66-69] and extend a previous stand-alone iDBT study [30]. The intervention also improved DBT skill acquisition and dispositional mindfulness in both groups by week 12, as seen by small-to-large positive effect size values and in line with the literature findings on face-to-face DBT [52,70,71]. Whether DBT skill acquisition mediated treatment outcomes in this study, as implied by previous research [68,69], is a hypothesis that could be examined in a follow-up analysis.

Limitations

Our ability to detect interactions during the acute phase of treatment was limited given that differences would have had to be medium or large to detect using our unbalanced waitlist design. The use of a waitlist control may have led some individuals to consider other treatment options or drop out of the study without connecting to the intervention, especially given its unblinded nature following randomization. Alternatively, the waitlist condition may have supported a nocebo effect as participants reported favorable changes in most outcomes despite a lack of treatment [72]. Although the randomization procedure was conducted in a blind manner, following the baseline session, all other follow-ups and contact with participants were unblinded, which may have introduced potential experimenter bias. The primary and most secondary outcomes were participant rated (ie, self-report), which is also less robust to bias than a blinded outcomes assessor.

In terms of feasibility metrics, although we saw that roughly half of the participants remained active on iDBT after 4 weeks, it is not clear how consistently active they were. Because we did not restrict access to other interventions, it remains unclear how specific the intervention effects were tied to iDBT in this study. We attempted to mitigate concerns about this by asking questions about different services that participants were receiving at each follow-up and found little to no increase in psychotropic medications, community support groups, and additional treatments. More analyses are needed to understand the dose-response relationship between the intervention and treatment outcome, which will be addressed in future work.

Pocket Skills 2.0 omits several aspects of in-person formats of DBT that may improve engagement and adherence, such as a significant group therapy component; more robust tracking of thoughts, emotions, and behaviors using diary cards; and handouts and worksheets for homework. These implementation differences compared with standard in-person DBT may have influenced treatment outcomes. As a technical limitation, most participants accessed iDBT on a home computer or laptop. Although we discussed the ability to sign in on mobile devices with participants, we typically asked them to sign in for the first time on a computer or laptop based on experiences during the piloting phase of this study (ie, there was more difficulty signing in on the mobile iOS platform). This procedural issue may have introduced a barrier to using iDBT on mobile devices; however, we could have spent more time ensuring that the intervention was working on both participants' smartphones and computer devices. Future implementations could include subsequent meetings with participants (eg, check-ins) to address any technological and compatibility issues more quickly.

Despite efforts to recruit a diverse sample, our sample was predominantly White, female, heterosexual, and largely aged between 18 and 45 years. Future research should attempt to replicate the outcomes of iDBT across more diverse samples, such as sexual, gender, and ethnoracial minority groups (refer to the study by Harned et al [73] for review). Our sample was heterogeneous with respect to their endorsement of alcohol or nonalcoholic substance difficulties. Measuring the frequency and severity of multiple substances in an efficient way is challenging. Owing to the use of different measures and rating scales to assess alcohol and nonalcoholic substances (as well as risky and impulsive behaviors), our raw data required rescaling to create new ordinal scales that approximately modeled the same frequency and severity across multiple scales. Future research could adhere to more standardized approaches that allow for responses to be collected and then coded more reliability. For example, the Timeline Follow Back interview has been used to self-report alcohol and substance use as well as risky sexual behaviors [74,75].

Conclusions

Notwithstanding the limitations of this study, our iDBT intervention *Pocket Skills 2.0* was supported as a feasible and acceptable intervention for those with SUDs and other mental health concerns. However, methods to improve engagement should be further evaluated. The intervention not only showed potential effectiveness for substance dependence but also demonstrated positive effects across various mental health symptoms, affirming its clinical utility. These findings add to the sparse literature on internet-based DBT and internet-delivered psychological interventions for SUDs. This format has the potential to increase accessibility and reduce the costs and resources required for in-person DBT. Several research priorities were identified to potentially improve engagement and optimize treatment outcomes as well as understand how our iDBT intervention can be integrated into the larger landscape of treatment options for SUDs and other conditions.

Acknowledgments

This study was supported by a Canadian Institutes for Health Research Fellowship Award (#458772) awarded to ARD. ARD would like to thank Daniel J Tse for help in organizing and creating formulas to summarize the website analytic data and Megan Brndjar for help in organizing and tabulating the outcome data. The authors sincerely thank Geraldine “Geri” Rodriguez and Psychwire for permitting us to use their training videos featuring Dr Linehan.

Data Availability

Deidentified data may be requested from ARD.

Conflicts of Interest

CRW receives consultation fees from Mindstrong Health, Click Therapeutics, and Behavioral Tech Research. CRW is one of the developers of Pocket Skills. EHP served, in addition to other duties, as a technical support during the study and piloted the intervention. All other authors declare no other conflicts of interest.

Abstract

Background: Rates of suicide have increased by over 35% since 1999. Despite concerted efforts, our ability to predict, explain, or treat suicide risk has not significantly improved over the past 50 years.

Objective: The aim of this study was to use large language models to understand natural language use during public web-based discussions (on Reddit) around topics related to suicidality.

Methods: We used large language model–based sentence embedding to extract the latent linguistic dimensions of user postings derived from several mental health–related subreddits, with a focus on suicidality. We then applied dimensionality reduction to these sentence embeddings, allowing them to be summarized and visualized in a lower-dimensional Euclidean space for further downstream analyses. We analyzed 2.9 million posts extracted from 30 subreddits, including r/SuicideWatch, between October 1 and December 31, 2022, and the same period in 2010.

Results: Our results showed that, in line with existing theories of suicide, posters in the suicidality community (r/SuicideWatch) predominantly wrote about feelings of disconnection, burdensomeness, hopelessness, desperation, resignation, and trauma. Further, we identified distinct latent linguistic dimensions (well-being, seeking support, and severity of distress) among all mental health subreddits, and many of the resulting subreddit clusters were in line with a statistically driven diagnostic classification system—namely, the Hierarchical Taxonomy of Psychopathology (HiTOP)—by mapping onto the proposed superspectra.

Conclusions: Overall, our findings provide data-driven support for several language-based theories of suicide, as well as dimensional classification systems for mental health disorders. Ultimately, this novel combination of natural language processing techniques can assist researchers in gaining deeper insights about emotions and experiences shared on the web and may aid in the validation and refutation of different mental health theories.

Introduction

Suicide rates have increased by 35% since 1999, and suicide remains a leading cause of death in the United States [1]. Despite concerted efforts, our ability to predict, explain, or treat suicide risk has not significantly improved over the past 50 years [2,3]. Thus, a top public health priority is understanding factors that contribute to suicide risk. Recent meta-analytic work,

comprising suicide risk factor research over the past 50 years (using 365 studies), found that no single set of risk factors (eg, mood disorders or impulsivity) accurately predict future suicidal thoughts and behaviors [2]. Past risk factor studies have been limited by (1) potential sampling biases (eg, overrepresentation of clinical populations), (2) structured clinical interviews and surveys, and (3) laboratory-based (rather than naturalistic) settings. With the rapid increase in the use of web-based

platforms, such as Reddit, people experiencing mental health symptoms have new outlets for sharing experiences, seeking support, and engaging in discussion regarding their mental health. Platforms such as Reddit provide unique opportunities for studying the experiences and perspectives of individuals at risk of suicide in the context of other mental pathologies and stressors [4-6]. To overcome previous limitations in suicide risk factor research, this study aims to analyze posts from a web-based community dedicated to providing support for individuals in crisis (ie, the r/SuicideWatch subreddit), to involve individuals who may not present for mental health studies or disclose their suicide risk and to obtain more nuanced insights into suicidality from the naturalistic and open-ended nature of anonymous web-based forums.

Understanding the factors contributing to suicidality is crucial for developing effective prevention strategies and interventions. Prominent theories of suicide—such as the Interpersonal Theory of Suicide (ITS) [7], Three-Step Theory (3ST) [8], and Integrated Motivational-Volitional (IMV) model [9]—are referred to as “ideation-to-action” frameworks. These theories attempt to explain how people develop suicidal ideation and transition to suicidal behaviors. Several common variables among ideation-to-action frameworks include feeling disconnected and burdensome to others, feelings of entrapment and hopelessness, and factors that may increase peoples’ capability to die by suicide (eg, traumatic experiences). Similar to many other psychological theories, they have been developed through researchers observing data patterns and testing their hypotheses (mainly) through self-reported survey data. Analyzing linguistic patterns in Reddit posts may provide an avenue for suicide theory exploration, confirmation, and refutation for these ideation-to-action frameworks, which could significantly impact future and existing intervention targets and assessment practices.

The use of natural language processing (NLP) with machine learning (ML) to gain new insights into mental health topics has increased dramatically over the last decade [10]. In mental health, this approach has mainly been used to confirm existing hypotheses through extracting meaning from texts (NLP) and then classifying these extractions (ML); however, this combination approach can be equally useful for exploration and discovery [10]. Specifically in suicide research, NLP and ML have primarily been used to help improve the accuracy of suicide risk identification [11]. However, NLP combined with ML is less frequently used in both mental health and suicide research to derive theoretical perspectives. Newer large language models (LLMs) that use Bidirectional Encoder Representations from Transformers (BERT) allow researchers to capture more complexities in human language than previous approaches, which are ideal for discovery as well as for testing directional hypotheses. Furthermore, the recent advances in explainable artificial intelligence (XAI) can be applied to NLP to help improve transparency, trustworthiness, and understanding of results in the context of mental health [12]. Using these modern techniques in tandem may help provide critical insights into

suicide risk. The primary aim of this study is to analyze the content of posts from the r/SuicideWatch subreddit as well as mental health-related and non-mental health-related subreddits, with the goal of contributing to our understanding of suicide risk to ultimately improve prevention strategies and interventions. Although there are several other anonymous platforms available for individuals to discuss suicide, we chose Reddit due to the size of its userbase (over 400,000 members), which may aid the generalizability of our findings, and for practical reasons—namely, data availability. For this, we used LLMs to produce numerical representations of these posts—called *embeddings* [13]—which may reveal *unique* suicidality linguistic patterns; we also used recent developments in generative LLMs [14] and XAI [15], which turn abstract embeddings into natural language text, to identify connections with theories of suicidal behavior.

Our study was primarily data driven, as we used *generic* LLM embeddings of the posts and only applied theoretical constructs for post hoc interpretation. This means that the numerical representation of the posts was based on how the sentences in them are related to sentences in very large text corpora used for training the LLM that cover vast swaths of topics.

Methods

Ethical Considerations

Reddit users are made aware that their posts are publicly accessible through Reddit’s Terms and Conditions. No personal identifying information (eg, names, locations, or IP addresses) were collected. Further, none of the authors participated in any discussions; thus, it was not necessary to inform users that their posts may be used for research. Because the collected data set is publicly available and already deidentified, the University of Georgia Human Subjects Office reviewed the submission and assigned a determination of “Not Human Research.”

Data Procurement, Selection, and Preprocessing

We downloaded posts from a list of subreddits from October 1 to December 31, 2022, and from October 1 to December 31, 2010, using The-Eye.eu [16], which contains an archive of Reddit’s full submission until December 2022. We used Python (Python Software Foundation) to process the data. Posts that were removed or deleted were not used. Empty entries or entries containing just a “?” were not considered. We analyzed 16 subreddits related to mental health and 14 subreddits not related to mental health to serve as controls. In Table 1, we compared the number of posts and words per post by 2 subreddit groups (mental health and controls). We saw that the number of posts was similar in both groups, but the range and variability (ie, SDs for the number of words and words per post) were much higher in the mental health subreddits. We noted that for the 2010 data, in general, the posts were much longer than those from 2022 data; in the 2022 data, some of the posts were just a single word (eg, “Pls,” “Yuh,” and “Help”), whereas for older data (2010), the posts were much longer.

Table . Statistical descriptors of the 16 subreddits related to mental health and the 14 subreddits used as controls.

Subreddits and statistics	2010 data		2022 data	
	Mean (SD)	Range	Mean (SD)	Range
Mental health				
Posts per subreddit	246 (225)	14-785	182,000 (240,000)	15,900-928,000
Words per subreddit	409,000 (415,000)	42,000-1,600,000	34,700,000 (48,800,000)	2,700,000-189,000,000
Words per post	1700 (446)	1000-3000	183 (31)	112-225
Controls				
Posts per subreddit	— ^a	—	195,000 (243,000)	9700-831,000
Words per subreddit	—	—	21,900,000 (28,300,000)	1,500,000-95,000,000
Words per post	—	—	114 (27)	72-163

^aNot applicable.

Linguistic Analysis and Interpretation

Overall Approach

After obtaining the posts, we followed these steps: (1) represented the posts in the latent space of LLM embeddings; (2) computed a representation for each subreddit, averaging all its posts; (3) computed different metrics of the structure of the subreddits in the embedding space; and (4) applied interpretation techniques to these structural metrics to obtain insights about the relationship between suicidality and other self-identified groups.

LLM Embeddings

Semantic text embedding is an NLP technique used to represent the meaning of text in numerical form. It accounts for the context of words or phrases rather than just their individual representations. By using advancements in text embedding, we used a more precise method in NLP using BERT [17]. Text embedding assigns a numerical vector to each text, enabling texts with similar contexts to be closer in the vector space. This allows us, using mathematical tools, to better understand and analyze the semantic similarities and differences between different texts. To represent a subreddit, we compute the centroid (average) of the embeddings of all the posts assigned to it. As mentioned above, these embeddings are *unbiased*: we did not use the metadata related to the subreddit provenance nor applied any theory-driven construct [18].

Subreddits Structure

To obtain a measure of similarity between subreddits, for each post, we computed a “linguistic label”—the label of the nearest centroid in the embedding space. Then, for each subreddit, we computed the percentage of posts that were assigned to any “linguistic label,” including the original label; the proportion of posts “linguistically assigned” to a subreddit other than the original one is a measure of the similarity between them.

Hierarchical Clustering

Hierarchical clustering operates on the principle of iteratively merging the closest pair of clusters, where the definition of

“closeness” varies according to different linkage criteria. We used the Ward linkage method, where the distance between 2 clusters is the increase in the summed square distance from each point to the centroid of its cluster after merging the clusters. A dendrogram (a tree-like diagram) visually represents the process and results of hierarchical clustering. Each leaf corresponds to a data point, and branches represent the successive merging of clusters, with the height of each merge proportional to the distance between the combined clusters. By examining a dendrogram, one can intuitively grasp the data’s structure and decide on an appropriate number of clusters by cutting the tree at a specific height. This visual tool aids in interpreting the complex relationships and nested structures within the data, offering insights into the underlying patterns and groupings. We performed hierarchical clustering on the embedding representative of the subreddit, that is, the average of all the embedding vectors of the subreddit.

Dimensionality Reduction

We factorized the subreddits centroids in the embedding space using singular value decomposition (SVD). We analyzed the relative location of the subreddits in the reduced representation of the first 3 SVD components, understood as latent semantic dimensions.

Generative LLM

We used a generative LLM to obtain insights into the latent patterns of the SVD components. In a Jupyter Notebook environment, we configured the *Langchain* library to use the GPT-4-0613 model (OpenAI) [14] with a zero-temperature setting, ensuring deterministic outputs for consistency in interpretation. We used the *ConversationChain* module coupled with *ConversationBufferMemory* to facilitate an interactive and memory-aware dialogue with GPT-4. This setup enabled us to iteratively query the model with our prompts and data, ensuring a contextually rich and coherent analysis of the subreddit postings. The use of a verbose mode in the conversation setup provided detailed logging of the model’s responses, further aiding in the transparency and traceability of our analytical process. We identified posts with the top and bottom 5

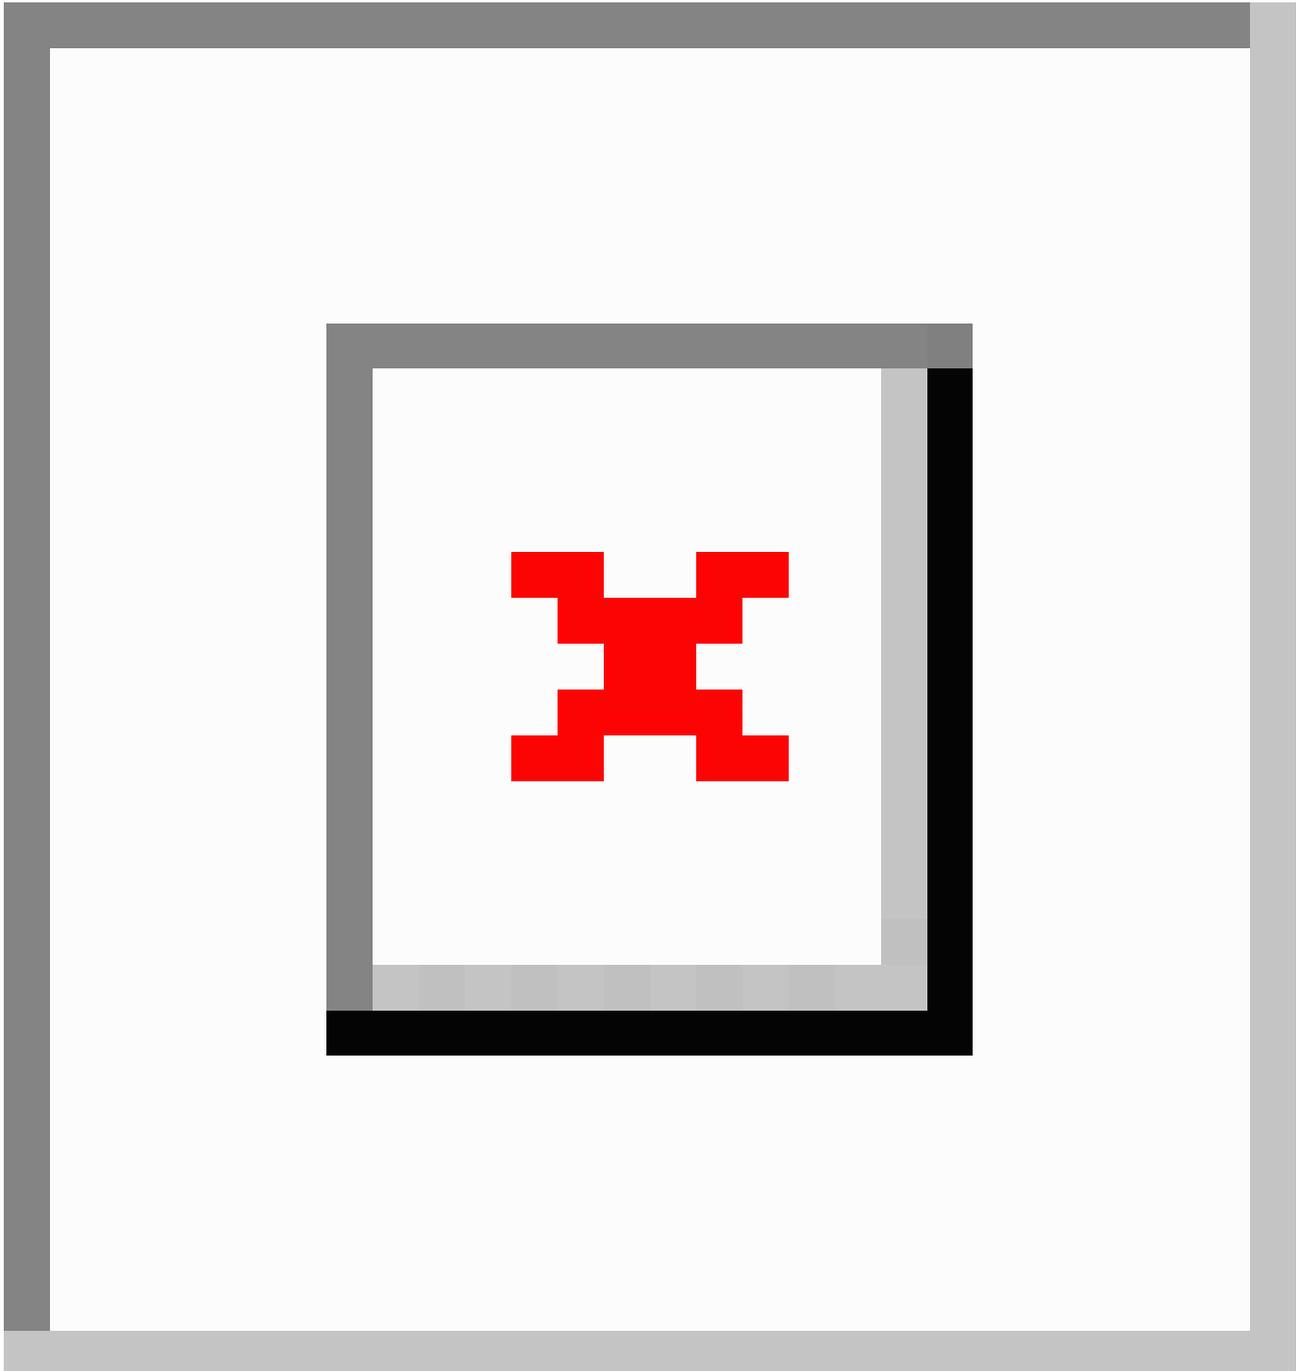

embedding positions in the first 3 dimensions of SVD projections, totaling 30 extreme postings.

XAI Techniques

XAI techniques are designed to provide insights into the factors or features that contribute to an artificial intelligence system's outputs, allowing users to understand and validate the reasoning behind those decisions. With this in mind, we use ProtoDash

[15], a technique used to choose representative examples that effectively represent the overall distribution of a data set, to help with the interpretation of the model. We fed the LLM embeddings and the associated posts from the r/SuicideWatch subreddit to ProtoDash and asked for the 5 most representative posts in the data set. Those selected prototypes of the data set were then fed to ChatGPT, to help obtain insight into the data. Figure 1 shows a visual overview of the study methodology.

Figure 1. Schematic description of the processing workflow in this paper. All Reddit postings were first fed into BERT to yield posting-level embeddings in a high-dimensional space, followed by dimensionality reduction (into 3D) using SVD. This procedure allows us to extract prototypical postings (using ProtoDash) as well as extreme postings along each of the 3 SVD axes, which were then fed into ChatGPT for semantic interpretations. Last, we also performed hierarchical clustering to recover the relational structure between different subreddits. BERT: Bidirectional Encoder Representations from Transformers; GPT: Generative Pre-trained Transformer; SVD: singular value decomposition.

Results

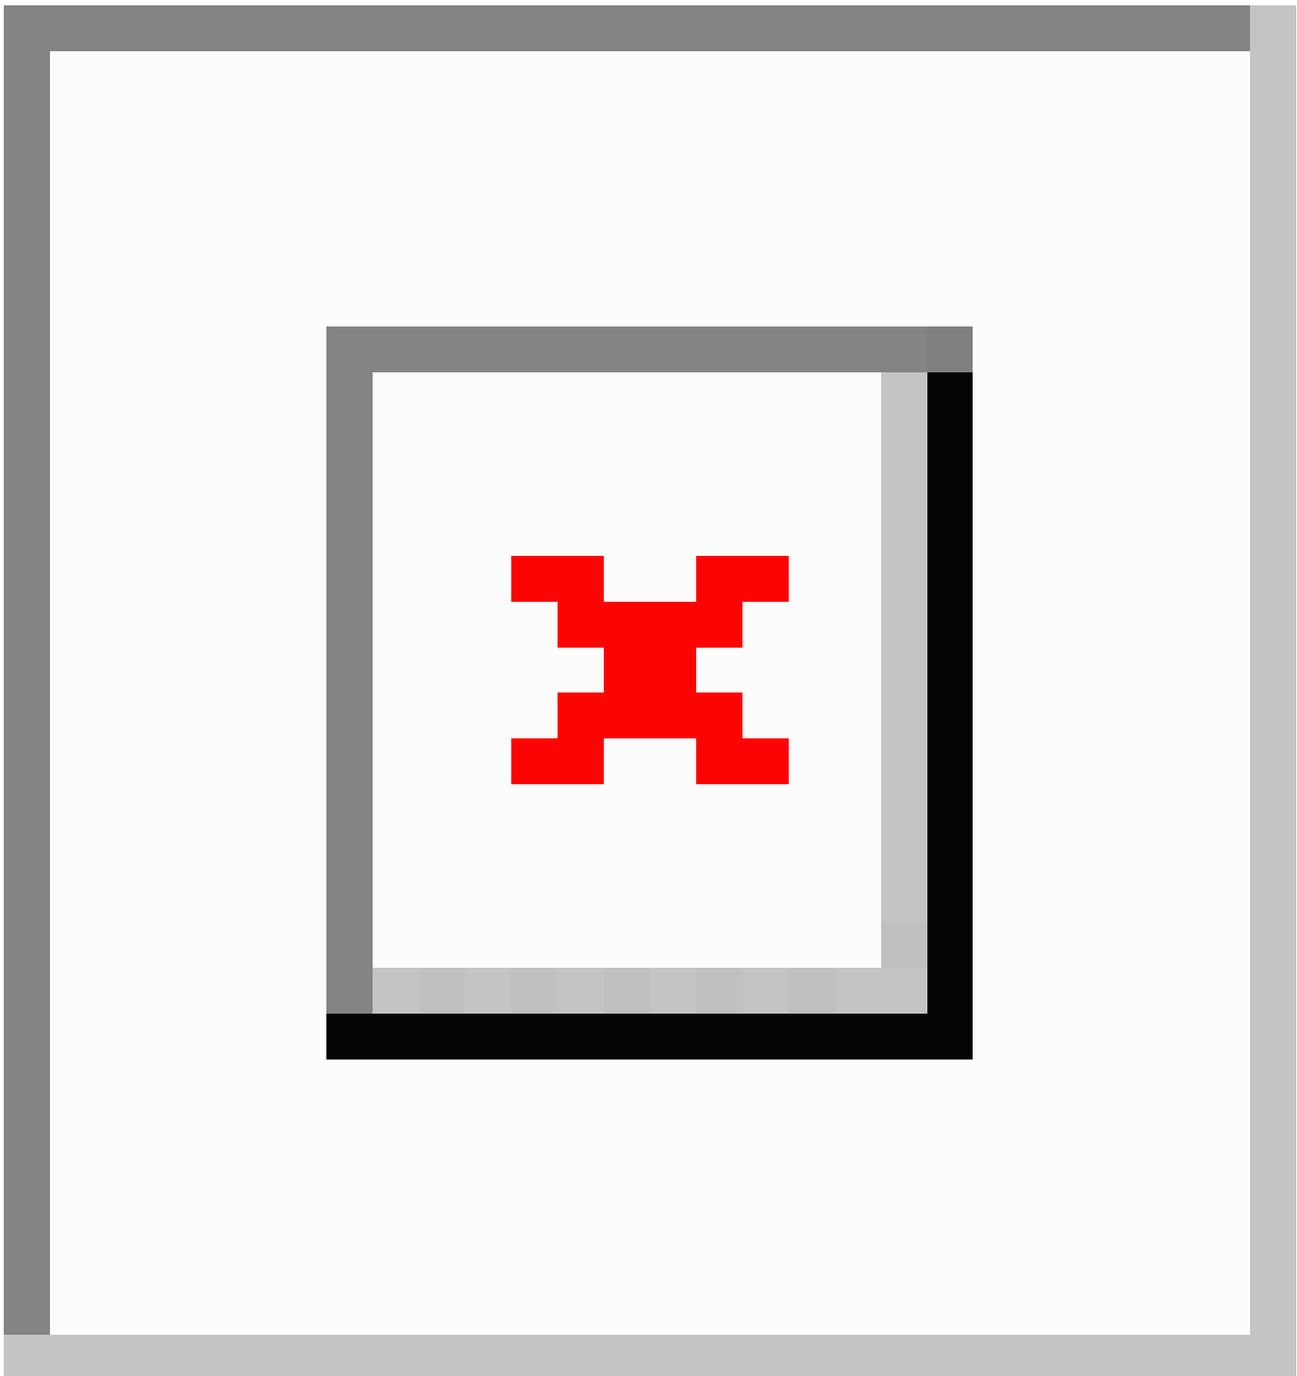

Unless explicitly indicated, we presented results on the 2022 data; the 2010 data were used to ascertain the stability of the structural features we determined with the most recent and larger data set.

Verbosity in Mental Health Subreddits

The total number of posts and the verbosity (the average number of words per post in a subreddit) are shown in [Figure 2](#).

Figure 2. The total number of posts (bar heights) and verbosity (number of words per post; green line) of subreddits. The verbosity of MH subreddits (blue) is significantly higher than non-MH ones (orange). BPD: borderline personality disorder; DnD: Dungeons and Dragons; EDAnonymous: eating disorders anonymous; MH: mental health; PTSD: posttraumatic stress disorder.

r/Depression is the most active of the mental health subreddits, and only behind the r/DnD (referring to Dungeons and Dragons) and r/gaming subreddits overall. The subreddits were sorted by verbosity (green line), which shows higher values for mental health posts as opposed to non-mental health posts. Moreover, within mental health subreddits, there are differences of more than 30% between the least verbose subreddits (r/schizophrenia and r/EDAnonymous [eating disorders anonymous]) and the high-verbosity subreddits (r/PTSD [posttraumatic stress disorder] and r/Depression).

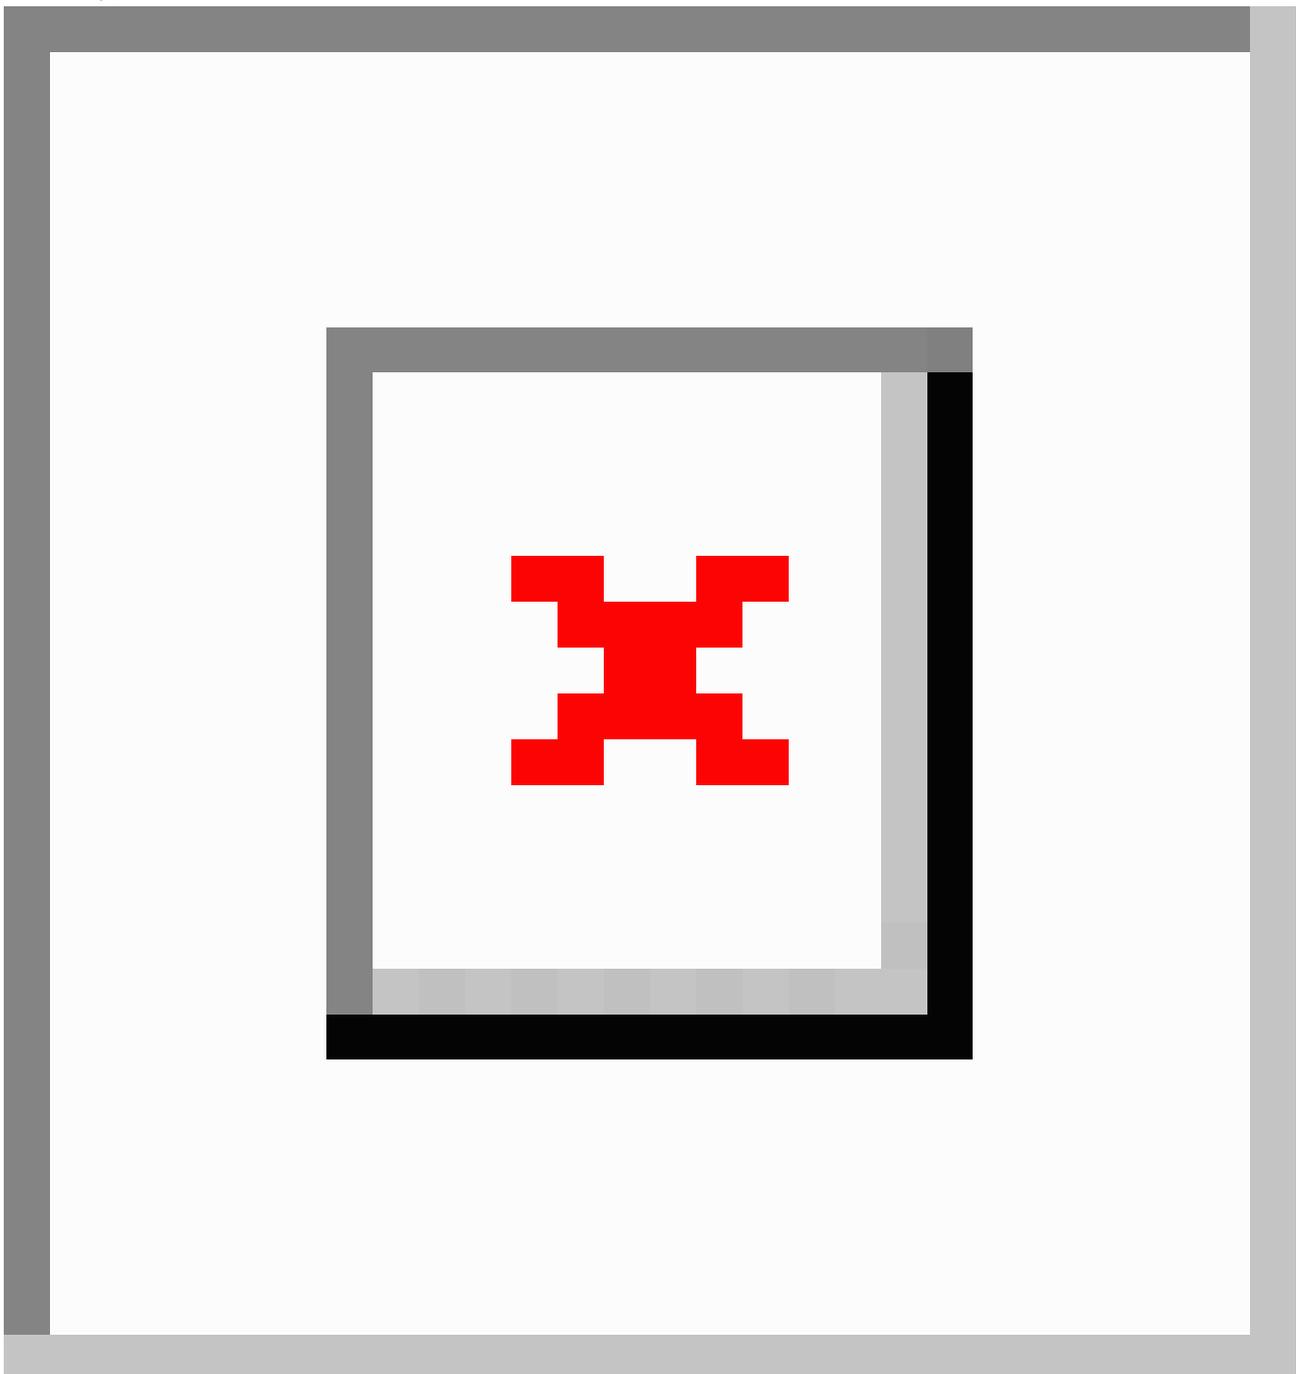

Structure of the Linguistic Embedding Space

The plot in [Multimedia Appendix 1](#) shows the measure of similarity to r/SuicideWatch for all subreddits. Almost half of the posts (234,406/479,321; 48.9%) from r/SuicideWatch were closer to their centroid than to any other centroid, with an additional 12.7% (60,854/479,321) being the closest to r/Depression, followed by r/BPD (borderline personality disorder) and r/SocialAnxiety. The extension of this approach

to all subreddits is shown in [Figure 3](#), which represents inter-subreddit similarities in the width of the links, thresholded at 7%. Besides the strong associations already present in [Figure 2](#) (of r/SuicideWatch with r/Depression and r/BPD), there are associations of r/BPD with r/Depression; r/SocialAnxiety and r/PTSD; and several associations between the different anxiety-related subreddits, r/Psychosis and r/schizophrenia, the 2 bipolar subreddits, and r/addiction with r/alcoholism.

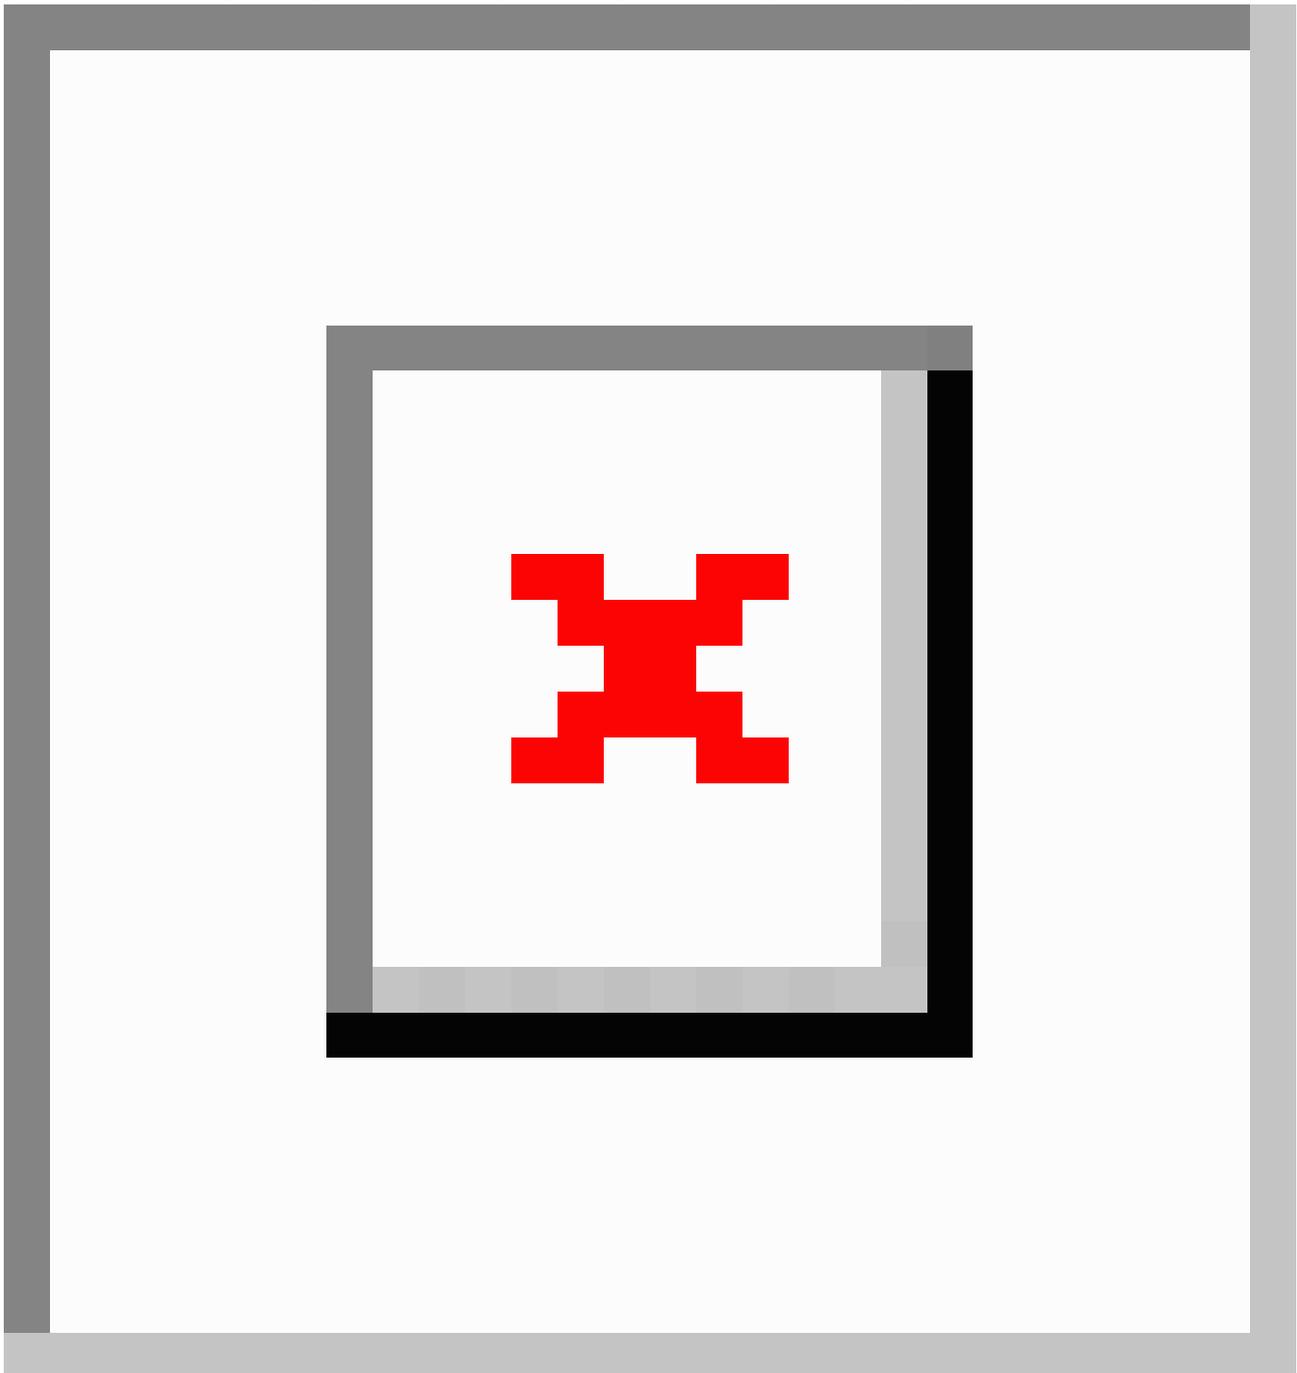

Figure 3. Proportion of posts from a given subreddit that are the “closest” to a different subreddit centroid. The r/SuicideWatch centroid is colored red, nodes connected to it are colored purple, and the rest of nodes are colored blue. The width of the edge is proportional to the number of posts that are the closest to each centroid. addition: r/addiction; alcoholism: r/alcoholism; anxiety: r/SocialAnxiety; bipolar: r/Bipolar; bipolarR: r/BipolarReddit; BPD: r/BPD (borderline personality disorder); depression: r/Depression; EDA: r/EDAnonymous (eating disorders anonymous); healthanx: r/HealthAnxiety; mhealth: r/MentalHealth; millness: r/mentalillness; psychosis: r/Psychosis; ptsd: r/PTSD (posttraumatic stress disorder); schiz: r/schizophrenia; socialanx: r/SocialAnxiety; suicide: r/SuicideWatch.

The dendrogram in [Figure 4](#) represents the result of the hierarchical clustering of the centroid coordinates for all the mental health subreddits in 2022 and 2010. The horizontal axis representing the linkage distance illustrates and supports the sequential merging of clusters. Clusters that merge at lower distances are more akin; as the distance increases, the clusters amalgamate into broader categories. The cluster with the shortest distance is grouping the subreddits [r/BipolarReddit](#) and [r/Bipolar](#). The following cluster consists of the subreddits that

discuss mental illness ([r/mentalillness](#)) and mental health ([r/MentalHealth](#)). The third most similar cluster is formed by [r/Psychosis](#) and [r/schizophrenia](#). [R/Anxiety](#) and [r/HealthAnxiety](#) cluster together (green), as do the subreddits regarding addiction ([r/alcoholism](#) and [r/addiction](#); red). Importantly, the clustering of the 2022 and 2010 subreddits were highly consistent, supporting the notion that the posts by the different subreddits revolve around the same topics related to the mental health condition they identify with.

Figure 4. Dendrogram of mental health vectors, using Ward linkage of subreddit's embeddings. The horizontal axis represents the linkage distance; clusters that combine at shorter distances are more similar to each other; as the distance grows, these clusters join together to form larger, more general categories. BPD: borderline personality disorder; EDAnonymous: eating disorders anonymous; PTSD: posttraumatic stress disorder.

Interpretation of the Linguistic Embedding Space

To obtain insights into the meaning of these topics, we performed a SVD factorization of the embedding space and used interpretation techniques on the resulting factors. Figure 5 shows the relative location of all the subreddits in the space determined by the first 2 SVD components. With the exception of r/Mindfulness, which is close to the mental health subreddits, there is a clear separation of classes along the SVD1 dimension. We also observed that r/SuicideWatch was ranked the second highest in SVD2, suggesting that this dimension may contain patterns relevant to suicidality.

The result of this procedure is presented in Table 2, which can be summarized by the following labels and directionalities: SVD1, *Emotional Well-Being: Despair to Resilience*; SVD2, *Seeking Understanding and Support: Closing In to Reaching Out*; and SVD3, *Severity of Distress: Low to High*. Using these

axis interpretations, we mapped the results from the second and third SVD projection only for the mental health subreddits, for better visualization and interpretation; Figure 6 shows only mental health cases, which fall within the left portion of Figure 5. A prominent feature of the 2 plots is that r/SuicideWatch mapped onto the high end of the *Understanding and Support (Reaching Out)* dimension, as well as on the high end of the *Severity of Distress (High Distress)* dimension in a completely data-driven way.

- Axis label prompt: “Identify the name of the axis spanned by these two groups of extreme postings given that if one extreme is hot, the other extreme is cold, then the axis is temperature.”
- High values prompt: “What are the similarities among the top (highest values on the axis) five postings.”
- Low values prompt: “What are the similarities among the bottom (lowest values on the axis) five postings.”

Figure 5. SVD factorization of the embedding space. With the exception of r/Mindfulness, all non-mental health subreddits have positive value on the first SVD component, whereas all mental health subreddits have negative value on the first SVD component. SVD: singular value decomposition.

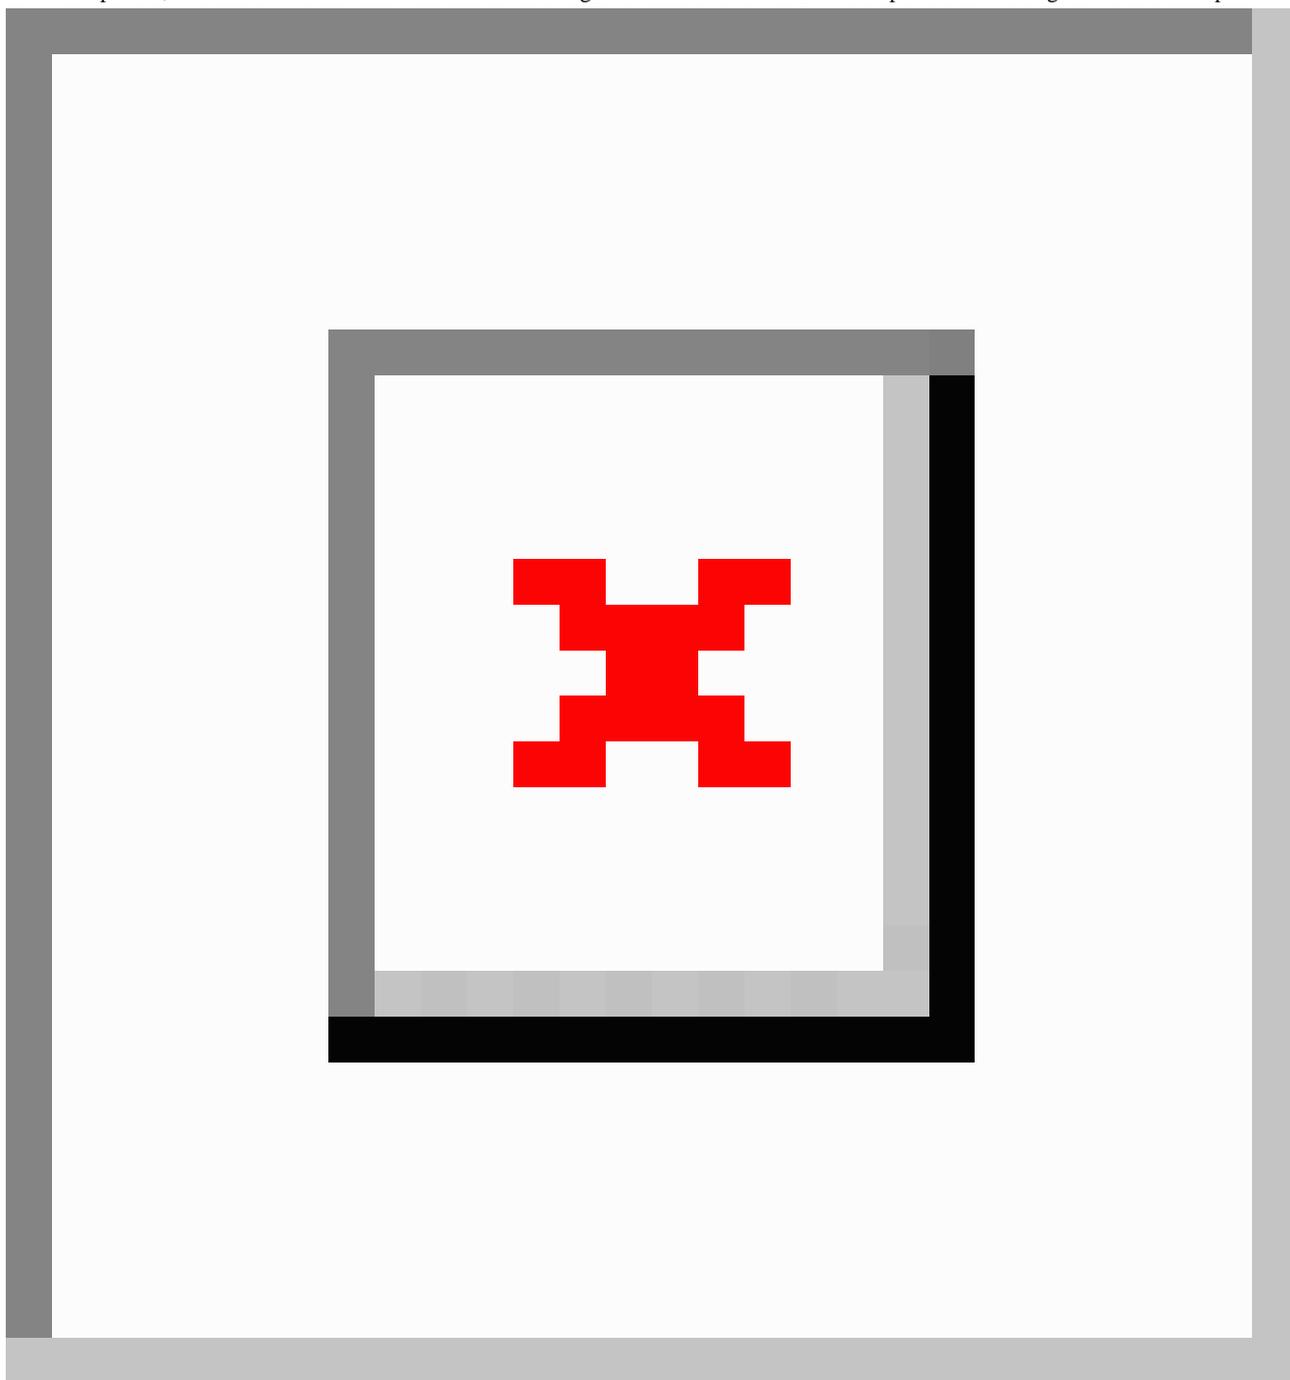

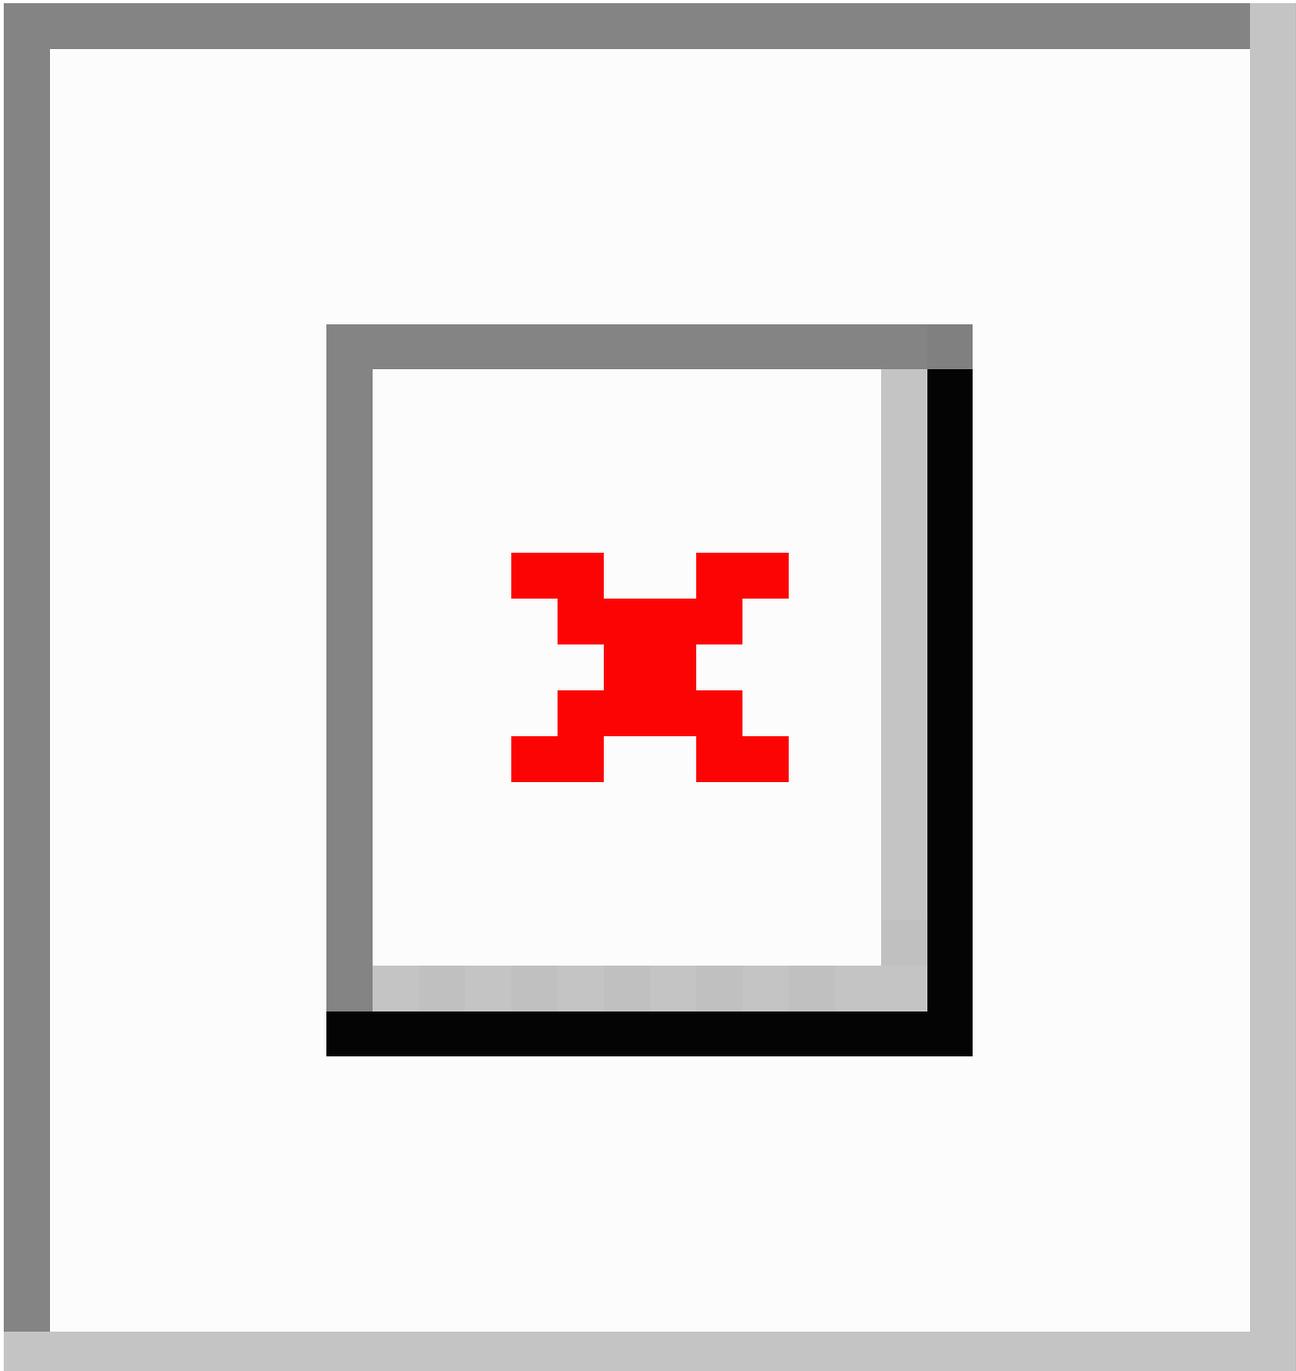

Table . Interpretation based on GPT-4 for prompts for the main 3 singular value decomposition (SVD) axes. Text from GPT-4 has been edited for grammar and clarity.

Values	Interpretation and axis label		
	SVD1, Emotional Well-Being: Despair to Resilience	SVD2, Seeking Understanding and Support: Closing In to Reaching Out	SVD3, Severity of Distress: Low to High
High	<ul style="list-style-type: none"> • Struggle and resilience • Experiencing significant anxiety, depression, and life changes • Learning to trust themselves and their abilities to handle their situations • Actively seeking help and trying to find ways to manage their mental health (eg, therapy, self-care, and relaxation techniques) • Making progress toward self improvement and happiness 	<ul style="list-style-type: none"> • Seeking guidance or advice • Desire for information, advice, or validation • Reaching out for insights, recommendations, or shared experiences • This emotion is intertwined with feelings of uncertainty, curiosity, and a desire for understanding or improvement 	<ul style="list-style-type: none"> • More intense and distressing content • Severe mental health struggles, including suicidal thoughts and feelings of extreme despair • Darker tone and more desperate
Low	<ul style="list-style-type: none"> • Narrative of struggle and despair • Feelings of sadness and emptiness • Express a sense of hopelessness about their situation • Previously sought help (eg, therapy and medication) but feel that these methods have been ineffective 	<ul style="list-style-type: none"> • Feelings of internal conflict, frustration, and being overwhelmed by personal challenges • Deep sense of pain stemming from mental health struggles, physical health issues, or personal insecurities • There's a recurring theme of individuals grappling with their emotions and seeking understanding, validation, or support 	<ul style="list-style-type: none"> • Moderate distress and struggles with mental health • Discusses personal experiences with mental health struggles, seeking help, and dealing with anxiety and social situations

Figure 6. SVD factorization of the embedding space for mental health subreddits. Centroids (representing each subreddit) are sorted from lowest to highest value on the second SVD factor in the top panel and on the third SVD factor in the bottom panel. On both panels, that is, for the second and third SVD components, the 4 extreme values correspond to r/SuicideWatch, r/SocialAnxiety, r/Depression, and r/BPD. BPD: borderline personality disorder; EDAnonymous: eating disorders anonymous; PTSD: posttraumatic stress disorder; SVD: singular value decomposition.

To complement our previous analyses that relied on extreme postings, here, we instead leveraged prototypical or representative postings within the r/SuicideWatch subreddit. To this end, we used ProtoDash to select the top 3 most representative postings, which were then fed into GPT-4 with the prompt of “Are these postings in line with current theories about suicide and suicidal ideation?” The following summarizes GPT-4’s response:

The first post describes feelings of hopelessness, despair, and anxiety, with a clear intent to commit suicide. The second post, despite stating a lack of

suicidal intent, expresses chronic emotional distress, a lack of enjoyment in life, and recurring thoughts of wanting to die, which may actually be signs of suicidal ideation. The third represents a state of severe emotional distress, feelings of hopelessness, despair, loneliness, and a sense of being misunderstood and neglected; it also mentions previous suicide attempts, a plan for a final attempt, and mentions hearing voices, which could suggest a psychotic disorder.

These posts are consistent with current theories of suicidality. The ITS, for example, posits that individuals are more likely to

die by suicide when they have both the desire to die, often stemming from feelings of burden and social isolation, and the capability to do so, often developed through previous exposure to painful or fear-inducing experiences.

Discussion

Principal Findings

We combined analytic and interpretability techniques to study linguistic contents in large numbers of postings derived from the r/SuicideWatch subreddit in relation to other mental health subreddits, as well as select non-mental health subreddits. This allows us to better understand, both qualitatively and quantitatively, how suicidal ideation linguistically presents in popular social media sites (Reddit). Our results offer new insights into the emotional and thematic content shared by individuals at risk of suicide on Reddit.

First, by applying GPT-4 to postings spanning the top 3 axes in our dimensionally reduced embeddings across all subreddit postings, we were able to determine the linguistic meanings of these axes, which describe generally what people tend to discuss on anonymous web-based mental health forums, including suicide-related discourse. These axes were (1) resilience versus despair, (2) validation versus advice, and (3) high versus low distress. R/SuicideWatch was characterized by narratives of struggles and despair (eg, hopelessness and previous treatment being ineffective) and showed the highest values of nearly all mental health subreddits for seeking advice (more so than validation) and high levels of distress. R/SuicideWatch posts also had the highest values for seeking guidance and advice—just above r/BPD and r/Depression and just below r/SocialAnxiety. These specific communities and those with associated disorders or phenomena may seek advice or guidance (ie, practical solutions) more than others because of their chronicity, recurrence, and historical difficulty to treat. For example, spanning across 50 years of intervention research for suicidal thoughts and behaviors, recent meta-analytic evidence shows that overall intervention effects are small regardless of the intervention or suicide-related outcome studied [3]. Further, although effective treatments are available, when left untreated, social anxiety and BPD are often chronic conditions [19,20], and depressive disorders are highly recurrent [21]. Individuals on Reddit may therefore be searching for additional solutions, potentially because past treatment engagement was not adequately effective in reducing their symptoms. Last, regarding distress, our study is in line with previous studies examining suicide-related social media posts that characterizes these postings as indicating high levels of distress [22].

More generally, these 3 axes exemplify broad common themes during clinical appointments, with people sharing messages of *hope and resilience* or *despair and hopelessness* (referred to as “Emotional Well-Being” by GPT-4). Similarly, individuals on mental health subreddits mention a desire for *validation or support* and *problem-solving or solutions*, both of which are core to several effective psychosocial treatments. Last, subjective distress represents a core component of what helps define a mental health disorder [23] and varies widely from disorder to disorder as well as individually, as indicated by the

values along this axis. Together, these axes may indicate that a therapy-like process naturally occurs in Reddit communities, where posters provide messages of despair or resilience with different degrees of distress and are searching for validation and solutions to their experiences.

Using ProtoDash in conjunction with GPT-4, we extracted and summarized common thematic and emotional contents from r/SuicideWatch postings. Results support the central variables within contemporary theories of suicide for explaining why the desire for suicide develops. Here, the 3 most prototypical posters predominantly wrote about feelings of disconnection, burden, hopelessness, desperation, resignation, and trauma. The ITS, 3ST, and IMV theories of suicide all state that disconnection (eg, thwarted belongingness), perceived burdensomeness, and feeling that their issues are intractable (eg, entrapment, hopelessness, and resignation) are necessary elements for developing a desire to die by suicide. Further, desperation—having a deep sense of despair, feeling overwhelmed, and lacking the ability to improve current conditions—is consistent with psychache [24] and the recently proposed diagnostic criteria for acute suicide conditions (eg, suicide crisis syndrome [25]), each of which cite despair as a core criterion for the development of suicidal ideation. Last, experiencing trauma (broadly defined) was frequently discussed in postings. Experiencing traumatic events is not posited as a necessary and sufficient condition for the development of suicidal ideation, but it has been put forth as a contributor for why people become capable of dying by suicide [7-9]. However, previous meta-analytic work has correlated traumatic experiences such as abuse with future suicidal ideation [2], and if the term is taken colloquially (ie, negative life stressors), it may contribute to theoretical constructs such as defeat or humiliation [9,25].

Next, we identified linguistically defined natural groupings among mental health subreddits. Our results seemed to suggest three different clusters: (1) r/SuicideWatch, r/Depression, r/MentalHealth, r/BPD, and r/Social Anxiety; (2) r/Psychosis, r/schizophrenia, and r/Bipolar; and (3) r/alcoholism, r/EDAnonymous, and r/addiction (see Figures 4 and 5). However, the 3 clusters mentioned above appear to (largely) support the superspectra put forth by the Hierarchical Taxonomy of Psychopathology (HiTOP)—a recent statistically driven diagnostic classification system for mental disorders [26]—compared to traditional clusters found in the *Diagnostic Statistical Manual of Mental Disorders, Fifth Edition* [23]. The three clusters mentioned above generally correspond to the following HiTOP spectra: (1) Internalizing Disorders; (2) Psychotic Disorders; and (3) Disinhibited Externalization Disorders. However, other mental health subreddits such as r/HealthAnxiety, r/Anxiety, r/mentalillness, and r/PTSD did not map as neatly onto any 1 dimension. In contrast with HiTOP, r/BPD was more aligned with internalizing disorders than externalizing disorders in this study. Similarly, while eating disorders (r/EDAnonymous) and substance or alcohol use disorders (r/addiction) are classified under different HiTOP spectra (Internalizing Disorders and Disinhibited Externalizing Disorders, respectively), their strong phenotypic associations and comorbidities are well documented in the literature (see a

recent study examining their shared genetic risks [27]). Taken as a whole, our results also support a more nuanced and dimensional view of HiTOP spectra (eg, internalizing vs externalizing disorders), where posters in r/BPD are more often discussing unsatisfying relationships, feelings of emptiness, desires for self-harm, anger, and other cognitive criteria rather than solely discussing externalizing behaviors (eg, physical fights and risky behaviors) that are central to the BPD HiTOP spectra (ie, externalizing disorders).

As indicated by the hierarchical structure of the dendrogram in Figure 4, the linguistic features in r/SuicideWatch have substantial overlap with postings in r/Depression, r/BPD, and r/SocialAnxiety. This is likely due to suicidal ideation being a symptom of depression and suicidal (and parasuicidal) behaviors, which are common features of BPD [23]. Regarding the (somewhat unexpected) linguistic similarities between postings from r/SuicideWatch and r/SocialAnxiety, we posit that they are likely driven by mentioning social and interpersonal issues (eg, loneliness), which are common among both. These similarity findings may help serve as additional validity for our results and may have implications for recently proposed diagnostic criteria for suicide-related thoughts and behaviors, such as acute suicide affective disorder [28] and suicide crisis syndrome [25], that highlight abrupt or accentuated feelings of social disconnection or social withdrawal as an indicator of suicide crisis risk.

From Figure 6, we note in the top panel that r/BPD had the third highest value on the axis for “Understanding and Support,” with r/SuicideWatch being the second highest. In the bottom panel, r/BPD has the fourth highest value on the axis for “Severity of Distress,” next to r/Depression, whereas r/SuicideWatch had the highest value. Individuals with BPD are at a notably higher risk of suicide, with commonalities between the 2 including impulsivity, intense emotional dysregulation, and chronic feelings of emptiness. These individuals often struggle with unstable interpersonal relationships and heightening feelings of loneliness and rejection, which can trigger suicidal thoughts and behaviors. Additionally, a significant proportion of those with BPD have a history of trauma and may have co-occurring mental health disorders, such as depression or anxiety, further exacerbating the risk. The prevalence of self-harm behaviors in individuals with BPD, although not always indicative of suicidal intent, is also a critical risk factor [29-32].

Last, the representative posts selected by ProtoDash and interpreted by ChatGPT showed that r/SuicideWatch discussions emphasized feelings of empathy, support, understanding, and gratitude. In addition, ChatGPT found that typical replies offered messages of hope that things will improve and encouraged seeking help, traveling to beautiful places or to find solace, and connecting with nature to find “self love.” Many of these actions

(eg, empathy, support, understanding, and encouraging help-seeking behavior) are what professional organizations (eg, National Suicide Prevention Lifeline and American Foundation for Suicide Prevention) advocate friends, family, and communities provide to individuals in crisis. Although some of the proposed suggestions do not have an evidence base for being effective in reducing suicidal desire (eg, traveling to beautiful places), survivors of suicide or individuals with lived experience (eg, other members of r/SuicideWatch) may provide additional perspectives that can be helpful when used alongside evidence-based therapies and interventions [33]. Overall, these findings indicate that some web-based communities, such as r/SuicideWatch, could be a source of support for many individuals experiencing suicidal thoughts and can act in accordance with the suggestions put forth by several professional suicide prevention organizations.

Limitations and Future Directions

We note a few limitations of our study. First, the data were limited to a 3-month period, which may not be sufficient to fully capture the range of experiences and emotions expressed in the r/SuicideWatch subreddit. Additionally, instead of more broadly looking into other social media platforms, the study focused solely on Reddit, and thus, the findings may not generalize to other web-based platforms. Future research could expand the time frame of data collection; explore other web-based platforms; and integrate additional data sources, such as user comments, to provide a more comprehensive understanding of web-based expressions of suicide risk. Last, the results from this study could not be validated against external criteria such as established measures of suicide risk or clinician judgment, potentially limiting the credibility of our findings. Future studies could incorporate multiple perspectives to help understand the accuracy and reliability of the extracted thematic interpretations.

Conclusion

In conclusion, we used a novel combination of NLP techniques to detect and interpret linguistic patterns of mental health subreddits to better understand how suicidal ideation presents in web-based communities. LLM embeddings allowed for a nuanced analysis of subreddit content that revealed unique patterns and shared themes that are specific to suicide-related content. Further, dimensional reduction revealed latent dimensions of mental health discussions and helped identify relationships between various subreddits. Last, we used generative LLM for XAI to gain deeper insights into the emotions and experiences of individuals posting about suicidal thoughts. Our results supported contemporary theories of suicide. Our study highlights the potential use of web-based linguistic patterns as valuable data sources to better understand mental health disorders and suicidality.

Acknowledgments

We thank the Reddit community for their openness in sharing their experiences and emotions, which made this research possible. We also acknowledge the contributions of ChatGPT (OpenAI) [14] for its assistance in data interpretation.

Data Availability

The data sets used and analyzed during this study were downloaded from The-Eye.eu [16].

Authors' Contributions

BB, RN, AL, and GC created the study concept. BB, AL, RN and GC were major contributors to writing the manuscript. ZAR provided the code to access Reddit data from The-Eye.eu [16]. BW provided the code to access ChatGPT programmatically. RN collected and analyzed the data. All authors read and approved the final manuscript.

Conflicts of Interest

AL is a cofounder of Keywise AI and has served as an adviser or consultant for Otsuka US and Buoy Health. BB, RN, ZAR, BW, and GC have no conflicts of interest.

Abstract

Background: There is growing concern around the use of sodium nitrite (SN) as an emerging means of suicide, particularly among younger people. Given the limited information on the topic from traditional public health surveillance sources, we studied posts made to an online suicide discussion forum, “Sanctioned Suicide,” which is a primary source of information on the use and procurement of SN.

Objective: This study aims to determine the trends in SN purchase and use, as obtained via data mining from subscriber posts on the forum. We also aim to determine the substances and topics commonly co-occurring with SN, as well as the geographical distribution of users and sources of SN.

Methods: We collected all publicly available from the site’s inception in March 2018 to October 2022. Using data-driven methods, including natural language processing and machine learning, we analyzed the trends in SN mentions over time, including the locations of SN consumers and the sources from which SN is procured. We developed a transformer-based source and location classifier to determine the geographical distribution of the sources of SN.

Results: Posts pertaining to SN show a rise in popularity, and there were statistically significant correlations between real-life use of SN and suicidal intent when compared to data from the Centers for Disease Control and Prevention (CDC) Wide-Ranging Online Data for Epidemiologic Research ($r=0.727$; $P<.001$) and the National Poison Data System ($r=0.866$; $P=.001$). We observed frequent co-mentions of antiemetics, benzodiazepines, and acid regulators with SN. Our proposed machine learning–based source and location classifier can detect potential sources of SN with an accuracy of 72.92% and showed consumption in the United States and elsewhere.

Conclusions: Vital information about SN and other emerging mechanisms of suicide can be obtained from online forums.

Introduction

Background

Suicide rates in the United States continue to rise and remain near their highest levels in more than 2 decades [1,2]. There were 48,183 suicides in the United States in 2021, which is 5% higher than the reported number in 2020 [3]. Poisoning is the most common mechanism of suicide attempts in the United States [4] and the third-leading mechanism involved in suicides

[5]. One factor complicating suicide prevention efforts is the continual emergence and promotion of new means by which one can attempt suicide, such as novel substances.

Since 2019, a growing trend of using sodium nitrite (SN), a common food additive, for self-harm has been reported [6,7]. SN has traditionally been used as a food preservative and coloring agent, in addition to use as a corrosion inhibitor. As such, it is widely available for purchase. An alarming development has been the sale of “suicide kits” in online

marketplaces, which comprise SN in addition to instructional material on attempting suicide [8]. Instances of the use of such suicide kits have been reported in the literature [9]. Furthermore, media reports of celebrity suicides from SN ingestion have raised public awareness of this means of self-harm. As a widely available, water-soluble salt with reported lethal dosages of as low as 0.7 g [10], the potentially growing popularity of SN as a suicide mechanism is concerning. Between 2018 and 2020, the annual suicide rate involving SN increased from 0.01 to 0.09 per 100,000 person-years in the United States [11]. Although there are concerns about increased youth suicides due to media contagion [12], studies show that adhering to suicide reporting guidelines [13] can raise awareness and have a protective effect through the coverage of positive coping mechanisms [14].

The consumption of SN induces methemoglobinemia, a condition resulting in hypoxia, and if not treated promptly, it can result in death. Although the unintentional consumption of SN due to misleading or dubious storage practices is of concern [15], the consumption of SN with the intent of self-harm has also been reported in countries such as Australia, Portugal, and South Korea [6]. It is believed that global popularization of SN, instruction on its use in suicide, and sharing of information about procuring SN has been facilitated by online forums such as “Sanctioned Suicide” [15], about which little is known.

Online Suicide Forums

Online forums provide a platform for users with similar interests to share their views on common topics of interest. Internet support forums exist for a wide variety of health-related issues, including mental health and suicide-related behaviors. Sanctioned Suicide is the successor of the eponymous subreddit (a topic-specific forum), which was banned in March 2018 for violating Reddit’s policies on content promoting self-harm and specific suicide methods [15]. The purpose of the website, as mentioned in their frequently asked questions [16], is to allow individuals to discuss suicide—including suicide methods—without the content screening that occurs on more prominent social media platforms. Thus, this forum encapsulates a large amount of suicide-related information that can be of high utility for planning and enacting public health measures to prevent suicides. The large volume of data, however, also makes it impractical to manually review the content continuously to generate timely and evolving insights.

Automated methods are thus required to optimally leverage this resource of publicly available information.

Objective

Although the use of SN for suicide has elevated to the level of congressional interest in the United States [17], little is known about epidemiologic trends from Sanctioned Suicide that could inform prevention efforts. The key strategies highlighted in the *Suicide Prevention Resource for Action* [18] by the US Centers for Disease Control and Prevention (CDC) call for “data-driven strategic planning with engagement from multi-sectoral partners” for making decisions associated with the prevention of suicides in the United States [17]. In line with the objectives and guidance set out in this resource, in this paper, we adopt a data-driven approach using natural language processing (NLP) and other techniques to study large-scale public posts from Sanctioned Suicide to answer critical questions relevant to suicide prevention efforts:

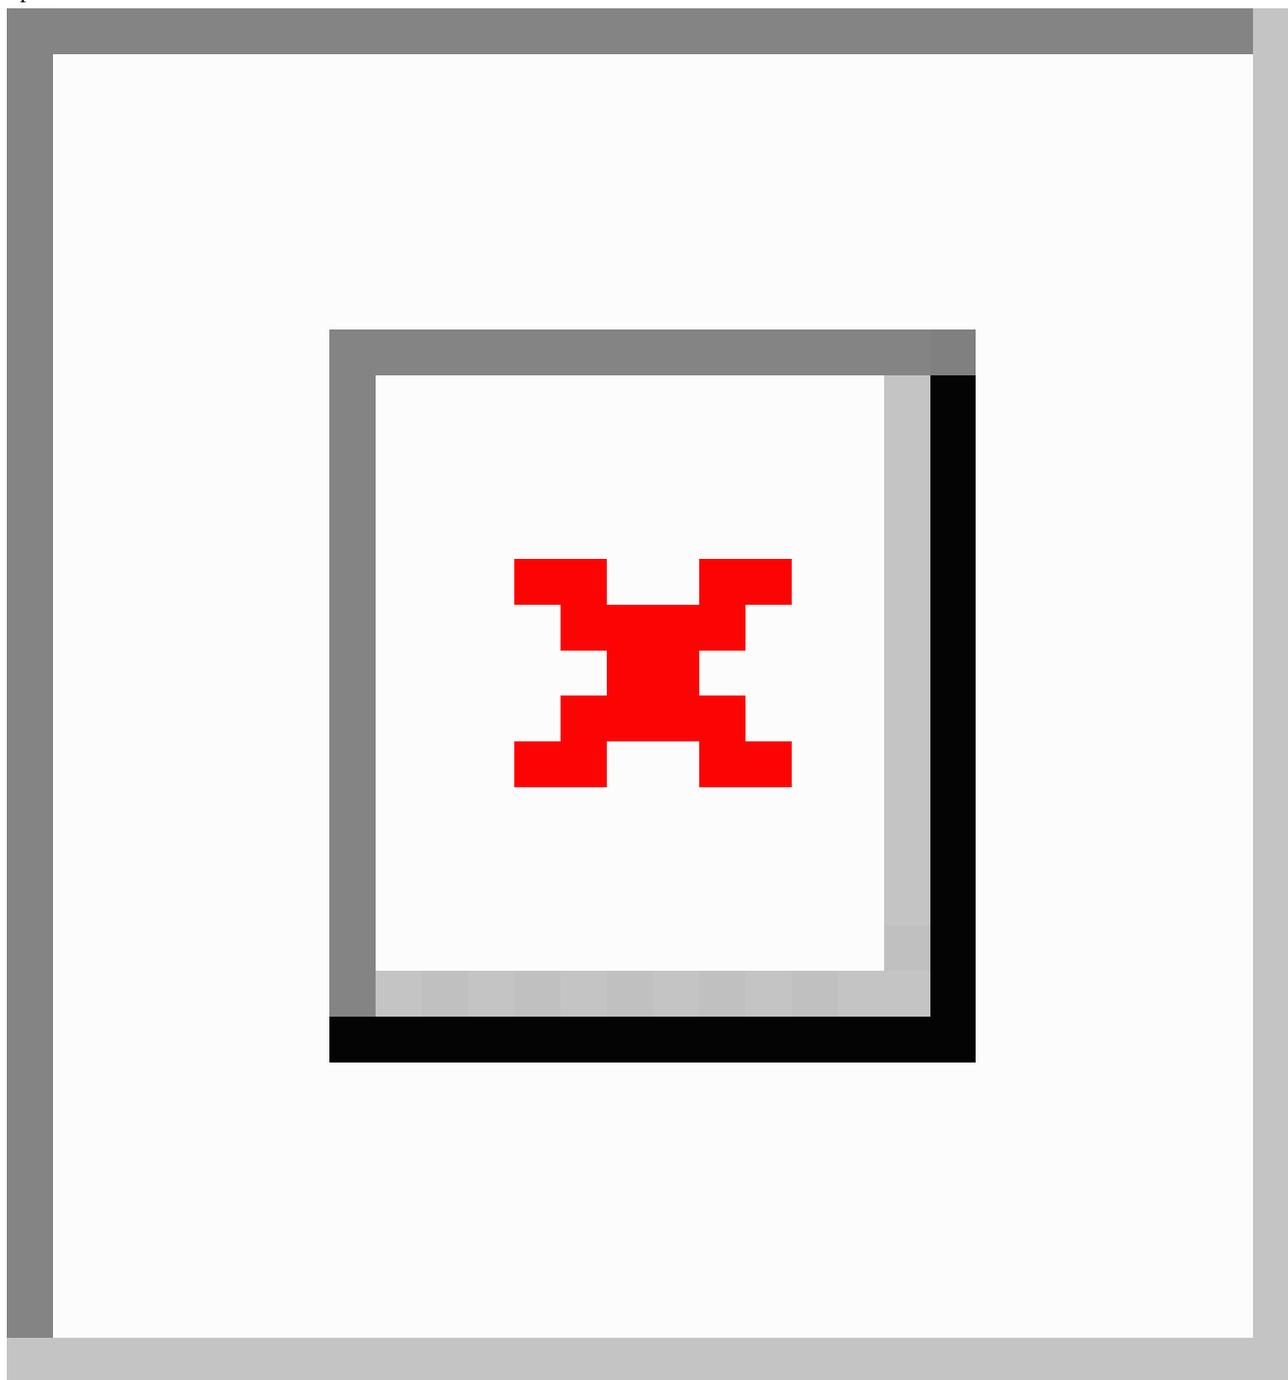

1. Does interest in SN appear to be increasing over time on the forum, and how does this interest compare to other mechanisms of suicide?
2. Are there other co-occurring substances or topics of interest relevant to SN?
3. What are the leading countries and vendors of SN that are being promoted?

Methods

Data Collection and Preprocessing

We collected data from the website “Sanctioned Suicide,” an online community dedicated to discussing “the topic of suicide without the censorship of other places” [16], which has received substantial attention because of its rising popularity in the recent past [15]. Figure 1 presents the structure of the Sanctioned Suicide network. As the figure illustrates, the social network is broadly divided into 3 types of discussion based on topic (*suicide*, *recovery*, and *off-topic*). We collected all posts available on the website from March 22, 2018 (the date on which the website went live), to October 7, 2022 (the date of data collection). We removed duplicate posts and applied preprocessing steps that are standard in NLP, namely tokenization, lowercasing, punctuation removal, stop-word removal, and lemmatization.

Figure 1. Overall structure of the Sanctioned Suicide website. Threads are organized under 3 broad categories: suicide discussion, recovery, and off-topic.

Data-Driven Analysis of Suicide Mechanisms

Suicide Mechanism Detection and Trend Analysis

Our first objective was to detect mentions of SN as well as other specific substances and suicide methods. As is common over social media, many lexical variants are used to discuss SN and other substances or methods. Not including commonly used lexical variants leads to low-sensitivity data collection [19]. We took a data-driven approach to identify all the relevant lexical variants for SN. We trained a Word2Vec model using n-grams (n=1, 2, and 3) from the entire data set, which enabled us to automatically identify lexical expressions that are the most semantically similar to SN. We manually reviewed these terms

and identified, in addition to alternative names for SN, keywords associated with other suicide mechanisms. In consultation with our subject matter experts, we manually grouped these keywords into 14 categories: “sodium nitrite,” “cyanides,” “firearms,” “hanging,” “acid regulators,” “ricin,” “plant-based poisons,” “antiemetics,” “other preservatives,” “nitric oxide,” “household chemicals,” “barbiturates,” “benzodiazepines,” and “opioids.” The complete list of suicide mechanism–related terms identified is given in Table S1 in [Multimedia Appendix 1](#).

We performed automatic searches over the whole data set to compute the frequencies of posts mentioning each method of suicide over time. A post that mentioned any number of lexical variants associated with a suicide method counted toward that

method. For example, a post mentioning only “NaNO₂” is assigned the group “sodium nitrite,” whereas a post mentioning “gun” and “full suspension” is assigned the group labels “firearms” and “hanging.” We computed the monthly and normalized frequencies of posts mentioning each of these categories to analyze their temporal trends.

Comparison of Trends With Traditional Data

We compared the temporal trends of SN mentions we discovered from the above analysis with relevant metrics reported in two more traditional sources: (1) intentional exposures to SN in the US National Poison Data System (NPDS) and (2) death counts in the CDC Wide-Ranging Online Data for Epidemiologic Research (WONDER) database. For the first comparison, we compared our data against the quarterly intentional exposures to SN from the NPDS reported by McCann et al [10]. For the second comparison, we compared against the reported deaths under the underlying cause of death codes U03, X60–X84, and Y87.0 and multiple causes of death code T50.6 from the CDC WONDER database. For the latter, to make the comparison better aligned with the traditional data source, we combined our keyword mention counts pertaining to “sodium nitrite” and “other preservatives.” We performed a Spearman rank correlation test to assess possible associations between the pairs of statistics.

Co-Occurrence Analysis and Topic Modeling

We performed a co-occurrence analysis to compute the number of times different suicide methods we already identified were

mentioned together. The intuition behind this analysis was that suicide methods that are considered together or substances that are taken together (eg, substances taken alongside SN) are likely to be mentioned more frequently in the same posts.

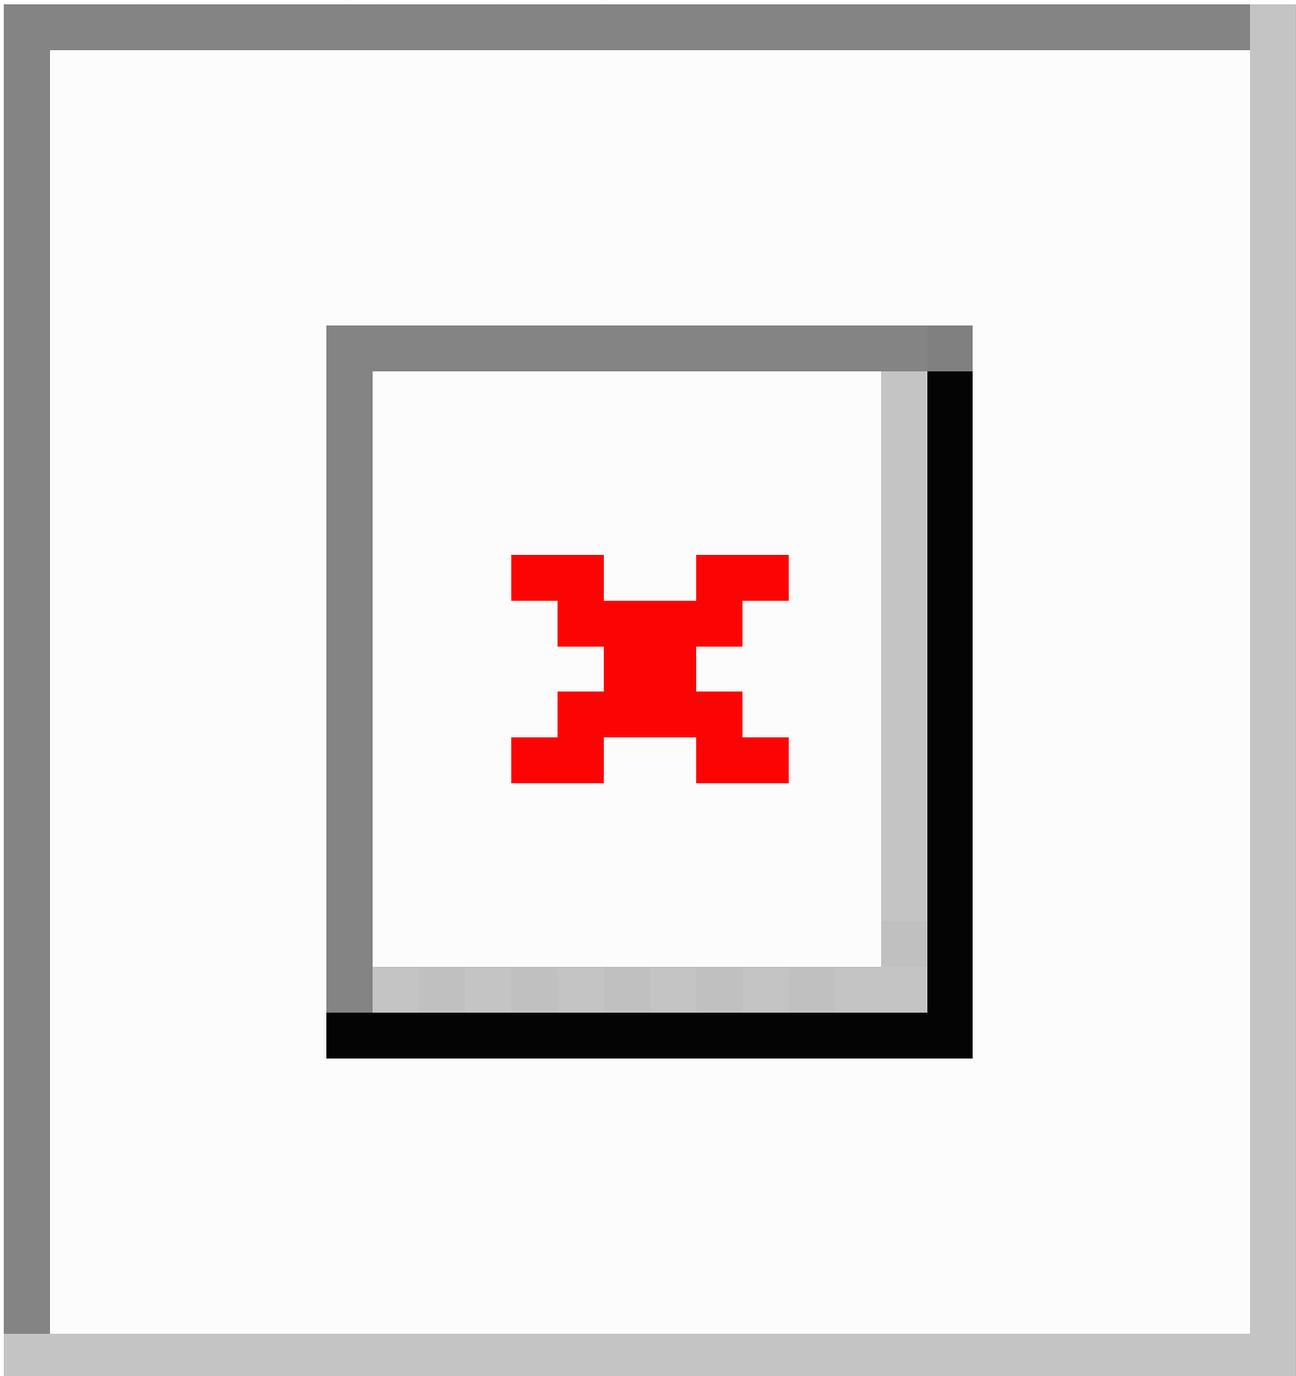

To obtain further insights about the topics associated with SN chatter, we conducted a topic modeling experiment. Topic modeling is a class of unsupervised algorithms that attempt to identify clusters of lexical elements that belong to latent topics from large sets of texts. Since the process is purely unsupervised, the topic clusters are not known a priori. We applied the BERTopic model, an unsupervised topic modeling approach that automatically clusters content from posts into a mathematically optimized number of topics [20].

Identification of SN Sources and Consumer Locations

Named Entity Recognition

Purchasing, sourcing, and procurement of SN were identified as common topics of discussion during the analyses mentioned above (see the *Results* section), so we used a 2-fold approach to identify information about both the retail venues and the geographic locations where SN was being sought for purchase. Specifically, we leveraged named entity recognition (NER) models trained on large web-based data sets to identify potential sources of SN: locations, organizations, and keywords used to look for SN on online marketplaces. NER is an information extraction technique used to discover named entities (such as organizations, locations, etc) in a textual corpus (Figure 2).

Figure 2. Examples of named entity recognition from Sanctioned Suicide posts from March 2018 to September 2022. Detected entities, their spans, and their inferred types are shown. GPE: geopolitical entity; ORG: organization; SN: sodium nitrite.

We used an NER algorithm available in the Python programming language (spaCy NER [21]) to detect possible locations or sources from which people seek or obtain SN. Apart from using spaCy's location entity label, we created a custom entity called "Suicide_Method" that would identify the substance in the text and highlight it. We used the rule-based pattern recognizer in spaCy to detect mentions of SN. In particular, we used the pattern "sn" to detect mentions of SN (the code snippet is shown in [Multimedia Appendix 1](#)). Posts where SN was mentioned in conjunction with location names were used for further analysis. The location entity recognizer of spaCy has a reported F_1 -score of 0.916 [22].

Location Mention–Intent Classifier

The locations identified by the NER methods represented both sources of SN and consumer locations, and thus, the process required further disambiguation. We modeled this disambiguation as a supervised classification task and trained a transformer-based location classifier to classify the locations obtained from NER as "consumer location" and "purchase location." Transformer models leverage large amounts of "pre-trained" language data, which can then be fine-tuned on a specific task—such as location type identification, in the case of this study [23]. Sentence-level annotation of location mentions was carried out by 2 of the authors to create a gold-standard training data set for fine-tuning the model. The

annotation process was carried out iteratively, with the annotation guidelines being refined after each round of annotation. Disagreements were resolved after a detailed discussion between 3 of the authors to reach a consensus after each round. Two rounds of annotation were performed, and interannotator agreement was computed based on Cohen κ , revealing good agreement for both source location ($\kappa=0.80$) and consumer location ($\kappa=0.84$) [24]. A total of 722 samples were annotated, of which 577 (80%) were used for training and the remaining 145 (20%) were used for testing.

From the many transformer-based models that are publicly available, we chose the RoBERTa model [25], which is based on Bidirectional Encoder Representations From Transformers [26] and has been shown to achieve state-of-the-art results on several language processing tasks similar to those by the base model, including for health-related, social media-based text classification tasks [27]. Our use of “state-of-the-art” refers to the best-performing machine or deep learning models currently available for each task, in the rest of the paper. We used the embeddings obtained from RoBERTa to fine-tune our model using the training data. We computed the distributions of the sources and locations identified automatically for analysis. Classification results and all outputs are provided in the *Results* section.

Ethical Considerations

This study was deemed to be exempt from review (publicly available data) by the Emory University Institutional Review Board. Our analyses use publicly available, user-generated

content from an online forum where users remain anonymous by default. We do not use any personally identifiable information and only report aggregated data.

Results

Data Collection and Frequency Analysis

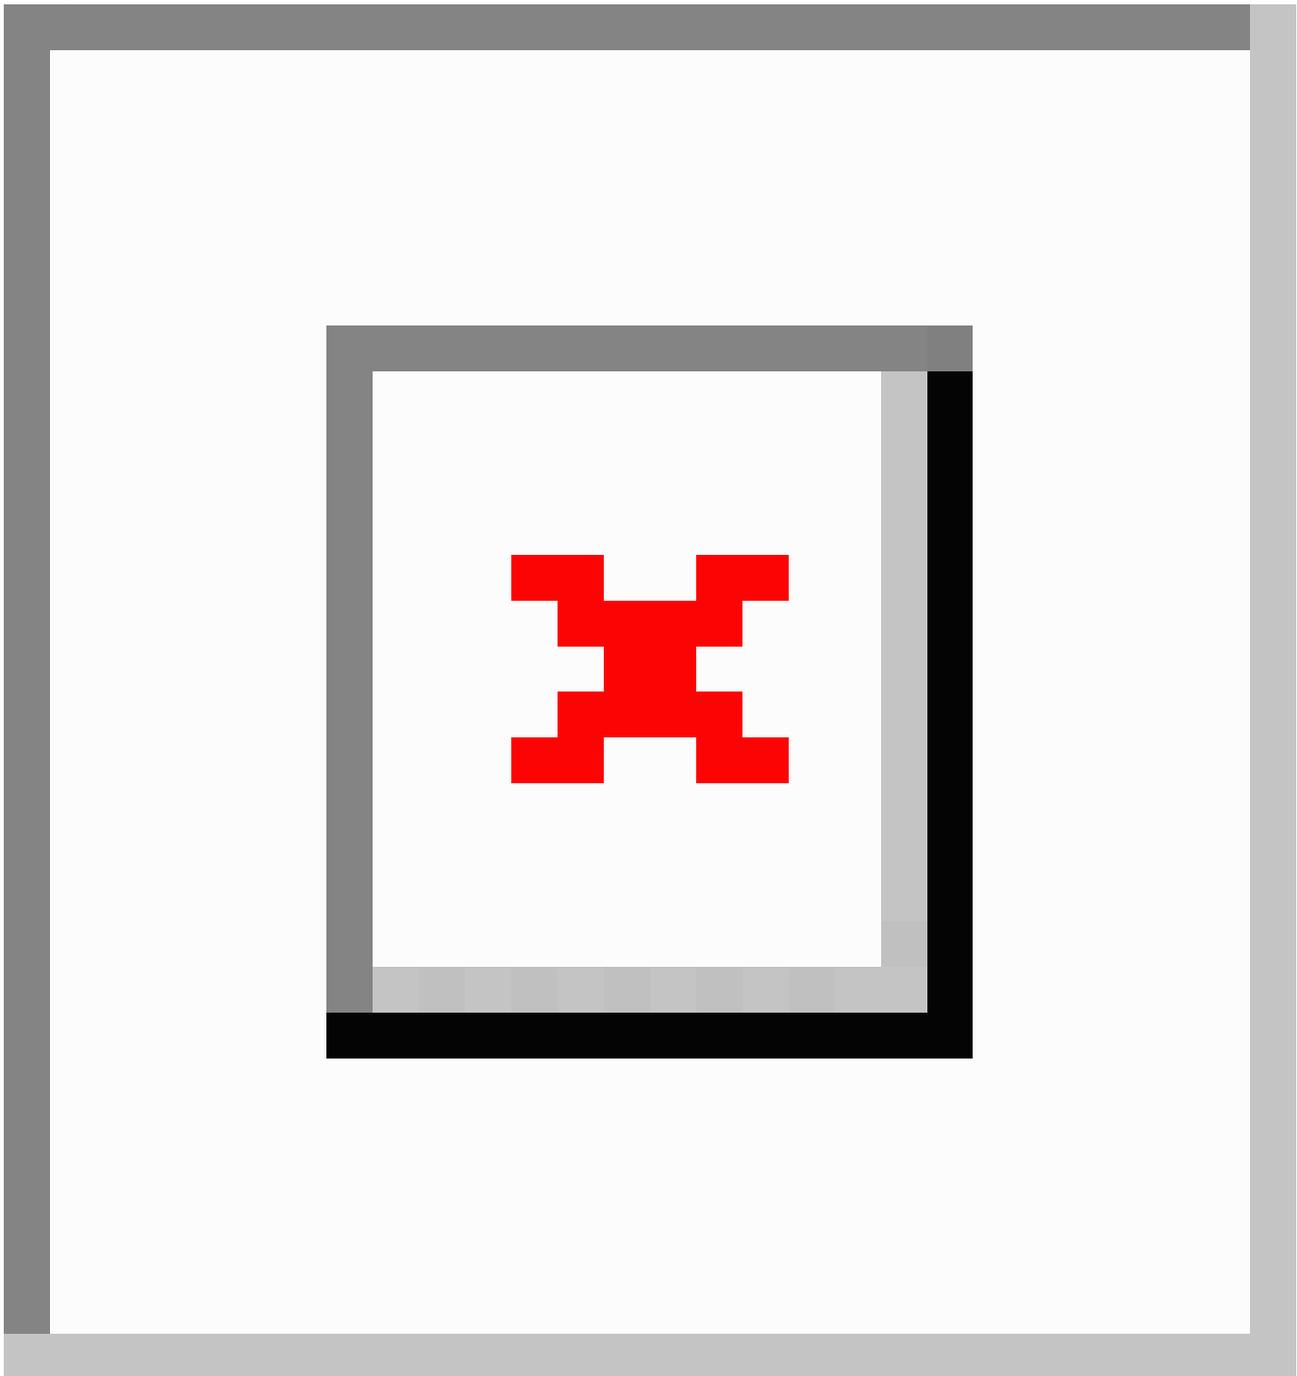

Overview

A total of 1,337,982 posts were collected. Of these, 1,302,620 were posted under the “Discussion” threads; 28,666 under the “Poll” thread; and 6696 under the “Question” threads. Preprocessing and removal of duplicate posts resulted in 1,329,042 total posts. There was a steady increase in the total number of posts from 2018 to 2020, followed by a slight decrease in 2021. The highest number of posts on the website was made in 2020. In the months leading up to September 2022, the final full month of data collection, the total number of monthly posts was generally higher than in the corresponding months in 2021 (Figure S1 in [Multimedia Appendix 1](#)).

Temporal SN Trends

Figure 3 shows the relative monthly frequencies for posts mentioning SN, as well as other substances and methods associated with suicides. From the figure, it can be observed that SN was the most popular means of suicide discussed in this online community, and the frequency of mentions of SN increased over time. A sharp rise in SN mentions can be seen towards the end of 2019, with the frequency of mentions remaining elevated thereafter.

Figure 3. Normalized frequencies of posts on Sanctioned Suicide mentioning potential suicide means and related substances per month from March 2018 to September 2022.

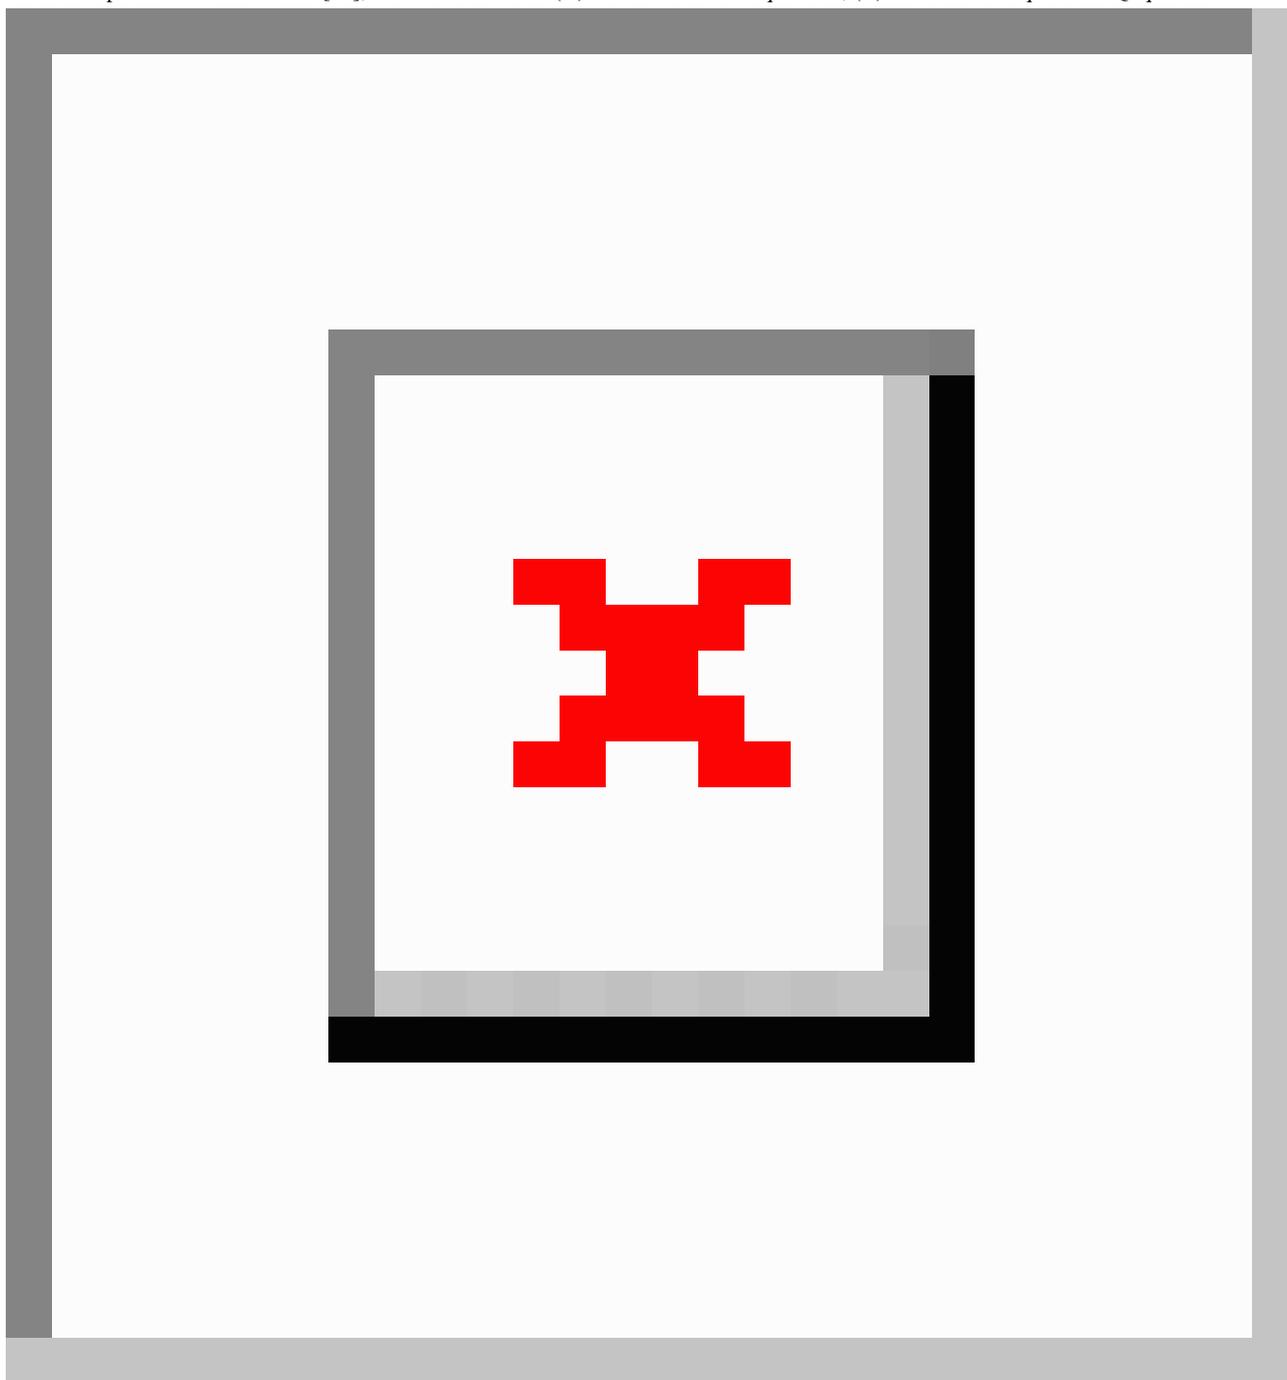

Comparison of Trends With Traditional Data

SN-related deaths due to intentional consumption have increased since 2019 [28]. Our analyses align with this uptick of SN ingestions and suicides: a sharp increase in the mentions of purchases of SN was seen toward the end of 2019 (Figure 3). In our comparison against the NPDS data, we obtained a Spearman of 0.866 ($P=.001$), revealing a statistically significant association between the 2 data sources. On visualizing the normalized frequencies of intentional exposures in the NPDS

and purchases made as obtained from our data set (see the *Sources and Consumer Locations* section), we found that both the noncumulative and cumulative frequencies showed similar trends (Figure 4) for the 10 quarters spanning from 2018 to 2020 for which data from both sources were available (quarters 1 to 4 for 2018 and 2019, and quarters 1 and 2 for 2020). Although the mentions of purchases on Sanctioned Suicide are not exclusive to the United States, the similar trends are a strong indicator of online suicide community content reflecting real-life suicide incidences.

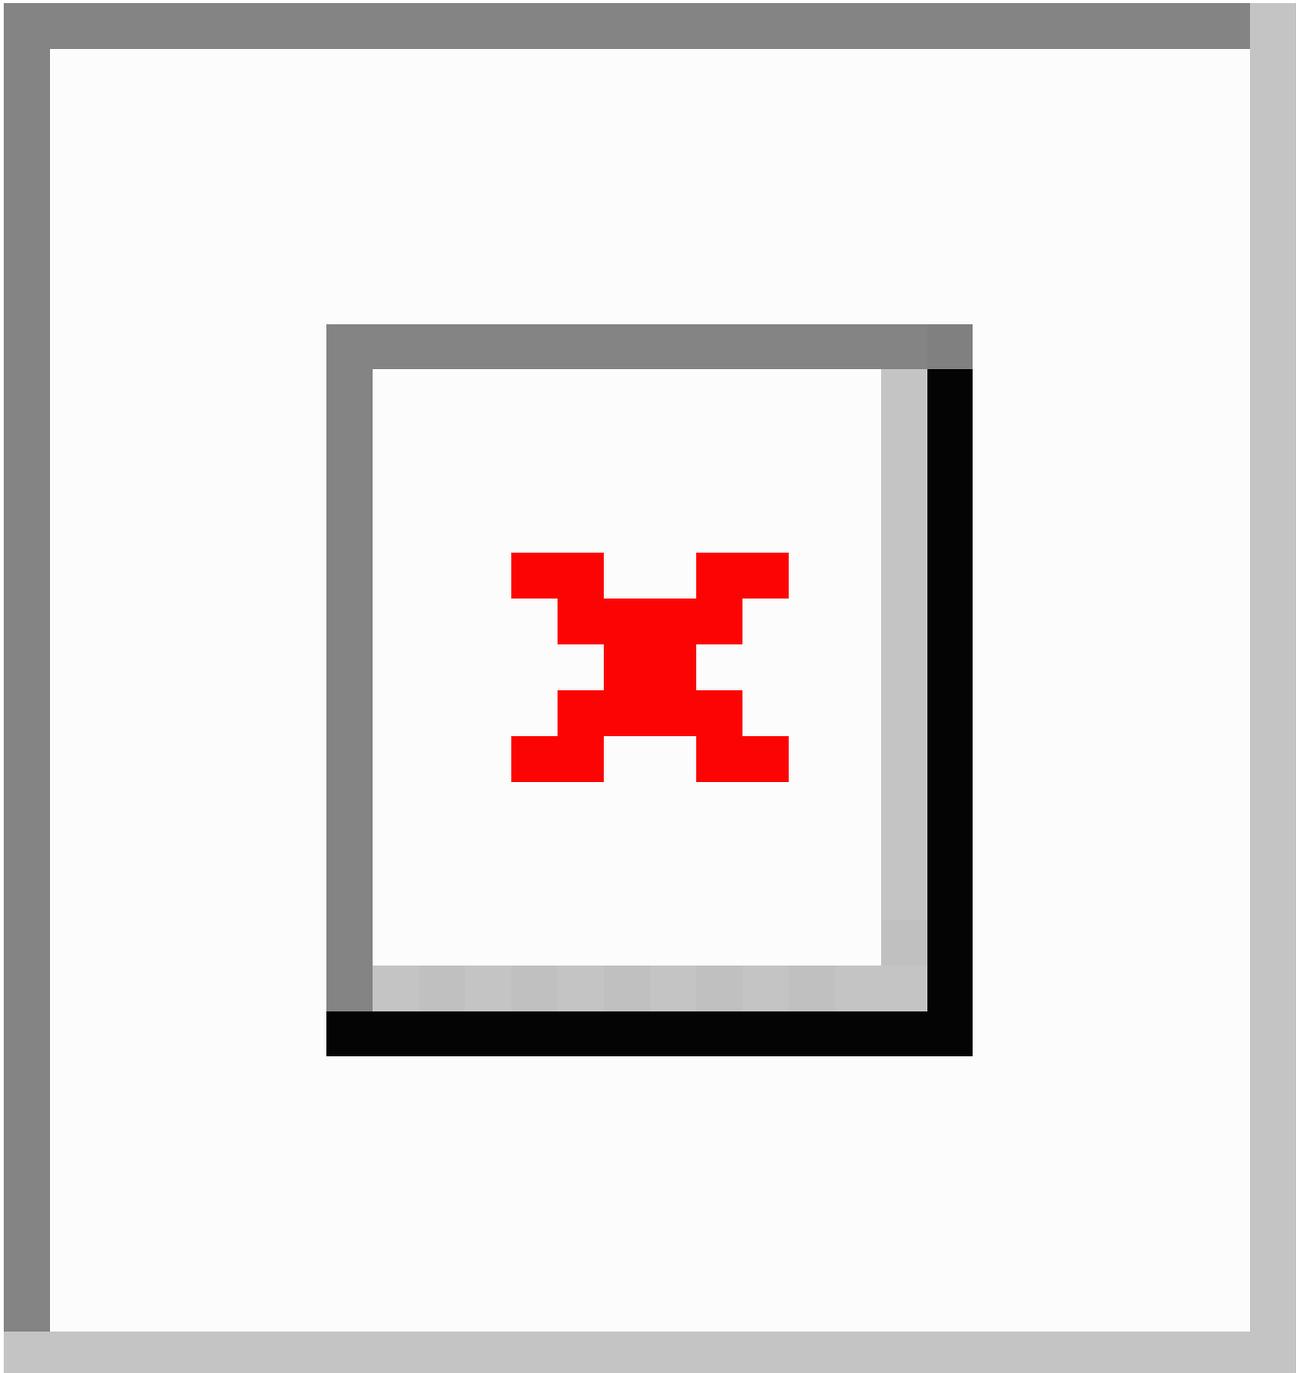

Figure 4. Comparison of normalized frequencies of purchase mentions on Sanctioned Suicide (SS) versus National Poison Data System (NPDS) exposures as reported in McCann et al [10], from 2018 to 2020. (A) Noncumulative frequencies; (B) cumulative frequencies. Q: quarter.

In the comparison against metrics from the CDC WONDER database, we obtained a Spearman ρ of 0.727 ($P < .001$) for month-by-month frequencies during the time period from March 2018 to December 2021 for SN purchases versus actual deaths

and a Spearman ρ of 0.775 ($P < .001$) for keyword mentions versus actual deaths, revealing statistically significant correlation in both cases (Figure 5).

Figure 5. Comparison of normalized frequencies. (A) Purchase mentions of “sodium nitrite“ on Sanctioned Suicide versus actual deaths reported in the CDC WONDER database from 2018 to 2021; (B) keyword mentions of “sodium nitrite” and “other preservatives” on Sanctioned Suicide versus actual deaths reported in the CDC WONDER database. Suicide deaths involving chelating agents were identified by using the *International Classification of Diseases, Tenth Revision* underlying cause of death codes U03, X60–X84, and Y87.0 and multiple causes of death code T50.6. CDC: Centers for Disease Control and Prevention; WONDER: Wide-Ranging Online Data for Epidemiologic Research.

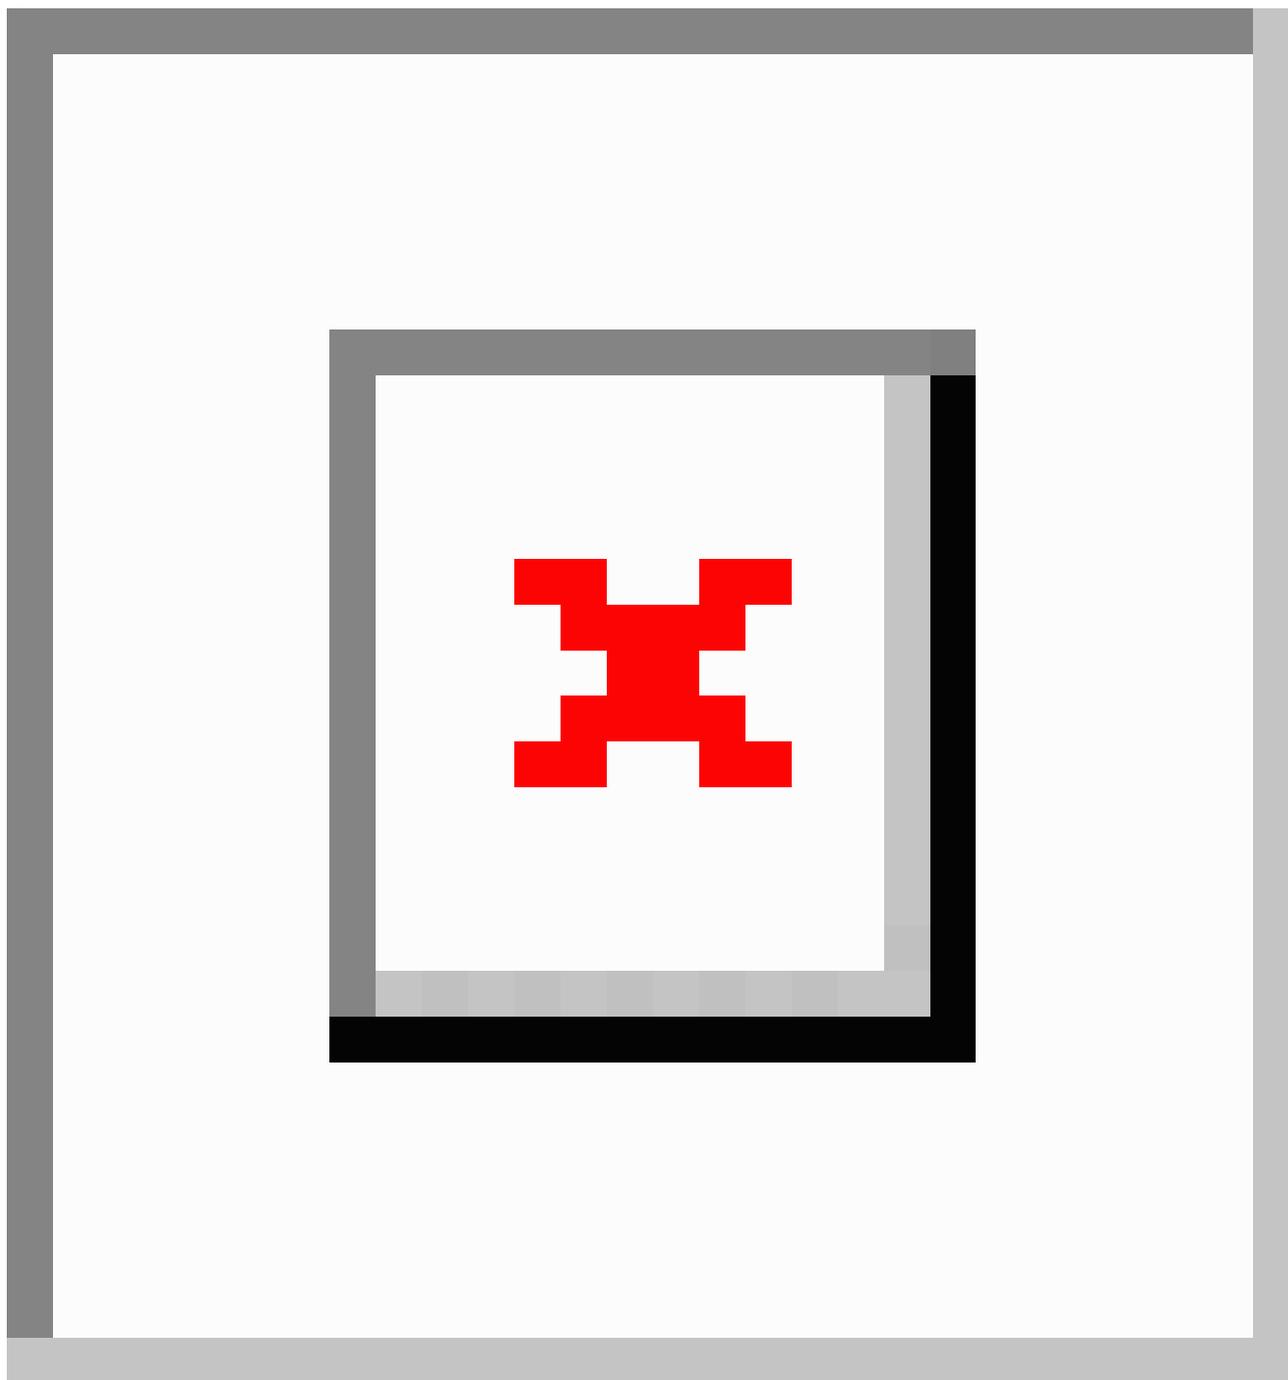

Co-mentioned Suicide Mechanisms

The heatmap in [Figure 6](#) presents the co-occurrence frequencies between different substances and methods. As illustrated in the figure, co-occurring mentions of SN and antiemetics are

common. Manual qualitative inspection of these posts revealed that antiemetics are often mentioned when discussing SN, as forum users recommended these substances to ensure that individuals do not feel nauseous after consuming SN.

Figure 6. Heatmap illustrating the most commonly co-occurring suicide mechanism mentions in Sanctioned Suicide posts from March 2018 to September 2022.

Topic Modeling

Topic modeling revealed further insights and some key differences in the content of posts. First, the topics discovered reinforced some of the insights revealed in [Figure 3](#). For the SN group, unigram and bigram topic clusters represented the following:

- Substances that are potentially coingested (benzodiazepines, antiemetics, and metoclopramide);
- Dosage amounts (“tablespoon” and “grams”);
- Sourcing-related questions and information (“I’m looking,” “source,” “ordered,” and “package”);

- Comparison with other mechanisms of suicide (“hanging” and “shotgun”);
- Mechanism of action and symptoms (“hypoxia” and “peaceful way”); and
- Descriptions of experiences, thoughts, and suicide notes (“failed attempt,” “feel like,” and “I’m sorry”).

Figures S2 and S3 in [Multimedia Appendix 1](#) present all the topics.

Sources and Consumer Locations

Overview

Based on the aforementioned topic modeling experiment results and supplemented with manual qualitative inspection of SN-related posts, we curated a list of phrases related to sourcing (eg, “seller,” “bought,” and “purchase”). The complete list is given in Table S2 in [Multimedia Appendix 1](#). Since we collected data from Sanctioned Suicide on October 7, 2022, we extrapolated the frequency of posts from 279 days before

(January 1, 2022, to October 7, 2022) by multiplying the per-day frequency with the total number of days in the year. Frequency analysis of sourcing-related posts pertaining to SN shows a sharp rise in “purchase” toward the end of 2019, with the highest raw annual “purchase” frequency observed in 2020 ([Figure 7](#)). [Figure 8](#) shows the sourcing frequency (purchase frequency) of SN normalized by the posting frequency of SN-related topics. We found that discussions about the sourcing of SN gradually increased over the years.

Figure 7. Raw yearly purchase frequency of sodium nitrite from Sanctioned Suicide posts from March 2018 to December 2022 (extrapolated to the period from October to December 2022).

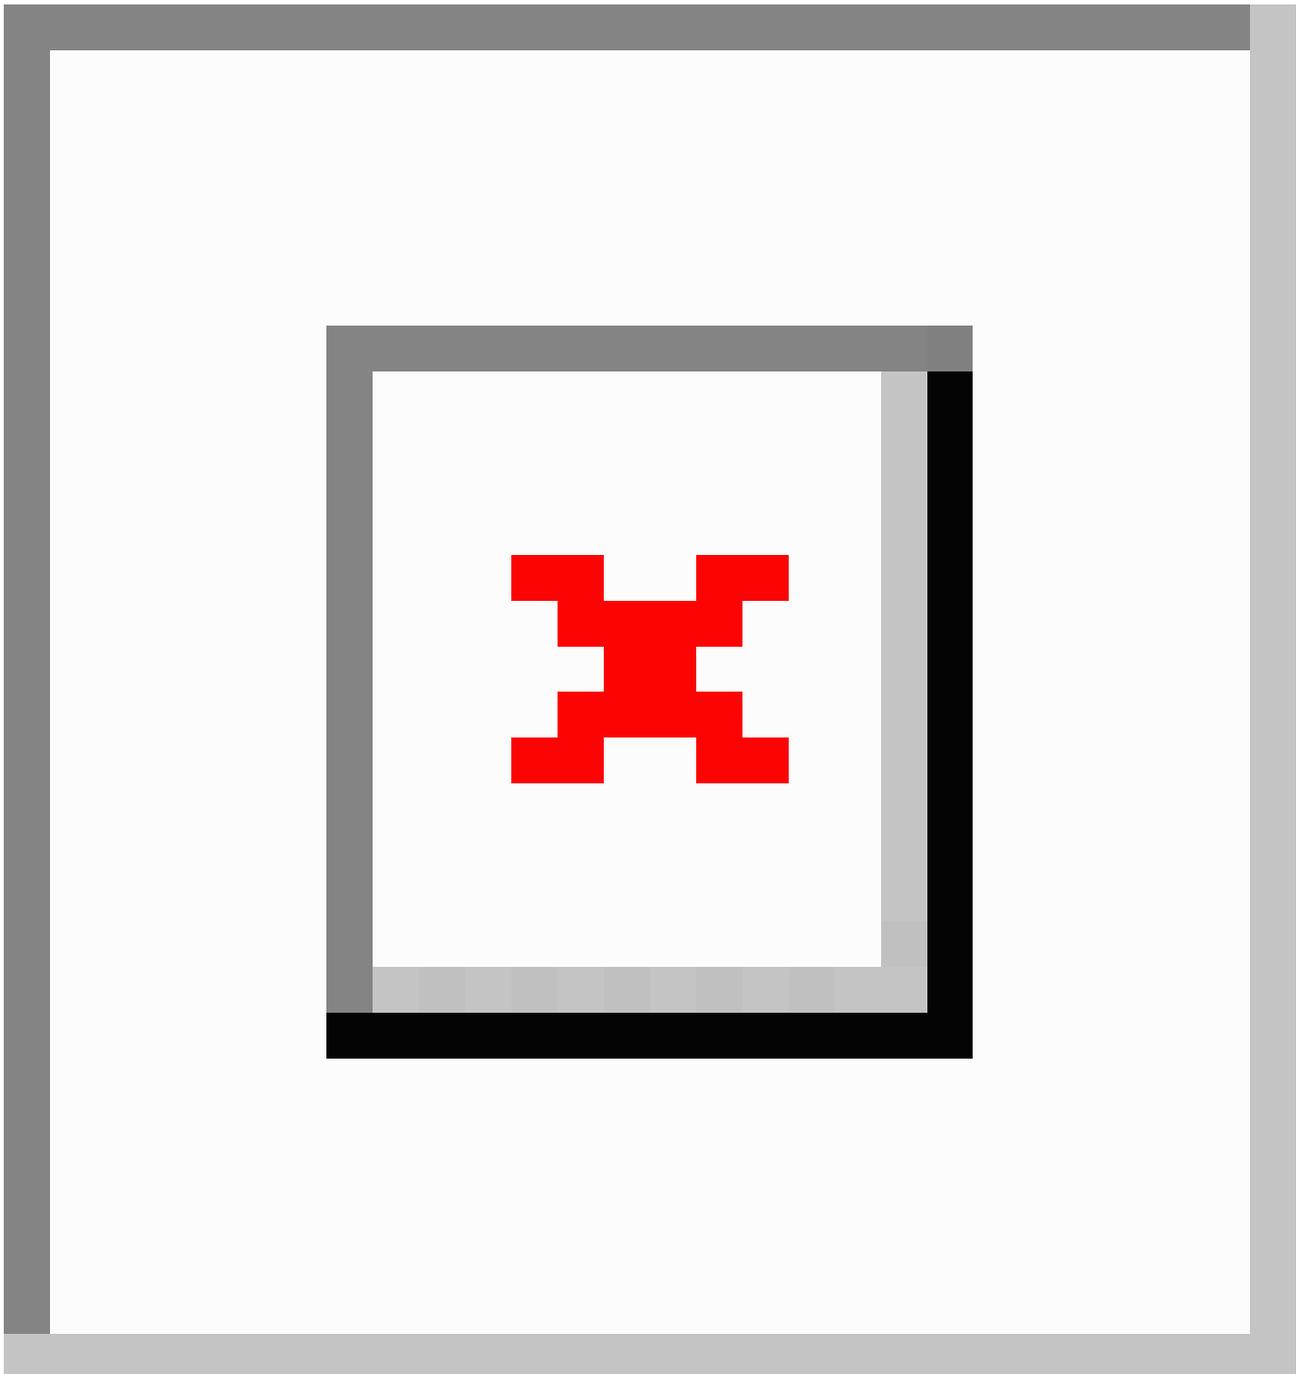

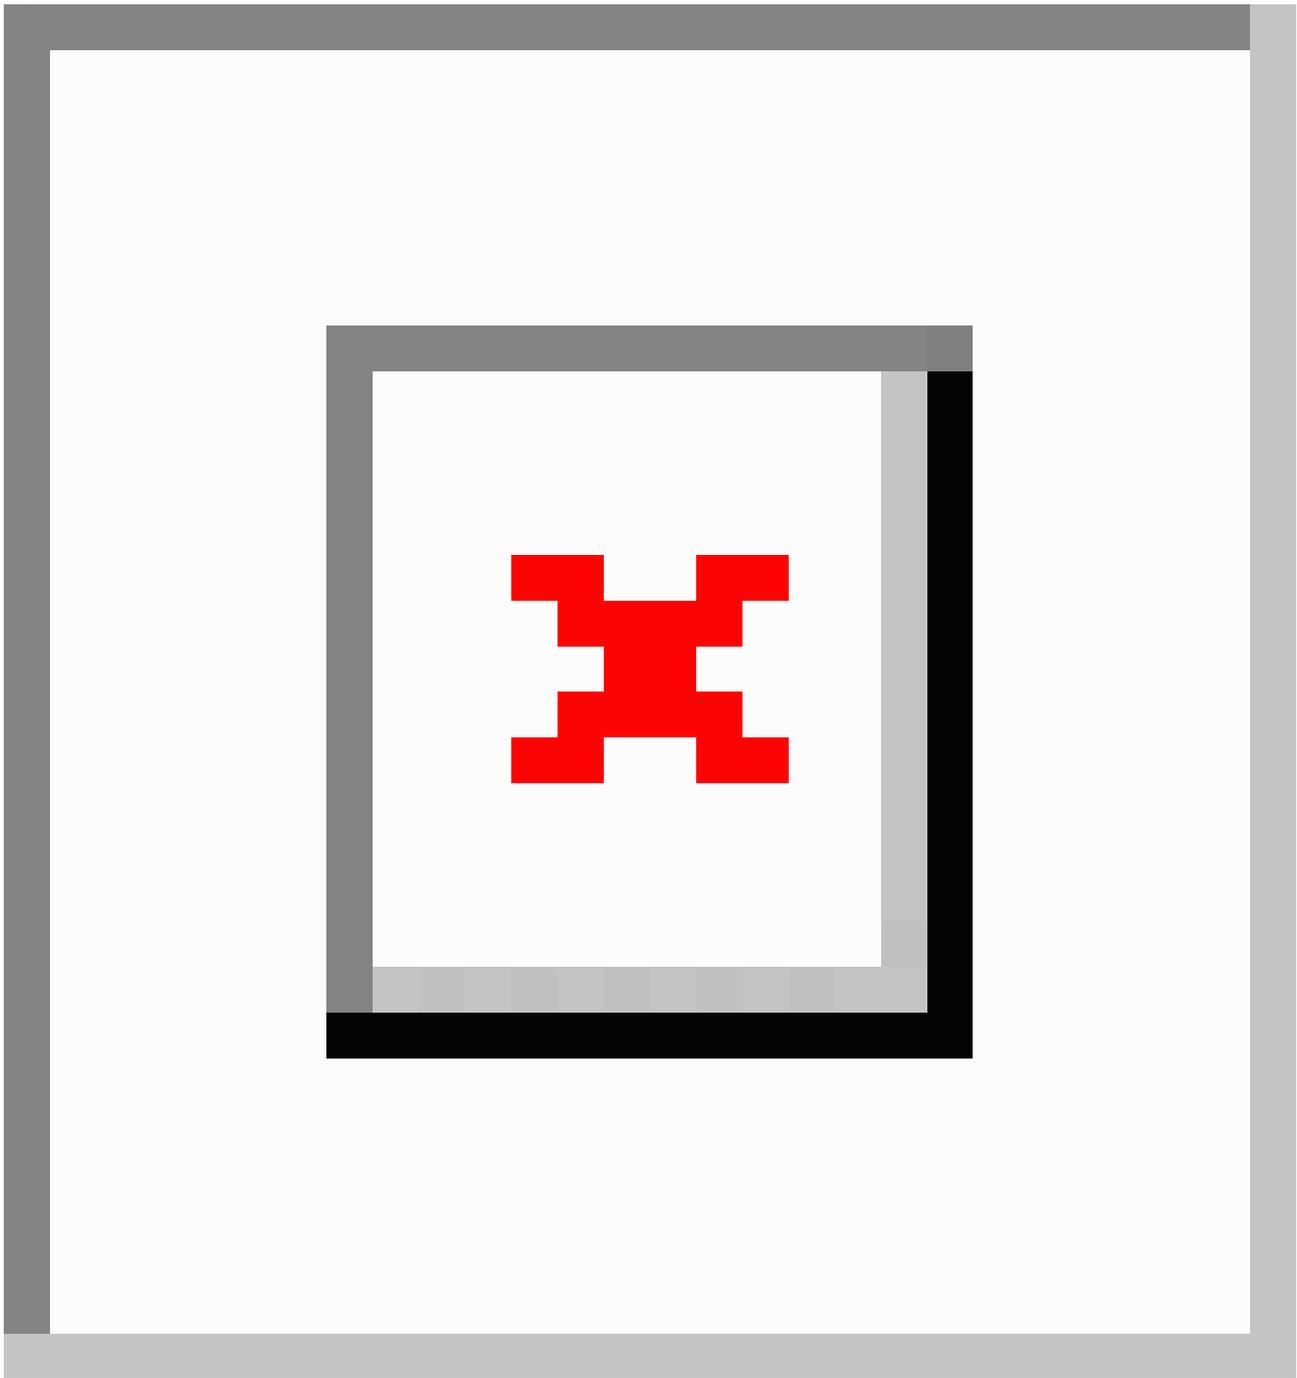

Figure 8. Normalized yearly purchase frequency of sodium nitrate from Sanctioned Suicide posts from March 2018 to December 2022 (extrapolated to the period from October to December 2022).

SN Sources and Consumer Locations

The NER approach detected locations that included countries, states, cities, counties, etc. We manually analyzed the detected locations to create a location-mapping dictionary, which was used to map cities to countries. The United States, the United Kingdom, Canada, China, and Germany were found to be the

most popular potential locations for obtaining or using SN (Table 1). Since the locations detected were primarily from the United States, we also mapped locations detected from within the United States to the state level. The states of California, New York, Florida, Texas, and Oregon were found to be mentioned the most often in association with SN.

Table . Identified geographical locations from Sanctioned Suicide posts, from March 2018 to September 2022, associated with the sourcing or use of sodium nitrite.

Rank	Country-level locations		US state-level locations	
	Country	Frequency, n	US state	Frequency, n
1	United States	1043	California	149
2	United Kingdom	774	New York	104
3	Canada	358	Florida	67
4	China	202	Texas	63
5	Germany	185	Oregon	50
6	Mexico	170	Washington	41
7	Australia	164	Pennsylvania	30
8	India	163	North Carolina and Virginia ^a	23
9	Netherlands	146	Illinois	20
10	Switzerland	144	Arizona	18
11	Russia	140	Massachusetts	17
12	France	128	Utah	16
13	Japan and Spain ^a	96	Michigan and Nevada ^a	15
14	Poland	90	Colorado	13

^aLocations with equal frequencies, presented in alphabetical order.

Location Mention–Intent Classification

Although NER-based geographical sources are informative, we found that consumers often tend to circumvent naming the geographical and online sources from where they obtained SN. Consider the following post: “I ordered it off of the big river in Brazil website.” NER identifies “Brazil” as a potential geographical source of SN in this example. However, the user

is referring to the online source “Amazon” rather than the geographical source “Brazil.” Furthermore, locations mentioned in posts may also refer to the consumer’s location rather than the location where SN was sourced. This necessitated building a classifier to identify the intent of mentioning the location. Our proposed location mention–intent classifier achieved an accuracy of 72.92% on the unseen test data set, outperforming traditional machine learning–based baselines (Table 2).

Table . Performance of the transformer-based, location mention–intent classifier on Sanctioned Suicide posts from March 2018 to September 2022.

Model	Random classifier	Support vector machine classifier	Our model
Accuracy	0.25	0.34	0.72
Precision	0.25	0.37	0.73
Recall	0.25	0.32	0.76
F_1 -score	0.25	0.35	0.74

Sources and Consumer Locations

Based on the NER and subsequent classification process, the United States, the United Kingdom, Canada, Australia, and

China were found to be the most popular source locations for obtaining SN (Table 3). The states of California, New Mexico, Florida, Rhode Island, and Oklahoma were reported to be the most popular sourcing locations for SN within the United States.

Table . Locations where sodium nitrite was potentially sourced from, as obtained from Sanctioned Suicide posts from March 2018 to September 2022.

Rank	Country-level locations		US state-level locations	
	Country	Frequency, n	State	Frequency, n
1	United States	586	California	55
2	United Kingdom	303	New Mexico	44
3	Canada	129	Florida	24
4	Australia	122	Rhode Island	21
5	China	83	Oklahoma	13
6	Germany and Mexico ^a	80	Virginia	12
7	India	67	Minnesota, New York, North Dakota, and Vermont ^a	8
8	Netherlands	53	Arizona, Georgia, Maryland, and Oregon ^a	7
9	Russia	45	Alabama, Illinois, Mas- sachusetts, and Texas ^a	6

^aLocations with equal frequencies, presented in alphabetical order.

The consumers who were interested in or attempted to obtain SN primarily were from the United States, the United Kingdom, Canada, Mexico, and Australia (Table 4). Within the United States, the states of California, New York, Texas, Florida, and

Pennsylvania were found to be the most common locations of consumers attempting to obtain SN. For user-level post frequency, the mean was 72.63 (median 13, IQR 4-46; range 1-14,795).

Table . Locations where consumers attempting to procure sodium nitrite were from, as obtained from the Sanctioned Suicide posts from March 2018 to September 2022.

Rank	Country-level		US State-level	
	Country	Frequency, n	State	Frequency, n
1	United States	150	California	22

Potential Online Sources

Our NER-based approach also revealed potential online sources of obtaining SN or information about obtaining SN. Online

marketplaces were the most commonly mentioned potential sources of SN (Table 5).

Table . Possible internet-based sources of sodium nitrite mentioned from Sanctioned Suicide posts from March 2018 to September 2022.

Rank	Online source	Frequency, n

Discussion

Principal Findings

Our study is the first to conduct a comprehensive, NLP-based assessment of a large, popular, and public suicide forum. Our findings show that SN is the most popular method of suicide discussed on the forum, perhaps indicating the rising popularity of SN in real life. The trends we discovered suggest that the popularity of SN might still be increasing. Our study also revealed topics associated with SN discussions, among which sourcing was a common one. The application of automated NLP methods such as NER and classification enabled us to rapidly aggregate the locations and sources and compute their frequencies. Our findings and the data mining resources we are releasing with this paper will aid much-needed future research on this topic.

Online Sources of SN

Our analyses show the distinct role of online marketplaces as a source of SN (Table 5). As a common food additive approved for use [29] in several countries, such as the United States [30], the United Kingdom [31], New Zealand, and Australia [32], SN is widely available for procurement. However, SN is now listed as a poison in the United Kingdom and, thus, is considered to be a reportable substance whose sale is regulated and requires an Explosive Precursors and Poisons license [31]. Some online marketplaces, such as Etsy and eBay [33], have now implemented restrictions prohibiting the sale of SN through their website [28]. Overall, however, there remains a wide availability of products containing SN on internet marketplaces.

Trends in SN Use for Self-Harm

SN as a suicide mechanism has been reported in the medical literature as early as 1979 [34]. Since then, there have been a limited number of case reports in the literature through 2019, including one paper presenting 10 cases of SN consumption with the intent for self-harm [6]. Since 2019, case reports of SN-related deaths due to intentional consumption have increased [28], which is reflected in both the online community data as well as reported exposures (Figure 4) and deaths from official databases (Figure 5). This trend of rising instances of SN use for self-harm is concerning and may benefit from broader scientific interest. The literature on the topic is still sparse though, particularly at the intersection of SN and social media or internet-based data.

Utility of Internet-Based Data

Internet-based data hold substantial potential for the surveillance of suicide methods, particularly emerging topics such as the one we studied in this paper. Recent advances in data-centric artificial intelligence methods, particularly NLP, have opened up opportunities for rapidly analyzing such data, as we did in this study. While our paper is the first to take such a data-driven approach to fully describe the contents of this forum from an epidemiologic perspective, other recent papers have attempted to analyze data from it. Sartori et al [35], for example, investigated the impact of COVID-19 by studying posts from this forum, and they found that COVID-19 appeared to be indirectly connected to causes of distress for the users, such as anxiety for the economy, but not directly to the growth of users on the forum. Dilkes [36] took a more linguistic investigation approach and analyzed changes in language to evaluate the social and psychological effect of participation in the forum. In

a more recent commentary, Dinis-Oliveira and Durão [37] further highlighted the importance of studying the forum, how it plays a role in providing guidance on how to use SN as a means of suicide, and the rapid increase in its popularity. Although our study takes a necessary next step in the use of this data source for public health work, this information can also be leveraged to address this emerging public health problem in the United States and globally in the form of locally targeted interventions, such as notices for emergency personnel about signs, symptoms, and treatment in locations prone to the issue [38,39].

Conclusion

In this study, we adopted a data-driven approach to analyze the trends in SN mentions on an online suicide forum using NLP and machine learning-based techniques. Our findings show that online forums can be an important source of information about emerging trends in suicide mechanisms. We also show that it is possible to obtain geographical trends of use and sourcing with our proposed location mention-intent classifier, with high accuracy. Since suicide is a rising concern in the United States and worldwide, we believe our study can be key to understanding temporal trends in suicide mechanisms and provide insights to the public health community by leveraging large amounts of online data sources.

Limitations and Future Work

Since we used Sanctioned Suicide as our primary data source, a limitation of our study is that the distribution of users appears to be largely from the United States. This is reflected in both the location-based analyses and the close association of

Sanctioned Suicide trends with the CDC WONDER and the NPDS data. Differences in access to the internet and cyber literacy across the world further contribute to this distribution. The posts used in this study were in English, which may also have caused users from non-English-speaking countries to be underrepresented. Our NLP and machine learning methods also impose some limitations—the classification abilities of our models are not perfect, and errors can affect downstream tasks. In our study, however, the presence of a large volume of data helps to offset the influence of individual errors; furthermore, the use of machine learning is necessary in analyzing data that are too large to qualitatively assess by manual processes.

In the future, we aim to attempt to improve our NER and classification approaches so that more accurate information about sources and locations can be obtained in close to real time. We will also attempt to develop NLP tools that can automatically discover novel substances and mechanisms gaining popularity in that community. The resources we are sharing with this publication (lexicons, lists of phrases and keywords, and language models) are intended to support researchers to conduct their own data-driven studies on the topic.

Intentional SN ingestion remains an ongoing concern for suicide prevention work. The ease of accessibility and lethality of the substance present a unique challenge for public health efforts. As nations consider both policy and programmatic options for enhanced prevention opportunities, the use of online data will remain critical to understand emerging trends in a timely fashion.

Abstract

Background: Despite being a debilitating, costly, and potentially life-threatening condition, depression is often underdiagnosed and undertreated. Previsit Patient Health Questionnaire-9 (PHQ-9) may help primary care health systems identify symptoms of severe depression and prevent suicide through early intervention. Little is known about the impact of previsit web-based PHQ-9 on patient care and safety.

Objective: We aimed to investigate differences among patient characteristics and provider clinical responses for patients who complete a web-based (asynchronous) versus in-clinic (synchronous) PHQ-9.

Methods: This quality improvement study was conducted at 33 clinic sites across 2 health systems in Northern California from November 1, 2020, to May 31, 2021, and evaluated 1683 (0.9% of total PHQs completed) records of patients endorsing thoughts that they would be better off dead or of self-harm (question 9 in the PHQ-9) following the implementation of a depression screening program that included automated electronic previsit PHQ-9 distribution. Patient demographics and providers' clinical response (suicide risk assessment, triage nurse connection, medication management, electronic consultation with psychiatrist, and referral to social worker or psychiatrist) were compared for patients with asynchronous versus synchronous PHQ-9 completion.

Results: Of the 1683 patients (female: n=1071, 63.7%; non-Hispanic: n=1293, 76.8%; White: n=831, 49.4%), Hispanic and Latino patients were 40% less likely to complete a PHQ-9 asynchronously (odds ratio [OR] 0.6, 95% CI 0.45-0.8; $P<.001$). Patients with Medicare insurance were 36% (OR 0.64, 95% CI 0.51-0.79) less likely to complete a PHQ-9 asynchronously than patients with private insurance. Those with moderate to severe depression were 1.61 times more likely (95% CI 1.21-2.15; $P=.001$) to complete a PHQ-9 asynchronously than those with no or mild symptoms. Patients who completed a PHQ-9 asynchronously were twice as likely to complete a Columbia-Suicide Severity Rating Scale (OR 2.41, 95% CI 1.89-3.06; $P<.001$) and 77% less likely to receive a referral to psychiatry (OR 0.23, 95% CI 0.16-0.34; $P<.001$). Those who endorsed question 9 "more than half the days" (OR 1.62, 95% CI 1.06-2.48) and "nearly every day" (OR 2.38, 95% CI 1.38-4.12) were more likely to receive a referral to psychiatry than those who endorsed question 9 "several days" ($P=.002$).

Conclusions: Shifting depression screening from in-clinic to previsit led to a dramatic increase in PHQ-9 completion without sacrificing patient safety. Asynchronous PHQ-9 can decrease workload on frontline clinical team members, increase patient self-reporting, and elicit more intentional clinical responses from providers. Observed disparities will inform future improvement efforts.

Introduction

In 2020, approximately 21 million adults in the United States experienced at least 1 major depressive episode, with only 66% receiving treatment, and nearly 46,000 people dying from suicide [1,2]. Primary care health systems can help prevent suicide by effectively screening and connecting patients with early intervention and treatment for depression [3,4].

The relationship between depression and the risk of suicide is well established and highlights the urgency of proactive intervention [5]. Depression is the most common psychiatric disorder in people who die by suicide [6]. A majority of individuals who die by suicide visited their primary care provider in the year preceding their death [7-9]. Thus, primary care is a pivotal setting for identifying suicide risk and initiating mental health care, starting with the implementation of effective screening processes [3,4].

Despite guidelines and recommendations for preventive annual depression screening that includes suicide risk assessment, health systems face a dilemma in integrating these measures into routine care [10-12]. Little evidence exists on the predictors and outcomes associated with asynchronous depression screening programs, such as which patient groups are more likely to engage in asynchronous depression screening and whether asynchronous screening affects a provider's clinical response [13-15]. Asynchronous previsit patient questionnaires can ease the administrative burden on frontline clinical staff and may help to efficiently identify problems ahead of primary care visits. However, concerns exist regarding the need for an immediate clinical response and the potential liability associated with patient responses indicating a high risk of severe depression that may result in self-harm or suicide. This concern results in health systems compromising by administering incomplete asynchronous depression screening that excludes questions overtly asking patients to report thoughts of self-harm or wishing they were dead. One resolution to this dilemma was the development of the Patient Health Questionnaire-8 (the 8-item version). This measure is an adaptation of the more widely adopted and validated Patient Health Questionnaire-9 (PHQ-9; the 9-item version) but does not include the ninth question, which is about suicidal thoughts [16].

Most depression screening and suicide risk assessments currently occur in an in-person clinical encounter, allowing for immediate evaluation, triage, and management of high-risk patients [17-19]. However, the dramatic shift from direct face-to-face patient care to remote care in the context of the COVID-19 pandemic rendered synchronous clinic-based screening programs insufficient. Meanwhile, during the COVID-19 pandemic, the prevalence of symptoms of depressive disorders nearly quadrupled [20]. This dramatic increase in depressive symptoms during the pandemic further heightened the urgency to adapt and optimize screening processes [21].

Screening for suicide risk remotely and asynchronously raises concerns about the risk of a patient harming themselves when support is not immediately available [22,23], particularly because no standards exist for immediate response to electronic screening for self-harm and suicidal intent [13]. However, there

is robust evidence that patients are unlikely to attempt or die by suicide within a week after positively endorsing question 9 on a PHQ-9 [24]. Stated plainly, while question 9 is an important marker of disease severity, it has little predictive utility for acute risk of suicide [16,24,25].

During the pandemic, our primary care system redesigned our depression screening program to be effective for both remote and in-clinic visits by including both asynchronous screening ahead of visits and synchronous screening during visits for those patients who did not complete the asynchronous PHQ-9. Our overarching goal was to increase depression screening during the pandemic while decreasing the administrative burden on overwhelmed frontline clinical teams. We launched an automated electronic previsit depression screening workflow with the support of a multidisciplinary integrated behavioral health (IBH) team. These efforts align with the National Action Alliance for Suicide Prevention's COVID-19 "guidance: screening for suicide risk during telehealth visits [22]. Our program has broad clinical implications, as it increased rates of identifying depression and suicide risk in our patients.

In this quality improvement study, we sought to describe and evaluate the differences in patient characteristics and provider responses based on asynchronous and synchronous completion of a depression screening questionnaire. Little evidence exists on the predictors and outcomes associated with remote depression screening programs [13-15]. Through this study, we aim to contribute valuable insights that can inform future strategies in suicide prevention within primary care settings.

Methods

Study Setting

This quality improvement study was conducted in 2 primary care health systems in Northern California from November 1, 2020, to May 31, 2021. Stanford Health Care (SHC) includes 11 clinics and cares for 60,000 patients annually. University Healthcare Alliance (UHA) comprises 32 clinics and cares for 120,000 patients annually.

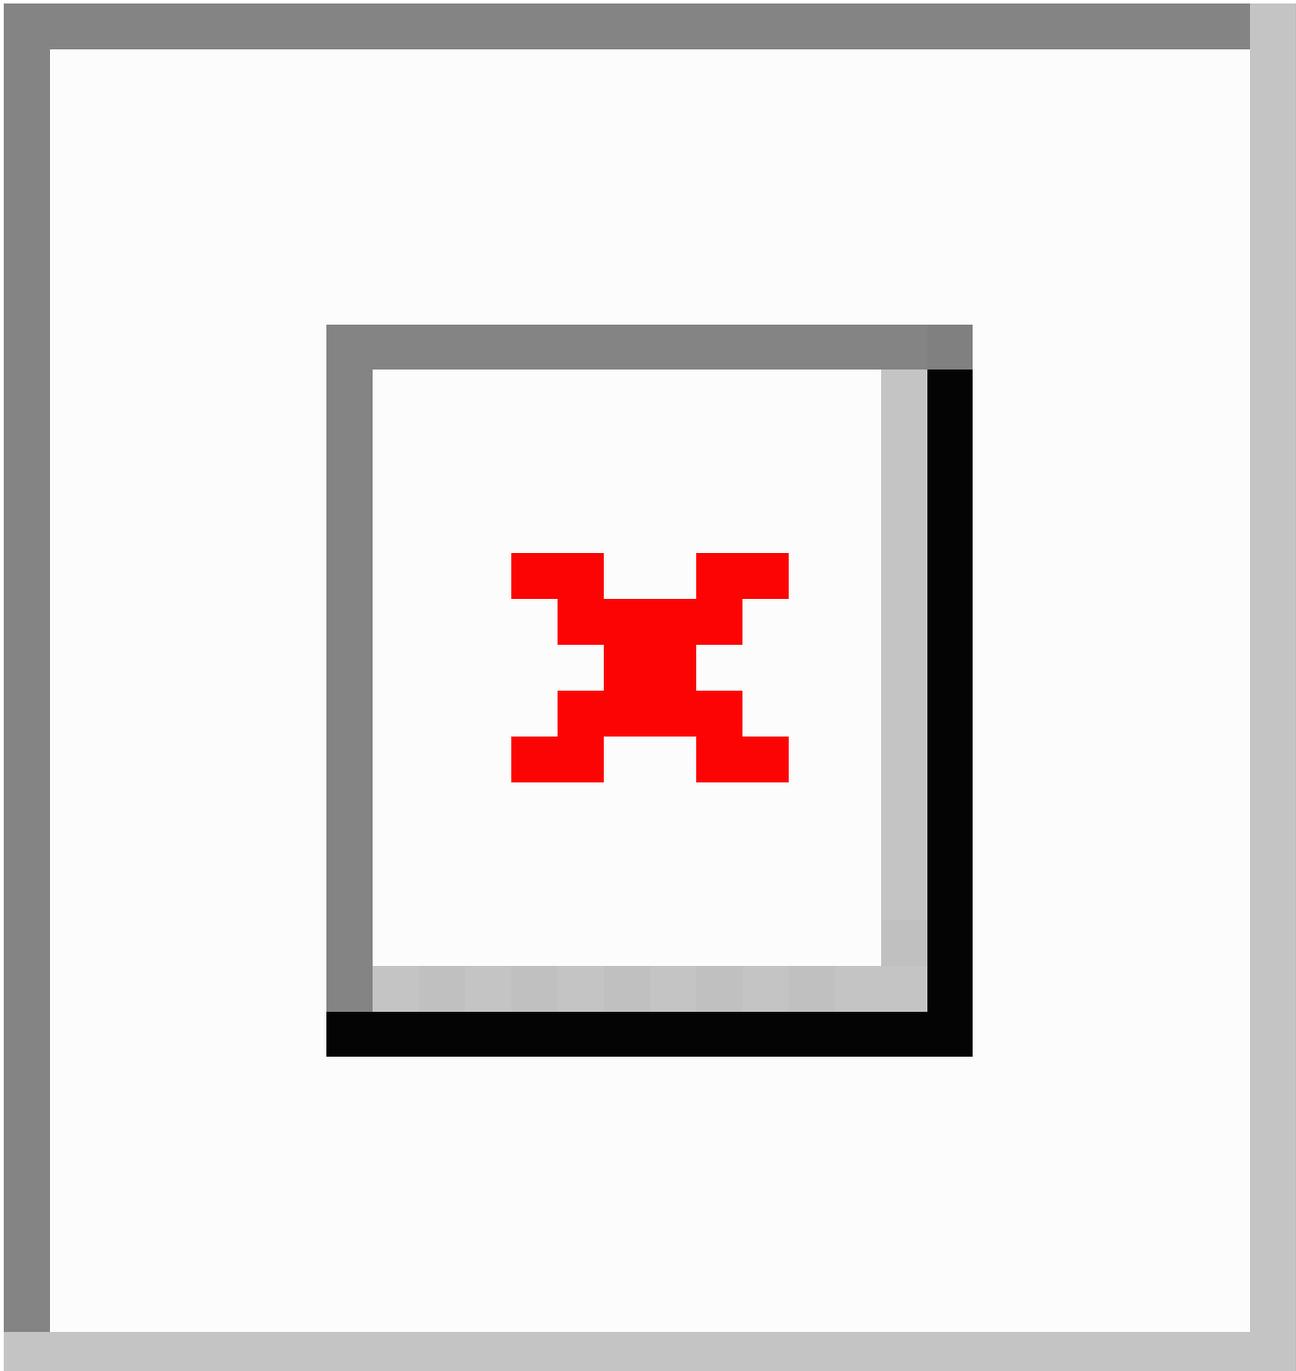

Depression Screening Program Description

Our universal depression screening program was launched in 33 clinics (28 at UHA and 5 at SHC) with an automated electronic questionnaire workflow and IBH-specific clinical resources to support primary care providers managing patients who screen positive for symptoms of depression. The PHQ-9 workflow included the following elements (Figure 1): (1) electronic PHQ presented to patients up to 3 days before a scheduled visit, as part of the electronic advance check-in procedure (branching PHQ-2-to-9 for patients without an existing diagnosis of depression or a full PHQ-9 for patients with an existing diagnosis of depression); (2) an automated electronic patient alert containing crisis resources displayed to patients at the time of questionnaire completion if they responded with a high-risk score; (3) reminders in the electronic medical record (EMR) prompting clinical teams to administer PHQs synchronously during visits if patients did not complete a previsit; (4) provider EMR alerts if a patient responded with a high-risk score; and (5) reminders in the EMR prompting

providers to document follow-up plans for patients with symptoms of depression and curated decision-support tools in the EMR to assist providers with point-of-care clinical decision-making. Clinical resources at SHC included a triage

nurse team, IBH social workers (SWs), and a consulting psychiatrist. Additional resources, such as psychiatrists and therapists, were available in the community for patients in both health systems.

Figure 1. Depression screening program process map. (1) Electronic PHQ questionnaires presented to patients up to 3 days before a scheduled clinic visit, embedded into the electronic check-in procedure; (2) automated electronic patient alerts containing crisis resources displayed to patients at the time of questionnaire completion if they responded with a high-risk score; (3) reminders in the EMR prompting clinical teams to administer depression screening questionnaires during visits if patients did not complete the previsit questionnaire; (4) provider EMR alerts if a patient responded with a high-risk score; (5) reminders in the EMR prompting providers to document follow-up plans for patients who screened positive for symptoms of depression and curated decision-support tools in the EMR to assist providers with point-of-care clinical decision-making. C-SSRS: Columbia-Suicide Severity Rating Scale; EMR: electronic medical record; PHQ: Patient Health Questionnaire; Q#9: question 9 of the PHQ questionnaire (“Over the last two weeks, how often have you been bothered by thoughts that you would be better off dead or of hurting yourself”).

Measures

To assess the short-term impact of the screening program, we tracked total, asynchronous, and in-clinic PHQ-9 completion

rates using an EMR report. The PHQ-9 has been widely applied and validated for use in primary care settings for the screening of depression with high sensitivity (74%) and specificity (91%) [26,27]. The ninth item evaluates passive thoughts of death or

self-injury and has more limited utility as a measure of suicidal risk unless paired with a validated suicide risk assessment instrument and appropriate clinical responses [28]. Specifically, question 9 reads as follows: “Over the last two weeks, how often have you been bothered by thoughts that you would be better off dead or of hurting yourself.” The response options were the following: Not at all (0), Several days (1), More than half the days (2), and Nearly every day (3). Patients with a score of 1 or higher on question 9 were included in the analysis. For this study, trained reviewers performed chart reviews of every patient who responded positively to the 9th question on a PHQ-9. Reviewers (MA and NJ) had experience navigating EMRs and were trained by an experienced clinician (AS) to identify relevant details and document them in a shared Excel worksheet.

Patient demographic characteristics were based on the EMR and included sex (male and female), race (White, Black or African American, Asian, and other/unknown), age in years, ethnicity (non-Hispanic, non-Latino and Hispanic/Latino), health insurance, encounter type (telemedicine or office visit), appointment status (completed, canceled, left, or no-show), and PHQ-9 score.

The record reviewers scanned the EMR for patient outcomes and providers’ clinical responses to evaluate patient safety and provider adherence to recommended clinical workflows. Clinical response included actions that providers took to manage or improve a patient’s depression, including prescribing new antidepressant medications; adjusting the dose of a current antidepressant medication; electronic consultation with a psychiatrist; referral to IBH SWs; referral to a psychiatry specialist; recommending ongoing management with an established behavioral health specialist outside our health system; linkage to the triage nurse for risk assessment; and completing a standardized suicide risk assessment, specifically the Columbia-Suicide Severity Rating Scale (C-SSRS). The C-SSRS is a psychometrically established and the gold standard for evaluating suicidal ideation severity and suicidal behaviors [29]. The scale contains 2 subsets of items with the first subset capturing the past-month severity of suicidal ideation and the second subset evaluating the past 3-month presence of suicide attempts.

Chart reviews for SHC patients included a review of free-text documentation in clinical notes and discrete data captured in standard reports. Chart reviews for UHA were limited to a review of discrete data captured in standard reports and focused review for any adverse patient events, such as suicide attempt or completion, that occurred between the time of questionnaire completion and the patient’s clinical encounter. For this reason, clinical response outcomes were only measured in the SHC sample. Patient safety was inferred based on whether a patient attended a subsequent clinical encounter. For patients who were deceased at the time of retrospective chart review, the cause of death was determined based on chart review and classified as “suicide” or “other,” such as terminal cancer.

Statistical Analysis

Descriptive statistics were used to summarize participant characteristics using frequency distributions, means, and medians. PHQ-9 categories were made based on the total score and grouped based on validated cut-offs of negative (0-4), mild (≥ 5), moderate (≥ 10), moderately severe (≥ 15), and severe (≥ 20) [25]. Because of the small sample size, Native Hawaiian, Pacific Islander, and American Indian/Alaska Native were recombined with “Other.” Health insurance was categorized into Private, Medicare, Medicaid, or other/unknown. Age was categorized into groups as follows: 12-17, 18-39, 40-59, 60-79, and ≥ 80 years.

Cross-tabulations and univariate logistic regressions were used for the primary analyses to understand the relationship between the independent variables of various patient demographic characteristics and the dependent variable of completing the PHQ-9 asynchronously or synchronously. In a post hoc analysis, a 2-tailed *t* test was used to compare the mean PHQ-9 score among patients who completed the PHQ-9 asynchronously and synchronously.

Another series of univariate logistic regressions were fitted to evaluate for a difference in clinical response based on completing the PHQ-9 before or during a visit. In these models, we evaluated the relationships between the clinical response outcomes as the dependent variable and 2 different independent variables, including the asynchronous completion of the PHQ-9 and response to the ninth item of the PHQ-9. Bonferroni corrections were applied to mitigate type I errors. All analyses were conducted using Stata (version 17; StataCorp).

Ethical Considerations

This project was determined not to be human subject research by the Stanford Institutional Review Board (IRB-62520) [30]. The data used for this study were deidentified.

Results

Descriptive Characteristics

During the study period, our program sent 202,681 PHQs to patients ahead of their clinic visit, and patients completed approximately 184,700 (91%) of them. Of the total questionnaires sent, 119,389 (58.9%) were completed asynchronously: 43,979 (65.2%) at SHC and 75,410 (55.8%) at UHA.

Of the 184,700 PHQs completed, 1683 (0.9%) patients responded with a score of 1 or higher on question 9 and were included in the sample (Table 1): 456 patients (1.0% of total patients screened) at SHC and 1227 (0.9% of total patients screened) at UHA. Nearly half completed the PHQ-9 asynchronously ($n=826$, 49.4%). The sample included primarily female ($n=1071$, 63.6%) and non-Hispanic ($n=1293$, 76.8%) patients, and the mean age was 46.4 (SD 21.1) years. Most of the sample consisted of White ($n=831$, 49.4%) or Asian ($n=314$, 18.7%) patients. Most had private health insurance ($n=1025$, 60.0%) or Medicare ($n=525$, 31.2%). A minority ($n=71$, 4.2%) had Medicaid.

Table . Descriptive characteristics comparing synchronous and asynchronous completion of the Patient Health Questionnaire-9 (PHQ-9).

Characteristics	Synchronous (n=857)	Asynchronous (n=826)	Total (n=1683)

Nearly every day	103 (59.5)	70 (40.5)	173 (10.3)

^aNot applicable.

At the time of chart review, 18 (1.1%) patients were deceased. Based on a detailed chart review, none of these patients died

by suicide. No patients in the sample were documented to have attempted suicide between the time of questionnaire completion

and their clinical encounter. Most patients responded to question 9 with “several days” (n=1205, 71.6%), followed by “more than half the days” (n=305, 18.1%) and “nearly every day” (n=173, 10.3%).

Regarding clinical responses, a minority of patients (n=361, 20.8%) received a new medication or dose adjustment (Table 2). A subset of patients were referred to psychiatry (n=205,

33.7%), SW (n=53, 11.5%), an external specialist (n=96, 21.1%), or a triage nurse (n=7, 1.5%). Some providers placed an eConsult to Psychiatry (n=34, 7.4%), where the provider directly communicated with the psychiatrist about a clinical question and received a response within 3 business days. None were sent to the emergency room for urgent evaluation. Most patients completed a C-SSRS during their visit (n=1176, 74.5%).

Table . Clinical response in the Stanford Health Care (SHC) and University Healthcare Alliance (UHA) samples by asynchronous and synchronous completion of the Patient Health Questionnaire-9 (PHQ-9).

Patient Characteristics Associated With the Modality of Questionnaire Completion: Asynchronous or Synchronous

Several patient characteristics were associated with asynchronous or synchronous completion of the PHQ-9 (Table

3). The relationship between patient race and completion modality did not meet the level of statistical significance designated by the Bonferroni correction, but the trend is worth noting ($P=.01$). Asian patients were more likely to complete the PHQ-9 asynchronously than White patients (odds ratio [OR] 1.40, 95% CI 1.08-1.82; $P=.01$). Hispanic and Latino patients

were less likely than non-Hispanic or non-Latino patients to complete the PHQ-9 asynchronously (OR 0.60, 95% CI 0.45-0.80; $P < .001$). Patient age was associated with modality of PHQ-9 completion, with patients aged 18 to 79 years having a higher likelihood of completing the PHQ-9 asynchronously than patients aged 80 years or older ($P < .001$). Patients with Medicare insurance were less likely (OR 0.64, 95% CI 0.51-0.79; $P < .001$) to complete the PHQ-9 asynchronously than patients with private insurance. Patients with office visits had

lower likelihood of completing the PHQ-9 asynchronously than patients with telemedicine visits (OR 0.24, 95% CI 0.20-0.30). Those with moderate to severe depression symptoms were 1.61 times more likely (95% CI 1.21-2.15; $P = .001$) to complete screening asynchronously than those with no or mild symptomatology. Finally, the mean PHQ-9 score (16.4, SD 5.3) for patients who completed the screening asynchronously was significantly higher than that for patients who completed screening synchronously (mean 15.6, SD 5.7; $P = .004$).

Table . Logistic regression of the association between patient characteristics and whether patients completed the Patient Health Questionnaire-9 (PHQ-9) synchronously or asynchronously (n=1683).

Differential Clinical Response to Suicide Risk by Asynchronous or Synchronous Modalities

The relationship between the timing of PHQ-9 completion and provider clinical response was evaluated (Table 4). Regardless of timing of PHQ-9 completion, there was a relationship between the response to question 9 and referral to psychiatry ($P=.002$). Those who reported suicidal thoughts “more than half the days” (OR 1.62, 95% CI 1.06-2.48; $P=.03$) or “nearly every day” (OR 2.38, 95% CI 1.38-4.12; $P=.002$) had a higher

likelihood of receiving a referral to psychiatry than those who endorsed question 9 “several days.” The likelihood of receiving a referral to psychiatry for those who completed a PHQ-9 asynchronously was lower (OR 0.23, 95% CI 0.16-0.34; $P<.001$) than for patients who completed the screening synchronously. In contrast, the likelihood of a patient completing the C-SSRS during the visit was 2.41 times higher (OR 2.41, 95% CI 1.89-3.06; $P<.001$) for patients who completed the PHQ-9 asynchronously than synchronously.

Table . Logistic regression of the association between completing the Patient Health Questionnaire-9 (PHQ-9) asynchronously or synchronously and clinical response for the Stanford Health Care (SHC; n=456) and University Healthcare Alliance (UHA; n=1227) samples.

Variable	SHC (n=456)						UHA and SHC (n=1683)

Discussion

Principal Findings

Shifting depression screening from an in-clinic task to a previsit questionnaire led to a dramatic increase in our system’s ability to effectively screen patients for depression without compromising patient safety. The remote delivery of our depression screening and monitoring program saved front line clinical teams time spent administering the PHQs, offered patients a private setting for symptom reporting, and facilitated more intentional clinical responses from providers.

Consistent with previous studies demonstrating that PHQ-9 scores are higher when completed by patients on their own time via a personal device, our patients reported more severe symptoms on asynchronous PHQs compared to in-clinic PHQs

[14,15]. In addition, of all patients who completed a PHQ-9, patients with moderate to severe symptoms were more likely to complete the PHQ-9 asynchronously, supporting the idea that patients with severe symptoms may feel more comfortable self-reporting outside of a clinic setting where they are not subject to time pressure or desire to please their provider [31].

Providers were also more likely to conduct a standardized suicide risk assessment when patients completed the PHQ-9 ahead of their visit. Evidence suggests that the ninth item of the PHQ-9 is an insufficient assessment tool for suicide risk and ideation and should be paired with a validated suicide risk assessment instrument [28]. In this study, once a patient completed a PHQ-9 asynchronously and endorsed question 9, the provider was immediately notified via a high-priority alert in the EMR. That previsit notification allowed providers to

prepare to address and appropriately prioritize assessing risk of self-harm when agenda-setting for the clinical encounter [32-34]. In contrast, if a provider learned of a high-risk score during a visit, it may be more challenging to prioritize, particularly if that was not a primary reason for the patient presenting to the visit. Mental health concerns can be complex and time-consuming to address. However, these symptoms can also be life-threatening, requiring timely clinical action. Placing a referral to psychiatry is appropriate clinical management of a patient with severe depression. However, when pressed for time or taken by surprise during a visit, and particularly when confronted with severe symptoms, providers may be more likely to delegate further evaluation and management to a psychiatrist. Conversely, when given advance notice of a high-risk score, providers may be better able to prioritize a patient's mental health concern and take the time to more completely assess, triage, and manage a patient's depression at the point of care, reducing the need to refer and providing more timely clinical intervention.

Asynchronous PHQ-9 completion offers some potential advantages, such as increased reporting of severe symptoms and supporting more intentional clinical responses, and should be accessible to all patients seen in health systems offering remote screening. Since suicidal risk can fluctuate over time [35], asynchronous screening programs offer an opportunity to evaluate risk in patients on a more frequent basis. Universal depression screening programs, in general, can reduce bias by addressing important barriers, such as care team discomfort and screening based on a provider's subjective risk assessment [36]. Asynchronous screening can offer a convenient method for vulnerable patient groups with low health care engagement to access resources more directly in primary care [37]. However, technology-enabled programs may disproportionately exclude patients with limited access to digital tools, particularly those with low health or technology literacy [37,38]. We observed that disparities in engagement with PHQ-9 completion existed, despite automation. Specifically, Asian patients were more likely than White patients to complete the PHQ-9 asynchronously, and non-Hispanic or non-Latino patients were more likely to complete screening asynchronously compared to Hispanic or Latino patients. Patients with Medicare insurance were also less likely to complete the PHQ-9 asynchronously, which may be explained by older patients having more of a preference for in-person care than telemedicine [37]. Due to the relative advantages of previsit PHQ-9 completion, health systems may benefit from designing processes to reduce disparities in engagement with electronic tools, such as eCheck-in, and designing in-clinic processes to promote equal opportunities for patients who cannot complete the electronic questionnaire ahead of their visit.

Limitations

This study was limited in scope and only included data for patients who endorsed question 9 of the PHQ-9 during the program's first 6 months. Our patient population had a high rate of technology literacy, with approximately 96% of patients enrolled in the web-based patient portal at SHC and 94% of patients enrolled in the web-based patient portal at UHA. Despite widespread engagement with electronic tools, our results suggest health disparities in previsit remote questionnaire completion. Future research should explore whether certain patient groups are more likely to engage in asynchronous questionnaire completion, particularly patients at high risk for depression, and how to bridge this gap.

Another limitation is the lack of clinical response data for UHA patients. Most clinical documentation is available only in free-text portions of providers' encounter notes, therefore not available discretely in reports and only accessible via manual and detailed chart review, making review of these data on a large scale time prohibitive. Finally, although we believe that no patient attempted or died by suicide in the study population, we only had access to a single data source, the EMR. To increase the likelihood of identifying relevant adverse clinical outcomes related to PHQ-9 completion, during chart review our team placed specific attention on reviewing documentation between the time of questionnaire completion and the patient's associated clinical encounter. A documented clinical encounter or electronic communication from the patient in the period following questionnaire completion provided confirmation of their living status.

Conclusions

This study suggests that screening patients for depression outside of a clinical care setting does not compromise patient safety, may increase honest self-reporting for those with severe symptoms, and can allow for more deliberate clinical evaluation and response by providers. Access to asynchronous depression screening may offer essential shifts in patient-centered healthcare access and provider-driven clinical responses. Disparities in patient characteristics associated with asynchronous questionnaire completion present future opportunities to engage non-White and older patients in reporting severe symptoms. Furthermore, this study demonstrates the benefit of exploring processes that support providers' ability to offer more intentional clinical responses when severe symptoms are identified during clinical encounters. These findings may or may not be limited to the primary care health systems in which the study was conducted. Nonetheless, these conclusions suggest that health systems should consider examining this issue for themselves and potentially reconsider how depression and suicide risk screening are systematically conducted at their institution.

Acknowledgments

The authors acknowledge the invaluable support and contributions of Dr Christopher Sharp, Patrick Cimino and their team for implementing the asynchronous previsit questionnaires. The authors would also like to thank Dr Alan Pinyavat for his critical review and feedback on this manuscript. This project would not have been possible without the support of the Stanford Health

Care (SHC) and University Healthcare Alliance (UHA) population health teams, ambulatory operations leadership, as well as the engagement and dedication of the SHC and UHA faculty and staff.

Abstract

Background: Misdiagnosis and delayed help-seeking cause significant burden for individuals with mood disorders such as major depressive disorder and bipolar disorder. Misdiagnosis can lead to inappropriate treatment, while delayed help-seeking can result in more severe symptoms, functional impairment, and poor treatment response. Such challenges are common in individuals with major depressive disorder and bipolar disorder due to the overlap of symptoms with other mental and physical health conditions, as well as, stigma and insufficient understanding of these disorders.

Objective: In this study, we aimed to identify factors that may contribute to mood disorder misdiagnosis and delayed help-seeking.

Methods: Participants with current depressive symptoms were recruited online and data were collected using an extensive digital mental health questionnaire, with the World Health Organization World Mental Health Composite International Diagnostic Interview delivered via telephone. A series of predictive gradient-boosted tree algorithms were trained and validated to identify the most important predictors of misdiagnosis and subsequent help-seeking in misdiagnosed individuals.

Results: The analysis included data from 924 symptomatic individuals for predicting misdiagnosis and from a subset of 379 misdiagnosed participants who provided follow-up information when predicting help-seeking. Models achieved good predictive power, with area under the receiver operating characteristic curve of 0.75 and 0.71 for misdiagnosis and help-seeking, respectively. The most predictive features with respect to misdiagnosis were high severity of depressed mood, instability of self-image, the involvement of a psychiatrist in diagnosing depression, higher age at depression diagnosis, and reckless spending. Regarding help-seeking behavior, the strongest predictors included shorter time elapsed since last speaking to a general practitioner about mental health, sleep problems disrupting daily tasks, taking antidepressant medication, and being diagnosed with depression at younger ages.

Conclusions: This study provides a novel, machine learning-based approach to understand the interplay of factors that may contribute to the misdiagnosis and subsequent help-seeking in patients experiencing low mood. The present findings can inform the development of targeted interventions to improve early detection and appropriate treatment of individuals with mood disorders.

Introduction

Mood disorders are debilitating psychiatric conditions that negatively affect a person's emotional state. They result in impaired ability to function and complete daily tasks, and an increased risk of self-harm and suicide [1]. Two of the most common mood disorders are major depressive disorder (MDD) and bipolar disorder (BD), which affect approximately 3.4% and 0.5% of the global population, respectively, at any given time [2]. Beyond the impact on the affected individuals, there are also economic and social consequences such as lost productivity, increased health care costs, and costs incurred by unpaid carers. In the United Kingdom alone, the economic burden of managing MDD and BD is estimated at £7.5 billion (US \$9.55 billion) and £5.2 billion (US \$6.62 billion), respectively [3], with a significant portion of this burden attributed to underdiagnosis and high rates of misdiagnosis of mood disorders.

Although misdiagnosis is prevalent in all areas of medicine, the heterogeneous nature of mental illness and lack of objective diagnosis make it more common for mental health conditions [4]. The diagnosis of mental health disorders is currently based on assessing patient symptom profiles using diagnostic manuals such as the Diagnostic and Statistical Manual of Mental Disorders, 5th Edition (DSM-5) [5] or the International Statistical Classification of Diseases and Related Health Problems, 11th Revision (ICD-11) [6]. As such, diagnosis relies heavily on symptom reporting and patients who do not recognize and thus do not report their symptoms or present with complex symptoms are more likely to be misdiagnosed [7]. For example, issues with symptom reporting are considered a major cause of BD misdiagnosis [8], with many patients with BD only seeking medical help during depressive episodes [9], which makes mania more difficult to identify. Consequently, as many as 78% of mood disorder diagnoses are missed in primary care [10], including approximately 40% of patients with BD who are initially misdiagnosed with MDD [11]. This, in turn, leads to incorrect treatment of BD with antidepressants which have lower efficacy than mood stabilizers in alleviating bipolar symptoms and have been associated with prolonged episodes of mania and accelerated cycling between manic and depressive states [12,13]. Understanding factors that lead to misdiagnosis could guide the development of more effective means for early identification and intervention in individuals at high risk.

An additional barrier to receiving a correct diagnosis and necessary care is the reluctance of affected individuals to speak to medical professionals about their mental health. The European Study of the Epidemiology of Mental Disorders carried out across 6 countries found that only 25.4% of respondents spoke to a medical professional about their mental health problems [14]. Likewise, active engagement with mental health services is consistently low, with almost 75% of patients experiencing a mental illness in England receiving no treatment [15]. One of

the reasons for the low rates of help-seeking in individuals experiencing mental health symptoms is concerns of potential public and self-internalized stigma. Consequently, individuals struggling with their mental health often turn to coping mechanisms such as social withdrawal, secrecy, and label avoidance [16,17] rather than seeking help [18]. Therefore, it is imperative to recognize barriers to help-seeking in mental health to facilitate early and accurate diagnosis in un and misdiagnosed individuals.

Although previous studies have investigated factors contributing to the misdiagnosis, poor help-seeking behavior, and barriers to receiving a diagnosis, only a few have used machine learning methods to do so [19]. The use of machine learning in mental health research has increased in recent years, with many studies focusing on detection and diagnosis, treatment and support, public health, and research and clinical administration [19]. While not without limitations, the use of machine learning can offer data-driven insights into complex relationships between high-dimensional data [20,21]. Although other, mostly qualitative investigations have identified the predictors of help-seeking and misdiagnosis by considering factors individually, this study aims to take a more holistic approach. By developing machine learning models based on extensive self-reported patient data, we aim to identify and quantify interdependent predictive factors for the misdiagnosis of mental health disorders, specifically mood disorders, and help-seeking behavior in individuals who may have been misdiagnosed. Identifying such predictive factors could aid in avoiding preventable misdiagnosis, encourage help-seeking, and improve outcomes in patients presenting with depressive symptoms.

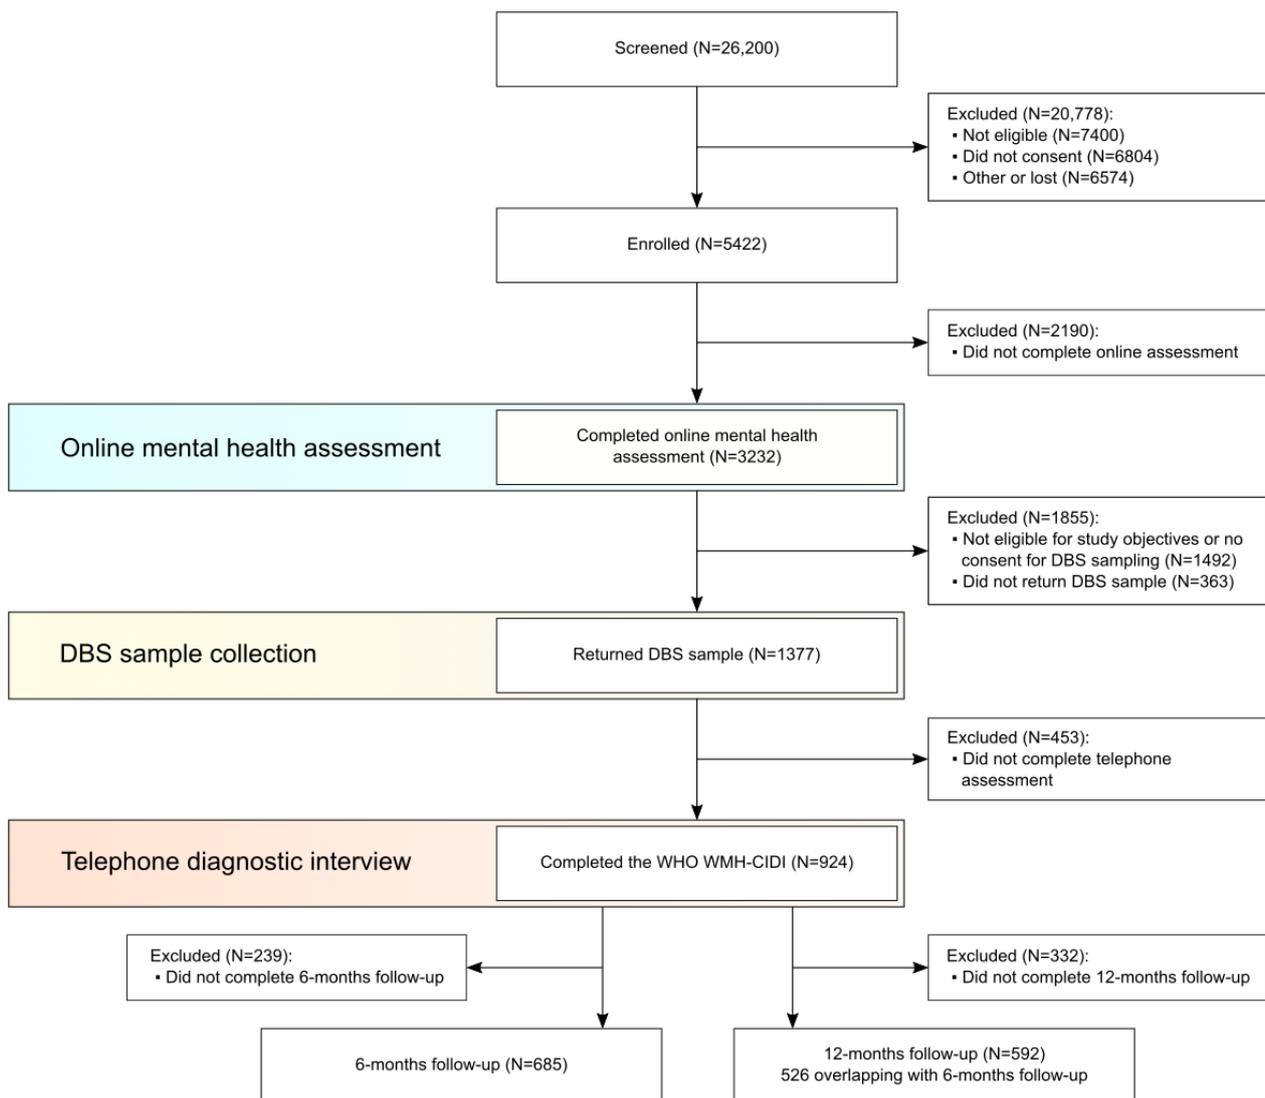

Methods

Data Acquisition

Overview

The data used in this report were collected as part of the Delta Study—a study aiming to facilitate a more accurate and earlier diagnosis of BD and MDD; carried out in the United Kingdom by the Cambridge Centre for Neuropsychiatric Research between 2018 and 2020 [22,23]. The study consisted of an adaptive digital questionnaire, the Composite International Diagnostic Interview (CIDI) [24], and 2 follow-up questionnaires at 6 and 12 months. The stages of the Delta Study are summarized in Figure 1. Participants were recruited nonrandomly through email, the Cambridge Centre for Neuropsychiatric Research (CCNR) website, and paid Facebook advertisements. The eligibility criteria included at least mild depressive symptoms, indicated by a score of ≥ 5 on the Patient Health Questionnaire-9 (PHQ-9) [25] at the time of recruitment, aged between 18 and 45 years, and residency in the United Kingdom. Participants who indicated current suicidal ideation or intent, were pregnant, or breastfeeding, were excluded.

Figure 1. Delta Study flow diagram [22]. DBS: dried blood spot; WHO: World Health Organization; WMH-CIDI: World Mental Health Composite International Diagnostic Interview.

Adaptive Digital Questionnaire

In total, 3232 participants completed the adaptive digital questionnaire available on the Delta Study digital platform. The questionnaire consisted of 635 questions, divided into six sections: (1) demographic information and personal history; (2) manic and hypomanic symptoms; (3) depressive symptoms; (4) personality profiling; (5) treatment, medication, substance use, and family psychiatric history; and (6) other psychiatric conditions. As the questionnaire was adaptive to answers given by participants, the maximum number of questions an individual could answer was 382, with an average of 284. Within the questionnaire, participants reported their baseline diagnosis, and their current well-being (within the previous 14 days) was quantified using the Warwick-Edinburgh Mental Well-Being Scale (WEMWBS) [26].

Composite International Diagnostic Interview

Participants who completed the web-based mental health questionnaire were invited to complete the CIDI version 3.0 via telephone. The CIDI is a structured diagnostic interview for mental disorders created by the World Health Organization

based on the International Classification of Diseases and Related Health Problems, 10th Revision (ICD-10). It was developed primarily for epidemiological studies and has been extensively validated, demonstrating high diagnostic reliability [27]. In this study, only sections pertaining to mood disorder diagnoses were applied, that is, the demographics, depression, and mania modules. Interviewers were trained by CIDI-certified instructors prior to conducting the interviews. In total, 924 participants completed the CIDI and received one of the following diagnoses in their results report: BDI, BDII, subthreshold BD, MDD with subthreshold BD, MDD, or no mood disorder diagnosis (referred to as “low mood”).

Follow-Up Questionnaires

Participants who completed the digital questionnaire were invited to fill out 2 follow-up questionnaires, 6 and 12 months after receiving their results report. The follow-up questionnaires aimed to determine the effects of participation in the Delta Study on participants’ quality of life and record subsequent changes in diagnosis and treatment. A total of 2064 participants

completed at least 1 of the follow-up questionnaires, with 1780 respondents at 6 months and 1542 respondents at 12 months.

Outcomes

Overview

For the purposes of this study, 2 dependent variables were defined.

Misdiagnosis

For participants who completed the CIDI, the mood disorder diagnosis reported at baseline was compared to the diagnosis obtained from the CIDI, including patients with no mood disorder diagnosis at baseline who should have been diagnosed. CIDI diagnosis was used as the gold standard, and any mismatch with the baseline diagnosis was defined as misdiagnosis. This definition of misdiagnosis was consistent with previous studies investigating under- and misdiagnosis of mood disorders based on comparing patient-reported diagnoses to the outcomes of structured clinical interviews [28,29].

Help-Seeking Behavior

In the 6- and 12-month follow-up questionnaires, participants were asked: “Have you had an appointment with a GP or psychiatrist to talk about your mental health in the past 6 months?” A positive response to this question at either time point was defined as help-seeking. In order to examine help-seeking in misdiagnosed individuals, only those who were identified as misdiagnosed within outcome 1 were included in the analysis.

Analysis

Overview

Raw data processing and feature engineering were performed in R (version 3.6.3; R Core Team) [30]. Subsequent analyses and modeling were carried out using Python (version 3.9.7; Python Software Foundation) [31]. Main libraries used included Pandas (version 1.5.2; Pandas Development Team) [32] and NumPy version 1.23.5 [33] for data manipulation; scikit-learn version 1.0.2 [34], XGBoost (version 1.6.1; The XGBoost Contributors) [35], and SHAP version 0.41.0 [36] for modeling and interpretation; and Seaborn version 0.12.1 [37] and Matplotlib version 3.6.2 [38] for plotting.

Data Preparation

Prior to analysis, constant and duplicate variables were removed. Answers to questions examining the same symptom or construct were concatenated, and new features were created to represent these aggregated answers. Missing data were imputed where possible (for example, the answer to the question asking “Has anyone suggested you drink less?” was set to 0 for participants who had indicated they do not drink), and otherwise remained nonrandomly missing. Categorical variables were 1-hot encoded, that is, unique dummy variables were created where the presence of each category was denoted by “1,” and its absence was represented by “0.”

Modeling and Interpretation

This analysis aimed to develop predictive models to identify variables influencing (1) misdiagnosis and (2) help-seeking

behavior in participants who were identified as potentially misdiagnosed. A decision tree-based machine learning algorithm Extreme Gradient Boosting (XGBoost) [35] was chosen to train the classification models due to being robust to outliers, agnostic to data distribution, having the ability to handle nonrandom missing data, offering good predictive power, and due to it allowing for good model interpretability. Repeated nested cross-validation (rNCV) was used for model training and evaluation to obtain accurate estimates of model performance in unseen data. rNCV relies on performing a k-fold cross-validation (CV) within each round of another CV. This allows for model-specific hyperparameter optimization in the inner loop, with the final model being trained using the best-performing set of parameters, and later evaluated in the outer loop of rNCV. For this analysis, a 4-fold stratified CV was used in both the inner and outer loops, where 3 of the folds acted as a training set and 1 as a test set. Tuned model parameters included the number of estimators (1 to 100), shrinkage rate (0.1 to 0.3) to prevent overfitting, and tree depth (1 or 2) to allow for first-order interactions between predictors. The training was repeated 100 times, generating a total of 400 models for each of the objectives. Generalized model performance was evaluated by calculating the area under the receiver operating characteristic curve (AUC). The classification cutoff was optimized for the Youden index [39] to balance the true positive and true negative rates and offset potential imbalances between classes. SHAP (Shapley additive explanations) analysis [36], which combines local interpretable model-agnostic explanations (LIME) [40] and Shapley sampling values [41] approaches, was used for model interpretation. Feature occurrence frequency was calculated as the percentage of the models that incorporated a given feature to generate predictions. Reported results represent mean and SD values across the rNCV models.

Ethical Considerations

The study protocol was approved by the University of Cambridge Human Biology Research Ethics Committee (HBREC 2017.11) and all enrolled participants signed a digital informed consent form.

Results

Misdiagnosis

The self-reported baseline diagnosis did not match the diagnosis assigned by CIDI for 471 (50.97%) of the 924 participants who completed the CIDI interview. These participants were therefore considered misdiagnosed. No between-group differences were observed in terms of age, sex, ethnicity, highest achieved education level, or relationship status between the correctly diagnosed and misdiagnosed groups (Table S1 in [Multimedia Appendix 1](#)). However, there were significant differences in employment status as well as well-being and PHQ-9 scores, with misdiagnosed individuals, on average, reporting lower well-being and more severe depressive symptoms.

On average, the models correctly classified 70% (SD 9%) of misdiagnosed participants and 71% (SD 9%) of correctly diagnosed participants, with a mean accuracy of 70% (SD 3%) and the out-of-fold AUC of 0.75 (SD 0.03; [Figure 2](#) and Table

S2 in [Multimedia Appendix 1](#)). Among the 1045 variables evaluated, the strongest predictors of misdiagnosis were more severe composite depressive symptoms and unstable self-image ([Figure 3](#)). Unstable self-image was measured by a 4-level Likert scale question “Is your image and sense of yourself and what you believe in unstable and constantly changing?” The next strongest predictor was the diagnosing clinician, with those who were undiagnosed at baseline or reported a diagnosis by a psychiatrist more likely to be misdiagnosed. The top 10

predictors also included variables related to age at diagnosis of BD and MDD, with late (≥ 35 years of age) diagnosis or no diagnosis at all, increasing the likelihood of being misdiagnosed ([Figure S1 in Multimedia Appendix 1](#)). Misdiagnosed participants were also more likely to recklessly spend money, experienced more frequent intense mood swings or mania in general, had higher weight gain during low mood episodes, and were more sexually active than usual at the time of data collection.

Figure 2. Out-of-fold model performance in predicting misdiagnosis. Green lines represent predictive performance on unseen out-of-fold data for each of the 400 final models. The thick blue line represents the average of all ROC curves. The grey area represents 1 SD. AUC: area under the receiver operating characteristic curve; ROC: receiver operating characteristic.

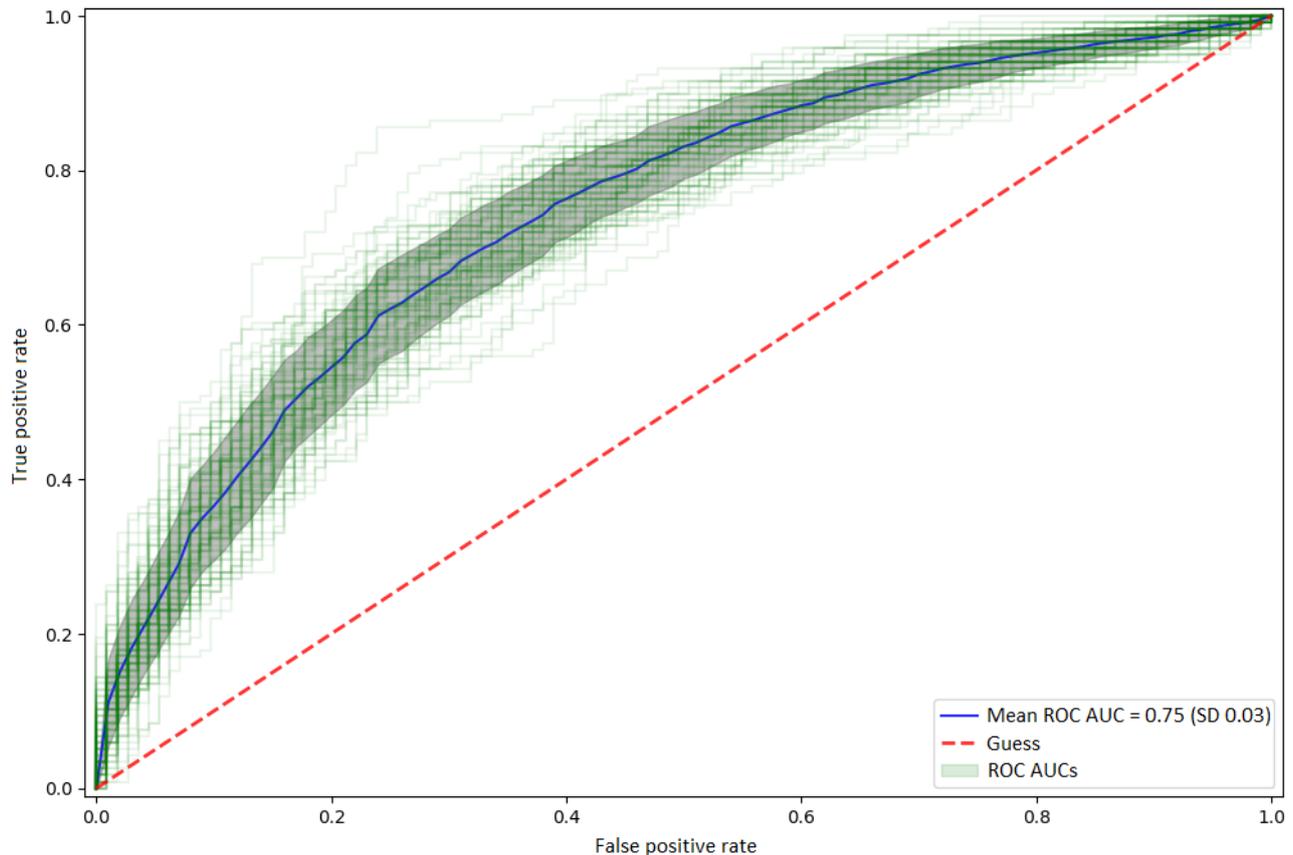

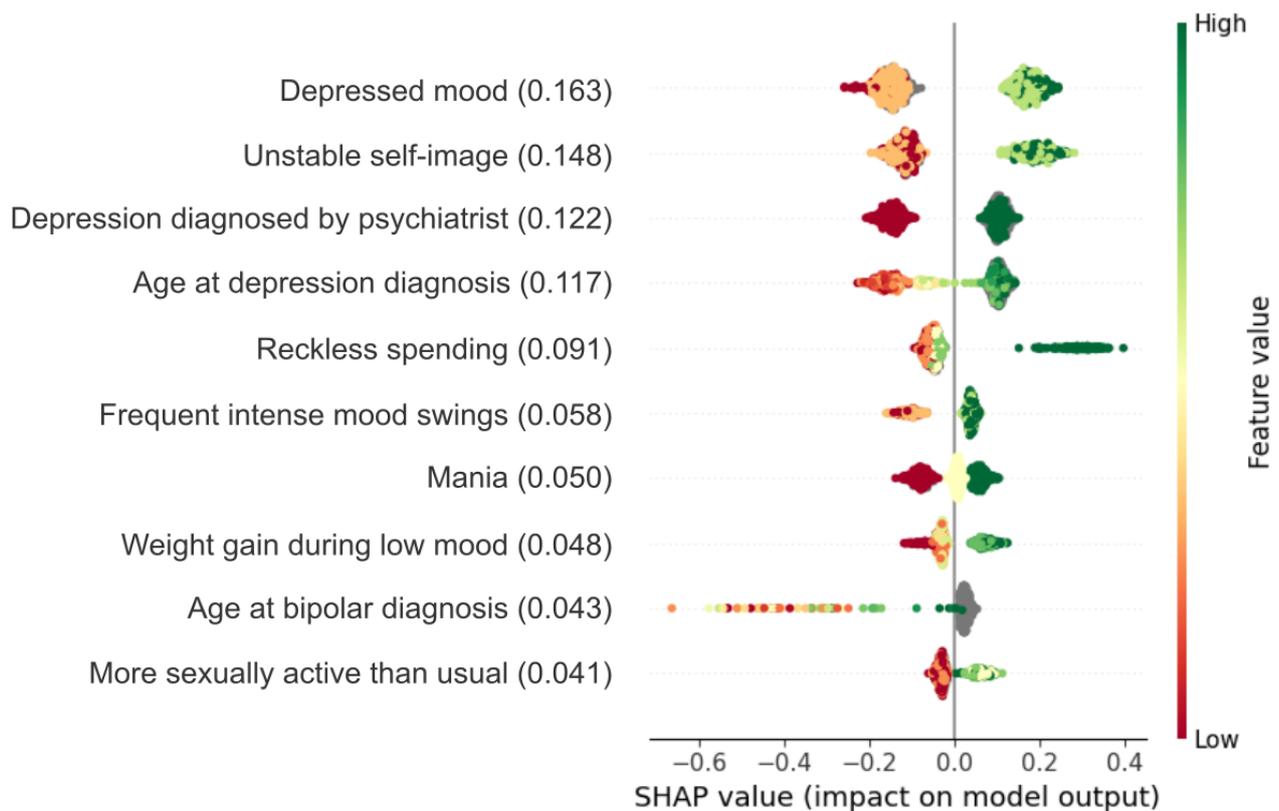

Figure 3. Results for the top 10 variables in the misdiagnosis model. Shown is SHAP analysis of the factors associated with misdiagnosis. The features (y-axis) are ordered by their average feature importance, indicated by the value inside the brackets, across all models. Each colored dot represents a participant, where the color gradient shows the value of the answer (red if low, green if high, and grey if missing), and the corresponding value on the x-axis shows directionality and the impact on model output, as determined using SHAP analysis. Values below 0 show directionality toward being correctly diagnosed, whereas values above 0 show directionality toward misdiagnosis. SHAP: Shapley additive explanations.

Model performance was largely driven by the top 5 predictors, with a steady decline in SHAP scores for subsequent variables. Of the top 10 predictors, 9 were selected in more than 75% (n=300) of the models, suggesting a relatively stable model composition. The exception was a variable related to “being more sexually active than usual,” which was selected in 71% (n=284) of the models. More detailed information on feature selection frequency is provided in Figure S3 in [Multimedia Appendix 1](#).

Help-Seeking Behavior

Help-seeking behavior was investigated in 379 participants who were misdiagnosed at the baseline and who had completed at least 1 of the follow-up questionnaires. Of those, 229 (60.42%) participants sought an appointment with a medical professional during the follow-up period to discuss their mental health and were therefore defined as “help-seekers.” The help-seeker and non-help-seeker groups differed significantly in the highest achieved education level, relationship status, well-being, and severity of depressive symptoms (Table S3 in [Multimedia Appendix 1](#)). Participants more likely to seek help were on

average less formally educated, more likely single, reported higher mean severity of symptoms, and worse overall well-being.

The model achieved an AUC of 0.71 (SD 0.04; [Figure 4](#)), with a sensitivity of 65% (SD 13%), specificity of 72% (SD 13%), and average accuracy of 67% (SD 4%; Table S4 in [Multimedia Appendix 1](#)). The strongest predictor was the shorter time since patients last spoke to a general practitioner (GP) about their mental health at baseline ([Figure 5](#)). It was followed by sleep problems disrupting daily tasks and taking prescribed antidepressants, both associated with increased help-seeking. Consistent with this, lower help-seeking was observed in participants who had never been prescribed antidepressants, namely selective serotonin reuptake inhibitors (SSRIs). Furthermore, there was a lower likelihood of help-seeking with higher age at both the first episode of low mood and diagnosis of depression, which was similarly predictive to not having been previously diagnosed with depression. Finally, impaired ability to work, lower well-being scores, feeling worthless, and lower self-rated mental health were associated with help-seeking behavior.

Figure 4. Out-of-fold model performance in predicting help-seeking. Green lines represent predictive performance on unseen out-of-fold data of each of the 400 final models. The thick blue line represents an average of all ROC curves. The grey area represents 1 SD. AUC: area under the receiver operating characteristic curve; ROC: receiver operating characteristic.

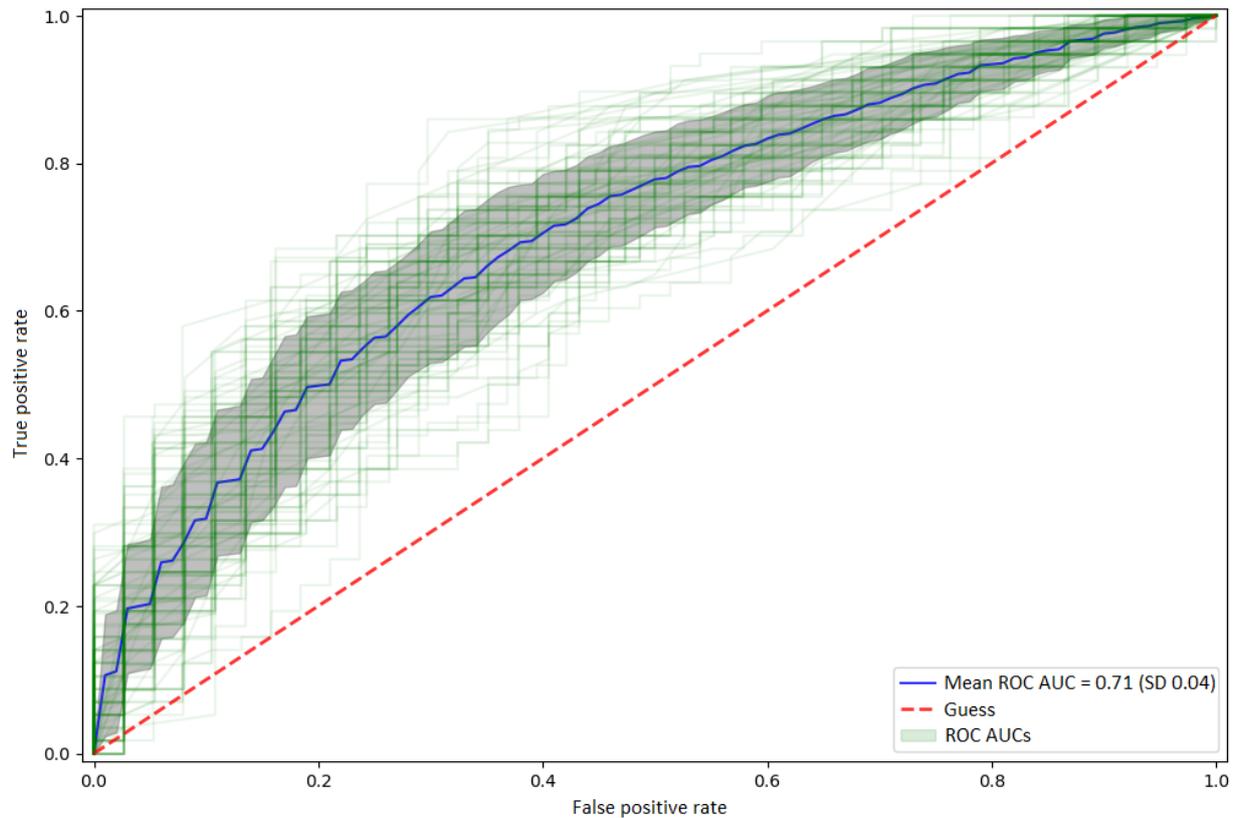

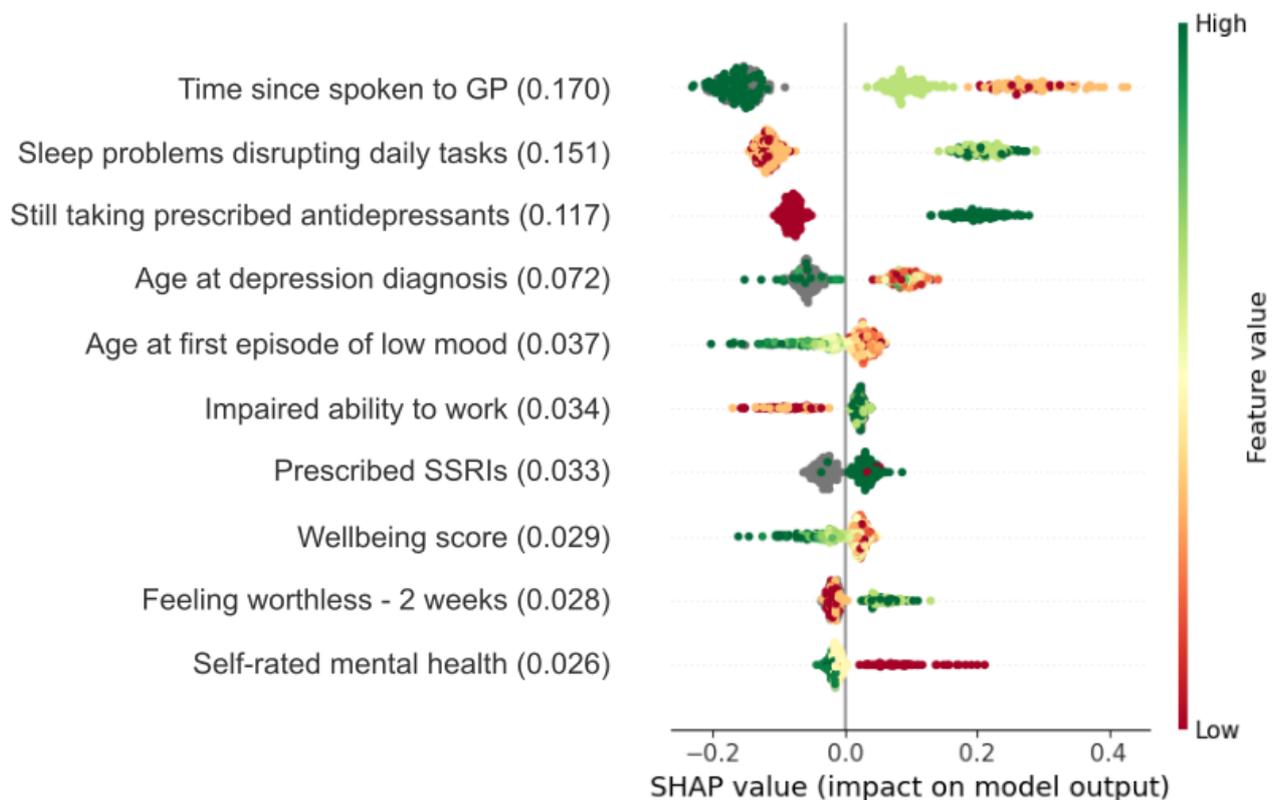

Figure 5. Results for top 10 variables in the help-seeking model in misdiagnosed individuals. Shown is feature SHAP importance (in brackets) and feature SHAP values (data points). SHAP values below 0 show directionality toward low help-seeking (ie, no appointment with GP or psychiatrist to discuss mental health), whereas values above 0 show directionality toward high help-seeking. GP: general practitioner; SHAP: Shapley additive explanations; SSRI: selective serotonin reuptake inhibitor.

The 3 variables, namely, time since last spoken to a GP, sleep problems disrupting daily tasks, and still taking prescribed antidepressants, were selected in nearly all models (Figure S4 in [Multimedia Appendix 1](#)), suggesting their high relevance for model predictions. Among other predictors, only age when diagnosed with depression was selected in more than 75% (n=300) of models, with the remaining features only selected in approximately 50% (n=200) of models, indicating their lower relevance.

Discussion

Principal Findings

This study aimed to develop machine learning models to explore factors potentially contributing to misdiagnosis and subsequent help-seeking in individuals experiencing low mood. For this purpose, we used data obtained through an extensive digital questionnaire concerning demographic, personality, and mental health data, as well as, the validated and standardized diagnostic interview, CIDI. Developed models achieved a fair level of predictive power, with AUCs of 0.75 and 0.71 for predicting misdiagnosis and help-seeking, respectively. Below, we discuss the main findings as well as the strengths and limitations of this analysis.

Misdiagnosis

The strongest predictor of misdiagnosis was the severity of depressed mood, with more severe depressive symptoms being associated with a greater risk of being misdiagnosed. This directionality was consistent with other top predictors of misdiagnosis, including unstable self-image, reckless spending, frequent intense mood swings, mania, weight gain during low mood, and being more sexually active than usual. Except for the instability of self-image, these predictors can be divided into either depression or mania or bipolar-related symptoms. Overall, the finding that individuals with more severe mental health symptoms are at a greater risk of being misdiagnosed is surprising, given the opposite could be expected as milder symptoms are harder to detect [42]. Several factors could contribute to this association, including the complexity of diagnosing mental health disorders [43], variability in symptom presentation [44,45], and the high degree of symptom overlap across different diagnoses [5]. A possible explanation for the increased risk of misdiagnosis among individuals with more severe symptoms is that they may present with prominent mood instability, such as that observed in patients with personality disorder, or rapidly cycling symptoms, making accurate diagnosis more challenging [9]. In addition, individuals with more severe symptoms often lack motivation to seek help, hence their symptoms may remain unrecognized for a longer time [46].

In the case of mood disorders, misdiagnosis of individuals with higher depressive symptom severity may result from the fact that patients with BD generally seek medical help during depressive episodes and often present with more severe depressive symptoms than patients with MDD, while underreporting manic phases [47,48]. In fact, less than a third of patients with BD report the presence of reckless behavior, excessive spending, and increased sexual interest or activity

[49]. This contributes to approximately 40% of patients with BD receiving an incorrect initial diagnosis of unipolar depression [50]. Also, the association of frequent intense mood swings with mood disorder misdiagnoses may be related to incorrect treatment of depressive symptoms of BD with antidepressants, rather than mood stabilizer medication, which has the potential to induce mania and rapid cycling [51,52].

The second most predictive feature of misdiagnosis identified in this study was unstable self-image. Previous literature has shown that an unstable sense of self is associated with frequent changes in diagnosis, and often linked to complex and unstable personality characteristics [53]. The high ranking of self-image stability could, however, be a result of the high comorbidity rates between BD and other disorders featuring unstable self-image that were not evaluated by the diagnostic interview used in this study, such as borderline personality disorder [54]. This is especially important considering that such disorders may share a high number of similarities with BD, leading to frequent misdiagnoses [55,56]. The 2 additional symptoms that are ranked high in terms of predictive value for misdiagnosis in this analysis regard reckless spending and increased sexual activity, representing reckless or impulsive behavior, which are included in the diagnostic criteria of both BD and borderline personality disorder [17].

Finally, among the top predictors of misdiagnosis were 3 variables related to psychiatric history, including psychiatrist involvement in the diagnosis, age at depression diagnosis, and age at BD diagnosis. Interestingly, the models attributed a higher risk of misdiagnosis to individuals whose depression was diagnosed by a psychiatrist. This may be caused by the fact that patients at high risk of misdiagnosis, such as those with more complex symptom presentation or suspected comorbidities, are usually referred to secondary care, following the National Institute for Health and Care Excellence (NICE) guidelines [57]. However, this finding should be interpreted with caution, as diagnoses made by psychiatrists are generally more accurate than those derived from the CIDI. Also, participants who received a diagnosis of a mood disorder at an older age, or not at all, were more likely to be misdiagnosed. This finding is surprising, as previous literature suggests that the severity and impact of symptoms decline with age, with 86% of patients with BD diagnosed by the age of 25 [58]. However, it is possible that due to milder symptoms, patients who are older may remain undiagnosed for longer periods of time.

Help-Seeking

Analysis of participants with a mismatch between their self-reported formal diagnosis and the CIDI outcome revealed several predictors of help-seeking related to patients' mental health history and symptoms.

The most predictive feature was time since last spoken to a GP at baseline, with patients who had visited their GP more recently being more likely to seek help. Interestingly, that was not the case for the time since last spoken to a psychiatrist, likely due to most participants not being under secondary care and the long waiting times for psychiatric assessment [59]. In line with previous literature [60], these findings indicate that help-seeking was also associated with more severe psychiatric symptoms and

having a previous diagnosis of mood disorder. Similarly, participants seeking help reported lower well-being, feeling more worthless, and more functional impairment in carrying out daily tasks and at work caused by symptoms and sleep problems.

Interestingly, while there was not a significant overall age difference between the help-seekers and non-help-seekers, further analyses showed a lower tendency to seek help in individuals who were over 35 years old at initial diagnosis of depression (Figure S2 in [Multimedia Appendix 1](#)). The pattern of people who are younger being more likely to seek help is in line with the published literature [61]. Together with the finding that the initial diagnosis at older age was a strong predictor of misdiagnosis [62], this result indicates that patients who are most likely to be misdiagnosed are also the least likely to seek help. Thus, older patients may require more support to tackle potential barriers to help-seeking and receiving a diagnosis, such as stigma and inadequate mental health education [63].

The final set of predictors of help-seeking was related to previous medication. Higher help-seeking was observed in misdiagnosed individuals who were still taking previously prescribed antidepressants, in particular SSRIs, as opposed to misdiagnosed individuals who either had never been prescribed SSRIs or other antidepressant medication or had stopped taking it. The association of antidepressant treatment with help-seeking indicates that the prescribed medication may have been ineffective, as is often the case when attempting to treat depressive episodes of BD with antidepressant monotherapy [64]. Compared with the patients with MDD, the patients with BD respond worse to antidepressant medication, with short-term nonresponse rates of 51.3% in BD versus 31.6% in MDD [65]. This difference is even more pronounced in the long-term, where the loss of response to antidepressants is 3.4 times more frequent in patients with BD, while withdrawal relapse into depression is 4.7 times less frequent in BD compared to patients with MDD [65]. Moreover, individuals with unrecognized BD who are treated with antidepressants sometimes develop symptoms of mania, which in turn may motivate patients or their relatives to seek consultation with a specialist [66].

Limitations

The main limitation of this study is the reliance on CIDI as the gold standard for mood disorder diagnosis. Although the CIDI demonstrates good agreement with structured diagnostic interviews conducted by clinicians [67], future studies should consider either retrospective or longitudinal study designs, and ideally access medical records for more accurate diagnoses, including those beyond mood disorders. Additionally, the study participants were recruited online following strict inclusion criteria and were predominantly White, necessitating further research in traditionally underrepresented ethnic minorities and more representative patient cohorts. Another limitation is the exclusion of individuals with current suicidal ideation, a characteristic that could be an important indicator of misdiagnosis. Finally, the observed associations do not necessarily imply causality, which can only be evaluated through prospective causal inference study designs.

Conclusions

This analysis leveraged comprehensive patient data, a robust machine learning algorithm, and an extensive validation framework, to identify predictors of mood disorder misdiagnosis in individuals experiencing depressive symptoms, and subsequent help-seeking. The results highlight the increased risk for misdiagnosis associated with incomplete symptom profiles, more severe or harder to detect symptoms, and older age. Therefore, comprehensive symptom monitoring outside of depressive episodes, mental health screening at earlier ages, and clinician knowledge of the influence of advanced age on misdiagnosis risk are important considerations for early and accurate diagnosis of mood disorders. Moreover, prior engagement with mental health services, functional impairment in performing daily tasks, and younger age were associated with a higher likelihood of help-seeking. Together, these results add to the growing application of machine learning techniques in examining existing barriers to accessing mental health services [19], and may ultimately lead to the development of novel screening tools or procedures for a comprehensive mental health risk assessment in individuals presenting with mood-related symptoms.

Acknowledgments

We are most grateful to all participants of the Delta Study for their time and efforts. We are also grateful to all members of the Delta Study Service User Advisory Group. We also thank all those involved in designing and conducting the Delta Study for their valuable input including Jason D Cooper, Sung Yeon Sarah Han, Lynn P Farrag, Emily Bell, Lauren V Friend, Sharmelee Thiahulan, Pawel Eljasz, Mark Agius, Neil Hunt, and the CIDI interviewers. This study was funded by the Stanley Medical Research Institute (07R-1888) and Psyomics Ltd. Stanley Medical Research Institute was not involved in any part of the research. Psyomics Ltd was involved in the design and conduct of the study; recruitment, data collection, and management; and review or approval of the study.

Authors' Contributions

SB and DC conceived the Delta Study, conceptualized, and supervised the development of the web-based mental health questionnaire. SB, DC, GBO, and T Olmert contributed to the design of the study. GBO and T Olmert collected the web-based mental health questionnaire data. GBO and JT processed the web-based mental health questionnaire data. JB, NL, and T Ong analyzed the data. SB, JT, NAMK, and ELF advised the analysis. JB and JT wrote the first draft of the study, with contributions from NL, T Ong, NAMK, ELF, and SB. All authors contributed to the final version of the study.

Conflicts of Interest

SB is a director of Psynova Neurotech Ltd and Psyomics Ltd. SB, ELF, and DC have financial interests in Psyomics Ltd. GBO had financial interests in Psyomics Ltd. SB, JT, and T Olmert have received payments from the University of Cambridge for licensing of data from the Delta Study. SB and JT may benefit financially from patents arising from the Delta Study. ELF is a consultant for Psyomics Ltd. All other authors declare no competing interests.

Multimedia Appendix 1

Demographics, model performance metrics, dependence plots, and feature selection frequencies for all objectives.

Abstract

Background: The use of mobile devices to continuously monitor objectively extracted parameters of depressive symptomatology is seen as an important step in the understanding and prevention of upcoming depressive episodes. Speech features such as pitch variability, speech pauses, and speech rate are promising indicators, but empirical evidence is limited, given the variability of study designs.

Objective: Previous research studies have found different speech patterns when comparing single speech recordings between patients and healthy controls, but only a few studies have used repeated assessments to compare depressive and nondepressive episodes within the same patient. To our knowledge, no study has used a series of measurements within patients with depression (eg, intensive longitudinal data) to model the dynamic ebb and flow of subjectively reported depression and concomitant speech samples. However, such data are indispensable for detecting and ultimately preventing upcoming episodes.

Methods: In this study, we captured voice samples and momentary affect ratings over the course of 3 weeks in a sample of patients (N=30) with an acute depressive episode receiving stationary care. Patients underwent sleep deprivation therapy, a chronotherapeutic intervention that can rapidly improve depression symptomatology. We hypothesized that within-person variability in depressive and affective momentary states would be reflected in the following 3 speech features: pitch variability, speech pauses, and speech rate. We parametrized them using the extended Geneva Minimalistic Acoustic Parameter Set (eGeMAPS) from open-source Speech and Music Interpretation by Large-Space Extraction (openSMILE; audEERING GmbH) and extracted them from a transcript. We analyzed the speech features along with self-reported momentary affect ratings, using multilevel linear regression analysis. We analyzed an average of 32 (SD 19.83) assessments per patient.

Results: Analyses revealed that pitch variability, speech pauses, and speech rate were associated with depression severity, positive affect, valence, and energetic arousal; furthermore, speech pauses and speech rate were associated with negative affect, and speech pauses were additionally associated with calmness. Specifically, pitch variability was negatively associated with

improved momentary states (ie, lower pitch variability was linked to lower depression severity as well as higher positive affect, valence, and energetic arousal). Speech pauses were negatively associated with improved momentary states, whereas speech rate was positively associated with improved momentary states.

Conclusions: Pitch variability, speech pauses, and speech rate are promising features for the development of clinical prediction technologies to improve patient care as well as timely diagnosis and monitoring of treatment response. Our research is a step forward on the path to developing an automated depression monitoring system, facilitating individually tailored treatments and increased patient empowerment.

Introduction

Background

Depression is one of the most prevalent health disorders worldwide [1,2]. The World Health Organization predicted that depression would be 1 of the 3 leading causes of disease burden by 2030 [3], even before its prevalence increased owing to the COVID-19 pandemic [4]. This disorder has symptoms that include depressed mood, loss of energy and interest, sleep problems, and diminished ability to concentrate [5]; thus, depression imposes a substantial burden on the patients as well as their surroundings, society, and the economy [6]. Most importantly, depression is a chronic disorder, characterized by multiple episodes over years or decades. However, strategies for secondary prevention or early detection of new episodes are missing.

The diagnosis and severity assessment of depression relies mostly on self- or caregiver reports, which are prone to retrospective and social desirability bias [7,8]. In addition, such assessments are time and resource intensive because clinical specialists are needed over the course of treatment and recovery [9]. Moreover, many new episodes remain undiagnosed or untreated, that is, secondary prevention is the main issue [10,11]. To reduce burden, the timely detection and diagnosis of (new) depressive episodes are critical.

In recent years, research has focused on the identification of mental health disorder indicators that can be derived automatically, driven by technological developments [12,13]. In particular, the innovation of the ambulatory assessment research technique has contributed strongly to this endeavor [14]. Different terms have been used for this kind of methodology: *ambulatory assessment* [15], *ecological momentary assessment* [16], *experience sampling* [17], and *digital phenotyping* [18]. Although the terms differ, all approaches use computer-assisted methodology to assess momentary self-reported symptoms (eg, via electronic diaries [ediaries]), behaviors, or physiological processes, or actively or passively collect smartphone and physical data or context information (eg, via wearables) while the participant performs normal daily activities in their natural environment [19]. The main advantages of ambulatory assessment are (1) the ability to collect real-life data in real time, thereby reducing retrospective recall bias and increasing ecological validity; and

(2) the ability to collect data continuously (passively), which allows us to capture dynamic changes. Accordingly, ambulatory assessment is a promising tool for the timely detection of upcoming clinical episodes to prevent further clinical deterioration [20-22]. In particular, parameters captured objectively by wearables are useful because they can be assessed passively with a high frequency over prolonged time periods [23].

Promising markers that can be assessed objectively are speech and language, which are also metaphorically called “the mirror of the soul” [24]. Even before objective measurements with ambulatory assessment technology were feasible, clinical observations described the voice of patients with depression as low, slow, and hesitant, with these patients speaking in a monotonous and expressionless manner [24,25]. Voice and speech production may be affected by typical characteristics of the clinical nature of depression; for example, psychomotor retardation, energy loss, and cognitive difficulties also affect the vocal folds, leading to a lower *intensity*, *rate*, and *loudness* of speech, which manifest in a monotone and toneless voice [26-28]. Recent reviews have highlighted the potential of using speech markers to assess a variety of psychiatric disorders [29], especially depression [30]. The use of speech as a marker has several advantages because it can be recorded (1) casually; (2) in a noninvasive manner at people’s homes or in public places (with consent provided); and (3) at low cost because microphones are integrated in many devices such as smartphones, smartwatches, and hearing aids. With the availability of open-source speech analysis software (eg, open-source Speech and Music Interpretation by Large-Space Extraction [openSMILE; audeERING GmbH] and Praat) and advances in automatic speech processing technologies based on machine learning techniques, research and development on the use of acoustic and linguistic features to identify mood disorders in particular [29] have been made possible.

Prior Work

Many studies have successfully discriminated between healthy controls and patients with depression based on speech features [30]. However, understanding within-person (vs between-person) depression-related voice changes is essential in detecting new episodes, that is, the secondary prevention. To the best of our knowledge, only a few studies in samples with clinical (not subclinical) depression have examined the variability of speech features within persons [31-36]. In a

6-week treatment-monitoring study, weekly speech samples were obtained from 35 patients with depression using an interactive voice response system [31]. Patients with an improvement in depressive symptoms showed a significant increase in *pitch* and *pitch variability*, an increase in *speech rate*, and shorter *speech pauses* while speaking at their final assessment compared with their baseline assessment. Importantly, patients whose depressive symptoms did not improve did not show these changes.

The data set of Mundt et al [31] was reanalyzed multiple times [32,34,35]. Quatieri and Malyska [34] integrated additional speech features and identified that lower *pitch variability*, *shimmer*, and *jitter* as well as an increased *harmonics-to-noise ratio* were correlated with lower depression severity. This is in contrast to the study by Mundt et al [31], who found that increased *pitch variability* was associated with lower depression severity, which Quatieri and Malyska [34] attributed to differences in the set of voice samples analyzed (read speech in the study by Mundt et al [31] and conversational speech in the study by Quatieri and Malyska [34] from the same patients).

Trevino et al [32] discussed *speech rate* extraction methods based on the data set of Mundt et al [31] and replicated results regarding *speech rate* in automatically derived phonologically based features. *Speech rate* was negatively correlated with depression scores and the psychomotor retardation item in particular. Moreover, the authors replicated the finding that *speech pauses* were positively correlated with depression severity.

Furthermore, Horwitz et al [35] reanalyzed a subset of data from the study by Mundt et al [31] with a focus on disentangling how speech features relate to the total assessment score and individual symptom items. The authors found a positive correlation between *pitch variability* and depression scores and a slower *speech rate* with increasing depression severity. Notably, they analyzed a different speech task and a different depression assessment in comparison with Mundt et al [31].

Mundt et al [33] replicated their results from Mundt et al [31] in a larger study. Here, 105 patients were observed in a 4-week randomized placebo-controlled study. Again, analyses entailed a comparison of the final and baseline assessments. For patients benefiting from the treatment, *total pause time* was lower, *pitch* was higher (*pitch variability* was not assessed), and *speech rate* was higher. For patients who did not benefit from the treatment, only *speech rate* increased; however, it increased significantly less than in patients benefiting from the treatment.

Yang et al [36] analyzed clinical interviews recorded in 7-week intervals. In contrast to Mundt et al [31], they did not find a change in *pitch variability* with a change in depression severity in the patients but rather in the interviewers. The authors also found shorter *switching pauses* between patient and interviewer (ie, both interlocutors) with lower depression severity.

Although not completely consistent, these findings support the assumption that voice features change within individuals when depression severity changes. However, although data were collected at multiple time points during the study (eg, weekly), except in the study by Yang et al [36], the analysis was limited

to a comparison between the baseline and final assessments. However, given that the goal is to detect and ultimately prevent new depressive episodes and deterioration, it is essential to understand within-person trajectories of voice features and how they are associated with momentary states with increased granularity. In this study, we used a naturalistic data set where a rapidly acting antidepressant treatment (ie, sleep deprivation therapy [SDT] [37]) was applied to patients experiencing a depressive episode. The antidepressant effect vanishes in most of the cases after recovery sleep. Baseline, the treatment effect of SDT, and relapse can be measured in a matter of 4 days, making it a preferable setting to study within-person fluctuations.

Aims and Hypotheses

To investigate the within-person relationship between fluctuations in depression severity and fluctuations in speech features, we used a longitudinal data set with an average of 32 (SD 19.83) assessments per patient. All patients had experienced an acute depressive episode and undergone SDT [37], a chronotherapeutic intervention that can rapidly improve depression symptomatology. The main advantage of this therapeutic is that we maximize the variance of affective states within the data set and ensure sufficient within-person fluctuations over time. As the amount of speech features is immense, resulting in alpha error inflation, we focused on 3 speech features with high face validity that have shown first hints in past research [31-36]. Specifically, we hypothesized that (1) changes in *pitch variability*, (2) shorter *speech pauses*, and (3) higher *speech rate* are associated with lower depression severity. In addition, we assessed the associations of these features with additional momentary affective states (ie, positive affect, negative affect, valence, energetic arousal, and calmness). We hypothesized that the associations of speech features with negative affect are similar to those for depression severity and that the associations of speech features with the other momentary affective states listed follow the opposite pattern.

Methods

Sample

We used a data set that was collected as part of a pilot study (Sleep Deprivation and Gene Expression [SLEDGE II]; German Clinical Trials Register: DRKS00022025) gathering digital phenotypes and multiomics data in a clinical sample undergoing SDT at the Central Institute of Mental Health in Mannheim, Germany. A total of 30 inpatients experiencing acute depressive episodes were enrolled in the study. The patients were diagnosed according to the *International Classification of Diseases, Tenth Revision* (ICD-10), codes by the senior clinician at admittance to the hospital. All patients received treatment as usual, which also included SDT (for a list of medications, refer to Textbox S1 in [Multimedia Appendix 1](#)). Exclusion criteria were comorbid substance use disorders or personality disorders. From this sample of 30 patients, the complete data sets of 8 (27%) patients were excluded from the final analyses (n=4, 50% did not record any videos; n=1, 13% did not say anything during the videos [23 videos]; n=2, 25% had no sound recorded in the videos owing to technical issues [30 recordings]; and n=1, 13%

recorded only 2 videos); thus, the final sample consisted of 22 (73%) patients (n=12, 55% male) aged between 18 and 63 (mean 33.5, SD 12.4; median 29, IQR 23.25-42.75) years.

Ethical Considerations

The study was approved by the Ethics Committee II of the Medical Faculty Mannheim, University of Heidelberg (2013-563N-MA). All patients received detailed information about the aims and procedures of the study and provided informed consent. Patients could withdraw from the study at any time and did not receive any compensation for participation. Data was deidentified to ensure privacy.

Study Procedure

Patients were given a study smartphone (Nokia 4.2 or Samsung Galaxy J7) at the beginning of the study (day 0), instructed on how to use it, and (if necessary) performed test runs supervised by the study personnel. A telephone number for technical support and an information sheet regarding the ambulatory assessment procedure were handed out. Data were collected using movisensXS software (movisens GmbH) [38]. Patients underwent SDT as part of their depression treatment, which involves staying awake for approximately 36 hours. Treatment effect and relapse can be measured in a matter of 4 days [37], thus ensuring a maximum of within-person variance in the data set. After at least 1 day of baseline assessment (day 0), SDT was conducted on day 1. Patients stayed awake from 6 AM on day 1 to 6 PM on day 2. Recovery sleep was allowed from 6 PM on day 2 until 1 AM on day 3. Data were collected before, during, and after SDT for up to 26 days. In the first week of the study, smartphones sent prompts 3 times per day (morning, afternoon, and evening); in addition, self-initiated assessments were possible to report specific events or to catch up with missed assessments. To reduce the burden on patients, the sampling schema was altered to 2 prompts per day (morning and evening). With each prompt, patients were requested to fill out items concerning their affective state and to record a selfie video reporting how they felt currently. Patients returned the smartphone at the end of the study. The study personnel uploaded the data from the smartphones to the movisensXS platform [38] and then downloaded the data for analysis.

Ambulatory Assessment: eDiary Ratings and Selfie Videos

The data set contains 3 sets of momentary assessments in the form of eDiary ratings at each prompt (Textboxes S2-S4 in [Multimedia Appendix 1](#)): (1) the short version of the Allgemeine Depressionsskala (ADS-K) [39] adapted to momentary assessment with 14 items on depressive mood rated on a scale ranging from 0=*rarely* to 3=*mostly* (we left out the item regarding sleep from the original questionnaire because its inclusion was not reasonable in the momentary assessment design); (2) a total of 15 positive (cheerful, content, energetic, enthusiastic, relaxed, and happy) and negative (lonely, sad, insecure, anxious, depressed, low-spirited, guilty, distrustful, and irritable) affect items [40] rated on a 5-point Likert scale ranging from 1=*not at all* to 5=*very much*; and (3) a 6-item short version of the Multidimensional Mood Questionnaire (MDMQ) [41] capturing time-varying momentary fluctuations in daily

life on the affect dimensions of valence (*unwell* to *well* and *discontent* to *content*), energetic arousal (*without energy* to *full of energy* and *tired* to *awake*), and calmness (*tense* to *relaxed* and *agitated* to *calm*). The items were presented on visual analog scales with 2 poles and a slider from 0 to 100. For each of the constructs, we computed mean values per scale, resulting in 6 outcome variables (depressive symptoms, positive affect, negative affect, valence, energetic arousal, and calmness). For the ADS-K, we also report sum scores as described in the tool's manual; however, to increase comparability among outcomes, we used the mean value for analyses. If necessary, we recoded items such that higher values indicated a (1) higher intensity of depressive symptoms, (2) higher positive affect, (3) higher negative affect, (4) higher positive valence, (5) higher energetic arousal, and (6) higher calmness.

In addition to the aforementioned eDiary ratings, patients were requested to record selfie videos with the following instructions: "Please keep the camera stable during the recording and record your whole face. Please describe in 10-20 seconds how you currently feel."

Clinical Assessments

The Montgomery-Åsberg Depression Rating Scale (MADRS) [42] was completed in the morning at 4 time points (baseline, morning before sleep deprivation, 1 week after sleep deprivation, and 2 weeks after sleep deprivation) and once at midday (the day after sleep deprivation night). The MADRS is a 10-item expert assessment of depressive symptom severity over the past week, with items rated on a 7-point scale ranging from 0 to 6; higher scores indicate higher severity.

Data Preprocessing

The data set contained 899 selfie videos in mp4 format. The full set of videos of 4 (13%) of the 30 patients had to be excluded owing to the reasons mentioned previously (55/899, 6.1%) and additional 2 videos had to be excluded because of technical damage (2/899, 0.02%). As our research questions focused on audio data (not visual data), we extracted the audio tracks of the remaining 842 (93.66%) from the original 899 selfie videos using the *ffmpeg* package in Python and archived them as wav files (sampling rate: 48 kHz; mono=1 channel). We excluded test runs (14/842, 1.7%), accidental short recordings with no content (29/842, 3.4%), recordings during which the microphone was masked by the patient (27/842, 3.2%), and assessments in which 1 of the 2 corresponding assessments (speech or affective state) was missing (18/842, 2.1%). In addition, if 2 consecutive assessments were <15 minutes apart from each other, only the first assessment was kept unless its audio quality was insufficient or only the second assessment included assessments of affective states; in such cases, the second assessment was kept (21/842, 2.5%). We also excluded recordings with background noise that restricted speech intelligibility (9/842, 1.1%) or that included the speech of third parties (8/842, 1%). We filtered the remaining recordings (716/842, 85%) using DeepFilterNet2 [43] to remove background noise.

Acoustic Features

For our main analyses, we focused on the acoustic features *pitch variability*, *speech pauses*, and *speech rate* (Table 1). We restricted the number of features to limit α error inflation and selected specifically these 3 features because they revealed sufficient empirical support to warrant an explicit hypothesis. We extracted acoustic features of the final recordings ($n=716$) using the functionals (v02) of the extended Geneva Minimalistic Acoustic Parameter Set (eGeMAPS) [44] of the open-source toolkit openSMILE implemented in Python [45,46]. eGeMAPS is a minimalistic set of acoustic features recommended for clinical speech analysis; it helps to guarantee comparability

between studies, given the proliferation of speech features. Features related to frequency, energy, spectrum, and tempo are included in the set. *Pitch variability* is represented by the SD of the logarithmic fundamental frequency (F0) on a semitone frequency scale starting at 27.5 Hz and measured in hertz. F0 is the lowest frequency of the speech signal and is perceived as *pitch*. *Speech pauses* are approximated as the mean length of unvoiced regions (F0=0) measured in seconds. With respect to *speech rate*, a transcription of the recordings is necessary, which we obtained using an automatic speech recognition system according to published procedures [47]. We corrected the transcripts manually. To determine *speech rate*, we calculated the ratio of words divided by the duration of the voice sample.

Table 1. Overview of extracted speech features.

Speech feature	Technical feature	Explanation
Pitch variability	F0semitoneFrom27.5Hz_sma3nz_stddevNorm	SD of the F0 perceived as the extent to which a person's <i>pitch</i> changes (in Hz)
Speech pauses	MeanUnvoicedSegmentLength	Mean of the length of unvoiced regions approximating silent parts of the speech sample (in seconds)
Speech rate	Words per second	Ratio of words counted on the basis of the automatically transcribed and manually corrected text divided by the duration of the speech sample

Beside our main analyses based on *pitch variability*, *speech pauses*, and *speech rate*, we decided to integrate further eGeMAPS features in an exploratory analysis. These features have been recommended in the context of affective states in particular because they contain additional cepstral and dynamic features [44]. We included the following features in the exploratory analyses: for voiced and unvoiced regions together, the mean and SD of the mel-frequency cepstral coefficients (MFCCs) 1 to 4 and spectral flux difference of the spectra of 2 consecutive frames; for voiced regions, the formant 2 to 3 bandwidths along with spectral flux and MFCCs 1 to 4; and for unvoiced regions, the mean and SD of the spectral flux [44].

Statistical Analysis

In addition to the *mean*, *SD*, and *range*, we present *min* and *max* as the mean of all patients' minimum and maximum scores, respectively, of each parameter throughout the whole study. Moreover, following the recommendations by Snijders and Bosker [48], we computed Pearson correlation analyses with person-mean-centered variables to evaluate the relationship between affective scores and speech features. To generate person-mean-centered variables, we subtracted the individual's mean from their score, which represents the variation around the individual's mean.

To evaluate psychometric properties, we calculated McDonald ω as the reliability coefficient using the *multilevelTools* package in R. For the MDMQ subscales, we used the *misty* package in R to calculate the Spearman-Brown corrected correlation coefficients because the subscales consist of only 2 items [49]. For the MADRS score at the time of inclusion, we calculated Cronbach α using the *psych* package in R.

To analyze the within-person association of speech features and subjectively evaluated affective states, we used multilevel modeling [48] using the *nlme* package in R. Multilevel modeling offers two specific advantages for the given data: (1) separation

of within-person effects from between-person effects and (2) allowing and considering different numbers of assessments per patient. Before the analyses, we centered time-variant level-1 predictors (*pitch variability*, *speech pauses*, and *speech rate*) at the person level and included the predictors *time* and *time*² in minutes (each centered at 2 PM) as covariates. To facilitate the comparison of the magnitude of effects among different predictors, we report standardized beta coefficients (standardized β) according to the recommendations by Hox and van de Schoot [50] following the equation: standardized $\beta = \beta \times (SD_{\text{predictor}} / SD_{\text{outcome}})$. We further calculated Hox R^2 values according to the recommendation by Hox and Maas [51] following the equation: $R^2_{\text{Hox}} = (\sigma^2_{\text{null}} - \sigma^2_{\text{model}}) / \sigma^2_{\text{null}}$. We set the α level at 5% and applied Bonferroni corrections for exploratory analyses ($\alpha_{\text{adj}}=.002$). We performed all analyses in R (version 4.2.1, 2022-06-23).

Our analyses can be split into 4 parts: the calculation of intraclass correlation coefficients (ICCs); separate models with all speech features as predictors and all affective scores as outcomes; combined models with all speech features as simultaneous predictors; and exploratory analyses, including additional speech features. Specifically, we first descriptively investigated whether our study procedure resulted in sufficient within-person variance. For this purpose, we calculated ICCs, including all momentary affective ratings and speech recordings, regardless of whether they were assessed before, during, or after SDT. In general, the ICC indicates the amount of between-person variance in unconditional (null) models. The 2-level models analyzed contained repeated measures (level 1) that were nested within patients (level 2). The second step contained our main analysis: we calculated separate models for each speech feature (*pitch variability* [model set 1], *speech pauses* [model set 2], and *speech rate* [model set 3]) and each affective state (depression severity [ADS-K], positive affect, negative affect, valence, energetic arousal, and calmness),

resulting in 18 models. In the third step, to evaluate the relative significance of *pitch variability*, *speech pauses*, and *speech rate*, we constructed combined models for each of the affective scores, including all 3 features simultaneously (6 models). In the fourth step, exploratory analyses were conducted with the inclusion of 24 additional speech features from eGeMAPS (Textbox S5 in [Multimedia Appendix 1](#)). These features were used as predictors for each of the affective scores separately.

Results

Descriptive Statistics

We included 716 speech-state pairs (mean 32, SD 19.83 per patient) in the final analysis. The mean MADRS score at the time of inclusion assessment was 30.1 (SD 5.8). This corresponds to 18 (82%) patients with moderate depression and 4 patients (18%) with severe depression out of 22 patients at study inclusion.

Regarding depressive symptoms (ADS-K; scale 0-3), patients had a mean score of 1.2 (SD 0.6; min 0.7, max 2.0) and a mean sum score of 16.9 (SD 8.1; min 9.6, max 26.1). At inclusion, the mean ADS-K score was 1.4 (SD 0.6; range 0.4-2.8), and the mean sum score was 20.0 (SD 8.4; range 6-39). For positive and negative affect (scale 1-5), the mean scores were 2.1 (SD 0.8; min 1.3, max 3.1) and 2.3 (SD 1.0; min 1.4, max 3.9), respectively; on the MDMQ (scale 1-100) valence subscale, the mean score was 44.9 (SD 21.5; min 9.4, max 67.5); on the energetic arousal subscale, the mean score was 41.7 (SD 21.0; min 16.4, max 62.7); and on the calmness subscale, the mean score was 43.8 (SD 22.8; min 6.9, max 70.7). The ICCs were 0.47 for the ADS-K, 0.45 for positive affect, 0.59 for negative affect, 0.27 for energetic arousal, 0.25 for valence and 0.40 for calmness, that is, the following amount of variance in the momentary assessments can be attributed to within-person fluctuations: 53% for the ADS-K, 55% for positive affect, 41% for negative affect, 73% for energetic arousal, 75% for valence, and 60% for calmness.

Regarding speech features, the mean *pitch variability* was 0.32 Hz (SD 0.09; min 0.14, max 0.44), the mean *speech pause* length was 0.26 seconds (SD 0.12; min 0.17, max 0.47), and the mean *speech rate* was 1.77 words per second (SD 0.57; min 1.16, max 2.75). The ICCs were 0.66 for *pitch variability*, 0.36 for *speech pauses*, and 0.57 for *speech rate*. This corresponds to the following amount of variance in the speech feature assessments that can be attributed to within-person fluctuations: 34% for *pitch variability*, 64% for *speech pauses*, and 43% for *speech rate*.

Correlational analyses (Figure S1 in [Multimedia Appendix 1](#)) included between 698 and 716 observations depending upon the specific pairing. We found correlations among and between affective scores and speech features, except for *pitch variability* and *speech rate*, neither of which correlated with negative affect and calmness; in addition, there was no correlation between *pitch variability* and *speech rate*. Specifically, ADS-K scores correlated negatively with positive affect, all MDMQ subscales, and *speech rate* and correlated positively with negative affect, *pitch variability*, and *speech pauses*. Negative affect showed the same pattern, except for the pairings with *pitch variability* and *speech rate*, for which no correlations were found. Regarding positive affect, we found the opposite correlation pattern, that is, positive correlations with all MDMQ subscales and *speech rate* and negative correlations with *pitch variability* and *speech pauses*. The MDMQ subscales showed the same relationships as positive affect, except for the pairing between calmness and *pitch variability* and *speech rate*, for which no correlations were found. Within speech features, we found a negative correlation between *pitch variability* and *speech pauses*, no correlation between *pitch variability* and *speech rate*, and a negative correlation between *speech pauses* and *speech rate*. Overall, correlations among affective scores were strong ($r > 0.5$). Correlations among speech features as well as between affective scores and speech features were weak ($r < 0.2$), except for a strong negative correlation between *speech pauses* and *speech rate*.

The psychometric properties for momentary affective ratings were good to excellent. Specifically, McDonald ω values [52] were 0.87 (within-person) and 0.90 (between-person) for depressive symptoms (ADS-K), 0.87 (within-person) and 0.95 (between-person) for positive affect, and 0.87 (within-person) and 0.96 (between-person) for negative affect. The Spearman-Brown coefficients were 0.83 (within-person) and 0.94 (between-person) for valence, 0.74 (within-person) and 0.89 (between-person) for energetic arousal, and 0.74 (within-person) and 0.89 (between-person) for calmness. Cronbach α for the MADRS score at the time of inclusion was acceptable (.67).

Association Between Speech Features and Momentary Affective Scores

Overview

In [Tables 2](#) and [3](#), we present the fixed effects of *pitch variability*, *speech pauses*, and *speech rate* separately for each affective state. Details, including the effects of time and time², are presented in [Table S1](#) in [Multimedia Appendix 1](#).

ADS-K Scores

In the column entitled *ADS-K* (Table 2), we report the results of all models with ADS-K scores as the outcome. *Pitch variability* (standardized $\beta=.14$; $P=.007$), *speech pauses* (standardized $\beta=.10$; $P=.005$), and *speech rate* (standardized $\beta=-.10$; $P=.02$) were significantly associated with the ADS-K score, indicating that higher *pitch variability*, longer *speech pauses*, and lower *speech rate* are associated with more severe depressive symptomatology.

Positive and Negative Affect

In the columns entitled *Positive affect* and *Negative affect* (Table 2), we show results for positive affect and negative affect, respectively, as outcomes. *Pitch variability* (standardized $\beta=-.18$; $P<.001$), *speech pauses* (standardized $\beta=-.17$; $P<.001$), and *speech rate* (standardized $\beta=.18$; $P<.001$) were significantly associated with positive affect, indicating that lower *pitch variability*, shorter *speech pauses*, and higher *speech rate* are associated with higher positive affect. The associations between negative affect and speech features were in the opposite direction

of the associations between positive affect and the speech features just presented: *speech pauses* (standardized $\beta=.09$; $P=.002$) and *speech rate* (standardized $\beta=-.08$; $P=.04$) were significantly associated with negative affect, indicating that longer *speech pauses* and lower *speech rate* are associated with higher negative affect. We further found a trend with respect to the association between *pitch variability* and negative affect, but this result was not statistically significant (standardized $\beta=.08$; $P=.05$). In addition, we found trends with respect to the associations between negative affect and time and negative affect and time², specifically in the models that included *pitch variability* (time: standardized $\beta=.04$; $P=.08$), *speech pauses* (time: standardized $\beta=.04$; $P=.08$; time²: standardized $\beta<.01$; $P=.06$), and *speech rate* (time: standardized $\beta=.04$; $P=.09$), but these results were not statistically significant.

MDMQ Results

In the columns entitled *Valence*, *Energetic arousal*, and *Calmness* (Table 3), we present the results for the MDMQ. *Pitch variability* (standardized $\beta=-.16$; $P=.008$), *speech pauses* (standardized $\beta=-.19$; $P<.001$), and *speech rate* (standardized $\beta=.17$; $P=.001$) were significantly associated with valence, indicating that lower *pitch variability*, shorter *speech pauses*, and higher *speech rate* are associated with higher (ie, positive) valence. In the model that included valence and *speech pauses*, we found a significant association between time² and valence (standardized $\beta<.001$; $P=.03$). In addition, we found trends with respect to the associations between valence and time², specifically in the models that included *pitch variability* (time: standardized $\beta<.01$; $P=.098$) and *speech rate* (time: standardized $\beta<.01$; $P=.07$), but these results were not statistically significant. Moreover, *pitch variability* (standardized $\beta=-.15$; $P<.001$), *speech pauses* (standardized $\beta=-.08$; $P=.049$), and *speech rate* (standardized $\beta=.11$; $P=.03$) were significantly associated with energetic arousal, indicating that lower *pitch variability*, shorter *speech pauses*, and higher *speech rate* are associated with higher energetic arousal. In all model combinations of energetic arousal and each speech feature, we found significant associations between time and energetic arousal (standardized $\beta=-.11$;

$P<.001$) and time² and energetic arousal (standardized $\beta<.01$; $P<.001$). Furthermore, *speech pauses* (standardized $\beta=-.12$; $P<.001$) were significantly associated with calmness, indicating that shorter *speech pauses* are associated with greater calmness. In all model combinations of calmness and each speech feature, we found significant associations between time² and calmness (standardized $\beta<.01$; $P=.013$ for *pitch variability*, $P=.003$ for *speech pauses*; $P=.009$ for *speech rate*). In addition, we found a trend with respect to the association between *speech rate* and calmness (standardized $\beta=.09$; $P=.07$), but this result was not statistically significant.

Combined Models

In Tables 4 and 5, we display the results for the combined models that included all 3 speech features. In the model of ADS-K scores, associations with *pitch variability* (standardized $\beta=.17$; $P<.001$) and *speech pauses* (standardized $\beta=.12$; $P=.01$) remained statistically significant. Regarding positive affect, associations with *pitch variability* (standardized $\beta=-.23$; $P<.001$) and *speech pauses* (standardized $\beta=-.19$; $P<.001$) remained statistically significant. We further found a trend regarding the association between positive affect and time (standardized $\beta=-.05$; $P=.09$), but this result was not statistically significant. Regarding negative affect, associations with *pitch variability* (standardized $\beta=.12$; $P=.008$), *speech pauses* (standardized $\beta=.12$; $P=.005$), time (standardized $\beta=.05$; $P=.03$), and time² (standardized $\beta<.01$; $P=.03$) remained statistically significant. In the model of valence, associations with *pitch variability* (standardized $\beta=-.22$; $P<.001$), *speech pauses* (standardized $\beta=.22$; $P<.001$), and time² (standardized $\beta<.01$; $P=.01$) remained statistically significant. Regarding energetic arousal, associations with *pitch variability* (standardized $\beta=-.17$; $P=.003$), time (standardized $\beta=.12$; $P<.001$), and time² (standardized $\beta<.01$; $P<.001$) remained statistically significant. Regarding calmness, associations with *speech pauses* (standardized $\beta=-.17$; $P=.002$) and time² (standardized $\beta<.01$; $P=.002$) remained statistically significant. We further found a trend for the association between calmness and *pitch variability* (standardized $\beta=.09$; $P=.097$), but this result was not statistically significant.

Exploratory Analysis

Analyzing additional speech features, we found significant associations of the *equivalent sound level*, the mean of *spectral flux*, and the mean of *spectral flux of voiced regions only*, individually, with all affective scores (Table S2 in [Multimedia Appendix 1](#)). With respect to *equivalent sound level*, this indicates that louder voice samples were linked to improved affective states (ADS-K: standardized β =-.30; positive affect: standardized β =.34; negative affect: standardized β =-.21; valence: standardized β =.29; energetic arousal: standardized β =.26; and calmness: standardized β =.19); with respect to the mean of *spectral flux*, this indicates that a faster change in the spectrum was linked to better affective states (ADS-K: standardized β =-.22, positive affect: standardized β =.28, negative affect: standardized β =-.15, valence: standardized β =.21, energetic arousal: standardized β =.17, and calmness: standardized β =.27); and with respect to the mean of *spectral flux of voiced regions only*, this indicates that a faster change in the spectrum in voiced regions was linked to better affective states (ADS-K: standardized β =-.23, positive affect: standardized β =.28, negative affect: standardized β =-.15, valence: standardized β =.20, energetic arousal: standardized β =.20, and calmness: standardized β =.16). Regarding the additional speech features, the following significant associations were found: the mean of *spectral flux of unvoiced regions only* was associated with positive affect, indicating that a faster change in the spectrum in unvoiced regions was linked to improved positive affect (standardized β =.13); and the mean of the *MFCC 2 of voiced regions only* was significantly associated with energetic arousal, indicating that a higher mean was linked to lower energetic arousal (standardized β =-.15). Furthermore, we revealed a significant association between the SD of the *MFCC 4 of voiced regions only* ADS-K scores (standardized β =.13) as well as positive affect (standardized β =-.10) and negative affect (standardized β =.09). Specifically, smaller SDs were linked to higher positive affect, reduced negative affect, and lower ADS-K scores.

Discussion

Principal Findings

This is the first study to investigate whether speech features are associated with depression severity and momentary affective states in a longitudinal data set of patients with a depressive episode undergoing SDT. Our findings showed that lower *pitch variability*, higher *speech rate*, and shorter *speech pauses* were associated with better momentary states (ie, lower depression severity; higher positive affect and lower negative affect; and higher positive valence, energetic arousal, and calmness), supporting prior clinical observations with innovative methods applied to an intensive longitudinal data set.

Lower depression severity was accompanied by shorter *speech pauses*. This is in line with past research findings reporting that shorter *speech pauses* were associated with lower depression severity [31-33,36]. Our findings extend prior results because we also found an association between *speech pauses* and affective states more broadly, not limited to depressed mood. Regarding *speech rate*, we revealed associations with depression severity and all other affective state scales except for calmness. In particular, we found that higher *speech rate* was associated with lower depression symptomatology and lower negative affect, higher positive affect, higher positive valence, and higher energetic arousal. This is in line with prior research [31-33,35], in which a higher *speech rate* was found for patients who benefited from treatment.

Regarding *pitch variability*, we found support for our hypothesis that *pitch variability* changes with depression severity; more precisely, lower *pitch variability* was associated with lower depression symptomatology. This is in line with the studies by Quatieri and Malyska [34] and Horwitz et al [35], where a positive correlation between *pitch variability* and depression severity was found. However, the results reported in the studies by Mundt et al [31] and Yang et al [36] contrasted with ours and those found in the studies by Quatieri and Malyska [34] and Horwitz et al [35], that is, that higher *pitch variability* was associated with lower depression severity. A possible explanation for contradictory results in major depression are

the heterogeneity of (1) the depression phenotype per se because diagnosis criteria include >400 possible symptom combinations [53,54]; and (2) the questionnaires, assessment approaches, statistical analyses, and speech feature extraction tools used in these studies. The within-person research design approach underlying our data set addressed the heterogeneity of the depression phenotype at least partially. Furthermore, we analyzed free speech collected naturally in a selfie task, whereas in the study by Mundt et al [31], read speech was used in the analyses. In line with what is suggested in the study by Quatieri and Malyska [34], this could also be a reason for the contradictory results. However, because assessing within-person fluctuations in daily life increases ecological validity, we regard our results as an important contribution.

Observing the full picture of associations, we note that the results for all 3 speech features are similar and do not provide evidence of specific associations (eg, association of 1 specific speech feature with 1 specific momentary affective state), showing no distinct patterns of momentary states for each speech feature. This is reasonable because the constructs overlap in content (eg, patients experiencing depression experience higher negative affect and lower positive affect).

In terms of the combined models evaluating the relative importance of the features, we found that in the 4 models (ADS-K, valence, positive affect, and negative affect) both *pitch variability* and *speech pauses* remained significant, whereas *speech rate* did not. *Pitch variability* remained the only significant parameter in the model of energetic arousal, and *speech pauses* remained the only significant parameter in the model of calmness. This suggests that *pitch variability* and *speech pauses* are speech features rather independent of each other, whereas the high correlation between *speech pauses* and *speech rate* might account for the fact that only 1 of these features (in this case, *speech pauses*) remained a significant predictor.

Limitations

First, this study examined a limited set of 3 speech features. Instead of applying brute force methods involving thousands of technical speech features, we selected speech features based on previous work and with high face validity, restricting the scope of our analysis. Although we did expand our scope of features in the exploratory analysis, it is very likely that other configurations and features (eg, the *ComParE feature set* containing 6373 features [55]) might also be predictive of affective states. Future work is needed to compare theory-driven approaches with brute force data-driven machine learning methods to find the best possible combination of speech features also considering aspects of computational power. However, selecting the features on a theoretical basis and restricting their pure number limits alpha error inflation and should increase replicability.

Second, although the sample size of our study was limited, this was a true within-person design with many data points per

patient. In addition, we regard this study as a pilot study providing important indications regarding feasibility in a clinical context. As some patients dropped out of the study, and some recordings had to be excluded, in future studies, data collection needs to be integrated better into clinical routines. Moreover, the instructions for patients may need to be revised to reduce the likelihood of missing data and recording errors. However, the data set at hand is still unique in the relatively high number of assessments per patient and the applied SDT, which yielded meaningful variation in the depression severity within a short time period. From a theoretical perspective, it is crucial to emphasize that to uncover existing relations among variables, meaningful variance in both parameters is needed.

Third and last, selfie videos were recorded in a clinical environment, which may limit generalizability to other contexts. In future studies, ambulant patients could be integrated and other environments explored to evaluate the replicability of the results. However, our approach, which involved sampling free speech, offers higher ecological validity to reading standardized text paragraphs because it provides a closer representation of people's everyday lives. The development of passive sensing will be helpful in this context (ie, the random assessment of audio bits in an ecological environment). To date, automated passive voice recordings in nonprotected environments have been restricted in 2-party consent states, such as Germany. However, in single-party consent states, a few speech-related applications can be used *in the wild* (eg, the Electronically Activated Recorder [56]). Although the development of technical devices is ongoing, future studies will have to consider ethical issues related to voice recording in natural settings (eg, ensuring that no third parties who did not give informed consent are recorded).

Conclusions

Our study provides evidence that fluctuations in the speech features *pitch variability*, *speech pauses*, and *speech rate* are associated with fluctuations in depression severity and other momentary affect states. Notably, the data were collected from clinically diagnosed patients (no subclinical sample or staged emotions) experiencing an acute depressive episode. A particularly important advantage is that our longitudinal ambulatory assessment data set ensured a maximum of within-person dynamics of depressive parameters within a short time period by applying a sleep deprivation intervention design. This is of great importance because future technology will try to predict upcoming depressive episodes on an individual level and will need information on within-person trajectories. For the development of such tailored precision medicine tools, *pitch variability*, *speech pauses*, and *speech rate* present promising features. Our research is a step forward on the path to developing an automated depression monitoring system, facilitating individually tailored treatments and increased patient empowerment.

Authors' Contributions

MR, JCF, JF, SHW, LS, MG, YY, and FS planned the investigation and developed the sampling scheme. MG and LS were responsible for data collection. L-MW preprocessed the data, carried out statistical analysis, and interpreted the results. UWE-P and MFL contributed to the analysis and interpretation of data. TS and AA contributed to acoustic analysis. L-MW drafted the manuscript with contributions from UWE-P and LS. All authors revised and edited the manuscript critically and had final approval of the version to be published.

Conflicts of Interest

UWE-P reports consultancy for Boehringer Ingelheim and speaker honorarium from Angelini Pharma, both of which had no influence over the content of this paper. All other authors declare no other conflicts of interest.

Abstract

Background: The reasons for mental health consultations are becoming increasingly relevant in primary care. The Catalan health care system is undergoing a process of digital transformation, where eHealth is becoming increasingly relevant in routine clinical practice.

Objective: This study aimed to analyze the approach to depressive episodes and the role of eHealth in the Catalan health care system from 2017 to 2022.

Methods: A retrospective observational study was conducted on diagnostic codes related to depressive episodes and mood disorders between 2017 and 2022 using data from the Catalan Institute of Health. The sociodemographic evolution and prevalence of depression and mood disorders in Catalonia were analyzed between 2017 and 2022. Sociodemographic variables were analyzed using absolute frequency and percentage. The prevalence of depressive episodes was calculated, highlighting the year-to-year changes. The use of eHealth for related consultations was assessed by comparing the percentages of eHealth and face-to-face consultations. A comparison of sociodemographic variables based on attendance type was conducted. Additionally, a logistic regression model was used to explore factors influencing face-to-face attendance. The analysis used R software (version 4.2.1), with all differences examined using 95% CIs.

Results: From 2017 to 2022, there was an 86.6% increase in the prevalence of depression and mood disorders, with women consistently more affected (20,950/31,197, 67.2% in 2017 and 22,078/33,169, 66.6% in 2022). In 2022, a significant rise in depression diagnoses was observed in rural areas (difference 0.71%, 95% CI 0.04%-1.43%), contrasting with a significant decrease in urban settings (difference -0.7%, 95% CI -1.35% to -0.05%). There was a significant increase in antidepressant use in 2022 compared to 2017 (difference 2.4%, 95% CI 1.87%-3.06%) and the proportion of eHealth visits rose from 4.34% (1240/28,561) in 2017 to 26.3% (8501/32,267) in 2022. Logistic regression analysis indicated that men (odds ratio [OR] 1.06, 95% CI 1.04-1.09) and younger individuals had a higher likelihood of eHealth consultations in 2022. Furthermore, individuals using eHealth consultations were more likely to use antidepressants (OR 1.54, 95% CI 1.50-1.57) and anxiolytics (OR 1.06, 95% CI 1.03-1.09).

Conclusions: The prevalence of depression in Catalonia has significantly increased in the last 6 years, likely influenced by the COVID-19 pandemic. Despite ongoing digital transformation since 2011, eHealth usage remained limited as of 2017. During the

lockdown period, eHealth accounted for nearly half of all health care consultations, representing a quarter of consultations by 2022. In the immediate aftermath of the COVID-19 pandemic, emerging evidence suggests a significant role of eHealth in managing depression-related consultations, along with an apparent likelihood of patients being prescribed antidepressants and anxiolytics. Further research is needed to understand the long-term impact of eHealth on diagnostic practices and medication use.

Introduction

Depression is a mental disorder that is a major health problem due to its high prevalence, direct repercussions on people's quality of life, and strong social impact [1,2]. According to the World Health Organization, it is estimated that 5% of the world's population suffers from depression [3].

Catalonia, an autonomous community of Spain, had a total of 7,747,709 citizens at the beginning of 2022 [4]. The Catalan health care system, characterized by being public, universal, comprehensive, and equitable, provides health coverage to 7.6 million people [5]. At the level of the Catalan territory, in 2015, according to data from the Catalonia health survey, 16.6% of the population older than 15 years suffered from anxiety or depression, which affected more women (20.8%) than men (12.2%) [6]. In 2020, 5 years later and taking into account the outbreak of the SARS-CoV-2 pandemic, an increase in emotional distress and moderate and major depression was observed. Specifically, 27.19% of women and 17% of men suffered from emotional distress, and 12.2% of women and 5.7% of men had moderate or major depression in Catalonia. Therefore, a decrease in the emotional well-being of the Catalan population has been observed [7].

Primary care (PC), one of the gateways to the health care system, is key in the detection, management, and follow-up of illnesses such as depression. High-quality PC is the foundation of a leading health care system and fundamental to optimizing the performance of the health care system, fulfilling the following 5 dimensions of the quintuple aim: (1) enhancing the care experience, (2) improving population health, (3) reducing costs, (4) care team well-being, and (5) advancing health equity [8-10]. PC has, among other characteristics, longitudinality and universal accessibility that make it the only area designed to be used by all people throughout their lives. As early as 1994, Starfield [11] showed how people living in countries with high-quality PC had better health indices, a more equitable distribution of available resources, and a more efficient health care system.

The reasons for mental health consultations are becoming increasingly relevant in PC, especially among the younger population in the wake of the COVID-19 pandemic [12,13]. Since there is no standardized protocol for mental health care in Catalonia, the approach to these issues varies significantly. This variability could be attributed to differences in

professionals' training or their sensitivity toward handling such problems [14]. Based on the report by the Public Health Agency of Catalonia regarding drug consumption with potential misuse, it was found that antidepressants were the most commonly used group of drugs by the population in 2021. Among most antidepressant drugs, the consumption ratio by women is between 2 to 4 times higher than that by men [15].

Over the last decade, information and communication technology is being introduced into the health care systems of different industrialized countries [16]. Following this trend, the Catalan health care system has been immersed in a digital transformation process. Currently, eHealth within PC in Catalonia involves communication both between providers and patients and amongst providers themselves. These interactions occur via different modes, including telephone or video calls and electronic consultations. It is important to emphasize that although the Catalan health care system had already incorporated technology before, the pandemic served as a clear catalyst for the adoption of eHealth in Catalonia. Regarding the typology of eHealth visits, the majority are conducted via remote consultations (referred to as eConsulta in Catalonia) or phone calls, with video calls being relatively infrequent [17].

Since 2011, several cross-cutting projects of significant importance have been developed in Catalonia, incorporating digital health as a key component [18]. The design of the Catalonia shared medical record began with the aim of being able to share patient information among the different health providers, as well as a personal folder (La Meva Salut) to give citizens access to their personal information, such as current medication plan, diagnoses, vaccines administered, clinical reports, test results, and examinations. Also, within this personal folder, in 2015, eConsulta was developed as an asynchronous digital communication tool involving health care professionals and patients, allowing the population to send queries at any time to their PC doctor or nurse and receive a response within a maximum of 48 hours on working days [19,20]. In this sense, eConsulta represents a significant advancement in eHealth within the Catalan public health system. Prior to the pandemic, eConsulta usage had a monthly growth rate of 7%; from March 15 to May 2020, an exponential growth rate was observed [21]. A study focusing on the profile of health care professionals who utilized remote consultations like eConsulta before the pandemic revealed that physicians engaging with eConsulta were typically aged between 45 and 64 years, exceeded the 80th percentile in the Quality of Care Index, had a high level of accessibility to

their patients, participated in educational activities, and operated within a health team framework in urban settings with a high socioeconomic status [22].

In the context of Catalan PC, eHealth has been widely implemented and adopted in routine clinical practice, even more so in the context of COVID-19 [23-25]. However, there are other digital health tools with great potential, such as mobile health or artificial intelligence, that have not yet been introduced into the public health care system in Catalonia.

In order to improve the management of depressive episodes in PC in the Catalan health care system and to obtain higher effectiveness rates close to the potential efficacy of the available treatments, the aim of this study was to analyze the evolution of the prevalence of depression and mood disorders in PC from 2017 to 2022, to examine the sociodemographic profile of the affected population, and to investigate the role played by eHealth in this context and assess its impact on consultations related to depression and mood disorders.

Methods

Study Design

This study was a retrospective observational study of diagnostic codes related to depressive episodes and mood disorders between 2017 to 2022 from the Catalan Institute of Health.

Sample

We analyzed the entire population of Catalonia that visited PC centers of the Catalan Institute of Health who had a face-to-face or eHealth consultations (eConsulta, telephone, or video consultations) associated with the selected diagnoses of depression and mood disorders in the period of January 2017 to December 2022. The Catalan Institute of Health is the main provider of health services in the public system. It manages approximately 80% of the PC teams in Catalonia and provides health care coverage to approximately 5.8 million people [16,21,26,27].

To obtain the study sample, the diagnostic codes were selected according to those typified in the International Statistical Classification of Diseases and Related Health Problems (ICD-10), which is the classification used by PC professionals when recording a diagnosis in the computerized PC clinic [28]. All diagnostic codes related to depression (mild, moderate, and major) and mood disorders (eg, cyclothymia and dysthymia) that are usually detected, managed, or followed up in Catalan PC were selected (Table S1 in [Multimedia Appendix 1](#)). Mood disorders are marked by persistent clinical manifestations. In the case of dysthymia, it necessitates at least 2 years of a consistently low mood, whereas cyclothymia involves oscillations between a depressed mood and euphoria, without fulfilling the criteria for major depression [29]. Therefore, these diagnoses were included because they are not reactive disorders of short duration. By including them, there is a reduced risk of missing cases of mild depressive disorders.

Finally, we excluded all consultations that did not have an associated diagnosis code among those selected. The part of the

population of Catalonia whose public health coverage was not provided by the Catalan Institute of Health was also excluded.

The database was obtained through the Information System for the Development of Research in Primary Care [30].

Variables

To study sociodemographic characteristics, we considered age, sex, drug use, recurrent depressive episode diagnoses, rurality, and the socioeconomic situation recorded through the MedeA index [31]. A variable was created to distinguish between individuals with recurrent depressive episode diagnoses (where depression had been diagnosed previously in their medical history) and those without such recurrent diagnoses. The MedeA is a deprivation index linked to each census tract of the population. This assessment focuses on the barriers to access employment, education, culture, and social development. The aim is to evaluate them at a level that is considered acceptable within the surrounding society or region. The assessment comprises subindicators for employment and education. It is only available for urban areas, which are defined as municipalities with more than 10,000 inhabitants and a population density of more than 150 inhabitants per km². Other areas were considered rural. The MedeA index is ranked in quintiles, from MedeA urban 1 indicating low deprivation to MedeA urban 5 indicating high deprivation [31]. The MedeA index was used to categorize rurality by grouping urban and rural groups.

Statistical Analysis

To observe the evolution of the profile of people diagnosed with depression and mood disorders, sociodemographic variables were described in 2017 and 2022. Categorical variables were described by absolute frequency and percentage. The difference between the years was calculated with percentage points.

To observe the evolution of the prevalence of depressive episodes and mood disorders over the years for the total sample, the prevalent cases for each year were divided with respect to the total population assigned to the Catalan Institute of Health PC centers throughout Catalonia. The percentage change was calculated to determine the year-to-year evolution of these prevalences.

To observe the use of eHealth in consultations related to depression and mood disorders over the years, the percentage of telematic and face-to-face consultations resulting in new diagnoses per year was calculated.

A comparison of the sociodemographic variables as a function of face-to-face attendance was performed. Categorical variables were described by absolute frequency and percentage. The difference was calculated as percentage points.

Lastly, a logistic regression model was applied to observe how the studied variables affected face-to-face attendance. The model incorporated the variables of sex, age, rurality, recurrence, antidepressants, and anxiolytics. The MedeA variable was not introduced into this model since the rurality variable was used.

Analyses were performed with R version 4.2.1 (R Foundation for Statistical Computing). All differences were examined using CIs, and a confidence level of 95% was established.

Ethics Approval

The study protocol was approved by the University Institute for Primary Care Research (IDIAP) Jordi Gol Health Care Ethics Committee (Code 23/013-P).

Results

Description of Sociodemographic Profiles of New Cases From 2017 to 2022

An analysis of the sociodemographic profile of new cases during 2017 (n=31,197) and 2022 (n=33,169) was performed to observe changes in the characteristics of this population group during the study period ([Table 1](#)).

^aStatistically significant difference.

^bGiven the symmetry of the binary variables, the difference and 95% CI have only been expressed for one of the categories.

The results showed that in both 2017 and 2022, the 45-54 years age range had the most diagnoses related to depressive episodes and mood disorders. However, in 2022 there was a significant increase compared to 2017 in diagnoses in the younger age

ranges (0-15 years: difference 0.57%, 95% CI 0.33%-0.81%; 16-24 years: difference 2.67%, 95% CI 2.31%-3.04%; 25-34 years: difference 2.46%, 95% CI 1.98%-2.91%). A significant reduction in diagnoses was also observed in the older age ranges

(65-74 years: difference -1.5% , 95% CI -1.99% to -0.87% ; 75-84 years: difference -2.3% , 95% CI -2.81 to -1.79) and among those older than 85 years (difference -0.94% , 95% CI -1.32% to -0.56%).

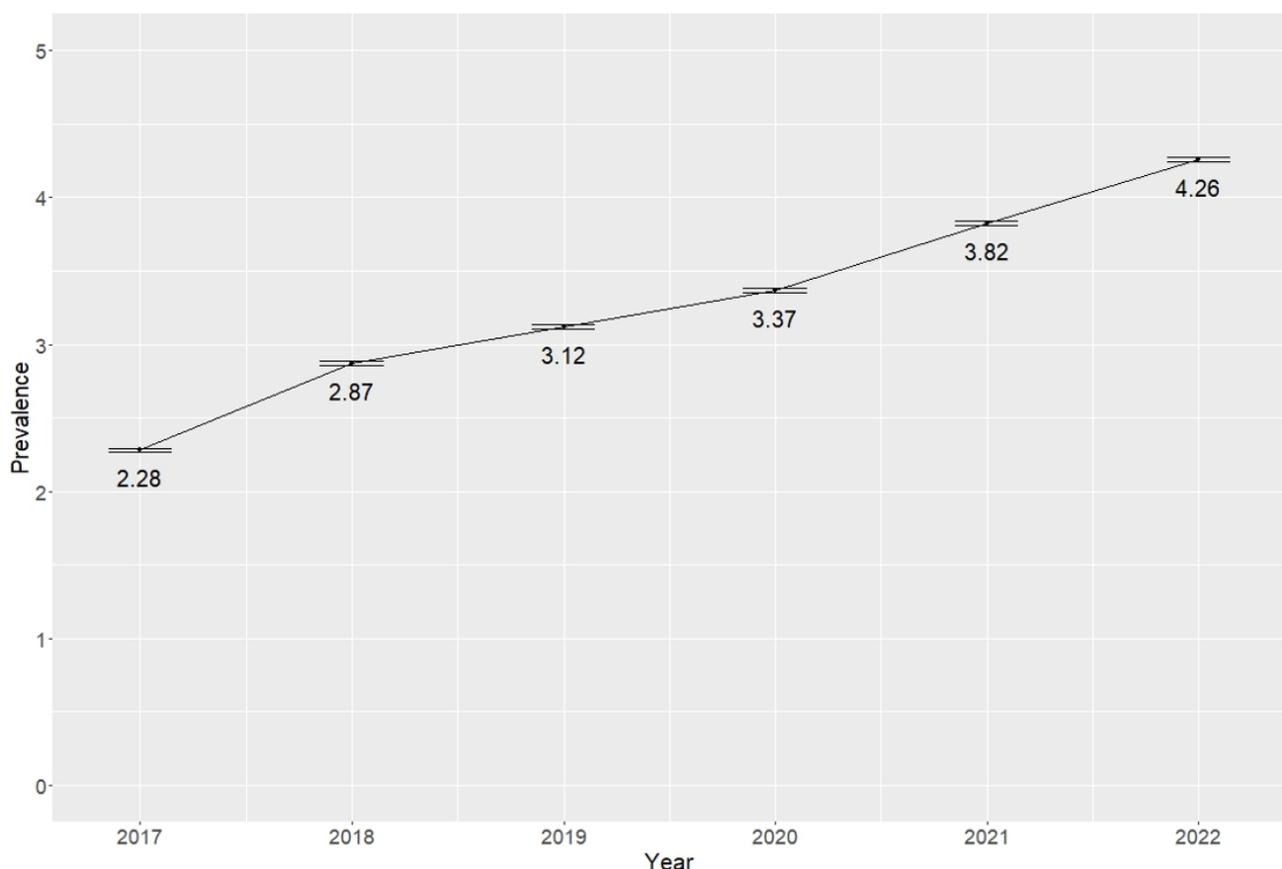

Regarding gender, it was observed that in both 2017 and 2022, women were the most affected gender (20,950/31,172, 67.2% and 22,078/33,135, 66.6%, respectively). Regarding the Medea index, a significant increase in diagnoses was observed in rural settings in 2022 with respect to 2017 (difference 0.71%, 95% CI 0.04%-1.43%), while a significant decrease was observed in urban settings, specifically in the urban population with low deprivation (difference -0.7% , 95% CI -1.35% to -0.05%). Regarding recurrent depressive episodes, there was a pronounced and significant increase in those diagnosed as recurrent compared to those diagnosed with a depressive episode for the first time (difference 3.07%, 95% CI 2.65%-3.49%). Regarding the use of eHealth for managing these illnesses, a notable shift was observed in the pattern of face-to-face attendance for the management of depressive episodes and mood disorders. A significant increase was observed in the use of eHealth as the approach for these diagnostic codes (difference

22%, 95% CI 21.46%-22.54%). Finally, regarding the most common medication used for depressive episodes and mood disorders, a significant increase in the use of antidepressants was observed in 2022 compared to 2017 (difference 2.4%, 95% CI 1.87%-3.06%), while no differences were observed in the use of anxiolytics.

Evolution of the Prevalence of Depressive Episodes and Mood Disorders by Year

The prevalence per year of all selected diagnostic codes was calculated during the period from 2017 to 2022, considering the total population assigned to the Catalan Institute of Health Primary Care Centers throughout Catalonia (Figure 1). Since 2017, an increase in diagnoses was observed. The steepest increase was in 2018, which went from 2.3% (95% CI 2.27%-2.29%) during 2017 to 2.9% (95% CI 2.86%-2.88%) in 2018. From 2019 to 2022, a progressive increase in prevalence was observed, reaching 4.3% (95% CI 4.24%-4.27%) in 2022. In short, the prevalence of depressive episodes and mood disorders increased by 86.6% during the study period. The results can be seen in Table S2 in Multimedia Appendix 1.

Figure 1. Depression prevalence (%) with 95% CIs between years.

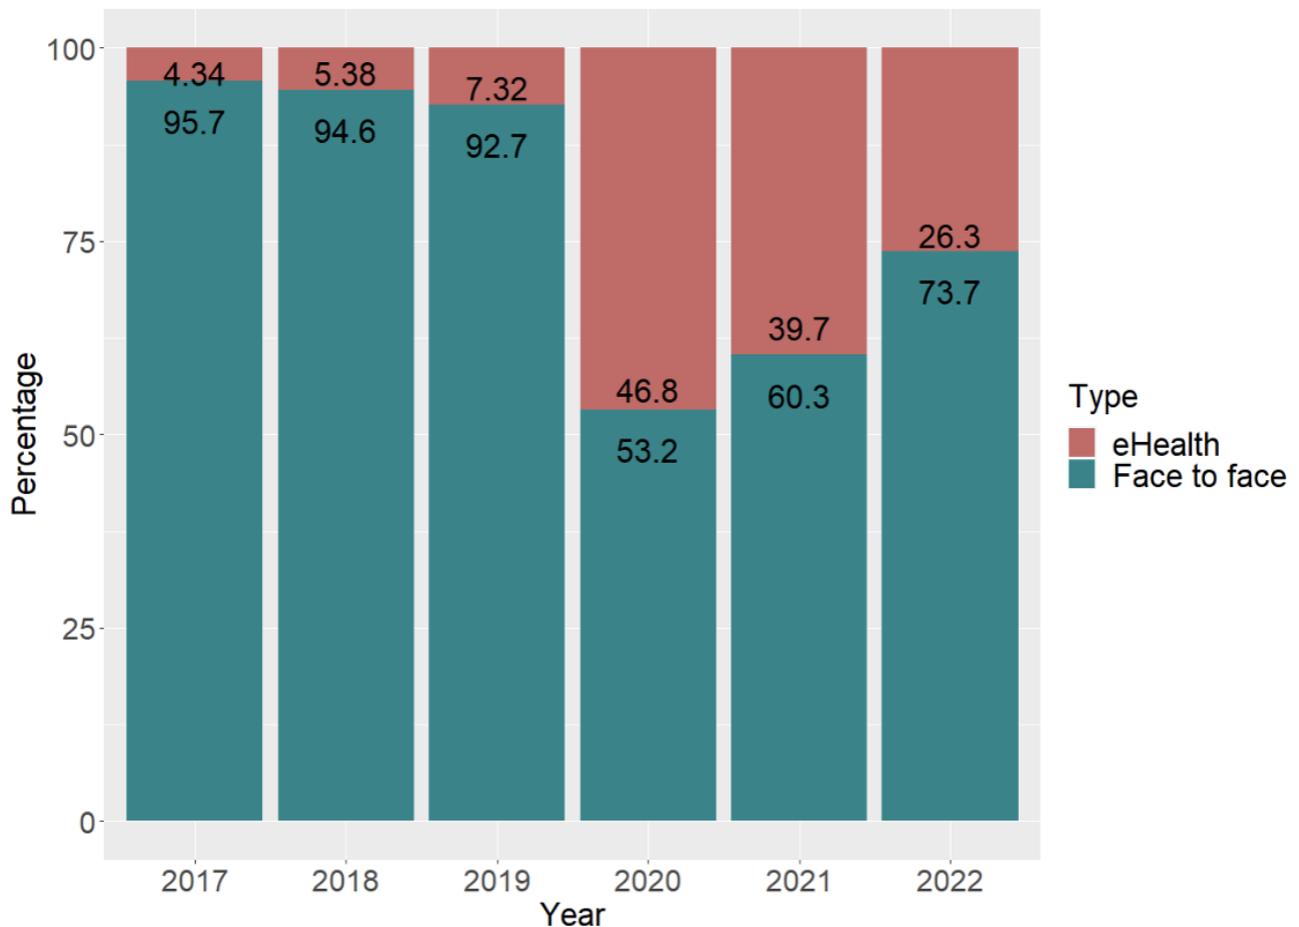

Use of eHealth for Consultations Related to Depression and Mood Disorders by Year

The percentage of face-to-face and eHealth visits for each year of new diagnoses was calculated to analyze the use of eHealth for consultations related to depression and mood disorders in the public health care system (Figure 2). It was noted that in 2017 eHealth consultations represented 4.34% (1240/28,561)

of all depressive episode and mood disorder visits, with an increase during 2018 and 2019. As of 2020, coinciding with the pandemic lockdown, eHealth consultations accounted for 46.8% (11,122/23,790), representing a more than 6-fold increase over the previous year. In 2021, there was some recovery of face-to-face consultations, but nevertheless, eHealth consultations still accounted for 39.7% (12,119/30,561) of total consultations. Finally, in 2022, eHealth consultations accounted

for 26.3% (8501/32,267), representing just over a quarter of all consultations for diagnoses of depression and mood disorders.

Figure 2. Percentage of telematic and face-to-face consultations from 2017 to 2022.

Comparison of Prevalent Cases in 2022 According to Face-to-Face Attendance

A comparative analysis of the sociodemographic variables of the prevalent 2022 cases was performed according to face-to-face consultations (Table 2). Regarding age, it was observed that the populations that used eHealth consultations the most were those aged 0 to 15 years (difference -1.18% , 95% CI -1.36% to -0.98%), 16 to 24 years (difference -0.64% , 95% CI -0.89% to 0.38%), and those aged 85 years and older (difference -4.37% , 95% CI -4.68% to -4.05%). In contrast, in 2022, it was observed that the populations that used face-to-face consultations the most were people aged 35 to 44 years (difference 0.7% , 95% CI 0.33% - 1.10%), 45 to 54 years (difference 0.7% , 95% CI 0.27% - 1.11%), 55 to 64 years (difference 0.8% , 95% CI 0.43% - 1.24%), 65 to 74 years (difference 3.1% , 95% CI 2.84% - 3.53%), and 75 to 84 years (difference 0.59% , 95% CI 0.59% - 1.31%).

Significant differences were also observed in the MedeA index. People living in urban settings with less deprivation (urban 1) made more use of eHealth (difference -1.9% , 95% CI -2.35% to -1.44%), while those with higher deprivation in urban settings (urban 3 and urban 4) used face-to-face consultations more often (difference 0.9% , 95% CI 0.48% - 1.34% and difference 2.4% , 95% CI 2.01% - 2.84% , respectively). Regarding recurrence, it was observed that individuals with recurrent depressive episodes sought consultation more frequently via eHealth (difference -2.46% , 95% CI -2.77% to -2.15%). In terms of rurality, individuals living in rural areas demonstrated a higher frequency of eHealth usage (difference -1.4% , 95% CI -1.94% to -0.97%). Finally, individuals receiving treatment with antidepressants or anxiolytics showed a higher tendency to use eHealth services for their health consultations (difference -10.1% , 95% CI -10.59% to -9.50% and difference -4% , 95% CI -4.53% to -3.51% , respectively).

Table 2. Comparative table of prevalent cases in 2022 according to attendance type.

^aStatistically significant differences.

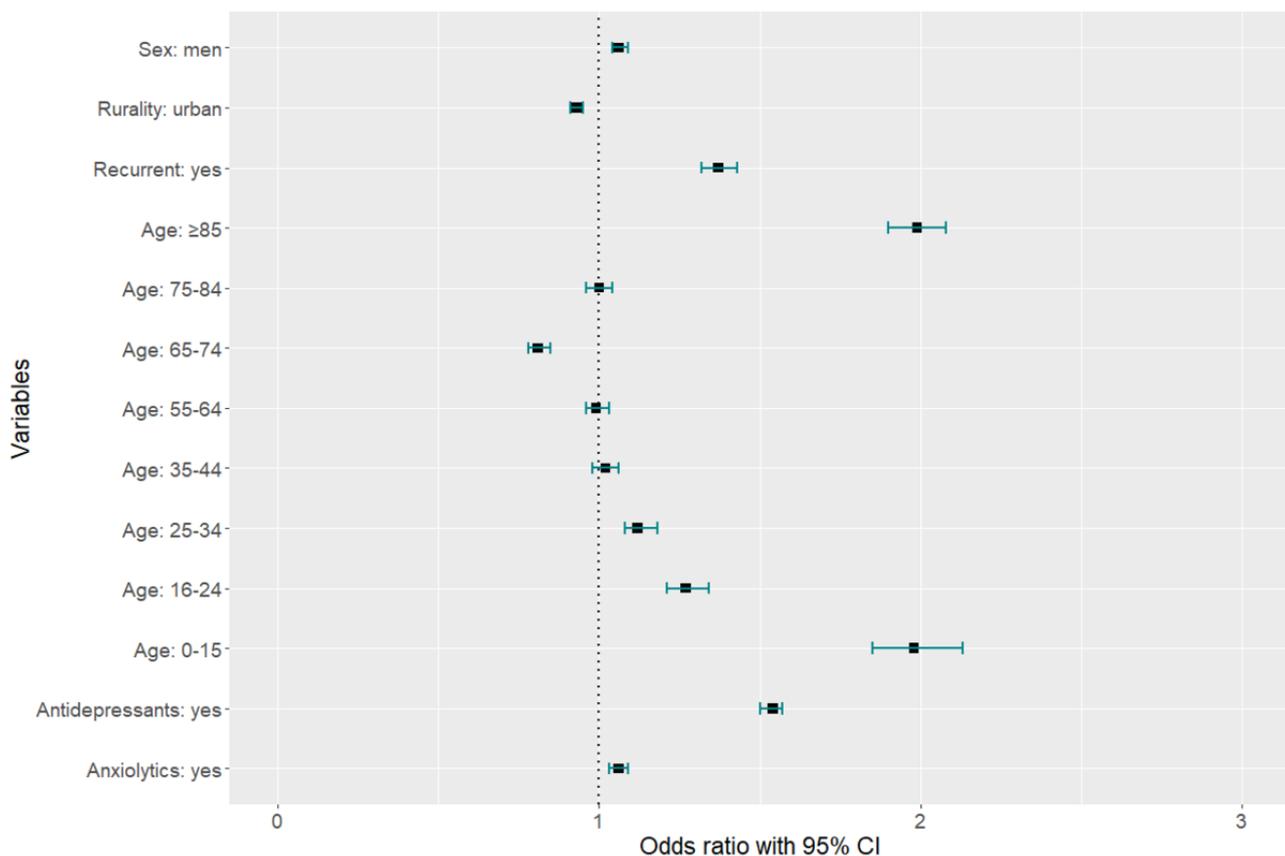

^bGiven the symmetry of the binary variables, the difference and CI have only been expressed for one of the categories.

Finally, a logistic regression model was used to observe the impact of the studied variables from the 2022 attendance data (Figure 3). Men were 1.06 times more likely (95% CI 1.04-1.09) to use eHealth in consultations than women, and those suffering from recurrent depressive episodes were 1.37 times more likely (95% CI 1.32-1.43) to use eHealth in consultations. It was also observed that the youngest age ranges (0-15 years: odds ratio

[OR] 1.98, 95% CI 1.85-2.13; 16-24 years: OR 1.27, 95% CI 1.21-1.34; 25-34 years: OR 1.12, 95% CI 1.08-1.18) were more likely to use eHealth in consultations, as was also the case among those aged 85 and older (OR 1.99, 95% CI 1.90-2.08). In contrast, people living in urban settings were 7% less likely (OR 0.93, 95% CI 0.91-0.95) to have an eHealth consultation. Finally, people who consulted more through eHealth were 1.54

times (95% CI 1.50-1.57) more likely to take an antidepressant and 1.06 times (95% CI 1.03-1.09) more likely to take an anxiolytic. The results can be seen in Table S3 in [Multimedia Appendix 1](#).

Figure 3. Logistic regression results. The reference categories were as follows: women, aged 45-54, nonrecurrent, rural, no antidepressants, and no anxiolytics. The black squares indicate the odds ratio estimate, and the horizontal lines indicate the 95% CI.

Discussion

Principal Findings

The aim of the present study was to analyze the context of depression within the Catalan health care system. Consequently, the prevalence of depression and mood disorders has been successfully analyzed over the years, along with the sociodemographic profile of this population. Additionally, the role played by eHealth and its impact on PC for these conditions has been studied.

Regarding the prevalence of depression and mood disorders in Catalan PC, an increase of 86.6% was observed during the study period. One possible reason explaining this increase in prevalence could be an uptick in the detection of these cases within the public health care system, possibly indicating increased awareness among both professionals and citizens. In 2006 in Catalonia, the Primary Care Support Programme was implemented to coordinate PC with mental health services, providing a budget to hire more psychiatrists and psychologists in order to reinforce PC [32,33]. However, it was not until 2017 that implementation was completed in all PC centers in Catalonia. In this context, despite the existence of critical reports regarding the operation of this support program, its initiation might have positively influenced professionals' awareness, potentially contributing to an increase in detections in PC since then. The results of the study revealed a more pronounced

increase (25.82%) in 2018, coinciding with the end of this program's operation.

Another possible reason explaining the increase in prevalence is the COVID-19 pandemic. The data analyzed cover the period from before the pandemic to the early postpandemic period, so the results may indeed be influenced by the consequences of lockdown and the isolation of individuals. In this context, the pandemic has generated great concern and an even more marked increase in mental health awareness, especially among the younger population. As the context of social isolation has strongly impacted the mental health of young people, as it is a crucial period for the development of social skills, it is noteworthy that from the prepandemic context in 2019, the overall prevalence increased by 36.52% in 2022 [34,35]. However, in line with the statistics already published, it is worth mentioning that women are the most affected group [6,7]. Over the past decade, the importance of sex- and gender-stratified biomedical research has grown significantly, as demonstrated by the observations of Oertelt-Prigione et al [36] of an increasing number of publications in medicine addressing this issue. It is now crucial to incorporate this perspective into the clinical approach to depression. Understanding how individuals' behaviors align with social expectations, coping strategies, and help-seeking tendencies can contribute to a more comprehensive approach to treatment. Regarding the medicalization of these conditions, it has been observed that approximately 80% of new

diagnoses of depression and mood disorders in both 2017 and 2022 were prescribed antidepressant drugs. That is, most people who were diagnosed for the first time were associated with antidepressants. In contrast, the prevalence of antidepressant use has been found to be around 40% to 50% in the entire prevalent population. The results suggest that although most people who are diagnosed with depression or mood disorders are prescribed medication, in most cases treatment is withdrawn, as indicated by clinical practice guidelines [37,38].

Regarding the use of eHealth for consultations on depression and mood disorders in the PC context in Catalonia, it has been observed that the use of eHealth is increasingly being integrated into daily clinical practices in Catalonia [18]. In fact, while in 2017 diagnoses made through eHealth consultations accounted for only 4.34% of consultations, in 2022 they accounted for 26.34%. Without a doubt, the pandemic has also been a clear catalyst in the use of eHealth. Although the volume of eHealth consultations in 2020 was not equivalent to that in 2022, the results from the latter year may suggest a shift in the pattern of consultations related to depression and mood disorders. In this sense, eHealth is gaining prominence in routine practice, as has been suggested by other studies conducted in Catalonia [17,39,40]. Nevertheless, the incorporation of eHealth into the health care system must be accompanied by training for the professionals who must use it. In other words, it is not just about providing infrastructure and resources for technology operation. It is also crucial to understand when the use of these tools aligns with the care process and equip the health care professional to make clinical and therapeutic decisions appropriately, as they hold responsibility for the procedure and its outcomes [41]. The results of the present study have also shown that one of the impacts of eHealth on depressive episodes and mood disorders is on the prescription of drugs. People treated with eHealth were prescribed 54% more antidepressant drugs and 6% more anxiolytics. A systematic review by Han et al [42] observed the impact of eHealth on antibiotic prescribing in PC. Although it was not possible to conclude with sufficient confidence that eHealth significantly impacts the prescribing of these drugs, 4 of the 12 studies analyzed reported higher prescribing rates through eHealth [42]. In a study conducted by Wabe et al [43] during the pandemic in Australia's PC, they compared the prescription of medication through face-to-face consultation versus eHealth methods. The findings revealed that prescribing through face-to-face consultations was more prevalent for all drug groups classified in the World Health Organization Anatomical Therapeutic Chemical Classification list [44], except for the group that includes nervous system drugs, such as antidepressants and anxiolytics. In the context of PC in Catalonia, it would be interesting to examine whether the results obtained related to the increased prescription of drugs via eHealth can be applied to other medical conditions. In this regard, the development strategies used in the approach to eHealth will be crucial to ensure consistency in clinical practice.

Strengths and Limitations

The most relevant strength of this study is the size of the sample, since it was possible to work with the consultations related to

depressive episodes and mood disorders of almost 5.8 million people. As a result, this study has yielded robust and realistic findings regarding the prevalence of depression, the use of eHealth, and the associated implications. Another strength of this study lies in the comprehensive analysis of the role and implications of eHealth in depression-related consultations. It not only highlights the current utilization of eHealth in depression consultations but also underscores the need to develop strategies that promote consistency between in-person and eHealth visits.

The main limitation of this analysis is that the data were collected only from the Catalan Institute of Health within Catalonia's public health care system. As a result, there is a lack of information from individuals who have sought treatment through private health care providers. Another limitation is that, since this was a cross-sectional study, it was not possible to follow up on each individual user, and therefore, it was not possible to establish a causal relationship between the variables studied, although the relationship between them was observed. However, due to the absence of subdivision in the original database regarding telematic consultations, specifically whether they were synchronous or asynchronous, a detailed breakdown of the proportions of telematic consultations could not be provided. Furthermore, it is essential to acknowledge the limitation that the data analyzed may reflect the impact of the lockdown imposed during the COVID-19 pandemic. The pandemic led to the isolation of individuals, which, in turn, resulted in a notable increase in diagnoses through eHealth and prescriptions of antidepressants and anxiolytics when comparing the period before COVID-19 to the postlockdown situation. In this context, the often-mandatory use of eHealth consultations during the lockdown, along with the isolation of the population, may have contributed to the increase in the detection rates and medication usage reflected in the results. Therefore, it would be valuable to replicate this study in the coming years to reassess the prevalence and sociodemographic characteristics of depression as well as the role of eHealth in addressing the observed diagnostic and pharmacological trends. This follow-up study would enable us to determine whether the findings observed in this study represent short-term consequences of COVID-19 or if they have more lasting implications over time.

Conclusions

The prevalence of depression in Catalonia has significantly increased from 2017 to 2022, with the pandemic likely having a profound impact. Although the Catalan health care system has been undergoing digital transformation since 2011, eHealth usage was limited in 2017. During the lockdown, it accounted for nearly half of the care, and by 2022 it represented a quarter of the consultations. In the short post-COVID-19 era, evidence suggests that eHealth plays a role in consultations related to depression and appears to increase the likelihood of taking antidepressants and anxiolytics. However, future studies in a context further removed from the pandemic could provide a more accurate indication of the role of eHealth in diagnosing and treating depression and mood disorders.

Acknowledgments

We would like to thank Manuel Moreno for extracting the study variables from the original database. This project was supported by the Department of Health of the Generalitat de Catalunya and received funding in the 2021 grant call from the Strategic Plan for Research and Innovation in Health (PERIS) for the 2022-2024 period. The project falls under the research projects focused on primary care, with the file code SLT021/21/000002.

Data Availability

The data sets generated and analyzed during the current study are not publicly available because the manuscript was based on confidential and sensitive health data but are available from the corresponding author upon reasonable request.

Conflicts of Interest

None declared.

Abstract

Background: Depression is a hidden burden, yet it is a leading cause of disability worldwide. Despite the adverse effects of depression, fewer than one-third of patients receive care. Internet-based cognitive behavioral therapy (i-CBT) is an effective treatment for depression, and combining i-CBT with supervised care could make the therapy scalable and effective. A stepped care model is a framework for beginning treatment with an effective and low-intensity intervention while adapting care based on the patient's needs.

Objective: This study investigated the efficacy of a stepped care i-CBT model for depression based on changes in self-reported depressive symptoms.

Methods: In this single-blinded, randomized controlled trial, participants were allocated to either the i-CBT-only group (28/56, 50%) or the i-CBT with stepped care group (28/56, 50%). Both groups received a 13-week i-CBT program tailored for depression. The i-CBT program was provided through a secure, online mental health clinic called the Online Psychotherapy Tool. Participants read through the sessions and completed the assignments related to each session. Participants in the stepped care group received additional interventions from their care provider based on standard questionnaire scores (ie, Patient Health Questionnaire-9 [PHQ-9], Quick Inventory of Depressive Symptomatology [QIDS], and Quality of Life Enjoyment and Satisfaction Questionnaire-Short Form) and their assignment responses. From lowest to highest intensity, the additional interventions included SMS text messages, phone calls, video calls, or a video call with a psychiatrist.

Results: For this study, 56 participants were recruited to complete an i-CBT program (n=28, 50%; mean age 37.9; SD 13.08 y; 7/28, 27% were men) or an i-CBT with stepped care program (n=28, 50%; mean age 40.6; SD 14.28 y; 11/28, 42% were men). The results of this study indicate that the i-CBT program was effective in significantly reducing depressive symptoms, as measured by the PHQ-9 ($F_{4,80}=9.95$; $P<.001$) and QIDS ($F_{2,28}=5.73$; $P=.008$); however, there were no significant differences in the reduction of depressive symptoms between the 2 groups (PHQ-9: $F_{4,80}=0.43$; $P=.78$; QIDS: $F_{2,28}=3.05$; $P=.06$). The stepped care group was not significantly better in reducing depressive symptoms than the i-CBT group (PHQ-9, $P=.79$; QIDS, $P=.06$). Although there were no significant differences observed between the number of participants who completed the program between the groups ($\chi^2_1=2.6$; $P=.10$), participants in the stepped care group, on average, participated in more sessions than those who prematurely terminated participation in the i-CBT group ($t_{55}=-2$; $P=.03$; 95% CI -4.83 to -0.002).

Conclusions: Implementing a stepped care approach in i-CBT is an effective treatment for depression, and the stepped care model can assist patients to complete more sessions in their treatment.

Introduction

Background and Rationale

Depression is a leading cause of disability, affecting approximately 3.8% of the population worldwide [1,2]. Major depressive disorder (MDD) is characterized by persistent feelings of sadness, negative mood, or loss of interest in life activities [3]. Detrimental and persistent changes in appetite, sleep, energy, and cognition may accompany these feelings. In addition to its deleterious impacts on mental health, depression is associated with increased morbidity, decreased quality of life, and reduced work productivity [4-6]. Despite the negative consequences of depression, only one-third of individuals receive treatment, and of those, only 3 in 5 people receive sufficient care [7,8].

Cognitive behavioral therapy (CBT) is an effective treatment for MDD [9-11]. It is a form of psychotherapy that focuses on cognitive restructuring strategies and behavioral activation techniques to help individuals with depression overcome their depressive symptoms and modify ineffective thinking patterns. Although effective, CBT on its own presents some challenges such as accessibility issues, lack of follow-ups, and increased costs [12-14]. Over the past 2 decades, issues of accessibility are being increasingly addressed through digital modalities, such as internet-based CBT (i-CBT) [11,15,16]. i-CBT allows for the delivery of CBT through digital media including computers and smartphones. It involves using web-based sessions with interactive components and practices to teach individuals ways to improve their mental health. Many studies have shown the efficacy of i-CBT for depression and anxiety, with results comparable with those of traditional in-person CBT [11,16-20]. The digital format allows for increased accessibility and convenience when delivering and receiving psychotherapy while remaining effective [21,22]; however, the digital format comes with limitations, including low adherence. Adherence rates are variable and can be affected by multiple factors including the digital modalities used and patient-therapist interactions [23-25]. Furthermore, attrition rates in CBT are the highest in patients with depression [26], and adherence can be compromised as disease severity increases [27]. With the benefit of being versatile and adaptable, i-CBT may be adapted to include support to address the issues of adherence.

The stepped care model is an approach to providing individuals with adaptable and effective care that is adjusted based on symptom severity [28-31]. This dynamic approach allows care to be adapted as required throughout an individual's treatment plan to best tailor care to the individual's needs. Stepped care

models aim to provide the most effective and efficient care by minimizing resources and costs for care. The least intensive intervention, such as self-help materials or psychoeducation, is first provided to patients in a stepped care model. The patient may then advance to the next level of care, which may include more extensive interventions such as increased support or medication if they do not improve or just partially improve. Until the patient gets the desired result or reaches the highest level of care, this process is repeated. This stepped care model allows for efficient allocation of resources, increases access to care, can reduce wait times, can lower costs, and can increase versatility in treatment options [28,31]. This model is effective in treating mental health disorders including MDD and focuses on a patient-centered approach to care [21,31].

In the stepped care model, all patients receive some form of treatment for their symptoms, and based on the symptom severity and progress through treatment, additional care is added to their treatment plan. The addition of therapist-guided support to i-CBT has demonstrated high levels of patient satisfaction and a general decrease in symptom severity [32]. It is also noted that dropout rates decrease as increased therapeutic support is provided to patients. A meta-analysis that gathered dropout rates of CBT based on treatment support levels found that without support, the dropout rate was 74%; with administrative support, the dropout rate was 38%; and with therapeutic support, the patient dropout rate was 28% [16]. This suggests that the type of support provided to patients is important. Therapist-guided support in an i-CBT setting can also include text (ie, messaging and emails) or audio-based (ie, telephone and video) formats, and the mode of therapy may influence treatment outcome [22,33,34]. Incorporating text and call interventions into online therapy can provide an additional support outlet for patients throughout their treatment by providing an additional means of communication while remaining accessible [35]. Phone and video interventions have both been shown to be effective in reducing symptoms and maintaining patients in care compared with in-person care for mood disorders [36]. Phone calls may be more broadly accessible than video calls owing to inherent technological barriers; however, video calls allow for additional nonverbal cues to be assessed in care [36]. They can serve as check-ins, encouragement, and reminders and help monitor patient progress between treatment sessions. Through this additional support, a review of therapeutic concepts and words of encouragement are found to help decrease symptom severity and improve therapy completion [37]. This method can help with building therapist-patient rapport throughout treatment and act as a valuable tool in online therapy.

Objectives

This study was a single-blinded, randomized controlled trial exploring the efficacy of a stepped care model in an i-CBT program compared with an i-CBT-only program for adults with MDD. The i-CBT program for depression was provided through a secure, online mental health clinic called the Online Psychotherapy Tool (OPTT) [38]. The stepped care model considered the varying digital modalities of text-based, phone-based, and video-based interventions to help support individuals in their care.

Methods

Ethical Considerations

The research study was approved by the Health Sciences and Affiliated Teaching Hospitals Research Ethics Board (file number 6031992) at Queen's University in Kingston, Ontario, Canada. The research study followed the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) guidelines and can be viewed in [Multimedia Appendix 1](#) [39].

No monetary compensation was provided to participants for participation in this study because they were provided with CBT treatment for their symptoms.

Data Privacy

To maintain participant confidentiality, each participant was assigned a randomized participant ID number. This ID was used to identify the participant for data analysis purposes. Only associated care providers had access to the participant's identity owing to the nature of the CBT intervention. If any technical issues on OPTH arose, this ID was used to resolve the issues to maintain participant anonymity.

Participant information maintained online was password protected, including consent forms, identities, and CBT content. All encrypted files were stored on a safe server run by Queen's University. Participant identities and consent forms are stored on-site at Queen's University's exclusive storage in Kingston, Ontario, Canada, for 5 years following the conclusion of the study because they are considered as medical records. Following the 5 years, the participant records will be destroyed. Participants were informed about the possibility to withdraw from the study at any time if they wished to do so. In upcoming plans for knowledge dissemination and publication of outcomes, participant identification will be secured and maintained anonymously.

The online platform used to deliver the i-CBT program, OPTH [38,40], serves as the repository for all data. OPTH complies with the Personal Information Protection and Electronic Documents Act, Health Insurance Portability and Accountability Act, and Service Organization Control-2. The cloud infrastructure of Amazon Web Service Canada is used to host all servers and databases, and Medstack manages it to ensure compliance with all the local, state, and federal privacy and security laws. For privacy reasons, OPTH does not gather any identifying personal data or IP addresses. Only anonymous

metadata were gathered by OPTH to enhance the quality of its services and provide the care provider team access to participant analytics (ie, interaction with the OPTH platform). No OPTH employee had direct access to participant data owing to data encryption procedures (ie, participant ID). All encrypted backups are stored at Queen's University.

Outcome Evaluation

Patient Health Questionnaire-9

The Patient Health Questionnaire-9 (PHQ-9) is a self-assessment questionnaire designed to examine a participant's depression severity through a 9-item questionnaire, with an additional question about functional health [41]. Each of the 9 items is scored from 0 (not at all) to 3 (nearly every day) and corresponds to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* criteria for MDD symptoms [3]. Each item is then scored for a total to indicate depression severity from none to severe, ranging from 0 to 27. High scores indicate high depression.

Quick Inventory of Depressive Symptomatology Questionnaire

The Quick Inventory of Depressive Symptomatology (QIDS) questionnaire is a self-assessment questionnaire designed to screen for depression and measure depression severity based on 16 items [42]. Each item correlates with the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* criteria for MDD symptoms and is scored using a 4-point scale (0-3), for a total score ranging between 0 and 27 [3]. To calculate the final score, the questions are summed using the highest response in the following domains: sleep patterns (questions 1-4), sad mood (questions 5), change in appetite (questions 6-9), concentration and decision-making (questions 10), self-view (questions 11), suicidal thoughts (questions 12), general interest (questions 13), energy level (questions 14), and psychomotor effects (questions 15 and 16). High scores indicate high depression severity.

Quality of Life Enjoyment and Satisfaction Questionnaire-Short Form

The Quality of Life Enjoyment and Satisfaction Questionnaire-Short Form (Q-LES-Q) is a self-assessment questionnaire designed to collect information about the level of enjoyment and satisfaction in various aspects of daily functioning through a series of 16 items [43]. Each item is rated on a scale from 1 (very poor) to 5 (very good). Of the 16 items, only the first 14 items are summed for a total raw score ranging from 14 to 70. High scores indicate great quality of life.

Measured Outcomes

The primary outcomes measured in this study included changes in depressive symptoms, as measured by the PHQ-9 and QIDS. Using the Q-LES-Q to measure changes in the participant's quality of life was also a primary outcome that was evaluated. Participants completed the PHQ-9 every 3 weeks (weeks 1, 4, 7, 10, and 13) and the QIDS and Q-LES-Q at 3 time points (weeks 1, 7, and 13) throughout the program. All the 3 questionnaires are intended to be completed at the 3-, 6-, 9-, and 12-month follow-up periods during the 1-year follow-up

phase ([Textbox 1](#)). Pretreatment and posttreatment changes in depressive symptoms (ie, PHQ-9 and QIDS) and quality of life (Q-LES-Q) between the control and experimental groups were compared. The number of sessions completed by each

participant was a secondary measure that was considered when evaluating compliance with the i-CBT program between the 2 groups.

Textbox 1. Schedule of the assigned clinical questionnaires sent to participants, including the 1-year follow-up period.

Session 1

- Patient Health Questionnaire–9 (PHQ-9), Quality of Life Enjoyment and Satisfaction Questionnaire–Short Form (QIDS), Quick Inventory of Depressive Symptomatology (Q-LES-Q), and demographic survey

Session 2

- No questionnaires are provided during these sessions.

Session 3

- No questionnaires are provided during these sessions.

Session 4

- PHQ-9 and initial stepped care assessment (if the participant is in the stepped care group, an intervention decision will be made at the end of every session, starting at session 4. Interventions will be implemented, beginning from session 5)

Session 5

- Interventions begin as needed (if the participant is in the stepped care group, an intervention decision will be made at the end of every session, starting at session 4; Interventions will be implemented, beginning from session 5)

Session 6

- No questionnaires are provided during these sessions.

Session 7

- PHQ-9, QIDS, and Q-LES-Q

Session 8

- No questionnaires are provided during these sessions.

Session 9

- No questionnaires are provided during these sessions.

Session 10

- PHQ-9

Session 11

- No questionnaires are provided during these sessions.

Session 12

- No questionnaires are provided during these sessions.

Session 13

- PHQ-9, QIDS, and Q-LES-Q

Follow-up 1

- PHQ-9, QIDS, and Q-LES-Q

Follow-up 2

- PHQ-9, QIDS, and Q-LES-Q

Follow-up 3

- PHQ-9, QIDS, and Q-LES-Q

Follow-up 4

- PHQ-9, QIDS, and Q-LES-Q

Participants

This study was registered at ClinicalTrials.gov (NCT04747873). Participants were recruited from the Providence Care outpatient psychiatry clinic and Kingston Health Sciences Center sites (Hotel Dieu Hospital and Kingston General Hospital), both of which are located in Kingston, Ontario, Canada. Physicians familiar with the Queen's Online Psychotherapy Lab (QUOPL) research team were also informed about the study and directed patients who may benefit from CBT toward the study when considered appropriate. Self-referrals were also accepted for this study. Recruitment was managed by the laboratory manager who was the initial point of contact for all participants.

Eligibility Criteria

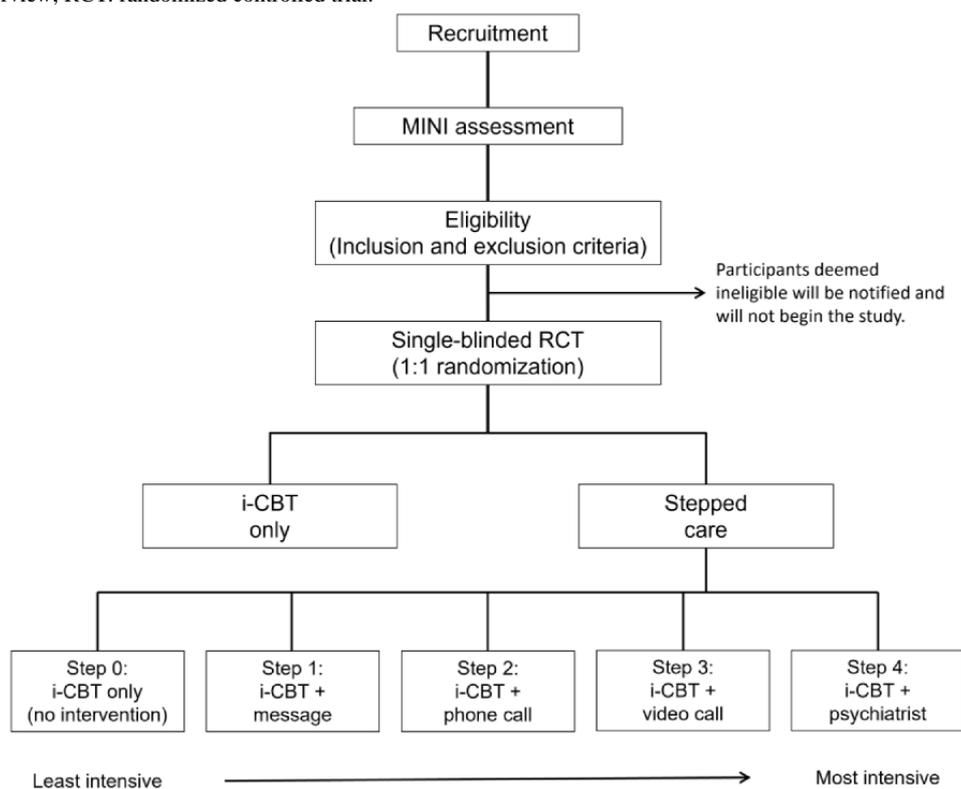

Individuals interested in the research study were provided with a letter of information and consent form to understand the study design before beginning the eligibility process. Following the informed consent process (written or verbal), a trained research assistant at QUOPL screened the individual based on the eligibility criteria. Individuals were eligible for the study if they met the following criteria: (1) aged ≥ 18 years, (2) met the criteria of MDD by a trained research assistant according to the Mini International Neuropsychiatric Interview (MINI) [44], (3) showed competence to consent to participate, (4) fluent in English because the i-CBT program was provided in English only, and (5) had consistent and reliable access to the internet. For the MINI assessment, individuals were first assessed by a trained research assistant to support a diagnosis of MDD. This MINI assessment was completed through a secure Microsoft Teams video call. Participants were ineligible for the research study if they presented with active psychosis, acute mania,

severe alcohol or substance use disorder, or active suicidal or homicidal ideation. If a participant received or was receiving CBT in the past year at the time of beginning the study, they were excluded from the study to avoid confounding effects on the efficacy of this i-CBT program.

Following the consent and eligibility screening process, participants were randomized in a 1:1 allocation ratio to either the i-CBT group (control group) or the i-CBT with stepped care group (experimental group). Randomization was computer generated in Microsoft Excel using the *RANDBETWEEN* function. This method returned an integer at random that indicated either 1 (designated as the i-CBT group) or 2 (for the stepped care group). This integer was used to determine the group allocation for the participant.

Using G*Power (version 3.1.9.7 [45]), a priori power analysis was performed to determine the minimum sample size required to test the study hypothesis. The average PHQ-9 score decreased from 16.2 before i-CBT to 11.48 (combined SD 5.45) after 12 sessions in our previous clinical trials and data collection regarding i-CBT for depression [46]. These figures led to an effect size (Hedge g of 0.86). A paired sample t test (1-tailed) would require 14 individuals to detect a significant impact, given the effect size and a power of 0.8. For online CBT programs, compliance and care adherence are common challenges; therefore, we predict 50% dropout rate based on previous clinical trials conducted in our laboratory [47,48]. Consequently, considering the proposed sample size calculation accounted for this dropout rate, we aimed to recruit 28 participants in each group. With the 2 treatment arms, our total sample size was expected to be 56 participants. Figure 1 summarizes the study design in a flow chart.

Figure 1. A flowchart providing an overview of the study design. i-CBT: internet-based cognitive behavioral therapy; MINI: Mini International Neuropsychiatric Interview; RCT: randomized controlled trial.

Care Providers

Participants were assigned a primary care provider to help build rapport through assigning sessions, providing feedback, and providing additional interventions as needed. All care providers were trained in psychotherapy by the lead psychiatrist who is a licensed psychotherapist and expert in internet-based psychotherapy. Each participant was assigned a care team that consisted of a care provider and a psychiatrist with extensive experience in i-CBT. Care providers were research assistants recruited and trained by the team psychiatrist. Their role was to provide participants with feedback about weekly homework and act as a point of contact for any questions that the participants may have regarding the study design. The care providers included master's degree students studying in the field of neuroscience and psychology, associated with QUOPL, and research assistants who have completed a medical degree. Through training, all care providers were well experienced in internet-based psychotherapy, with a specific focus on CBT techniques. They were all taught the standard care pathway and the aim, and content of each therapeutic session. They also continued receiving specialized training through webinars, CBT workshops led by a psychiatrist trained in CBT, and exercises with feedback during the study. Moreover, they were provided pre-designed feedback templates tailored to each session to be used when writing the weekly feedback. The feedback templates helped standardize the feedback by providing a basic structure that ensured all aspects of the homework were acknowledged and that the newly presented CBT concepts were reviewed. Feedback templates varied between sessions, and care providers personalized each template for each participant's homework. The use of feedback templates that were drafted by the team psychiatrist trained in online psychotherapy allowed some control over treatment consistency across sessions and participants. Before submission to the participant, feedback was always reviewed by another care provider (MSc candidate) trained in psychotherapy and overlooked by a psychiatrist to

ensure the quality of the feedback. The team psychiatrist fulfilled the role to overlook the feedback; manage any crisis events if necessary; and provide support in the stepped care model, specifically the highest-intensity intervention, step 4.

Intervention

i-CBT Program

All participants (56/56, 100%) were provided with the same 13-week i-CBT program designed for MDD through OPTT—a secure, cloud-based, digital mental health platform [38]. This i-CBT program, titled “Electronic Cognitive Behavioural Therapy (e-CBT) For Depression,” is a set of pre-designed modules created to address depressive symptoms through various CBT techniques to work on cognitive restructuring [46,49-51]. This specific program has undergone validation through previous studies and has been shown to significantly decrease depressive symptoms [47,49]. The program was intended to imitate in-person, standard CBT for MDD in an asynchronous format. In this study, 1 module was assigned to participants on the same day of each week. A module included 20 to 30 slides of CBT content and took approximately 45 to 50 minutes to view (Multimedia Appendix 2). Each module focused on 1 CBT technique (Table 1). Each module followed a similar outline, beginning with an introduction to the topic for the week, an overview of the technique with examples, and concluding with homework related to the weekly technique [50]. The homework consisted of a few questions based on a stressful event that occurred in the participant's life in the past week and provided participants with the practice of the new CBT technique. Participants were provided with 4 days to asynchronously review the module and submit their homework to their assigned care provider on the OPTT platform. Participant answers were then reviewed by the assigned care provider over 3 days who provided participants with feedback about their answers along with their next session on the assigned day of the week.

Table 1. A brief description of each session for the internet-based cognitive behavioral therapy (i-CBT) program, titled “Electronic Cognitive Behavioural Therapy (e-CBT) For Depression,” on the Online Psychotherapy Tool platform.

Module	Title	Description
1	What is depression?	<ul style="list-style-type: none"> Introduced i-CBT and discussed common depressive symptoms while setting expectations for the course
2	The 5-Part Model	<ul style="list-style-type: none"> Described the 5-Part Model: connections and interactions between a situation, thoughts, feelings, physical reactions, and behaviors
3	Sleep hygiene	<ul style="list-style-type: none"> Focused on how to improve rest through sleep habits and offered a variety of techniques
4	Strategies for stressful situations	<ul style="list-style-type: none"> Provided a general review of practical strategies that can be applied under difficult circumstances, including breathing techniques and activities
5	Thoughts, feelings, behavior, physical reactions, and environment	<ul style="list-style-type: none"> Explained the 5-Part Model in detail and how modifications to 1 part can influence the remaining 4 parts
6	The thought record	<ul style="list-style-type: none"> Featured the first 3 columns of the thought record: a tool for challenging ineffective thoughts The first 3 columns included the situation, feelings, and automatic thoughts associated with the situation
7	Automatic thoughts	<ul style="list-style-type: none"> Explored the function of automatic thoughts and how they affect emotions This included learning how to recognize automatic thoughts and the “hot thought” Common cognitive errors were also discussed
8	Activity scheduling	<ul style="list-style-type: none"> Described the activity record: a tool for recording weekly activities and finding connections between activities and associated moods
9	Evidence	<ul style="list-style-type: none"> Back to the thought record, the fourth and fifth columns were explained, which included looking at evidence for and against the most intense thought
10	Alternative and balanced thinking	<ul style="list-style-type: none"> Concluded the 5-Part Model with the final 2 columns outlining alternative or balanced thinking and rerating feelings
11	Experiments	<ul style="list-style-type: none"> Introduced a behavioral activation technique of experiments to promote belief in alternative or balanced thinking
12	Action plans	<ul style="list-style-type: none"> Promoted working on the identified problems using a structured tool called the action plan
13	Review	<ul style="list-style-type: none"> Reviewed the 12 modules in the program and summarized the key tools and techniques

The feedback was based on predesigned feedback templates created by the lead psychiatrist and i-CBT expert at QUOPL. The feedback for each session followed a similar structure and was delivered as a letter addressed to the participant. The feedback template mirrored the following structure: (1) addressed the participant and thanked them for their work over the week while acknowledging any adverse events that occurred; (2) commented about their mood and sleep quality in the previous week; (3) summarized the content of the module, highlighting the main concepts; (4) summarized the participant’s answers; (5) empathized with the participant based on their shared experiences and encouraged them to use the learned CBT techniques; and (6) thanked them again for their time and provided the participant with a brief introduction about the next module’s content ([Multimedia Appendix 3](#)—sample feedback template for session 1). Overall, the feedback itself focused on the participant’s mood and sleep patterns over the week, progress on their weekly goals, and their understanding of CBT concepts. The care providers personalized the feedback template based on the participant’s responses.

The OPTT platform provided participants and care providers with a modality to communicate asynchronously regarding the availability of the next module and any questions or concerns regarding the OPTT operations or the study design. These questions and concerns were limited to the study design and technical issues, rather than personal or therapy-related concerns. Care providers viewed and replied to these OPTT messages at least once a week. For concerns regarding the OPTT platform and technical issues, participants were redirected to OPTT’s technical support team.

i-CBT With Stepped Care

Although all participants (56/56, 100%) had access to the i-CBT program, a designated care provider, and weekly feedback, only participants in the stepped care group received additional interventions as per the proposed stepped care model. The stepped care interventions were provided by their care provider or the team psychiatrist associated with their care as required. The structure of the stepped care model used in this study followed the 4 identified steps of a preventative stepped care model based on 10 randomized controlled trials [52]. These

four steps included the following: (1) watchful waiting, (2) self-help psychotherapy, (3) face-to-face psychotherapy, and (4) referral to specialists. The intervention that participants received was dictated by the participant's care team: the care provider and the team psychiatrist. This model initiated all participants at the lowest intervention of i-CBT beginning at session 1 and provided additional interventions beginning at session 5 after monitoring their progress through the first 4 sessions and obtaining 2 PHQ-9 scores as a quantitative assessment measure, to help with the decision (Textbox 1). Subsequently, an intervention could be added or changed in each session by the care team, following session 5. Beginning stepped care at session 5 allowed for a watchful waiting period as the initial step to understand the patient's symptoms better, as seen in preventative stepped care models for anxiety and depressive disorders [52]. The first 3 interventions, steps 1 to 3, are similar in content and care provider, but the delivery modality varies. These first 3 steps included varying intensities to care and effort required by the care provider. Step 4 differed from the first 3 steps in that the team psychiatrist was involved and the content of care in this intervention was different. Details of each step in the intervention are provided in the following sections.

Step 0: i-CBT Only

This intervention was considered to have the lowest intensity because the participant was provided with an i-CBT program for depression that is effective in treating MDD [49]. This was also known as the starting point for all participants. All participants began at step 0, which included completing the i-CBT program. In this step, no intervention was added to the participants' care, which allows for patient monitoring during a watchful waiting phase as they receive a low-intensity treatment [52]. Furthermore, many studies have control groups that encompass waitlist groups; however, more studies should focus on implementing i-CBT treatments as the control group for a wholesome review of the effects of stepped care models placed in these i-CBT programs. Therefore, step 0 mimics the procedure for the control group to allow for comparable effects between the 2 groups.

Step 1: i-CBT With Messaging

This intervention was the first added intervention following step 0 and included the addition of asynchronous check-in messages to the participant from their care provider on the OPTT platform. When the care provider sent the next session, they also sent a personalized message based on the message templates for that weekly session (Multimedia Appendix 3—sample message template). The message focused on addressing the participant and checking in with them by asking them how their week was so far. This intervention was a brief exchange between the participant and their care provider and a way to add active human support to the participant's care through direct messaging [53,54]. Upon receiving the participant's response, care providers acknowledged their experiences and reminded them to complete their next session.

Step 2: i-CBT With a Telephone Call

This intervention included a brief telephone call from the care provider for live, verbal support [55-57]. The call is limited to one 15 to 20-minute call during the week [58]. After sending the weekly session, care providers called the participant before the next session. The telephone call focused on asking participants how their week was and acknowledging the participant's experience (Multimedia Appendix 3—sample call template). Care providers also asked for updates regarding module completion for the week and reminded participants to submit their weekly homework. This template was similar to that of step-1 messages, except that it included direct verbal encouragement.

Step 3: i-CBT With a Video Call

This intervention included a brief, secure, Microsoft Teams video call from the care provider for live support and visual contact between the participant and care provider, in addition to verbal cues. The video call is limited to one 20 to 30-minute call during the week [22,59]. Care providers set up a video call with the participant before the next session. The video call focused on the participant's experience over the past week and how they are doing (Multimedia Appendix 3—sample message template). Care providers also encouraged participants to submit their weekly homework if they had not submitted yet. This template was similar to that of step-2 telephone calls and included direct, live encouragement in hopes to mimic a face-to-face setting.

Step 4: i-CBT With Psychiatrist Call

This intervention was the highest-intensity intervention provided in the stepped care model. This intervention included a web-based, one-on-one psychiatrist appointment with the team psychiatrist using Microsoft Teams. The psychiatrist discussed the participant's current challenges and potential options for the participant. This may include the possibility of adding medication to the participant's care based on the severity of the case. The selection of medication was based on the Canadian Network for Mood and Anxiety Treatments guidelines, and these guidelines were referenced to decide the first or second line of treatment for each participant [60].

When deciding the appropriate intervention, a participant's care was not always increased sequentially; instead, a participant who exhibited severe symptoms by the end of session 4 was provided a high step as opposed to step 1. The decision about which intervention the participant would receive was dependent on a few factors considered by the care providers. These included (1) changes in participant's PHQ-9 scores, (2) engagement with treatment, (3) progress in weekly goals, and (4) homework submission.

Changes in PHQ-9 Scores

PHQ-9 scores for each participant were collected every 3 weeks (ie, weeks 1, 4, 7, 10, and 13). The initial step-up decision was based on the first 2 PHQ-9 scores collected at weeks 1 and 4. If the participant's PHQ-9 score at week 4 increased by >2 points compared with week 1, the participant was stepped up in their care to either step 1 (message) or step 2 (phone call). During the subsequent weeks, changes in the subsequent PHQ-9

scores were compared with the previous week's score (ie, increase of >2 points) to determine whether an additional intervention was required [61].

Treatment Engagement

A systematic review including 35 studies showed that great treatment engagement significantly improved postintervention mental health outcomes [62]. Thus, participant engagement with treatment through the OPTT platform was another factor that was considered when determining which intervention would be most suitable for the participant. If the participant exhibited limited interaction with the platform (eg, read receipts for messages indicating that messages were not seen when notifying participants about session availability) or expressed difficulties in navigating the platform, the participant was provided with the step-2 (phone call) intervention. This limited engagement indicated that step 1 (messages) would be ineffective because the participant was not viewing the intervention. Therefore, the step-2 (phone call) intervention was identified as a more effective modality than the step-1 (messages) intervention. In addition, if participants did not respond to step-1 (messages) intervention, step-2 (phone call) interventions were provided as a follow-up.

Homework Submission

Participants' answers to weekly homework were also considered as a factor when deciding their care intensity [63]. If participants indicated ongoing depressive symptoms that have not changed within the past 2 sessions, they were stepped up in care intensity. Similarly, if depressive symptoms did not improve within the past 2 weeks and if they did not find the current intervention of steps 1, 2, or 3 helpful, step 4 (psychiatrist support) was provided to the participant. Finally, if the care provider sensed any form of suicidal or homicidal ideation or any severe depressive behavior at any point, step 4 (psychiatrist support) was referred to the participant.

Goal Progress

Beginning in session 1, participants were encouraged to set a goal that they would like to achieve by the end of the program. Each week, participants were prompted to complete a small step toward the goal to help them achieve it. The weekly progress toward this goal rather than absolute achievement was used as another indication of whether a step-up in intervention was required [64]. Studies have shown some support for goal planning in positive treatment outcomes for mental health care through assisting the therapeutic relationship by building rapport and allowing for open communication [65,66]. If participants struggled with the progression in their weekly small step for >2 consecutive sessions, they were stepped up in their intervention.

Data Analysis

A combination of descriptive statistics, independent *t* tests, and ANOVA were used to determine any difference between the primary outcomes across the 2 groups. All analyses were performed at a 1-tailed significance level of $\alpha=.05$. To determine any significant difference in the clinical questionnaire scores between the 2 groups, ANOVA was used. A 2×5

repeated-measures ANOVA was conducted for PHQ-9 scores, and a 2×3 repeated-measures ANOVA was performed for Q-LES-Q and QIDS scores. The time points at which meaningful differences appear were examined using the Bonferroni post hoc method. If Mauchly test of sphericity was significant, a Huynh-Feldt correction was applied. A chi-square test was conducted to compare treatment compliance across the 2 groups based on the number of participants completing all 13 sessions of the program. An independent samples *t* test was also performed to compare the number of sessions completed by participants in the 2 groups. In addition, an intention-to-treat (ITT) analysis was completed to assess the clinical outcomes of treatment on participants who withdrew prematurely. No intermediate analyses were performed, and all statistical analyses were completed after the trial. IBM SPSS Statistics (version 28) was used to conduct all analyses [67].

Results

Participants

Recruitment was initiated in May 2021 after receiving approval from the Queen's University Health Sciences and Affiliated Teaching Hospitals Research Ethics Board. Recruitment was conducted between May 2021 and June 2022, and 69 individuals were found to be eligible for this study. Table 2 displays the participant demographics. Of the 69 eligible individuals, 34 (49%) were randomized to the control group and only 28 (41%) initiated treatment. Of the 28 participants in the control group, 9 (32%) completed the full round of therapy (ie, 13 sessions of i-CBT). Of the 35 individuals randomized to the stepped care group, 28 (80%) initiated treatment. In the stepped care group, only 54% (15/28) of the participants completed all 13 sessions of the i-CBT program. Unfortunately, owing to some data collection errors, some questionnaire scores were not collected during the program, leading to some gaps in pretreatment, midtreatment, or posttreatment scores. These scores were treated as missing and were not imputed during data analysis. Figure 2 shows the participant flow.

Participants in the stepped care group were allocated to the stepped care intervention as follows: step 0 (8/28, 29%), step 1 (message; 2/28, 7%), step 2 (phone call; 15/28, 54%), step 3 (video call; 1/28, 4%), step 4 (psychiatrist consultation; 2/28, 7%). Overall, of the 28 participants, a total of 20 (71%) participants were stepped up in their care. This includes participants who dropped out prematurely and those who completed all 13 sessions. Of the 15 participants who completed all 13 sessions, 12 (80%) participants were stepped up in their care at some point during the program. Table 3 provides information regarding the number of occurrences of each step, and Table 4 provides a summary of each participant's progression in the stepped care program throughout the treatment, beginning at session 5. Currently, the 1-year follow-up period is ongoing, in which PHQ-9, QIDS, and Q-LES-Q scores are collected at the 3-, 6-, 9-, and 12-month follow-up periods after the treatment. The follow-up period is expected to be completed in November 2023.

Measured Outcomes

PHQ-9 Score

At baseline, for the participants who initiated the i-CBT program, the mean PHQ-9 score was 16.63 (SD 4.40; 27/28, 96%) for the control group and 17.75 (SD 5.33; 28/28, 100%) for the stepped care group, showing no statistically significant difference in pretreatment scores between the 2 groups ($t_{53}=-0.85$; $P=.40$; 95% CI -3.77 to -1.53). A 2×5 repeated-measures ANOVA determined that the mean PHQ-9 scores differed significantly between time points ($F_{4,80}=9.95$; $P<.001$; Figure 3), but there was no significant difference at

different time points between the 2 groups ($F_{4,80}=0.43$; $P=.78$; Figure 4). Post hoc analysis with Bonferroni adjustment revealed that PHQ-9 scores significantly decreased from pretreatment period (week 1) to the second time point (week 4; 4.554, 95% CI 1.264-7.843; $P=.003$), from pretreatment period (week 1) to the third time point (week 7; 4.973, 95% CI 1.904-8.042; $P<.001$), from pretreatment period (week 1) to the fourth time point (week 10; 4.384, 95% CI 0.862-7.906; $P=.008$), and from pretreatment period (week 1) to posttreatment period (week 13; 5.357, 95% CI 2.169-8.546; $P<.001$). All between-time point scores were statistically significant (Figure 3). A detailed breakdown of the results are summarized in Multimedia Appendix 4.

Figure 3. Estimated marginal means of Patient Health Questionnaire-9 (PHQ-9) scores at 5 treatment time intervals corresponding to sessions 1, 4, 7, 10, and 13, including both groups—internet-based cognitive behavioral therapy (i-CBT) only and i-CBT with stepped care. Error bars depict -2 or $+2$ SE.

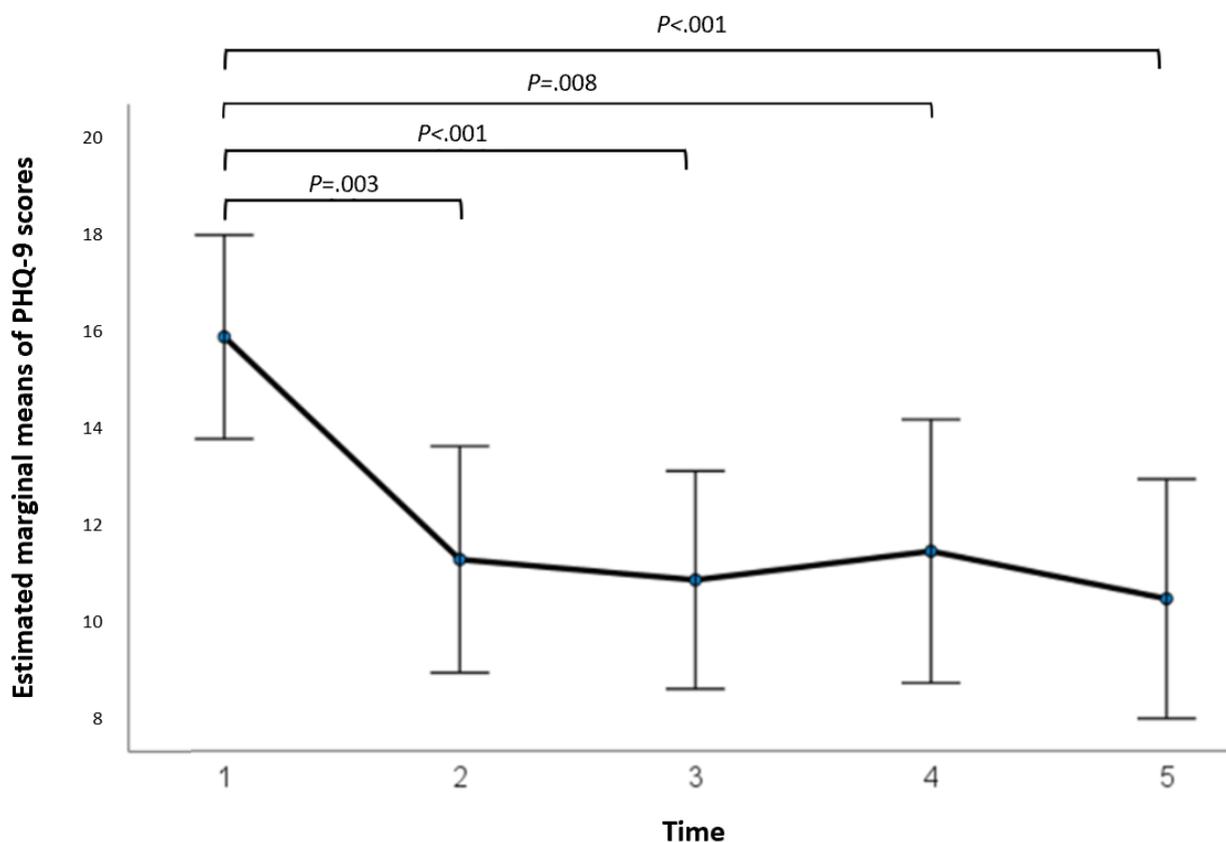

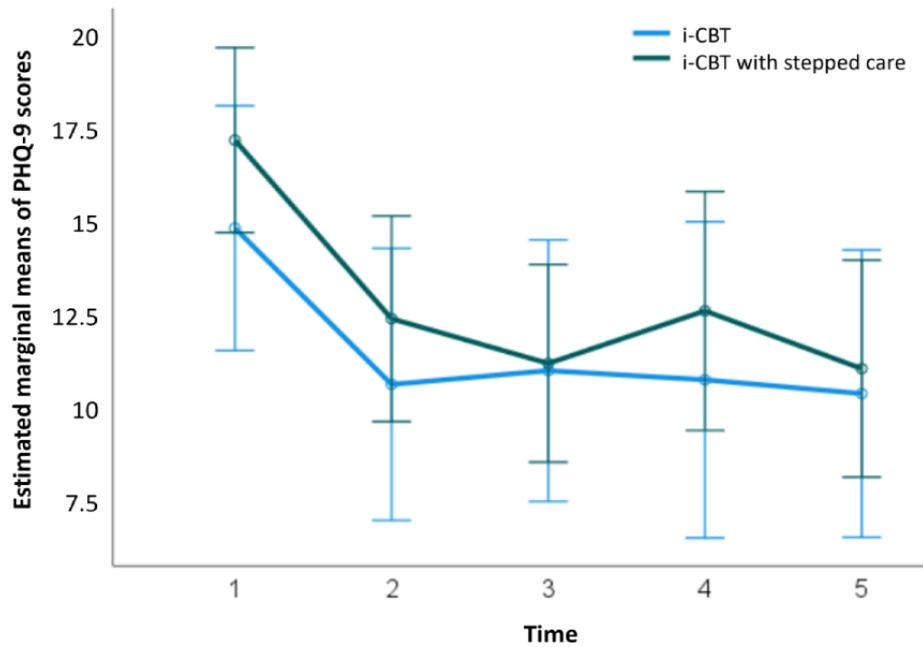

Figure 4. Estimated marginal means of Patient Health Questionnaire–9 (PHQ-9) scores at 5 intervals of treatment (sessions 0, 4, 7, 10, and 13), in both internet-based cognitive behavioral therapy (i-CBT; blue) and i-CBT with stepped care (green) treatment conditions. Error bars depict –2 or +2 SE.

QIDS Score

At baseline, for the participants who initiated the i-CBT program, the mean QIDS score was 14.62 (SD 4.64; 21/28, 75%) for the control group and 16.83 (SD 4.43; 23/28, 82%) for the stepped care group, showing no statistical significance in pretreatment scores between the 2 groups ($t_{42}=-1.61$; $P=.11$; 95% CI –4.97 to 0.55; independent samples t test). A 2×3 repeated-measures ANOVA determined that the mean QIDS scores differed significantly between time points ($F_{2,28}=5.73$; $P=.008$; Figure 5), but there was no significant difference at

different time points between the 2 groups ($F_{2,28}=3.05$; $P=.06$; Figure 6). Post hoc analysis with Bonferroni adjustment revealed that QIDS scores significantly decreased from pretreatment period (week 1) to posttreatment period (week 13; 4.12, 95% CI 0.76-7.47; $P=.02$). There was no significant difference between pretreatment period (week 1) and midtreatment period (week 7; 2.08, 95% CI –1.10 to 5.26; $P=.29$) or between midtreatment period (week 7) and posttreatment period (week 13; 2.03, 95% CI –1.34 to 5.41; $P=.37$; Figure 5). A detailed breakdown of the results are summarized in Multimedia Appendix 4.

Figure 5. Estimated marginal means of Quick Inventory of Depressive Symptomatology (QIDS) scores at 3 treatment time intervals corresponding to sessions 1, 7, and 13, including both groups—internet-based cognitive behavioral therapy (i-CBT) only and i-CBT with stepped care. Error bars depict –2 or +2 SE.

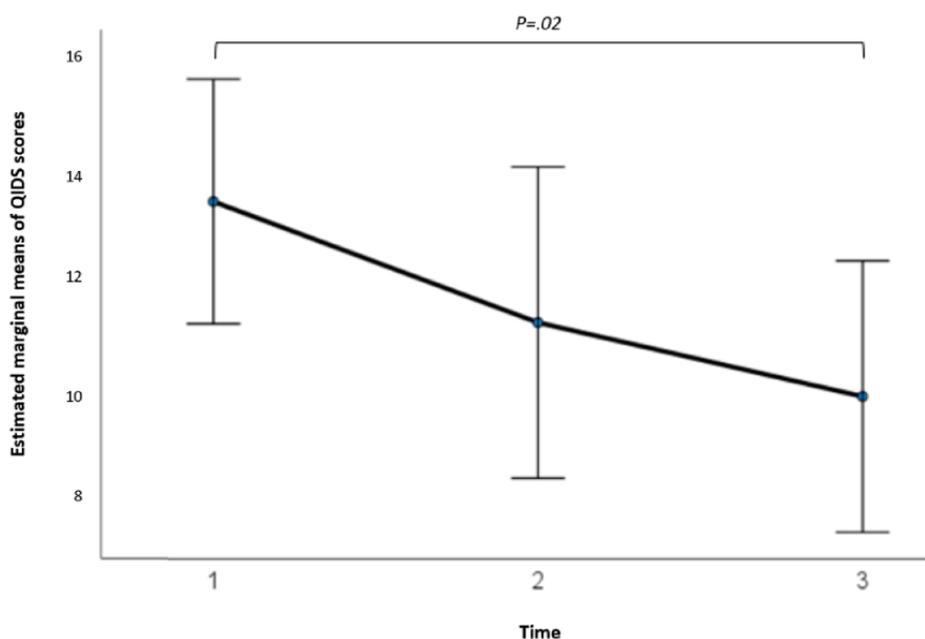

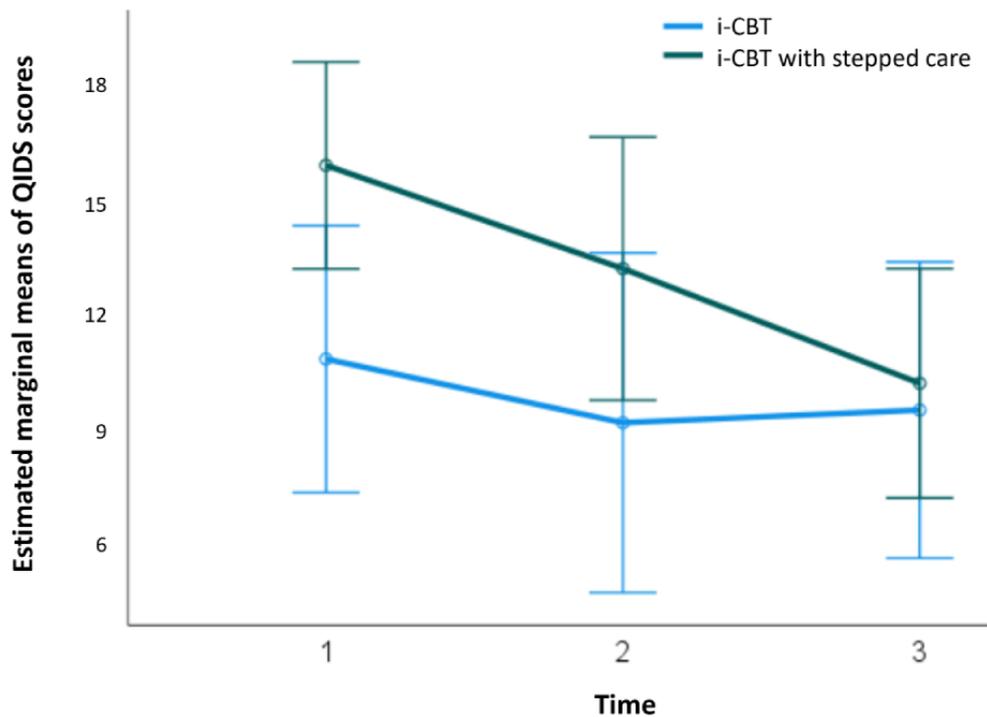

Figure 6. Estimated marginal means of Quick Inventory of Depressive Symptomatology (QIDS) scores at 3 intervals of treatment (sessions 0, 7, and 13), in both internet-based cognitive behavioral therapy (i-CBT; blue) and i-CBT with stepped care (green) treatment conditions. Error bars depict -2 or $+2$ SE.

Q-LES-Q Score

At baseline, for the participants who initiated the i-CBT program, the mean Q-LES-Q score was 36.88 (SD 7.80; 26/28, 93%) for the control group and 36.25 (SD 7.81; 28/28, 100%) for the stepped care group, showing no statistical significance in pretreatment scores between the 2 groups ($t_{52}=0.30$; $P=.77$; 95% CI -3.63 to 4.90 ; independent samples t test). A 2×3 repeated-measures ANOVA determined that the mean Q-LES-Q scores differed significantly between time points ($F_{2,38}=4.18$; $P=.02$; Figure 7), but there was no significant difference at

different time points between the 2 groups ($F_{2,38}=0.19$; $P=.83$; Figure 8). Post hoc analysis with Bonferroni adjustment revealed that Q-LES-Q scores significantly increased from pretreatment period (week 1) to midtreatment period (week 7; -5.50 , 95% CI -10.91 to -0.94 ; $P=.045$). There were no significant differences between pretreatment period (week 1) and posttreatment period (week 13; -4.77 , 95% CI -11.03 to 1.49 ; $P=.18$) and between midtreatment period (week 7) and posttreatment period (week 13; 0.73 , 95% CI -5.18 to 3.72 ; $P=.99$; Figure 7). A detailed breakdown of the results are summarized in Multimedia Appendix 4.

Figure 7. Estimated marginal means of Quality of Life Enjoyment and Satisfaction Questionnaire–Short Form (Q-LES-Q) scores at 3 treatment time intervals corresponding to sessions 1, 7, and 13, including both groups—internet-based cognitive behavioral therapy (i-CBT) only and i-CBT with stepped care. Error bars depict –2 or +2 SE.

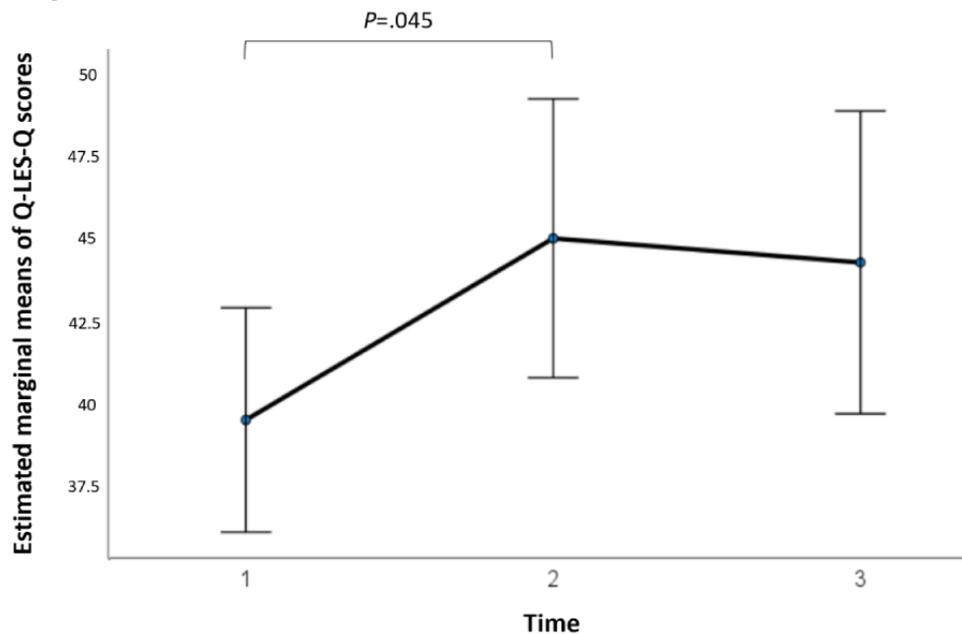

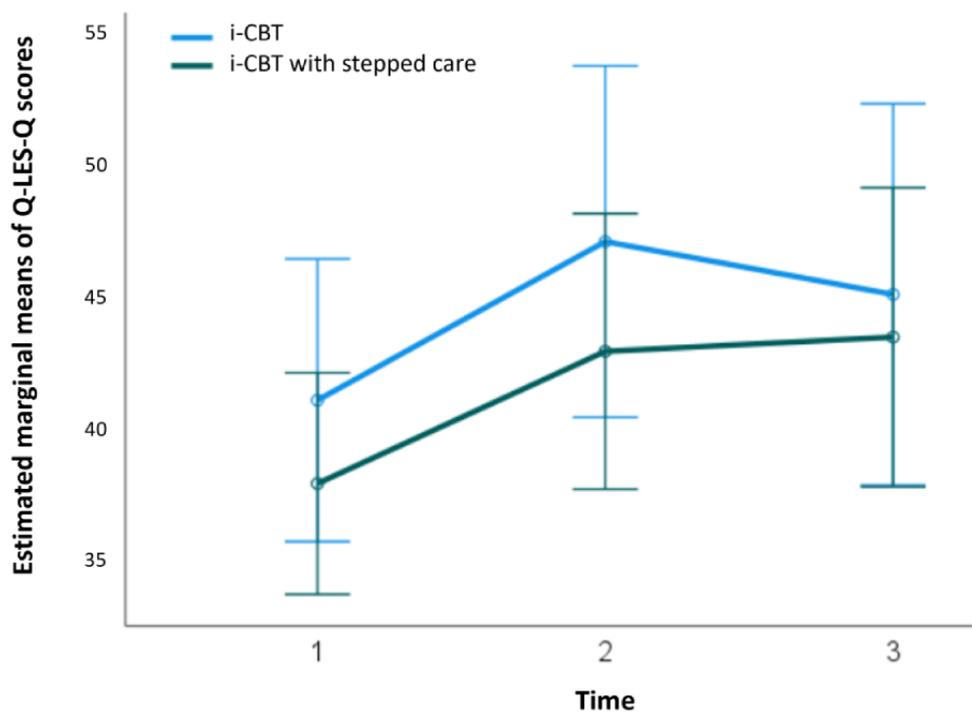

Figure 8. Estimated marginal means of Quality of Life Enjoyment and Satisfaction Questionnaire–Short Form (Q-LES-Q) scores at 3 intervals of treatment (sessions 0, 7, and 13), in both internet-based cognitive behavioral therapy (i-CBT; blue) and i-CBT with stepped care (green) treatment conditions. Error bars depict –2 or +2 SE.

Treatment Compliance

The proportion of participants completing the full round of therapy (ie, 13 sessions) was 32% (9/28) in the i-CBT-only group and 54% (15/28) in the stepped care group. There was no significant difference between the 2 groups regarding completion of the i-CBT program for depression ($\chi^2_1=2.6$; $P=.10$; chi-square test). An independent samples *t* test was conducted to determine whether there was a difference in the number of completed sessions between the i-CBT group and

the stepped care group for the individuals who had begun the program. The results indicate significant difference between the average number of sessions completed by participants in the i-CBT-only group (mean 7, SD 4.64; 28/28, 100%) and stepped care group (mean 9.41, SD 4.44; 28/28, 100%; $t_{55}=-2$; $P=.03$; 95% CI –4.83 to –0.002; independent samples *t* test). [Multimedia Appendix 5](#) shows the distribution of the sessions completed in each group.

ITT Analysis

A linear mixed model analysis was used to conduct the intent-to-treat analysis for each participant across the program. The group (i-CBT or stepped care) and evaluation time points were indicated as fixed factors. This analysis included participants who did not complete the full program and dropped out of the study before completion. As seen previously, there was significant change in PHQ-9 scores across the time points ($F_{4,48.79}=10.98$; $P<.001$), but there was no significant difference between the 2 groups ($F_{1,107.07}=2.79$; $P=.10$). In addition, for the QIDS scores, there was significant change in scores across the time points ($F_{2,41.08}=8.53$; $P<.001$), but no significant difference between the 2 groups ($F_{1,54.44}=2.72$; $P=.10$). Q-LES-Q scores imitated a similar pattern, with significant difference in scores across the time points ($F_{2,44.99}=9.36$; $P<.001$), but no significant difference between the 2 groups ($F_{1,60.75}=3.28$; $P=.08$).

Discussion

Principal Findings

This study evaluated the effectiveness of an i-CBT program with and without stepped care for depression among adults. The results of this study indicate that the proposed stepped care model was not significantly better in reducing depressive symptoms, as measured by PHQ-9 and QIDS, than the i-CBT program alone. Some previous studies have also found no significant differences between stepped care treatments and care as usual in improving depressive symptoms [52,68]. Ho et al [52], who reviewed stepped care for both depressive and anxiety disorders, found that stepped care treatment was significantly better in improving anxiety symptoms but did not find any significant difference in reducing depressive symptoms. This suggests some differences in the populations and the sensitivity of the stepped care structure in addressing different mental health issues. When viewing the results of both groups together, this study indicated that the i-CBT program itself was effective in significantly reducing depressive symptoms from pretreatment period to posttreatment period, as measured by the PHQ-9 and QIDS; however, there were no significant differences in the reduction of depressive symptoms between the 2 groups. The stepped care group did not show to be significantly better in reducing depressive symptoms than the i-CBT group. This finding is consistent with other studies of i-CBT programs, which show improvements in depressive symptoms for mild to moderate depression [69,70]. This also reinforces the efficacy of the i-CBT program for depression on OPTT used in this study, based on similar results from previous clinical trials using this program [47,49].

Furthermore, the results suggest that the i-CBT program indicated significant difference in the quality of life, as measured by Q-LES-Q; however, post hoc analysis revealed that overall, there were no significant differences before and after treatment in improving the quality of life. Significant difference was observed between pretreatment period and midtreatment period, which may suggest that the i-CBT program had the greatest impact on improving quality of life in the early stages of the

program. No significant differences were observed between the i-CBT and stepped care groups. A systematic review and meta-analysis reviewed 3 studies of the effects of i-CBT on the quality of life and found inconclusive evidence of i-CBT compared with in-person outcomes [71]. We found no significant difference between the effects of i-CBT with stepped care and i-CBT without stepped care on the quality of life.

Although the completion rates between the 2 groups were not significantly different, participants in the stepped care group significantly completed, on average, 2 more sessions of therapy than those in the i-CBT group. The increase in the number of completed sessions may have been caused by the added support offered in the stepped care group. This is consistent with previous studies that report improvement in treatment adherence in mental health treatment with additional interventions in care [21,28,63]. Specifically, phone and video calls assist with keeping patients in care compared with in-person treatment [36]. Compared with in-person treatment, receiving care for depression over the phone [56,72] or via video [22] is associated with high completion rates and few dropouts. Further studies are required to decipher whether the stepped care group's high completion rate of sessions is associated with better treatment outcomes than the i-CBT group.

Furthermore, [Multimedia Appendix 5](#) shows that although participant dropout occurs uniformly across the first 10 sessions in the stepped care group, most participants (19/28, 68%) in the i-CBT group dropped out in the first half of the program (ie, first 7 sessions): 25% (7/28) of participants in the stepped care group dropped out of the program before the midpoint of treatment (ie, session 7) and 68% (19/28) of participants in the i-CBT group. Previous studies have noted that most patients drop out of treatment programs after 2 to 4 sessions [16,31,73]. During this time, participants were provided with i-CBT care only in both groups (additional interventions for the stepped care group were introduced at session 5 after monitoring their PHQ-9 scores and interaction with the i-CBT program); however, introducing a possibility of intervention soon in the stepped care group may have helped participants who were indicated as an early dropout (ie, before session 5) complete more sessions. Concurrently, it is noteworthy that the i-CBT program's 13 sessions were not completed by several participants (32/56, 57%) in both groups. This is consistent with previous studies that reveal high dropout rates in depression i-CBT programs. Compliance is generally a challenge for i-CBT programs, with dropout rates averaging approximately 32% and ranging between 0% and 75% [26,37], whereas traditional CBT dropout rates are approximately 25% on average, ranging between 0% and 68% [74]. However, another study found that additional human support results in a large effect size regarding the efficacy of i-CBT ($g=0.673$) than providing no additional support ($g=0.239$) [34]. Thus, it was expected that the stepped care group would exhibit significant improvements following treatment, but this was not observed in this study. This may be owing to the nature of the study design, as the i-CBT group received some support during the treatment through the homework feedback and did not encompass a truly no-support intervention. Upon reviewing participant progression in the stepped care model ([Table 4](#)), it was seen that on average, most

participants (13/28, 46%) spent their time in step 0 of the stepped care model, which mimics the control group (i-CBT only). This may be a factor in the observed nonsignificant differences between the 2 groups because not many participants were stepped up in their care across treatment. Moreover, the small sample size may have influenced the outcomes. A previous study has shown that patients who terminate CBT prematurely show high symptom severity compared with patients who complete therapy, but the 2 groups did not vary in the rate of symptom change [75]. This suggests that the increase in symptom severity may arise from completing few sessions of treatment in the dropout group compared with the completer group and explains the differing results observed between the 2 groups as dropout was high. Given the effectiveness of i-CBT treatment and the high dropout rates, it is important to assist patients in completing more sessions by providing sufficient resources and care. Our proposed stepped care model assisted participants in completing a great number of sessions. Stepped care has been associated with high treatment satisfaction, which may have assisted in participants completing more sessions in this group [68,76]. Future studies should examine the variables that may be responsible for treatment attrition in i-CBT programs and devise methods to raise the rates of treatment engagement and completion.

Limitations

It is important to consider further limitations of this study. This includes the relatively small sample size; observed sex imbalance, with 61% (34/56) women in the study (approximately 15% more women in the i-CBT group compared with the stepped care group); and lack of long-term follow-up, which is currently ongoing. It is important to note that the sample size for analysis of the i-CBT group was smaller than that of the stepped care group. In addition, the participants in this study may not be representative of the general population, as they were predominantly women, English speaking (owing to the limitations of the i-CBT program), employed full time, and recruited from a specific clinical setting of self-referrals and clinics limited to Kingston, Ontario (Table 2). Missing data were also a challenge that affected the total sample size. A large portion of the data was unavailable owing to collection errors and dropouts (Figure 2). We attempted to address this issue by using ITT analysis and observed similar results with no significant differences between groups but observed significant differences across various time points for PHQ-9, QIDS, and Q-LES-Q scores.

This study was not specifically designed to investigate the effects of the different treatment interventions in the stepped care group and how they influenced the results. In hindsight, using 4 different factors to decide about the stepped intervention results in increased variability in the stepped care decision and limits our ability to decipher the effectiveness of the approach. Most stepped care models use clinical questionnaire scores, such as the PHQ-9 score, to decide when to step up or step down care [68,76-78]; however, our study did not include strict cutoff guidelines and instead adopted a subjective monitoring approach of PHQ-9 scores as one of the evaluating factors. Changes in PHQ-9 scores (scale ranging from 0-27) and homework submission (submitted or not submitted) can be quantized

predictors for stepped care; however, monitoring engagement with the OPTT platform and goal progression are variables that are multifactorial and are subject to interpretation. This design prevented us from making conclusions about a best-fit intervention model. Furthermore, beginning the stepped care interventions in session 5 allowed for a watchful waiting period that allowed reflection about patient status to determine the correct intensity of care if they did not improve with a low-resource intervention (ie, i-CBT). However, this may be a limitation of the proposed stepped care model, as the waiting period may be harmful because it may delay optimal treatment [68]. With a small sample size, it is difficult to analyze the effects of these deciding factors. Future studies need to be conducted to explore the effects of the individual stepped interventions provided in this study and any potential relationships among the modalities of care.

Therapeutic alliance in psychotherapy is another significant factor in predicting treatment outcomes [79-81]. The i-CBT-only group had limited interaction with their assigned care provider, and the ability to build rapport with participants was limited. In the stepped care group, participants were potentially able to gain a deep connection with their care provider, beginning in session 5, based on the intervention provided to them. Therapeutic alliance follows two important phases: (1) initial alliance development, usually occurring within the first 5 sessions, and (2) challenging the patient more actively, which can cause strain to the therapeutic relationship [79]. With stepped care interventions being provided in session 5, the first phase seems to be neglected and may affect the potential relationship, thus the structure of the program hinders participants from achieving the desired treatment outcome and reducing their depressive symptoms. Some studies demonstrate that a positive outcome is more predictive by the quality of the alliance rather than the type of the intervention [79,82-84]. In this case, the quality of the alliance was affected by the limited interaction with the care provider and may reflect one of the limitations of online therapy. Some studies found that building therapeutic alliances face to face is significantly more effective than online psychological treatments [85-89]. In contrast, other studies have found the opposite and report no correlation between the therapeutic alliance and treatment outcomes in digital interventions [90-93]. Further studies are required to better understand the characteristics of therapeutic alliance in digital contexts [25,94]. It would also be interesting to assess participant and care provider opinions about their therapeutic alliance during the study to better understand this limitation.

Conclusions

This study provides further evidence that i-CBT is effective for treating depressive symptoms. However, the study showed no significant evidence that the proposed stepped care model was more effective than i-CBT alone. The stepped care model allowed participants to complete 2 more sessions on average than the i-CBT-only group, indicating that stepped care is an effective method for guiding patients to treatment completion. Future studies should examine the long-term effects of such interventions and the efficacy of specific stepped care interventions in large and more diverse groups. To improve the design and implementation of such a model, studies might also

investigate the processes through which stepped care quality of life. interventions reduce depression symptoms and enhance the

Acknowledgments

The authors would like to thank all the care providers involved in this program for ensuring that participants were supported throughout the study. The authors are also grateful to the participants of this study who provided their time and trust in the process to help the authors complete and further investigate this online cognitive behavioral therapy approach.

Multimedia Appendix 2

Sample of the e-cognitive behavioral therapy program for depression used in the study, showcasing session 5.

[PDF File (Adobe PDF File), 3875 KB - [mental_v11i1e51704_app2.pdf](#)]

Multimedia Appendix 3

Feedback templates for e-cognitive behavioral therapy used throughout the study by care providers including feedback for session homework and live interactions between the care provider and participants.

[DOCX File , 20 KB - [mental_v11i1e51704_app3.docx](#)]

Multimedia Appendix 4

Statistical analysis results.

[DOCX File , 31 KB - [mental_v11i1e51704_app4.docx](#)]

Multimedia Appendix 5

The frequency of participants' last completed sessions organized by 2 groups—internet-based cognitive behavioral therapy (i-CBT) only and i-CBT with stepped care.

[PNG File , 62 KB - [mental_v11i1e51704_app5.png](#)]

Abstract

Background: The widespread occurrence and devastating impact of adolescent depression warrant health service research focused on feasible and acceptable digital health tools to supplement evidence-based intervention (EBI) efforts, particularly in the context of shelter-in-place guidelines disrupting youth socialization and service use in the wake of the COVID-19 pandemic. Given the promise of SMS text message interventions to enhance EBI engagement, our team developed the HealthySMS system as an adjunct to one of the most empirically supported interventions for adolescent depression: cognitive behavioral therapy (CBT) group services. The system sends daily SMS text messages requesting responses assessing mood, thoughts, and activities; weekly attendance reminder messages; daily tips about adherence (eg, a prompt for activity completion); and personalized responses based on participants' texts.

Objective: This study aims to evaluate the feasibility and acceptability of HealthySMS in a real-world setting and explore potential mechanisms of change in EBI engagement, before evaluating the system's impact on adolescents' group CBT engagement and, ultimately, depression outcomes.

Methods: Over the course of 2020, we invited all 20 adolescents receiving CBT group services for depression at an outpatient psychiatry clinic to enroll in our HealthySMS study; ultimately, 17 (85%) adolescents agreed to participate. We tracked participant initiation and engagement with the HealthySMS system as well as the content of SMS text message responses to HealthySMS. We also invited each participant to engage in a semistructured interview to gather additional qualitative inputs on the system.

Results: All (n=17, 100%) research participants invited agreed to receive HealthySMS messages, and 94% (16/17) of the participants maintained use during the first month without opting out. We uncovered meaningful qualitative themes regarding the feasibility and acceptability of HealthySMS, as well as its potential impact on EBI engagement.

Conclusions: Taken together, the results of this pilot study suggest that HealthySMS adjunct to adolescent CBT group depression services is feasible and acceptable, as evidenced by high rates of HealthySMS initiation and low rates of dropout, as well as meaningful themes uncovered from participants' qualitative feedback. In addition, the findings provide evidence regarding iterative improvements to the HealthySMS system and research protocol, as well as potential mechanisms of change for enhanced EBI engagement and, ultimately, adolescent depression outcomes, which can be used in future effectiveness research.

Introduction

Background

Depression is a major public health concern for adolescents [1-3]; it is a risk factor for mental health problems that occur in adults, medical illnesses, disability, substance abuse, and suicide [2-6]. Evidence-based efforts to improve adolescent depression and related risks became more imperative during the COVID-19 pandemic owing to concerns about adolescents' mental health deterioration in the context of shelter-in-place (SIP) guidelines causing substantial educational and social disruptions [7-10]. Further, most in-person services were halted during the implementation of SIP guidelines, rapidly necessitating a transition to telehealth and digital health (dHealth) supports [7,11-14]. In response, the need for pilot feasibility and acceptability testing of dHealth tools targeting adolescent depression in real-world settings became glaringly apparent. Such efforts would provide an essential first step toward testing the effectiveness of dHealth tools for adolescent depression. The impact of this work would extend beyond the initial COVID-19 SIP context, given that research suggests that many systems will and should continue using telehealth and dHealth supports in the foreseeable future [13,15,16], which may be particularly beneficial in reducing disparities for historically marginalized populations [15].

Evidence-Based Intervention for Adolescents With Depression

There are several effective evidence-based interventions (EBIs) for adolescent depression [17-19]. The most well-supported psychosocial approach is cognitive behavioral therapy (CBT [18,19]), which targets unhelpful thinking patterns and the avoidance of goal-directed and social activities, which are characteristic of depression [20-22]. CBT can be effectively delivered via a group format [23], demonstrating efficacy similar to that of individual CBT in decreasing depression in a more cost-effective modality [24]. CBT can also be delivered electronically (electronic CBT [eCBT]), enhancing accessibility by eliminating the requirement for patients to travel for in-person services [25-29]. The potential benefits of electronically delivered EBIs became increasingly evident in the context of the implementation SIP guidelines during the COVID-19 pandemic, which prohibited many individuals from receiving in-person mental health treatment. Importantly, our society may experience future SIP guidelines during COVID-19 surges, safety lockdowns, or natural disasters in response to climate change. Fortunately, recent research supports the effectiveness and efficacy of eCBT in decreasing depression [25-29].

Despite the promising efficacy research supporting CBT as an EBI for adolescent depression, the effect sizes are heterogeneous and low, demonstrating room for improvement [23,30]. Optimal treatment of adolescent depression requires patient engagement, including the initiation of treatment after referral, the attendance

of sessions, the completion of homework between sessions, and the continued engagement in treatment (ie, getting the whole "dose" of treatment [31]). Thus, poor initiation, poor adherence, and treatment dropout are barriers to effective services in real-world settings and are known to mediate treatment outcome [31]. A meta-analysis of EBIs concluded that the average treatment dropout rate is approximately 29% and that patients with depression are at a higher risk for dropout [32]. Treatment dropout appears particularly pronounced among youths and in web-based mental health interventions; therefore, efforts to enhance engagement with eCBT among youth populations are especially called for [33].

SMS Text Message Interventions as Automated dHealth Supports Aiming to Enhance EBI Engagement

There is a strong scientific premise and public health call to develop and evaluate dHealth supports adjunct to EBIs that are easy to implement, efficient, and sustainable. Using SMS text messages is a promising approach aiming to enhance adolescent EBI engagement by making use of a tool that is readily available and widely used by adolescents. The use of mobile phones is ubiquitous among adolescents, and SMS text messages are used at high rates. As of 2015, more than 85% of adolescents across races and ethnicities had access to a cell phone, and 90% of them used cell phones to send SMS text messages [34]. In fact, two-thirds of adolescents reported that they are more likely to use their cell phones to text rather than talk to friends, and a typical adolescent in the United States sends ≥ 30 SMS text messages each day [34]. Importantly, in mobile health (mHealth) research, youths report high satisfaction and readily engage with technology [35-37]. In addition, digital technology allows for the automation of SMS text messages; thus, an SMS text message intervention leveraging automation should not add to providers' burden, making it a more sustainable and efficient services intervention.

SMS text messaging interventions have several advantages over other forms of dHealth interventions, such as app-based and website-based interventions, and are particularly well suited to improve engagement. SMS text messages allow for a more equitable delivery of care, given that they can reach anyone with a phone and do not rely on smartphone ownership or internet access, which are affected by socioeconomic, racial, and ethnic disparities [38]. In addition, although dHealth interventions have demonstrated promise, web-based and mobile app-based interventions are subject to more difficulties with engagement, such as problems with adherence and dropout [26,39].

Some dHealth SMS text message interventions were designed as stand-alone supports (eg, those in the works of Aguilera et al [40] and Bendsten et al [41]; MacDougall et al [42] conducted a scoping review of SMS text message-delivered adolescent mental health interventions); however, there may be unique benefits to SMS text message interventions designed to

supplement EBIs and enhance treatment engagement. There are many effective examples of adjunctive SMS text message interventions for disease management and health behavior change (eg, smoking cessation and diabetes management [43]), including SMS text message interventions for adolescents [44]. In the emerging literature on SMS text message interventions, adolescents generally react favorably and show good compliance [35,42,45,46]. Pilot research on integrating SMS text messages into individual CBT has also demonstrated encouraging results [47].

Given the promise of SMS text message interventions to enhance EBI engagement, our team developed the HealthySMS system as an adjunct to group CBT depression services. HealthySMS sends customized SMS text messages to participants, inquiring about mood as well as reminding them to attend CBT and practice strategies learned during group treatment. For safety, adolescent SMS text message responses are monitored for keywords or phrases that could indicate whether someone is expressing suicide risk; providers are sent immediate alerts if the system is triggered by an adolescent SMS text message response with these keywords or phrases. Safety keyword triggers are important features of any automated dHealth system implemented in real-world settings to keep participants safe and providers informed; in addition, this feature may be particularly helpful during the implementation of SIP guidelines, given the probable decrease in adolescent safety monitoring from other settings, such as schools. The addition of HealthySMS to CBT for adults with depression in a public sector treatment setting was associated with an increased number of sessions attended and a longer duration of treatment [48]. The mood ratings sent by adults through HealthySMS also predicted attendance [49]. Thus, adding HealthySMS to EBIs for adolescent depression may be a promising change to existing services, targeting increased engagement and, ultimately, improving outcomes.

This Study

As a first step in the process of implementing and evaluating the HealthySMS system adjunct to the most evidence-based treatment for adolescent depression (ie, CBT), we conducted a feasibility pilot study in an outpatient clinic embedded within an academic medical center's department of psychiatry and behavioral sciences. Our primary objectives were to investigate the feasibility and acceptability of HealthySMS in a real-world setting and explore potential mechanisms of change in EBI engagement, before evaluating the system's impact on adolescents' group CBT engagement and, ultimately, depression outcomes. We also aimed to monitor the HealthySMS safety keyword alert triggers and provider responses to inform system and research protocol adjustments before future HealthySMS

research. This multiphase design featuring a preliminary feasibility pilot to inform decisions about future effectiveness testing is aligned with the Medical Research Council framework [50,51], which has been prolifically used in mental health and dHealth intervention research. We predicted the following hypotheses:

1. Hypothesis 1: most adolescents invited to use HealthySMS (ie, $\geq 75\%$) would initiate and maintain use without opting out during their group CBT experience.
2. Hypothesis 2: adolescents enrolled in HealthySMS would display high rates of engagement with the SMS text message system (ie, $\geq 50\%$ response rate).
3. Hypothesis 3: our team would uncover meaningful qualitative themes from participants' SMS text message responses and semistructured interviews about the feasibility and acceptability of HealthySMS to inform iterative system and research protocol improvements supporting future HealthySMS effectiveness research.
4. Hypothesis 4: our team would uncover meaningful qualitative themes from participants' SMS text message responses and semistructured interviews about the potential impact of HealthySMS on EBI engagement to inform decisions on which mechanisms of change to evaluate in future HealthySMS effectiveness research.

Methods

Participants

Participants were adolescents aged 13 to 18 years. They were recruited from the University of California San Francisco (UCSF) Department of Psychiatry and Behavioral Sciences Child and Adolescent Services clinic between December 2019 and September 2020. Adolescents were eligible to participate if they were enrolled in the clinic's group CBT for depression running from January 2020 to September 2020.

Of the 20 eligible adolescents who started the group CBT for depression, 17 (85%) agreed to participate in the study. Participant characteristics are listed in [Table 1](#). Briefly, the average age of the participants was 15.4 (SD 1.5) years, and most participants (15/17, 88%) were diagnosed with major depressive disorder. Most participants (12/17, 71%) had engaged in prior mental health care. Moreover, 18% (3/17) of the participants had a history of at least 1 suicide attempt, with most participants (11/17, 65%) reporting suicidal ideation in the past year. A little more than half (9/17, 53%) of the participants engaged in concurrent individual therapy, family therapy, or a combination.

Table 1. Participants' demographic and clinical information (N=17).

	Values
Demographic information

Concurrent therapy^a	
Individual CBT ^h	6 (35)
Family therapy	4 (24)
None	8 (47)
Concurrent medication management	15 (88)

^aResponse options are not mutually exclusive.

^bIOP: intensive outpatient treatment.

^cPHP: partial hospitalization program.

^dSI: suicidal ideation.

^eNSSI: nonsuicidal self-injury.

^fIEP: individualized education plan.

^gADHD: attention-deficit/hyperactivity disorder.

^hCBT: cognitive behavioral therapy.

Of note, our research protocol did not make any changes to how the real-world clinic provided services. Adolescents were not incentivized to start treatment, attend sessions, or complete their homework; they only were incentivized for completing additional research tasks (see below). Adolescents in the clinic could be engaged in individual therapy, family therapy, or both while attending group treatment.

Ethical Considerations

All study procedures were approved by the UCSF Institutional Review Board (reference number 255820). When participants were minors (ie, age <18 years), their parent or legal guardian completed informed consent and they completed assent procedures; 18-year-old participants completed informed consent procedures. As part of these procedures, participants (and their parents or legal guardians, if applicable) were informed that their information would be kept private and housed on a secure UCSF server only accessible to the study team; they were informed that participants would be compensated with a US \$30 gift card for attending the interview).

CBT Group Intervention

The Cognitive Behavioral Therapy for Depression Group for Adolescents (CBT-D) consists of three 4-week modules on thoughts, activities, and people (ie, 12 group sessions in total). It is based on the Building Recovery by Improving Goals, Habits, and Thoughts (BRIGHT) group CBT manual for depression for adults developed by Miranda et al [52], which was subsequently adapted for adolescents with a diagnosis of major depression or persistent depressive disorder. The thought module involves cognitive interventions with a focus on awareness of helpful and harmful thoughts, the activity module focuses on pleasant activities and behavioral activation, and the people module encourages group members to improve relationships and evaluate the impact of positive and negative social relationships on mood. The sessions are structured with an initial homework check-in followed by a didactic discussion on the covered topic, an interactive discussion led by 2 group providers, and the setting of homework goals related to skill use. In this study, the first 7 group sessions were held in person; the remainder were held via the Health Insurance Portability and Accountability Act-compliant Zoom (Zoom Video

Communications, Inc) platform after SIP orders were implemented in March 2020.

The HealthySMS System

We used the Health Insurance Portability and Accountability Act–compliant, web-based texting platform called HealthySMS, developed by our team member (AA), to send and receive SMS text messages, administer weekly surveys, and track attendance. HealthySMS sent four types of automated SMS text messages to participants: (1) daily mood prompts asking participants to rate their mood and reflect on their mood, thoughts, and behavior (“[First name], what is your mood right now on a scale of 1 to 9 (9 being best)? Please respond with a number and a message about what you are doing or thinking”); (2) personalized and reinforcing responses to 20% of participants’ mood ratings (ie, encouraging the participants to engage in behavioral activation in response to a low mood rating and reinforcing the participants in response to a high mood rating); (3) daily reminders about the concepts and skills learned during the corresponding CBT module for that month; and (4) weekly reminders to attend and come prepared to CBT sent the day before the group session. The participants could opt out of receiving SMS text messages at any point by texting “stop.”

Our clinical research team oriented adolescent participants to the HealthySMS system. We also oriented providers to the SMS text messages and HealthySMS web-based provider dashboard, which visualizes client responses to the SMS text messages, including graphs of mood ratings. HealthySMS monitors participants’ SMS text message responses and alerts providers to words and phrases that may correspond to suicidal behaviors (eg, “die,” “kill,” and “cut”), and providers were trained on how to respond to these alerts in alignment with existing clinic policies and procedures.

Measures

Participants’ Demographics and Clinical History

The participants were asked to complete a demographic survey before beginning group CBT. CBT-D providers recorded psychiatric diagnoses and treatment history information for each participant, including other therapy or medication management services, based on their evaluation and review of the medical record.

HealthySMS Engagement

We tracked the number of participants who were invited to receive HealthySMS messages, as well as those who agreed to initiate receipt of HealthySMS messages. We also tracked the number of participants who texted “stop” to opt out of SMS text messages before ending participation in the group, as well as how long each participant received the SMS text messages before opting out. We measured engagement with the HealthySMS messages by tracking the number of mood ratings that participants texted in response to mood rating request messages.

HealthySMS Safety Keyword Triggers

We tracked the number and content of participant SMS text message responses that were flagged for the risk of suicide ([Multimedia Appendix 1](#) provides the trigger words). We also kept observation notes about the provider responses.

Qualitative Feedback

We collected qualitative feedback in several ways. We tracked responses to our monthly SMS text message prompts to participants asking, “What is the most positive part of receiving these text messages?” and “What do you not like about receiving the text messages?” We also invited all adolescent participants to share feedback in a semistructured interview after their CBT-D completion with an incentive of US \$30 Amazon gift card. The interviews were moderated by a member of our clinical research team who followed a semistructured guide containing the study objectives to explain, questions to pose, and prompts to use when needed. Specifically, we explained that researchers hoped to obtain information about mHealth interventions such as HealthySMS and group CBT services for depression. Next, we asked for general feedback about the HealthySMS system and then specifically asked about different aspects of HealthySMS, such as the mood prompts, responses to mood ratings, and group reminders. We also showed participants a list of the HealthySMS texts and asked for feedback on their impact, content, and phrasing. [Textbox 1](#) lists the interview questions and prompts. Each interview lasted between 19 and 45 (mean 32, SD 8.8) minutes, with the length depending on the amount of details provided by the respondents.

Textbox 1. Qualitative semistructured interview questions and prompts.

How did you like the LET'S TEXT! message program overall?

- Was there anything that made it difficult for you to receive the messages? For example, how did you like: the timing of the messages, the amount of messages, the phrasing of messages?
- Was there anything that made it difficult for you to respond to the messages? For example, how did you like: the timing of the messages, the amount of messages, the phrasing of messages?
- Is there anything about it you would suggest we change?

How did you like the LET'S TEXT! Mood Prompts and Responses? (after general feedback was given, participants were shown the list of printed texts for specific feedback on this question)

- What did you think worked well?
- What was difficult or did not go well?
- Is there anything you would change?
- Did these messages change your mood, thoughts, or behavior?

How did you like the LET'S TEXT! Skill Practice Reminders? (after general feedback was given, participants were shown the list of printed texts for specific feedback on this question)

- What did you think worked well?
- What was difficult or did not go well?
- Is there anything you would change?
- Did these messages change your mood, thoughts, or behavior?
- For example, did you need more/less help with any of the skills; was the purpose of the reminders clear; -were the messages too few/many; were the reminders relevant to your goals; were they phrased appropriately?

How did you like the LET'S TEXT! Group Reminders?

- Did these messages change your mood, thoughts, or behavior?

Some teens find...

- ...it easier to participate if they feel: comfortable, respected, and understood by the group members and group leader attached to the messages. How was your relationship with the group and group leader and did that affect your experience with the text messages?
- ...that the messages help them become more active. Do you think your activity completion was impacted by the text messages?
- ...the messages help them go to group and participate more often and/or effectively. How was your group engagement and did that change with the text messages?
- ...the messages are reinforcing and help them practice the group skills more often and/or effectively. How was your practice of the group skills and did that change with the text messages?

Is there ANYTHING ELSE you would like to share that we haven't asked you?

Data Analytic Plan

We analyzed quantitative data on participant characteristics, HealthySMS engagement, and safety keyword triggers using descriptive statistics in SPSS (IBM Corp). We calculated the SMS text message response rates by dividing the number of responses by the number of SMS text messages received for mood ratings.

We analyzed the qualitative data in a multistep process using thematic analysis principles [53]. First, we developed a hierarchical coding system based on recurrent concepts that we uncovered when conducting the qualitative interviews and in consideration of the related theoretical literature. Next, members of our research team reviewed the qualitative message content and interview transcriptions to collaboratively refine recurrent

themes while iteratively updating the coding system. Our team selected exemplary quotes for each theme.

Results

Hypothesis 1

Our first hypothesis was that most of the adolescents (ie, >75%) invited to HealthySMS would initiate and maintain use. All participants who agreed to the research study (n=17, 100%) opted to enroll in the HealthySMS system and initiate the receipt of messages upon starting CBT-D; 94% (16/17) of the participants maintained use during the CBT-D group experience. Only 1 (6%) participant opted out of the SMS text messages by texting "stop" 30 days after initiation.

Hypothesis 2

Our second hypothesis was that adolescents enrolled in HealthySMS would display high rates of engagement with the SMS text message system (ie, $\geq 75\%$ response rate). As shown in Table 2, the HealthySMS response rate varied among participants. The average response rate to daily mood ratings

was 61%, with a range of 0.00 to 1.77 responses per message. Of the 17 participants, only 1 (6%) participant did not respond to any of the SMS text messages prompting mood ratings, and 2 (12%) participants responded multiple times to several prompts (indicated by a response proportion >1). Most participants (10/17, 59%) responded to $>50\%$ of the daily mood rating prompts.

Table 2. HealthySMS engagement.

Participant	Proportion of responses to mood ratings	Weeks until opting out
1	0.04	N/A ^a
2	0.16	N/A
3	0.30	N/A
4	0.64	N/A
5	0.01	N/A
6	1.54	N/A
7	0.00	N/A
8	0.87	N/A
9	0.05	N/A
10	0.82	N/A
11	1.77	N/A
12	0.12	N/A
13	0.87	N/A
14	0.77	N/A
15	0.79	N/A
16	0.75	N/A
17	0.84	4

^aN/A: not applicable.

Hypothesis 3

Our third hypothesis was that we would uncover meaningful qualitative themes from participants' SMS text message responses and semistructured interviews about the feasibility and acceptability of HealthySMS. We posited that meaningful themes would be beneficial in informing iterative system and

research protocol improvements supporting future HealthySMS effectiveness research. When examining the context of participants' SMS text message responses to our monthly message prompts and semistructured interviews asking for feedback, we identified themes and exemplary quotes regarding the feasibility and acceptability of HealthySMS (Tables 3-5).

Table 3. Qualitative themes uncovered and example quotes regarding HealthySMS's feasibility

Theme	Example quote supporting feasibility	Example quote about limited feasibility
Text modality	"I am not really great with the emails. I think just going through texts is almost always better."	"For a while, I just didn't even open the texts."
Consistency of delivery	"I always got the text and sometimes if I didn't reply, like with my mood, I would get like a reminder, maybe 10 minutes later, respond your mood. So I would say technically or technologically, it was all good. I didn't run into any issues."	"Sometimes my mood ratings just wouldn't come in. Like some days, like towards the ending of it, they just came in periodically like not every day."
Amount of effort to use	"[It was fine to] like, give a number, how was your day? But if it was like kind of describe your day, I don't think anyone would want to do that because it would take too long."	"If you didn't like type in your mood right away, it would like send you a reminder a lot. So I got those a lot if I wasn't doing it."
Timing of texts	"I definitely didn't get anything like super early or late. I would say they did a pretty good job of, like, changing up time, so it wasn't like the same time every like 8AM and 10PM, like it was pretty good at switching up times so you could get like different times of the day."	"I guess sometimes they came at weird times, like really early in the morning or really late at late night...It kind of felt less helpful if they came later in the day because either I had already figured it out or like got past it or it just didn't help anymore."
Amount of texts	"I don't remember getting, like, bombarded with them. So I would say the amount is probably pretty good and reasonable."	"It felt sometimes like it was getting too many. But that was mainly because that was like at a time when I didn't need them and so it just felt like a waste of message if that makes sense."
Text length	"They're all quick...It's short and simple and sweet..."	"I liked it, but it was also like kind of a lot sometimes."

Table 4. Qualitative themes uncovered and example quotes regarding HealthySMS's acceptability

Theme	Example quote supporting acceptability	Example quote about limited acceptability
Group reminders	"I liked it, because sometimes when things got a little hectic, I would forget about group so it's a useful reminder."	"They weren't the most helpful, especially because I'm pretty sure I only ever got one text and it was just 'there is group tomorrow. Don't forget your binder,' which I realize is probably works a lot better when you actually have to go somewhere to do it. But like I already said, I have nothing else going on [in quarantine], so I remember yep, that's tomorrow. I felt like there definitely could be some variation in things like maybe it could bring up, like, remember the skills you learned or don't be scared to share or something like that, that could be a little more emotional based."
Personalized response texts	"I did like how if your mood was like a bad mood, it would give you like, it wouldn't it just be like that sucks feel better, but it would give you like advice and strategies of how you can get better. I think that was nice. And I liked when if you were in a good mood, it would kind of still give you like a different kind of advice to keep you in that space and like be like, like you could use that experience to feel better later when you remember."	"...having a little bit of background about like who it is I'm responding to, like, is it a computer or is it a person like this data is being used for what, kind of thing might be helpful."
Mood ratings	"The rating of the mood...it kind of helped me figure out how I was feeling, like in a number form."	"I would say it was kind of easy when I was like doing super well or super bad..., but little bit harder, I guess, like to be: 'OK, well, I don't really know. I'm average.'"
Skill reminder texts overall	"I thought they really were helpful...a really nice boost, and it was and it would remind me of the other things I had learned that I could also use to feel better."	"Um if I was able to do something like kind of just the reminder was helpful. But with COVID a lot of the times, it wasn't applicable."
Activity skill reminders	"I always think it's good to like set goals for yourself so you have something to work towards. So it's almost like a little bit of motivation."	"...like: 'do a new activity'...a lot of activities have like kind of gotten harder to do with everything [in the context of the COVID-19 pandemic]."
Social skill reminders	"I liked the people [texts], because I struggle with my relationships with people."	"Sometimes I couldn't hang out with friends. So then sometimes that even made me, like, a little frustrated."
Cognition skill reminders	"I think sometimes like I get so stuck in like the past or just like in the moment that it's good to just like think about your future and like the good things that are to come."	"...it was just odd getting text telling me to, like, change the way I'm thinking because I know like the way my brain works, it's not going to just happen...So it was just annoying because I would like to make [the thoughts] go away, but they're not going to."
Statements vs questions	"I felt that they were good, I like them more when they were more statement based...I felt that just a clear like statement or like advice boost helped more for me personally."	"I got confused a bit with the questions they'd ask because I wasn't sure if I was supposed to, like, respond to them and it would respond back or it was just kind of a moment to reflect."

Table 5. Qualitative themes uncovered and example quotes regarding HealthySMS's potential impact on evidence-based intervention (EBI) engagement.

Theme	Example quote supporting impact on EBI engagement	Example quote about limited impact on EBI engagement
Participation in group sessions	"It was just like a reminder to like start thinking about group. So like before group, I'd just like start thinking about it so I'd like have more to say."	"I wouldn't really say that the text messages changed my experience in the actual group. It felt more like kind of a recap throughout the week, and less than, sort of a second part of group, if that makes sense. Yeah like we talked about the text messages a bit in group, but the text messages were always about the thing that happened last week, and so we'd want to move on. It could be helpful if the text messages like cover, like some newer things to introduce you, but um yeah."
Group homework completion	"That was kind of like a good check in where I was like, OK, did I have homework? What was it? Could that help me? So I would keep that in there."	"I would definitely do techniques more if I got a text message reminding me to do it [the specific homework rather than the general skill reminder] in the week."
Connection with others in the group	"It felt like we were closer because we were all getting the same messages and we were all in the same boat together."	"My experience with my group and group leader was pretty good, but I wouldn't really say my experience in group and my experience with the text messages were linked."
Validation and support	"And it felt like someone was like caring about me."	"But it also could backfire on if you don't do it [the suggestion in the text], feeling guilty."
Impact on mood	"It kind of gave me some positivity boost, and it was nice to have someone or something to talk to me while I was feeling that way."	"I wasn't doing anything because I couldn't go out and it just made me think about it more...So it just made me a little bit more sad."
Behavior change and skill use	"I got something like the, call or spend time with people who make you feel happy...And I ended up calling one of my closest friends and she did bring up my mood a little bit..."	"I didn't usually act on it, probably just because it was like, OK, well, right now I'm doing something. So then I wouldn't really remember to do it later, but I can see how, what the idea was."

Hypothesis 4

Our final hypothesis was that we would uncover meaningful qualitative themes from participants' SMS text message responses and semistructured interviews about the potential impact of HealthySMS on EBI engagement. We posited that meaningful themes would be beneficial in informing decisions on which mechanisms of change to evaluate in future HealthySMS effectiveness research. When examining the context of participants' SMS text message responses to our monthly message prompts and semistructured interviews asking for feedback, we identified themes and exemplary quotes regarding the potential impact of HealthySMS on EBI engagement (Table 5).

Safety During the HealthySMS Intervention

A secondary aim of our pilot study was to monitor the HealthySMS safety keyword alert triggers and provider responses to inform system and research protocol adjustments before future HealthySMS research. During the study period, 76 (7.58%) of the 1002 total SMS text messages sent by participants alerted providers to potential suicide risk throughout our flagged keyword system. When examining the content of participants' SMS text message responses that were flagged for risk of suicide, only 2 (3%) of these 76 messages were determined to contain true risk-related content (eg, texts about wanting to hurt oneself or die by suicide). In one case, the notified provider determined that the text may be an indication that the participant was about to self-harm, and they followed the clinic's safety protocol; no indication that harm occurred was received, and the participant continued attending the group sessions and engaging in the study. In the second case, the

notified provider determined that the text did not represent an increase in risk and addressed the client's worry about the future in their following session.

Discussion

Principal Findings

The results of this feasibility pilot study demonstrate that the use of HealthySMS adjunct to adolescent group CBT depression services (CBT-D) appears feasible and acceptable, as evidenced by high rates of HealthySMS initiation and low rates of dropout, as well as meaningful themes uncovered from participants' qualitative feedback. Importantly, the findings also provide evidence regarding iterative improvements to the HealthySMS system and research protocol, as well as potential mechanisms of change for enhanced EBI engagement and, ultimately, adolescent depression outcomes, which can be used in future effectiveness research. It is compelling that the results of this study were obtained in the context of ongoing clinical services at a real-world outpatient clinic experiencing a transition to telehealth services amidst the onset of the COVID-19 pandemic and that the research protocol did not alter the clinical service procedures in any way, such as by incentivizing adolescents to attend the group sessions. Furthermore, it should be noted that we were able to implement this intervention in a safe manner during a time when an increasing number of youths were at a risk for suicide; the 2 instances of HealthySMS alerts indicating risk were managed via clinical procedures, and no adverse outcomes occurred to any participant during the study.

HealthySMS Feasibility and Acceptability

As predicted, adolescents enrolled in and maintained the use of HealthySMS at high rates; in fact, no adolescent who agreed to the research study declined initiation of HealthySMS, and only 1 (6%) of the 17 enrolled adolescents opted out after a month of use. HealthySMS response rate was slightly lower than predicted but, of note, varied among participants. Some adolescents had very low response rates (ie, n=1, 6% never responded to any messages), and some adolescents had high response rates (ie, n=1, 6% responded multiple times to most prompts). Overall, most adolescents responded more than half of the time to daily mood rating prompts (ie, response rates averaging >60%). Qualitative feedback suggested that quick and short messages, as well as midday versus early or late message timing, may be the most feasible to respond to. In addition, some adolescents shared that they were motivated to respond by the “interactive” nature of the mood rating texts, which triggered responses 20% of the time. We received feedback that the number of HealthySMS messages and reminders felt appropriate for some participants; however, we received other feedback indicating a preference for less frequent messages and reminders. A future direction to explore is whether personalizing the message and reminder timing and frequency (eg, by requesting participants to share their preferences in the initial survey and monthly feedback prompts to adapt the system to allow for differences by preference) may increase response rates. Interestingly, some adolescents also sent SMS text messages back to the skill reminder messages (ie, response rates averaging 12%), although there were no explicit requests for responses. Adding explicit response requests to skill reminder messages may be another way to explore the potential benefits of HealthySMS.

Regarding the HealthySMS safety triggers, the system appeared to appropriately monitor risk. Throughout the 10 months of the study, 76 (7.58%) of the 1002 total messages sent by participants during the study period triggered provider alerts via flagged keywords (eg, cut, kill, and die; listed in [Multimedia Appendix 1](#)). We added words to the system for the current trial after consulting with data from the adolescent crisis text line. Importantly, only 2 of the alerts in this study indicated a potential suicide risk and required clinical follow-up. Providers complied with the established clinical policies and procedures, and no known adverse outcomes occurred among participants throughout the study. In fact, the vast majority of alerts were false positives (eg, “I just got my haircut,” “I went for a bikeride over the bridge,” and “my throat hurts”). One of the most sensitive keywords appeared to be “end,” given that it is a frequently used word and is included in many words (eg, “almost the end of the day” and “FaceTime with friend”). This information can be used to iteratively improve the HealthySMS system to balance the need to detect safety concerns with high sensitivity while trying to avoid false positives and, therefore, reducing providers’ burden in reviewing the alerted SMS text messages, such as by programming keyword alerts to trigger only when the word “end” by itself is sent and not when it is included in other words, such as “friend.” It will be important for future HealthySMS efforts to consider how future HealthySMS research designed to evaluate the appropriateness

of the safety keyword triggers and subsequent provider responses to prevent self-harming behaviors would be beneficial.

Potential Impact on EBI Engagement to Be Evaluated in Future Effectiveness Research

When asked about the utility of HealthySMS, we received input providing initial evidence that the system may indeed enhance EBI engagement. Our identified themes may be used to inform decisions on which mechanisms of change to evaluate in future HealthySMS effectiveness research designed to measure the impact of the system on EBI engagement and, ultimately, adolescent depression outcomes. To begin, most adolescents gave feedback that group reminder texts may have increased their likelihood to attend and meaningfully participate in the group sessions, although one of the participants felt that the group reminder texts were intrusive and did not impact engagement in the group sessions. Variation in responses again highlighted that a personalized SMS text messaging system would be ideal for accommodating individual needs and desires.

Qualitative responses also suggest that the HealthySMS skill messages provided beneficial reminders and motivation for some adolescents to engage in CBT strategies, including behavioral activation and helpful thinking. Some participants did suggest that we sync skill messages with the content being delivered each week (rather than with each module, as is the current setup) to optimize relevance. Although weekly agendas are generally known from the beginning, given the CBT-D format in this study, group providers may adjust agendas to meet the needs of the current group members. Thus, personalizing the timing and content of messages and syncing messages more precisely to weekly content would likely be perceived as helpful by participants but would need to be weighed against the feasibility of such measures, which could increase providers’ burden.

We were also interested in the impact of HealthySMS on the interpersonal connection of the adolescents in the current trial, given the reports of adults in our team’s prior trial of HealthySMS that participants felt cared for and supported by the messages, as well as closer to the CBT group (sources removed for masked review). We received feedback suggesting that HealthySMS may help some adolescents feel more connected to the group leader and other members, as well as validated and supported even with the knowledge that it is a “bot” responding. One of the providers shared that a participant felt that HealthySMS was like a “friend.” Feedback from participant interviews indicated that this sense of connection was especially true when they received the responses to their mood rating texts, which were aligned with how they rated their mood (ie, different responses were sent for high, medium, or low mood ratings).

Limitations and Future Directions

Our study has several limitations that should be acknowledged and addressed in future work. First, our pilot study investigating the feasibility and acceptability of HealthySMS in a real-world treatment setting was not designed to evaluate the system’s role in improving the ultimate target of adolescent depression. To accomplish this, future effectiveness research building on the

lessons learned and iteratively updated deliverables (ie, the HealthySMS system and research protocol) from this study is warranted. Specifically, although we were able to explore the potential impact of HealthySMS on EBI engagement in participants' qualitative feedback, we did not have the data or sample size required to quantitatively evaluate this construct. In addition, our decision to conduct this pilot study in a real-world setting without making changes to existing clinical procedures created several potentially confounding variables among participants, such as the number of other EBI services engaged in adjunct to CBT-D. Subsequent studies fully powered to detect mechanisms of change as well as control for potential covariates to EBI engagement and outcomes using a control group are called for. Finally, this pilot study took place in the initial months of SIP enforcement owing to the COVID-19 pandemic; thus, it is not known how well our findings will generalize beyond this context.

Conclusions

Our pilot study suggests that HealthySMS adjunct to the most evidence-based treatment for adolescent depression (ie, CBT)

is feasible and acceptable, warranting future effectiveness research evaluating the system's impact on adolescent EBI engagement and subsequent depression outcomes. As SMS text messaging is cheap and uses technology already in the hands of most adolescents, it is well suited to be added to existing clinical services. Feedback from the participants in our studies suggested that mHealth may be particularly helpful during times of SIP enforcement, given the limited ability for adolescents to engage in activities, social interactions, in-person mental health treatment, and safety monitoring by adults in their lives (eg, teachers and providers). However, it is possible that SMS text message systems are beneficial adjuncts to EBIs in all contexts, given their potential to increase the likelihood and effectiveness of service participation, enhance feelings of connectedness and validation, and encourage skill use in-between sessions. Continued service research on the implementation and effectiveness of mHealth tools has the potential to improve mental health services for a population experiencing drastic increases in depression and suicide risk: adolescents.

Conflicts of Interest

AA is the owner of the HealthySMS program license and has licensed it to other researchers for use in their studies. He was not paid for the license for this study.

Abstract

Background: Suicide safety planning is an evidence-based approach used to help individuals identify strategies to keep themselves safe during a mental health crisis. This study systematically reviewed the literature focused on mobile health (mHealth) suicide safety planning apps.

Objective: This study aims to evaluate the extent to which apps integrated components of the safety planning intervention (SPI), and if so, how these safety planning components were integrated into the design-based features of the apps.

Methods: Following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines, we systematically analyzed 14 peer-reviewed studies specific to mHealth apps for suicide safety planning. We conducted an analysis of the literature to evaluate how the apps incorporated SPI components and examined similarities and differences among the apps by conducting a comparative analysis of app features. An independent review of SPI components and app features was conducted by downloading the available apps.

Results: Most of the mHealth apps (5/7, 71%) integrated SPI components and provided customizable features that expanded upon traditional paper-based safety planning processes. App design features were categorized into 5 themes, including interactive features, individualized user experiences, interface design, guidance and training, and privacy and sharing. All apps included access to community supports and revisable safety plans. Fewer mHealth apps (3/7, 43%) included interactive features, such as associating coping strategies with specific stressors. Most studies (10/14, 71%) examined the usability, feasibility, and acceptability of the safety planning mHealth apps. Usability findings were generally positive, as users often found these apps easy to use and visually appealing. In terms of feasibility, users preferred using mHealth apps during times of crisis, but the continuous use of the apps outside of crisis situations received less support. Few studies (4/14, 29%) examined the effectiveness of mHealth apps for suicide-related outcomes. Positive shifts in attitudes and desire to live, improved coping strategies, enhanced emotional stability, and a decrease in suicidal thoughts or self-harm behaviors were examined in these studies.

Conclusions: Our study highlights the need for researchers, clinicians, and app designers to continue to work together to align evidence-based research on mHealth suicide safety planning apps with lessons learned for how to best deliver these technologies to end users. Our review brings to light mHealth suicide safety planning strategies needing further development and testing, such as lethal means guidance, collaborative safety planning, and the opportunity to embed more interactive features that leverage the advanced capabilities of technology to improve client outcomes as well as foster sustained user engagement beyond a crisis. Although preliminary evidence shows that these apps may help to mitigate suicide risk, clinical trials with larger sample sizes and more robust research designs are needed to validate their efficacy before the widespread adoption and use.

Introduction

Background

Suicide is one of the leading causes of death in the United States, accounting for >45,000 deaths annually [1]. Over the last decade, suicide rates have doubled for youth aged 10 to 24 years [2] and have steadily increased for racial and ethnic minority youth [1,3,4]. Suicide ideation and attempt rates have also risen [5,6], especially among youth and minoritized populations [5,7-11]. Numerous studies have shown that untreated mental illness, limited or lack of available care, and low perceived need for mental health treatment are common, yet preventable, suicide risk antecedents [12-19]. Moreover, stigma, difficulties recognizing suicide warning signs, preferences for self-reliance and autonomy, fear of burdening others, and negative treatment experiences can negatively affect help-seeking intentions and engagement in mental health services [20-24].

Researchers have identified various suicide prevention strategies to reduce the public health problem of suicide [25,26]. Safety planning is an integral component of suicide care [27] and has been empirically validated for reducing suicidality [28,29]. The process of safety planning involves collaboration between a clinical and client, as well as with the at-risk individual and their support network. This means that the support network could also be part of the safety planning process [30]. Safety planning involves jointly identifying, problem-solving, and communicating strategies to keep an individual safe if a crisis arises. Core strategies focus on uncovering warning signs or triggers that precede an emotional event, identifying and reinforcing the use of healthful self-management strategies to cope with distress, encouraging the use of positive socialization strategies for distraction and support, creating a network of external support and professional contacts to solicit assistance and support, and reducing access to lethal means [31]. The individualized nature of creating a safety plan (ie, a written document detailing the plan to keep an individual safe during a crisis) allows the person at risk of suicide the ability to incorporate culturally relevant and meaningful strategies, thereby making these plans useful and relevant for diverse populations [30,32].

Suicide safety planning is a brief intervention that has been used in both acute and clinical settings [31,33,34] and as a self-help tool [35]. Overall, researchers have found this intervention to be feasible, acceptable, and useful to facilitate support and reduce suicide risk [32,33,35-37]. Researchers have found safety plans and related interventions, such as crisis response planning [38], to be effective in reducing the risk of hospitalization, increasing engagement in mental health treatment, and promoting the use of healthful coping strategies when used alongside other therapeutic approaches [33,34,36,39,40]. Although safety planning has shown initial success in reducing suicidal urges and offering a sense of hope to individuals in

crisis [41], some clinicians and researchers have criticized this process [42,43]. For example, safety planning encourages clinicians to revisit and update safety plans with their clients over time [44], which can prove challenging if service use barriers prevent clients from reaccessing care or if clients misplace or throw away their paper-based safety plan.

Considering these challenges, mobile health (mHealth) technologies could offer a timely and effective solution to address some of the criticisms directed at traditional safety planning methods. mHealth, particularly the use of apps, represents a common tool used by consumers with access to mobile phones [45,46]. In addition, mHealth has garnered attention as a practical and convenient method for implementing mental health interventions [47], with increase in the quantity and functionality of applications and tools resulting in increased use [48]. In general, mHealth apps have been used to effectively help individuals identify and manage symptoms of various mental health problems and conditions such as depression, anxiety, substance abuse, posttraumatic stress, and eating disorders [49,50]. Thus, incorporating mHealth apps into mental health treatment and adjunctive interventions may prove beneficial.

Furthermore, incorporating mHealth apps into established evidence-based interventions may also serve as a culturally inclusive way of disseminating treatment to younger, more technologically savvy generations who also happen to demonstrate higher rates of suicidal thoughts and behaviors than adults [6]. mHealth apps may also help address service use barriers and risk factors (eg, stigma) that hinder individuals from seeking help and participating in treatment for suicidality. Combining suicide safety planning practices with mHealth apps may combat accessibility concerns as well, including a commonly reported flaw of the traditional intervention—the reliance on a paper format [35]. Given the widespread proliferation of mHealth apps for suicide prevention, there is a need to examine the components and features that have been incorporated into the design of suicide safety planning apps.

Objectives

The purpose of this systematic literature review was to first assess the extent to which suicide safety planning mHealth apps integrated the 6 steps or components of a widely used safety planning intervention (SPI) developed by Stanley and Brown [31] (research question [RQ] 1). Next, we independently reviewed available mHealth suicide safety planning apps via download from iOS and Android app stores to assess the integration of SPI components and to categorize different app design features used to personalize the end users' experience (RQ2). We also examined the evidence on the effectiveness of these apps in terms of usability, acceptability, app engagement, and suicide-related outcomes (RQ3). This review aims to synthesize the extant research to inform suicide prevention

efforts, clinical practice, and future development of suicide safety planning mHealth apps.

Methods

Overview

In accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 statement guidelines ([Multimedia Appendix 1 \[51\]](#)), a comprehensive systematic review of existing literature on suicide safety planning via mHealth apps was conducted. The process is described in the following sections.

Systematic Literature Review

Eligibility Criteria

The inclusion criteria for the reviewed research studies were as follows: (1) a primary focus on suicide safety planning involving the use of a mHealth app, (2) publication in a peer-reviewed article written in English, and (3) availability of the full text of the article. Studies were excluded if (1) the word suicide, safety plan, or app was not included in the title; (2) they included other forms of mHealth technologies as the primary focus (eg, web-based applications); (3) the apps were designed with safety planning as a secondary focus (ie, not exclusively for suicide safety planning, not intended as a crisis intervention, or use of safety planning as a secondary tool to other treatment modalities); and (4) they were part of other systematic reviews or meta-analyses. We included studies across the entire system development life cycle (eg, formative evaluations and 1 group pre-posttest designs) owing to limited research on the topic and the relatively recent emergence of such research.

Information Sources

The following 5 bibliographic databases were used to systematically review the literature: PsycINFO, PubMed, ACM Digital Libraries, Academic Search Premier, and ERIC. We limited our results to articles published between January 2000 and May 2023. All databases were last searched on July 2, 2023.

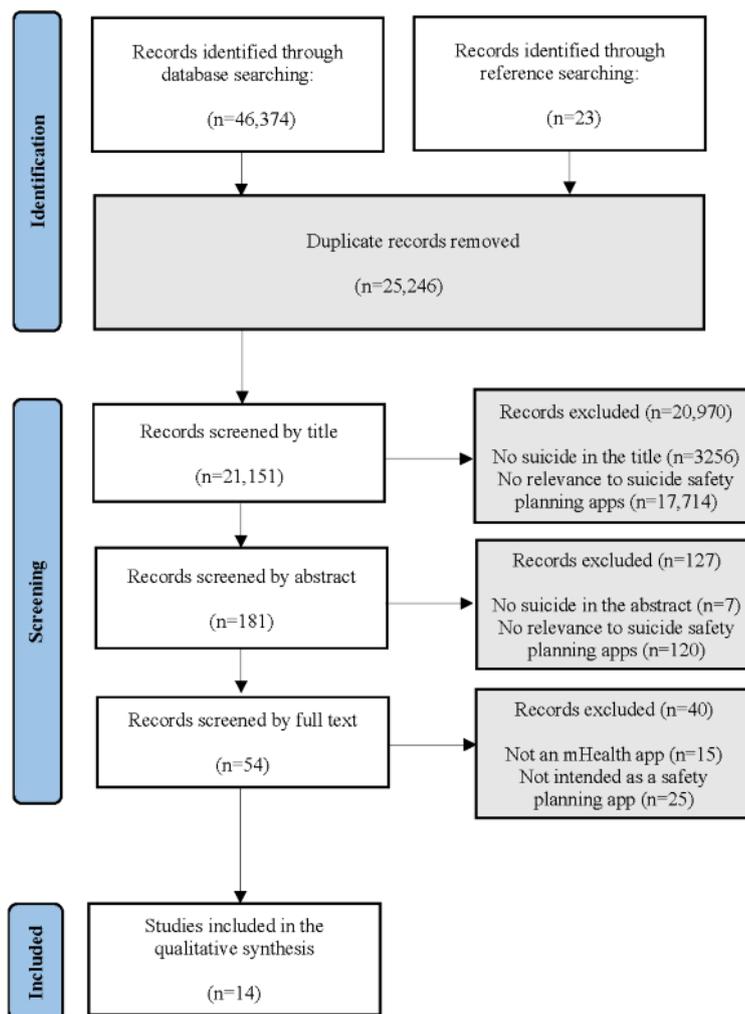

Search Strategy

We used the following keywords to search for the topic of interest in each scientific database: “Safety Plan*” AND (“Applications” OR “Apps”); (“Suicide” OR “Safety Plan*” AND (“Applications” OR “Apps”); “Suicide Interven*” AND (“Applications” OR “Apps”); “Suicide Prevent*” AND (“Applications” OR “Apps”); “Suicide Contract” AND (“Applications” OR “Apps”); “mHealth” AND “Suicide”; “Crisis Response” AND “Plan*.” Asterisks were added to search for words that began with the preceding letters (eg, prevent*: prevent, prevention, and preventing). An example of the search strategy outlined above is provided in [Multimedia Appendix 2](#).

Selection Process

Citations obtained from electronic databases were imported into Zotero (version 6.0.16). Two reviewers (KG and VLO) independently screened the articles to remove duplicates and assessed inclusion and exclusion criteria by title and abstract. For articles about which the reviewers were uncertain after the title and abstract review, 4 reviewers independently analyzed the full-text articles to determine whether they met the inclusion criteria. The reviewers discussed discrepancies until they reached a consensus. The references of all articles that met the inclusion criteria were reviewed and cross-referenced for additional relevant articles. We included all eligible studies (N=14) in this systematic review ([Figure 1 \[51\]](#)).

Figure 1. Flowchart of the studies in line with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. mHealth: mobile health.

Data Collection Process

Data from eligible studies were analyzed using the Cochrane Collaboration's data extraction template for included studies (version 1.8) [52]. We added study-specific items to the template to answer RQ1 and RQ2. Specifically, to answer RQ1, we reviewed articles describing each mHealth app and coded, using a dichotomous (yes or no) coding scheme, for the following SPI components: (1) personal warning signs, (2) coping strategies, (3) ways to distract oneself through social activities, (4) identification of and ways to access trusted individuals (eg, family and friends) for support, (5) identification of and ways to access community supports (eg, mental health professionals, nonmental health adult supports, crisis, or emergency services), and (6) information about keeping the environment safe (eg, restricting access to lethal means). To answer RQ2, we downloaded available mHealth apps via the Apple App Store or Google Play Store or contacted app developers to conduct an independent review of SPI components and app features described in the articles. Next, we created codes to describe app features, organized and categorized codes based on similarities, and generated 5 themes to capture the core aspects of features. To answer RQ3, we extracted both qualitative and quantitative

findings reported on primary and secondary outcomes. We categorized the study outcomes into 3 main research themes.

Two reviewers coded 2 research articles to assess interrater reliability based on the coding template and made refinements as necessary (eg, added operational definitions to describe SPI components and provided examples of app features). Once finalized, the reviewers used the template to extract the data from the remaining studies. Data items included (1) general article information (eg, author, publication year, and country); (2) study methods (eg, aims and research design); (3) study characteristics (eg, sample size, sample demographics, and setting); (4) SPI intervention characteristics (RQ1); (5) mHealth app design features (RQ2) and primary and secondary outcomes (RQ3); and (6) study implications and future directions (Multimedia Appendix 3 [42,43,53-64]). A similar process was used to independently code the SPI components and app features of the mHealth apps available for download.

Risk of Bias Assessment

The risk of bias for each study was assessed by 2 independent reviewers (KG and VLO) using Joanna Briggs Institute (JBI) appraisal tools for quasi-experimental [65] and qualitative research study designs [66]. For studies that included mixed methods designs, we used both tools as recommended by the

JI. Each appraisal tool used a rating scale with yes, no, unclear, and nonapplicable responses. The overall appraisal rating was based on the following categories: include, exclude, and seek further information. Disagreements between the reviewers were discussed until they reached a consensus ([Multimedia Appendix 4](#) [65,66]).

Synthesis of Results

Owing to the heterogeneity of the study designs, participants, and outcomes collected, we could not perform a meta-analysis of the identified studies in this review. Therefore, we present a narrative synthesis of the study findings.

Results

Study Selection

The initial search of electronic databases and hand-searched references resulted in a total of 46,397 peer-reviewed articles. After duplicate records were removed, 21,151 studies remained. Titles were screened for relevancy (eg, relating to suicide, suicide safety planning, and mHealth apps), and 20,970 articles were excluded. A total of 181 abstracts were reviewed. Following full-text reviews of 54 articles, 40 articles were removed (15 studies did not include an mHealth app and 25 were not intended as a suicide safety planning app). A total of

14 articles met the inclusion criteria (refer to [Figure 1](#) for breakdown).

Study Characteristics

Overview

The detailed study characteristics of the selected articles (N=14) are presented in [Multimedia Appendix 3](#). Most studies (12/14, 86%) were conducted outside the United States [42,53-63]. The year range of the selected articles was between 2015 and 2023.

Study Design

As shown in [Tables 1](#) and [2](#), a total of 7 mHealth suicide safety planning apps were studied across the 14 articles in our data set ([Multimedia Appendix 3](#)). We classified the articles based on the research design (ie, formative feedback, usability assessment, single cohort pre-posttest, and random control trial protocol). Formative designs assessed SPI components and features to guide app development [43,56,61,64], whereas usability designs assessed interface design issues and functionality (eg, task difficulty and time to complete tasks) [55,60,61,64]. Other studies evaluated the acceptability or feasibility of a fully developed mHealth app [54,58-60,62,63]. Across these studies, participants rated the frequency and duration of app use; ease of navigation; and level of satisfaction, comfort, confidence, or engagement in using the app.

Table 1. Formative, usability, and acceptability assessments of mobile health suicide safety planning apps (n=8 articles).

Safety planning app	Year span	Formative feedback only	Usability assessment	Random control trial	Use period	Key findings
Unnamed [43]	2015	Clinicians (n=9), at-risk youth, and guardians (n=20)	N/A ^a	N/A	None	Qualitative feedback to inform app design; no app developed
SERO [56]	2022	Clinicians, at-risk individuals (n=11), and relatives (n not reported)	N/A	N/A	None	Summary of 6 suicide prevention strategies aligned with app design
ED-SAFE [64]	2023	Clinicians and subject matter experts (n=7), and at-risk adults (n=6)	Emergency department patients after discharge (N=14)	N/A	Unclear	High usability scores and low uptake (use); no significant clinical outcomes reported
MYPLAN [53,54,62]	2016, 2017, and 2020	At-risk youth, adults, relatives, and clinicians (n=26)	N/A	Protocol only (N=546)	Familiarity with app	Qualitative feedback only; no clinical outcomes assessed
SafePlan [57,61]	2020 and 2023	Clinicians and experts (N=15)	Students (N=18)	Protocol only (N=80)	Single use	High usability scores; no clinical outcomes assessed

^aN/A: not applicable.

Table 2. Pre-posttest assessments of mobile health suicide safety planning apps (n=6 articles).

Safety planning app name	Year span	Formative feedback only	Usability assessment	Single cohort pre-posttest	Use period	Key findings
Brake of My Mind [55]	2020	Expert heuristic evaluations (N=5)	Clinician interviews (N=6)	At-risk youth (N=3)	1 week	High usability scores; sample size too low to assess clinical efficacy
BackUp [42,60,63]	2017, 2018, and 2022	Designed informed by the expert panel (n=8) and at-risk adults (n=21)	Usability assessment combined with pre-posttests	Protocol only, single cohort design (N=80); at-risk adults (n=21) and at-risk adults (n=12)	1 week and 3 months	High usability scores, no significant decrease in suicidal thoughts; low clinical and patient uptake (use)
BeyondNow [58,59]	2019 and 2020	N/A ^a	N/A	At-risk youth and adults (n=22) as well as at-risk youth (n=17)	2 months and 6 weeks	High usability scores. Significant reduction in severity and intensity of suicidal ideation; significant increase in coping; and no significant change in suicide resilience for mixed samples. For youth only sample, no significant decrease in suicidal thoughts and significant increase in suicidal resilience. No conclusions regarding clinical efficacy.

^aN/A: not applicable.

Sample Characteristics

Across studies, the study sample varied in age, type of participant (eg, youth or adults at risk of suicide and clinicians collaborating with suicidal clients), and setting (eg, suicide prevention clinic and pediatric inpatient facility). Among studies that recruited participants to inform or evaluate mHealth suicide safety planning apps [43,54-56,58-64], the sample size ranged from 11 to 36 participants. However, after reporting dropout

rates, sample sizes dropped to as low as 2 participants and as high as 22 participants.

Integration of SPI Components Within mHealth Apps

Most articles (5/7, 71%) describing the mHealth apps incorporated SPI components into the design of their apps [54,58,61,63,64] (Table 3). Creating a safe environment from lethal means was the missing component in 29% (2/7) of the apps [55,56].

Table 3. Safety planning intervention (SPI) components and app features.

We used the JBI quasi-experimental appraisal tool [65] to assess the risk of bias across 5 studies [55,58-60,63]. These studies did not include a control or comparison group, increasing the

threat to internal validity. Pre- and posttest measures were used to assess the immediate effects of the mHealth apps. However, the lack of repeated outcome measures over time, selection bias

(nonrandom samples), and small sample sizes pose a risk of bias within and across these studies.

The qualitative appraisal checklist tool [66] was used to assess the risk of bias in 4 studies [43,54,56,62]. Across 2 studies [43,54], the cultural or theoretical orientation of the researchers and their influence on the research process was unclear. These issues were noted in the other 2 studies [56,62] as well. In these studies [56,62], it was also difficult to identify the philosophical perspective and congruity between the research methods, data analysis, and interpretation. The studies included more of a description of the design of the apps and included general perceptions from stakeholders.

The remaining studies [61,64] were assessed using both the quasi-experimental and qualitative appraisal tools owing to their mixed methods designs. In both studies, it was unclear whether the researchers' cultural or theoretical orientation, their influence on the research, and the adequate representation of the participants and their voices were addressed. Other key issues included the lack of a control or comparison group, nonrandom and small sample sizes, and the use of posttest measures to assess usability at only 1 time point. JBI appraisal results are included in [Multimedia Appendix 4](#).

On the basis of our independent review of available mHealth suicide safety planning apps, SPI components described in each article were verified in 71% (5/7) of the apps [54,56,58,61,63]. The app features described in the articles were also confirmed in these apps. App features not highlighted in the articles but found within the apps are listed in [Table 3](#). We were unable to verify SPI components and app features in 2 of the reviewed apps in the literature [55,64].

Comparative Analysis of SPI Components and App Features

In our analysis of the literature and available mHealth apps for download, we synthesized the commonalities of app features and categorized them into 5 broad themes: interactive features, individualized user experience, interface design, guidance and training, and privacy and sharing. These features are described in the following sections.

Interactive Features

Three of the suicide safety planning mHealth apps [54,56,61] allowed users to associate suicide warning signs or precipitating stressors with their personalized coping strategies (aligns with SPI 1 and 2 in [Table 3](#)). O'Grady et al [61] stressed the importance of including this feature in apps, as this functionality can serve to preemptively address an impending crisis before it fully manifests. Most of the suicide safety planning mHealth apps (6/7, 86%) also included social distractor features in which users had access to their phone's camera with the ability to upload or view media content (eg, pictures, quotes, music, activities, videos, and inspirational stories; SPI 3) [54,55,58,61,63,64]. In the *BackUp* app [63], loved ones, trusted supports, and suicidal users were able to upload media and share content to inspire hope and distract users from negative thinking.

Each mHealth app also included a built-in feature for users to save and contact trusted individuals within their social support

networks (SPI 4). Typically, users entered contact information into the mHealth app directly or linked to their contact directories. A unique feature of the *MYPLAN* app [54] allowed users to create prewritten messages that they could send to their social supports during times of distress. Although this feature was created to inform loved ones of the app user's emotional state during a crisis, participants (ie, app users) noted concerns about messages being misunderstood, whereas relatives felt that messages could minimize emotional states or provide inaccurate information about the app user's safety. All apps included the ability to access community supports such as mental health professionals (SPI 5). Three apps [54,55,61] included GPS capabilities, which enabled users to search for nearby counseling agencies or emergency services, and, after selecting a search result, users received directions for quick access (SPI 5 and 6). The *ED-SAFE* app [64] included a referral search engine that allowed users to find behavioral health care by specialty and zip code. Emergency service numbers, mostly displayed via a phone icon or brief words (eg, "Crisis"), were clearly visible (listed on all pages) in 57% (4/7) of the mHealth apps [56,58,61,63], which is the suggested ethical guideline from prior work [67]. Three apps did not include access to emergency service numbers on all pages but provided them somewhere else within the app [54,55,64].

Individualized User Experience

All apps (7/7, 100%) allowed users to continually add to or revise their safety plans. Examples included the addition of new warning signs, reasons for living, and identifying coping strategies. None of the apps maintained a historical record of the previous safety plans or provided a visual mechanism to track daily, weekly, or monthly patterns based on stressors encountered or coping strategies used. Other personalization aspects included the ability to enable or disable therapeutic modalities [61], the inclusion of web-based resources to take an aptitude and personality test [55], exercises to express moods [55], and mood tracking [55,56,61]. In addition, all apps had built-in features to make esthetic customizations, such as personalizing the home screen, changing the color palate, and adding background pictures [54-56,58,61,63]. In 57% (4/7) of the apps, notifications were enabled to remind users about using their safety plan or skills to practice [54,56,61,63].

Interface Design

Several studies used iterative feedback from content and app design experts to create easy-to-navigate interfaces [58,61,63]. To enhance the navigation experience, a simple layout, clear or user-friendly language, and accessibility features were important design considerations included in some mHealth apps [54,58,61,64]. For example, *SafePlan*'s layout mimicked the paper version of the safety plan to better transition users from using the paper version to the app [61].

Guidance and Training

In-app tutorials or instructional videos were included in 86% (6/7) of the suicide safety planning mHealth apps [54-56,58,63,64]. Some of these tutorials focused on how to use the app, whereas others explained the safety planning process. For example, the *BeyondNow* app [58] included a video

outlining the process of safety planning and links to other helpful information. The most extensive tutorials were seen in the companion app to *ED-SAFE* [64], where tutorials could be received from a female provider, a male community member, or an avatar. The mHealth suite of apps also included self-care education materials about suicidality, safety plans, and life plans. In addition, the *BackUp* app [63] provided supportive contacts with web-based information on ways to identify warning signs and strategies to talk with suicidal individuals. The *Brake of My Mind* app [55] included an introduction from the developer with additional web-based resources to increase app usability.

Privacy and Sharing

Researchers also highlighted app privacy and sharing capabilities as important features to consider when designing mHealth suicide safety planning apps. Given the personal nature of the information saved, most mHealth apps required a username and password to log in [54-56,61,63,64]. For example, *ED-SAFE* [64] used the username and password feature to verify user identity and connect information collected in the emergency department setting to the mHealth app. Other apps disabled GPS for location tracking or did not use external servers to store users' information for privacy and security concerns [61,63]. Several apps (5/7, 71%) included features allowing users to share self-monitoring data or share safety plans with clinicians or trusted individuals [54,56,58,61,64]. For instance, *ED-SAFE* [64] allowed users to share safety plans as well as appointment information, self-care education, helplines, referrals, and distractions through password-protected privileges given to authorized family members.

mHealth App Evidence of Effectiveness

The qualitative and quantitative findings were categorized into 3 main research themes: app usability and acceptability, app use and engagement, and suicide-related outcomes.

App Usability and Acceptability Findings

Across 71% (10/14) of the studies [54-56,58-64] that assessed the initial usability or acceptability of mHealth suicide safety planning apps, stakeholders' experiences testing the mHealth apps were generally positive. Four studies [55,60,61,64] included standard rating scales (ie, System Usability Scale [68]) to assess the perceived usability of their apps, and scores exceeded the minimum usability standards (ie, >70). The remaining studies used qualitative feedback from focus groups, case reports, and open-ended questionnaires. For example, in the study by Buus et al [54], participants found the *MYPLAN* safety planning app useful in recognizing patterns of impending crises and for reinforcing personalized strategies to cope with distress. In describing the benefits of the *BeyondNow* safety planning app, participants in the study by Melvin et al [58] reported developing a sense of hope and connection from using the app. Researchers have attributed these findings to the accessibility of the app and its customizable features. According to the authors, stakeholders regarded apps as highly intuitive, easy to use, and visually appealing interface in terms of the design [59,61,62,64].

App Use and App Engagement

Five studies examined app use over time [58-60,63,64]. Overall app engagement and use were minimal. Across 3 studies, >70% of the participants used the apps at least once during the testing period, which ranged from 1 to 10 weeks [58,59,63]. In the study by Melvin et al [58], 77% (17/22) of the participants reported using the mHealth app "occasionally" or "a lot," including to make changes to safety plans. Most participants also reported using the mHealth app during a suicidal crisis (15/22, 68%) or when experiencing suicidal ideation (18/22, 82%). Increased frequency of app use during a crisis or among participants with high levels of suicide ideation was reported in studies by Pauwels et al [63] and Muscara et al [59]. Larkin et al [64] reported that 2 (40%) out of 5 participants reported downloading the *ED-SAFE* patient mHealth app after discharge. Low uptake rates were mostly attributed to the participants' forgetfulness to download the app. Although most participants acknowledged the benefits of using mHealth suicide safety planning apps during times of crisis [58,63], participant feedback from the study by Muscara et al [59] suggested that participants did not believe or were unsure whether the use of the *BeyondNow* safety planning app could help them manage their symptoms or keep individuals safe during a crisis. Only 35% (6/17) of the participants favored using the app in the future. Conversely, participants in the study by Nuij et al [60] noted that easy access to the *Backup* mHealth app provided a sense of reassurance and helped to deter suicidal thoughts.

Suicide-Related Outcomes

Suicide-related outcomes were examined across 29% (4/14) of the small-scale pilot studies (with sample sizes ranging between 3 and 22) [55,58,59,63]. The study by Jeong et al [55] assessed the Theory of Planned Behavior constructs, including attitudes, subjective norms, perceived behavioral control, and intentions toward engaging in suicide attempts, using a pre-posttest design with a small (N=3) sample of adolescent survivors of suicide attempts. The results showed statistically significant changes in attitudes, perceived behavioral control, and intentions, suggesting that the suicide safety planning app helped to positively shift attitudes toward life and reduce beliefs and intentions to engage in self-harm behavior.

Suicide coping or resilience was evaluated in 2 studies using pre-posttest designs [58,59]. Both studies used the same safety planning app (ie, *BeyondNow*) to examine the changes in protective factors. Melvin et al [58] found a statistically significant increase in suicide-related coping among youth and adult participants (n=22). This finding suggests an increase in knowledge and confidence to use internal coping strategies and external resources to manage suicide ideation. However, the researchers did not observe statistically significant changes in suicide resilience (ie, the perceived ability to manage suicidal thoughts and feelings). In contrast, Muscara et al [59] found a significant increase in 1 subscale of suicide resilience, emotional stability (ie, the ability to regulate emotions), among youth participants (N=17) in their study.

Suicidal ideation or self-harm behavior were measured in 3 studies [58,59,63]. In an open-label, single-group design, Melvin et al [58] found statistically significant reductions in both the

severity and intensity of suicide ideation following exposure to an 8-week trial that evaluated the clinical effectiveness of using the *BeyondNow* suicide safety planning app as an adjunct to treatment as usual (ie, existing mental health services). In an evaluation of the same mHealth app, but with the addition of a personalized toolbox app (ie, *BlueIce*), instead of treatment as usual, Muscara et al [59] also found a reduction in suicide ideation and self-harm behaviors (ie, attempts to harm oneself with and without suicidal intent). However, these findings were not conclusive or statistically significant owing to the small sample size and lack of a control group. Pauwels et al [63] found a similar, nonsignificant decrease in suicide ideation scores in a study examining pre-posttest changes following exposure to the *BackUp* suicide safety planning app. Although these studies provide some evidence of clinical utility, these researchers noted study limitations and the need for further evaluation using randomized controlled trials (RCTs).

Discussion

Principal Findings

The primary aim of this study was to conduct a comprehensive analysis of the integration and inclusion of the SPI components developed by Stanley and Brown [31] in the design of mHealth suicide safety planning apps. The secondary aim was to synthesize and assess the research methods of studies that reported on the effectiveness of these apps. Implications of these findings and practical recommendations for future directions in mHealth suicide safety planning research are described in the following sections.

Integrating Components of Suicide Safety Planning Into mHealth Apps

Overall, most apps included the core components of the SPI developed by Stanley and Brown [31], such as the identification of suicide warning signs, coping strategies, and supportive persons. Therefore, the results from this review provide evidence of some level of successful integration of SPI components into mHealth suicide safety planning apps (RQ1). Lethal means safety was 1 component that was not incorporated in 2 of the apps reviewed. Reducing access to lethal means is a critical part of suicide safety planning [31] and warrants inclusion in mHealth apps as it brings attention to methods that could be used to attempt or die by suicide if not removed from a user's environment.

An important aspect of suicide safety planning is access to one's safety plan. In this review, having access to safety plans at any time [54,55,58,60,61] and being able to continually revise the plan were considered benefits over traditional paper-based safety planning. In some apps, users could create associations between different suicide safety planning components (SPCs; eg, triggers and coping strategies) to better contextualize their experiences and create actional plans for mitigating crises [54,56,61]. We recommend that additional linkages between the SPCs be included to further personalize users' experiences.

Despite the integration of SPI components within mHealth suicide safety planning app designs, we also identified important gaps in the literature that warrant the attention of app designers,

researchers, and mental health professionals who may use this type of technology within their clinical practice. For instance, researchers have consistently emphasized the importance of completing the initial safety plan alongside a knowledgeable clinician [42,54,58,61] to ensure that at-risk users and loved ones understand the components and purpose of a safety plan. However, many of the analyzed apps allowed users to complete the safety plan without the recommended clinical support, and in some cases, they lacked disclaimers. Therefore, additional guidance from a professional when using mHealth suicide safety planning apps would further serve to assist users and ensure that the safety planning process is carried out as intended.

This review also found that most of the apps did not go beyond the traditional SPCs of paper-based protocols to integrate more interactive features that could potentially improve adherence or engagement. For instance, daily or weekly check-ins have been shown to improve adherence in other mHealth contexts, such as for smoking cessation [69] and the management of schizophrenia [70]. Visualization graphs of patterns or trends in suicide warning signs, triggers, and coping behaviors logged over time may serve to increase engagement and improve outcomes, as visualizing behavior change over time has been recommended in other mHealth contexts [71], such as alcohol reduction [72]. Furthermore, other meaningful ways to actively and continuously engage one's support contacts (eg, clinicians, parents, and family members) and to reinforce the use of healthful coping strategies would be an advantageous direction for future exploration in mHealth app design. Beyond general support contacts, prior research has found that parental support is a significant protective factor against youth suicide [73,74]. For youth, in particular, it may be advantageous to include parents, family members, or other trusted adults in the mHealth suicide safety planning process to increase uptake, enhance help-seeking and coping behaviors, and reinforce ways to keep one's environment safe. However, future research would need to carefully design and evaluate such interventions to ensure they are effective before making these interventions widely available through the dissemination of mHealth apps for suicide safety planning.

Another variation across the apps was that some apps provided default values for suicide SPCs (eg, suggested coping strategies), whereas others did not. Therefore, an area of future research could be to study whether providing default values is beneficial or detrimental to the safety planning process. Finally, rather than training focused on the technical aspects of using the mHealth app, there is a need to include psychoeducation for suicide safety planning [75], especially related to coping strategies and lethal means restriction, which should be modeled as a collaborative process between at-risk users and their support systems [76].

Usability and Design Considerations for mHealth Suicide Safety Planning Apps

Overall, our review highlights three important recommendations to consider when designing safety planning mHealth apps (RQ2): the need to (1) encourage end user collaboration in the design and implementation of the intervention, (2) incorporate personalization or customization capabilities, and (3) develop

appropriate privacy safeguards to prevent liability and address other safety concerns that may arise when integrating mental health care and technology. A key strength of most studies in our review was the interdisciplinary collaboration between app developers, computer scientists, and clinical researchers that facilitated the design, development, and evaluation of the various mHealth suicide safety planning apps. In addition, multiple stakeholders were included in the design process, including individuals at risk of suicide, clinicians, usability experts, parents, and extended family members. Only in 1 instance, end users engaged who were not considered part of the target population of at-risk users (eg, students). We strongly recommend that future research continue to include researchers from across multiple disciplines (eg, psychology, public health, social work, medicine, computer science, and human-computer interaction), intended end users, and mental health professionals across each stage of the research process. For instance, researchers from different disciplines may be able to raise important threats to validity during the research design process that could lead to more robust study designs.

A key weakness highlighted within several studies was limited uptake or sustained use of the mHealth suicide safety planning apps over time. Such findings shed suspicion on the feasibility of this type of intervention being effective outside of research, regardless of the high usability and acceptability ratings. Some studies attributed lack of use to the reduction of suicidal behaviors over time, but others suggested that the suicide safety planning process, as designed to be carried out within the apps, was only suited for in-crisis situations and not appropriate for sustained use over time. Although this may be the case, it is also possible that the lack of interactive or engaging features within the apps made them less appealing to users. Being able to customize and personalize app features may help to enhance the user's experience and increase app engagement. Many of the apps included social distractions (ie, music and pictures) or other features, such as diary cards, which might help increase overall app engagement during noncrisis periods. However, as suicidality is episodic, future research should be conducted to understand how different modalities or features (eg, mood tracking, journaling, mindfulness, and art) could be combined with suicide safety planning in a complementary way for long-term use and engagement. Future work should also consider leveraging advanced technologies and assessments, such as artificial intelligence and ecological momentary assessments [77,78], that could be used to anticipate heightened suicide risk and prompt users to engage in the mHealth app suicide safety planning process when they need it most.

Threats to Validity and Inconclusive Clinical Outcomes Associated With the Use of mHealth Suicide Safety Planning Apps

This review provides some preliminary evidence suggesting that suicide safety planning via mHealth apps could be an easy-to-use mechanism to provide individualized care to those who may otherwise go unserved due to common treatment barriers (RQ3), such as poor accessibility to service providers, lack of knowledge about suicide, and stigmatizing beliefs about help seeking [20-24]. At the same time, several threats to

validity were uncovered by our assessment of risk bias, which can inform directions for future research. First, the robustness of the qualitative studies could be improved by stating the positionality of the researchers as well as a clear justification for the design of the mHealth apps. In some cases, articles were published by interdisciplinary teams, whereas in other cases, authors appeared to be from a single discipline (eg, computer science). Details about the composition and expertise of the research team are important, as well-implemented mHealth apps require interdisciplinary skill sets that span clinical, design-based, and technical expertise. Furthermore, the quantitative studies analyzed in our review were constrained by small sample sizes and no published RCTs. Among the pre-posttest studies conducted thus far, the clinical outcomes were inconclusive.

As such, RCTs with control groups, random assignment, and repeated measure outcomes assessed over time are needed in the future to evaluate the efficacy of using suicide safety planning mHealth apps compared with traditional paper-based safety plans [54,57], specifically related to reducing suicidal urges and behaviors and increasing use of coping strategies, as well as increased engagement in crisis and mental health services after the crisis. When doing so, researchers should recruit larger samples to ensure that the results are conclusive and can be generalized to the populations of interest. Furthermore, additional use metrics collected by the apps to track behavioral data associated with using different app features, such as user engagement with the 6 components of the SPI developed by Stanley and Brown [31], should be considered to better understand the potential mediating factors and behaviors that may influence clinical outcomes. Although the usability of the apps would be an important consideration to control for in future studies, it is necessary to move beyond such measures to determine the efficacy of mHealth apps in reducing suicide-related outcomes. In summary, the inclusion of more advanced study design methodologies and recommendations from lessons learned in future mHealth apps could serve to mitigate suicide risk and promote overall safety.

Limitations and Future Research

This systematic review included 14 peer-reviewed articles that designed, developed, and evaluated mHealth apps for suicide safety planning. There are several limitations of this study that should be addressed in future research. First, although our search process was comprehensive, it is possible that our keywords missed relevant articles and mHealth apps that should have been included in the review. Second, as many of the apps described in the articles were not publicly available for download, we requested access from the corresponding authors to conduct our review. In 2 cases, we were unable to gain access to the apps; therefore, our analysis was based on the description of those apps based on the published paper. As such, it may be possible that some features were not described in the original papers; thus, they were not included in our review. Future research should also consider conducting a systematic feature analysis of mHealth suicide safety planning apps that are publicly available for download but not studied within the peer-reviewed literature. Finally, a limited number of published RCTs at the time of the review restricted our ability to report on app use and

suicide-related outcomes. As such, the main call-to-action from this review is the need to move beyond usability studies of newly developed mHealth suicide safety planning apps to robust clinical research designs to examine their efficacy in reducing suicidality among at-risk user populations.

Conclusions

Overall, most articles included in this review did little to evaluate the efficacy of mHealth suicide safety planning apps beyond usability assessments, signaling that these apps and corresponding research are still in their infancy in terms of validating clinical outcomes. Although most of the mHealth safety planning apps included in our review are not yet downloadable and broadly available for public use, the

prevalence and popularity of mHealth suicide prevention and mental health support apps on the open market that have been deployed without rigorous peer-reviewed research is a concern. As such, there is a critical need for future research to ensure that mHealth apps for suicide safety planning integrate the lessons learned from empirical user-based and clinical research, are upheld to high ethical mental health care standards, and show clinical efficacy for reducing suicidality before the apps are released to end users. This is especially true given the delicate and important goal of preventing suicide among at-risk populations. It is promising to see that future randomized clinical trials have been registered to build upon this important preliminary work on mHealth suicide safety planning apps.

Acknowledgments

The authors would like to thank the following authors who provided access to their apps to conduct this feature analysis: Niels Buus and JL Stovgaard Larsen (MYPLAN); Glenn Melvin (BeyondNow); James Duggan (SafePlan); and Lea Meier, Caroline Gurtner, and François von Kaenel (SERO).

Abstract

Background: Major depressive disorder affects approximately 1 in 5 adults during their lifetime and is the leading cause of disability worldwide. Yet, a minority receive adequate treatment due to person-level (eg, geographical distance to providers) and systems-level (eg, shortage of trained providers) barriers. Digital tools could improve this treatment gap by reducing the time and frequency of therapy sessions needed for effective treatment through the provision of flexible, automated support.

Objective: This study aimed to examine the feasibility, acceptability, and preliminary clinical effect of Mindset for Depression, a deployment-ready 8-week smartphone-based cognitive behavioral therapy (CBT) supported by brief teletherapy appointments with a therapist.

Methods: This 8-week, single-arm open trial tested the Mindset for Depression app when combined with 8 brief (16-25 minutes) video conferencing visits with a licensed doctoral-level CBT therapist (n=28 participants). The app offers flexible, accessible psychoeducation, CBT skills practice, and support to patients as well as clinician guidance to promote sustained engagement, monitor safety, and tailor treatment to individual patient needs. To increase accessibility and thus generalizability, all study procedures were conducted remotely. Feasibility and acceptability were assessed via attrition, patient expectations and feedback, and treatment utilization. The primary clinical outcome measure was the clinician-rated Hamilton Depression Rating Scale, administered at pretreatment, midpoint, and posttreatment. Secondary measures of functional impairment and quality of life as well as maintenance of gains (3-month follow-up) were also collected.

Results: Treatment credibility (week 4), expectancy (week 4), and satisfaction (week 8) were moderate to high, and attrition was low (n=2, 7%). Participants self-reported using the app or practicing (either on or off the app) the CBT skills taught in the app for a median of 50 (IQR 30-60; week 4) or 60 (IQR 30-90; week 8) minutes per week; participants accessed the app on an average 36.8 (SD 10.0) days and completed a median of 7 of 8 (IQR 6-8) steps by the week 8 assessment. The app was rated positively across domains of engagement, functionality, aesthetics, and information. Participants' depression severity scores decreased from an average Hamilton Depression Rating Scale score indicating moderate depression (mean 19.1, SD 5.0) at baseline to a week 8 mean score indicating mild depression (mean 10.8, SD 6.1; $d=1.47$; $P<.001$). Improvement was also observed for functional impairment and quality of life. Gains were maintained at 3-month follow-up.

Conclusions: The results show that Mindset for Depression is a feasible and acceptable treatment option for individuals with major depressive disorder. This smartphone-led treatment holds promise to be an efficacious, scalable, and cost-effective treatment option. The next steps include testing Mindset for Depression in a fully powered randomized controlled trial and real-world clinical settings.

Introduction

Major depressive disorder (MDD), characterized by hallmark symptoms of persistent depressed mood and loss of interest in activities [1], is highly prevalent. In 2020, an estimated 21 million adults in the United States were impacted (8.4% population prevalence) [2]. The rates of elevated depressive symptoms have continued to rise since the COVID-19 pandemic, now affecting nearly 1 in 3 adults [3]. Depression is the leading cause of disability worldwide [4] and is associated with economic costs exceeding US \$326.2 billion in the United States alone [5]. Despite the substantial personal and societal impact of MDD, a minority of individuals meeting diagnostic criteria—let alone those at risk or with subthreshold symptoms—receive care; even fewer receive minimally adequate treatment (estimates range from 3% in low- to middle-income countries and 23% in high-income countries [6]), such as cognitive behavioral therapy (CBT), the most widely studied and recommended psychotherapy [7]. At a systems level, the limited availability of trained clinicians is a substantial contributor to low treatment utilization [8]. There simply are not and will not be enough clinicians to meet current demands for mental health care. Additionally, many people do not seek treatment for depression due to obstacles such as geographic distance from care providers, high costs, and stigma [8,9]. Given the prevalence of MDD and the substantial treatment gaps that exist, there is a clear need for low barrier, more widely accessible, effective treatments for MDD.

The technology could bridge such gaps. Smartphone apps or other digital tools could reduce the time and frequency of sessions by supplementing clinician effort with automated, validated support that can be used flexibly between sessions [10,11]. However, standalone apps are not sufficient or appealing for many patients [12,13]. The majority of apps, even those that are grounded in empirically supported treatments, have high dropout rates, which limits their effectiveness [14-16]. The absence of concurrent human support is often cited as the major reason for nonadherence or nonengagement [13,17-19]. Some engagement is likely a minimum requirement for an app-based therapy to be effective; guidance from a trained provider should further mitigate issues of comprehension, personalization, problem-solving, and interference from comorbid or life concerns [20]. Equivalent effects of face-to-face CBT and internet-delivered CBT for depression have been found for treatments that are *therapist guided*, meaning patients are in contact with a therapist throughout treatment (eg, weekly sessions, check-in phone calls, asynchronous, messaging, and weekly feedback emails) [21-23]. Moreover, many users simply want access to a therapist and are less willing to engage in

self-directed digital treatments [24,25]. Thus, a digital service that combines mobile-based CBT with brief remote individual sessions with a clinician (ie, teletherapy monitoring) has the potential to greatly enhance the scalability of high-quality app-based treatment, particularly for moderately and severely ill patients while reducing clinician burden and cost [26-28].

The purpose of this study was to conduct an open trial to test the feasibility, acceptability, and efficacy of the Mindset for Depression app (a novel, smartphone-based CBT program) with brief video-conferencing appointments with a therapist. We hypothesized that the treatment would be feasible and acceptable. We also hypothesized that treatment would yield statistically significant reductions in depression symptom severity (primary clinical outcome) as well as improvements in functioning and quality of life (secondary clinical outcomes) from baseline to posttreatment (week 8). The treatment was tested for patients with moderate to severe depression: those who would typically be referred for one-on-one outpatient therapy [29].

Methods

Study Design

This open trial tested the Mindset for Depression app when combined with brief (16-25 minutes) video-conferencing visits with a CBT therapist over 8 weeks. The primary outcomes were feasibility, acceptability, and preliminary efficacy, as measured by change in depression symptom severity. To increase accessibility and thus generalizability, all study procedures were conducted remotely.

Ethical Considerations

The study was approved by the institutional review board of Massachusetts General Hospital (2020P001958). All participants provided informed consent prior to the initiation of study procedures and were given the ability to opt out at any point. Data were deidentified to protect participants' privacy. Participants were compensated US \$25 at mid-treatment, end of treatment, and 3-month follow-up assessments.

Participants

Eligible participants, recruited between May 2022 and February 2023, were at least 18 years old, living in Massachusetts, presenting with a current primary *Diagnostic and Statistical Manual of Mental Disorders: 5th Edition (DSM-5)* diagnosis of MDD, and experiencing at least moderately severe symptoms (Patient Health Questionnaire-9 [PHQ-9] score ≥ 10). Participants taking psychotropic medication were on a stable dose for at least 2 months prior to enrollment and were asked to remain on the same stable dose throughout the study period.

Exclusion criteria included 4 or more prior sessions of CBT for depression (assessed via self-report and interview with an independent evaluator), current severe substance use disorder, lifetime bipolar disorder or psychosis, acute and active suicidal ideation as indicated by clinical judgment, a score ≥ 2 on the past month suicidal ideation subscale of the Columbia-Suicide Severity Rating Scale [30], concurrent psychological treatment, and inability to engage with treatment (eg, did not own a supported smartphone).

Procedure

Treatment

The Mindset for Depression app provides key CBT-derived content for adults with MDD and was designed to be used in conjunction with a therapist over 8 weeks. The duration of CBT trials typically ranges from 6 to 20 sessions [31]. Mindset for Depression was built in collaboration between researchers at the Massachusetts General Hospital and Koa Health. The app-based format allows participants to review CBT content and accompanying skills practice exercises at their convenience and own pace and with support from their therapist.

The app and clinician dashboard were developed through collaborative, user-centered design, integrating perspectives from clinicians (MDs and psychologists with expertise in MDD and CBT), digital health researchers, patients with MDD and experience with CBT and other therapies, engineers, and designers. Through this approach, the product being tested was deployment ready (eg, built on a commercial platform, able to be quickly scaled and professionally maintained to minimize technical difficulties, and ensure compliance with up-to-date privacy and security standards) and therefore well positioned to succeed outside of research studies [32].

CBT Modules

The app delivers content in 8 steps, corresponding to the 8 weeks of treatment. A summary of these steps is visualized in Table 1. Participants were also allowed access to the app during the 3-month follow-up period. Core CBT skills included across treatment include psychoeducation, cognitive restructuring and core beliefs, behavioral activation, mindfulness, and relapse prevention [33,34]. Step 1 comprises psychoeducation about MDD and the CBT model and background and skills practice for identifying and restructuring “thinking traps,” or maladaptive automatic thoughts [35,36]. Step 2 focuses on the short- and long-term impact of withdrawal and avoidance on mood and provides a structure for recording daily activities and monitoring associated moods. Step 3 introduces behavioral activation and scheduling and provides guidance for identifying valued or new activities and setting specific, measurable, achievable, relevant, and time-bound (SMART) goals [37,38]. Activity scheduling and monitoring (ie, recording completed activities and associated mood ratings), with an emphasis on personal values and meaning, continue for the remainder of treatment. Step 4 introduces mindfulness (present-focused and nonjudgmental awareness) and offers a guided mindful breathing audio exercise [39]. Steps 5 and 6 provide users with additional mindfulness approaches, including grounding and letting go of unhelpful thoughts. Step 7 builds on prior cognitive skills and delves into the definition of core beliefs, their relationship to automatic thoughts and feelings, and strategies to identify and challenge them (eg, downward arrow technique and building self-esteem). Step 8 concludes with relapse prevention by helping users consolidate treatment skills, anticipate future challenges, and plan for continued practice and flexible use of skills. Example screenshots from the smartphone app are included in Figure 1.

Figure 1. Screenshots from the Mindset for Depression smartphone app. CBT: cognitive behavioral therapy; SMART: specific, measurable, achievable, relevant, and time-bound.

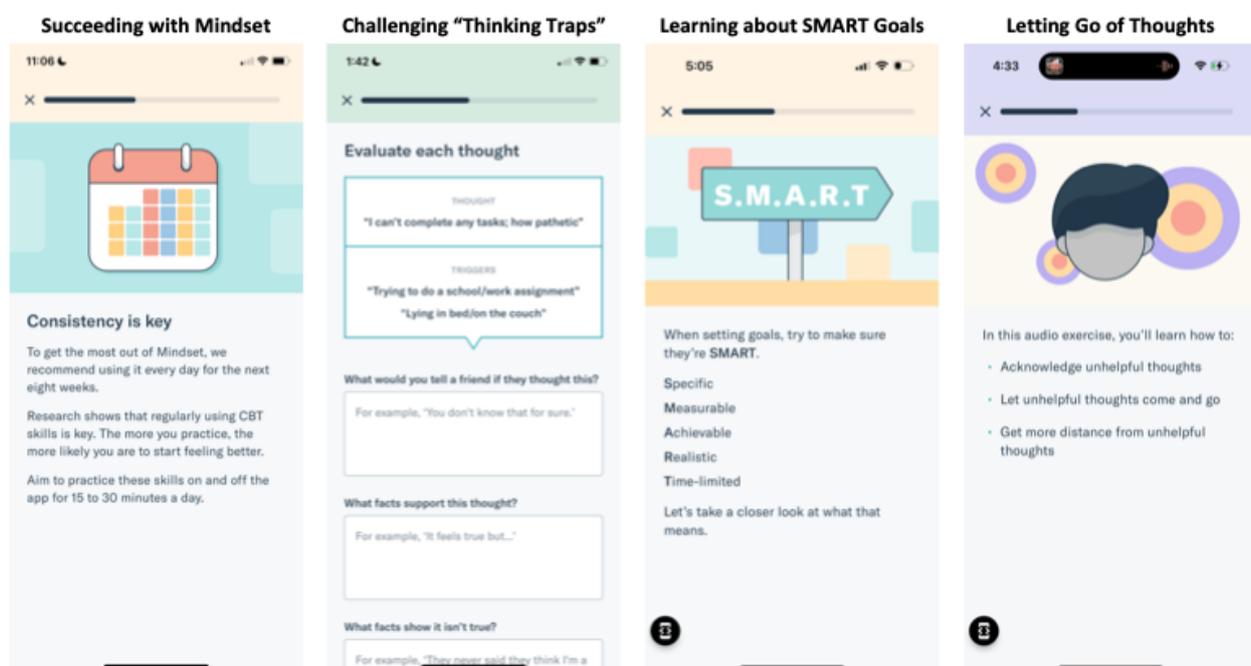

Table 1. Summary of steps in the Mindset for Depression program.

Therapists

Each participant was matched with a licensed doctoral-level therapist. Therapists were trained in and actively practicing CBT for MDD and provided with study-specific training in using the Mindset app and therapist dashboard prior to beginning the trial. To ensure proficiency, therapists were required to complete the Massachusetts General Hospital Psychiatry Academy CBT training course and pass (>90% correct) both the corresponding CBT knowledge test and an MDD knowledge test. Weekly supervision from the principal investigator (expert in CBT) was also provided. To ensure ongoing high-quality treatment, including that implementation fidelity targets were met and non-CBT techniques were absent, sessions were audio recorded, and 40 of the 224 planned sessions (18.9% of the 212 sessions ultimately conducted) were randomly selected and rated for competency and treatment adherence by an independent rater. Adherence raters were experienced in CBT for MDD and further trained and supervised. Core elements of each treatment session (5-6 items) were rated for adherence on a 7-point scale (1=not at all to 7=completely adherent) and then a global rating of adherence was assigned. The full adherence scale is included in [Multimedia Appendix 1](#). Competence was rated on 12 aspects (32 items) of CBT for MDD (eg, positive outlook, knowledge, clear communication, empathy, flexibility, and empowering the patient). Each item was scored on a 5-point scale (1=not at all to 5=completely competent) and then a global rating of competence was assigned. Overall, adherence and competence were high, with 100% of all rated sessions evaluated as “completely” adherent and 100% of all rated sessions evaluated as “mostly” or “completely” competent.

Therapists offered each patient 8 video-conferencing appointments (16-25 minutes; via HIPAA [Health Insurance Portability and Accountability Act]-compliant video conference) to be conducted weekly. This duration of appointment corresponds to a clinician billing code (CPT-90832), helping to ensure that the reimbursement of clinician time would not become a barrier to scale-up following the research. As needed, because of a therapist's or patient's schedule, up to 2 sessions were able to be scheduled per week. Throughout the treatment, participants were able to communicate with their therapists between sessions through asynchronous in-app secure messaging. Sessions were meant to support a patient's progress through the app-led treatment. In this way, the model mimicked the “flipped classroom,” a new pedagogical approach shown to

improve student learning [40]. In a flipped classroom, students watch or read lectures and complete initial practice problems asynchronously, reserving valuable classroom time for active problem-solving with an instructor. As such, sessions were intended to monitor risk as needed, help participants set goals, enhance motivation, clarify and practice the skills learned via the Mindset app to best meet the patient's needs, brainstorm ideas for homework, and problem-solve treatment barriers that arose. Therapists were instructed to work within a CBT framework and not to introduce other treatment modalities. Such fidelity was monitored in weekly supervision, via therapist self-checks included within session records (“Did you use any of the following non-CBT techniques? [check *all* that apply]”) and via adherence ratings (ie, the degree to which forbidden content was introduced). The therapist dashboard was a separate web-based portal wherein therapists could receive and respond to messages and track participant progress in the app.

Assessments

Assessments were conducted by master's or doctoral-level independent evaluators who were not involved in treatment, were complemented by participant self-report, and occurred at baseline, mid-treatment (week 4), end of treatment (week 8), and follow-up (3 months posttreatment). Evaluators completed training on all clinician-administered measures and were required to maintain high reliability (>0.75 intraclass correlation coefficient), with a gold standard expert rater; 18.9% (20/106) of randomly selected assessments were rated to prevent rater drift. Evaluators were not privy to participants' progress in treatment (eg, app content reviewed and session notes). Adverse events, life events, and changes in medication or outside treatment were surveyed at each assessment or when a patient reported to study staff.

Measures Descriptions

Baseline Diagnostic Assessment

The Mini International Neuropsychiatric Interview was used to establish eligibility and characterize the sample. It is a reliable, validated semistructured diagnostic assessment of *DSM-5* psychiatric disorders [41].

Feasibility and Acceptability

Participants completed the self-reported measures as follows. The Credibility/Expectancy Questionnaire (CEQ) [42], completed at baseline and week 4, is a 6-item, self-reported

Likert-type questionnaire that assesses patients' judgments about the credibility of the treatment rationale and treatment expectancy. Items on both subscales are summed together for total outcome scores that can range from 3 to 27, where higher scores mean higher treatment credibility and higher outcome expectancy. We assessed the internal consistency of scales with coefficient omega (McDonald ω), given the heterogeneity of variances across scale items; coefficient ω can be interpreted in the same way as Cronbach α . The internal consistency of the credibility items in this sample ranged from $\omega=0.69$ at baseline to $\omega=0.77$ at week 4; for the expectancy items, internal consistency ranged from $\omega=0.82$ at baseline to $\omega=0.96$ at week 4. The Mobile Application Rating Scale User Version (uMARS) [43], administered at week 8, collects evaluations of mobile health apps. The 26 items assess participants' evaluations of engagement, functionality, aesthetics, information quality, app subjectivity quality, and perceived impact. Items are rated on differently worded 5-point Likert scales ranging from 1 (inadequate) to 5 (excellent). An overall app rating score can be calculated as the mean score of the first 4 subscales (engagement, functionality, aesthetics, and information quality; a range of 1-5), where higher scores indicate higher overall perceived app quality. In this sample, the internal consistency of the 4 subscales used in the overall mean scores were $\omega=0.76$ for engagement, $\omega=0.83$ for functionality, $\omega=0.72$ for aesthetics, and $\omega=0.62$ for information quality, with an overall item consistency of $\omega=0.83$. The Client Satisfaction Questionnaire (CSQ) [44], completed at weeks 4 and 8, is an 8-item questionnaire assessing satisfaction with clinical services received. Each item uses a 4-point Likert scale. Items are summed for a total score ranging from 8 to 32, with higher scores indicating greater satisfaction. The internal consistency of the CSQ was $\omega=0.93$ at week 4 and $\omega=0.89$ at week 8. Treatment use was assessed with a single question: "On average, how much time (in minutes) do you spend using the app or practicing skills from the app in total, per week?" Answers were collected as the number of minutes in integer format, where more time spent on and off the app was interpreted as greater treatment use. In addition, app use data were collected automatically based on the actions participants completed in the app. Due to technical issues, 2 participants' app use data were inadvertently not recorded. The internal consistency values for the CEQ credibility subscale at baseline and the uMARS information quality subscale fell below 0.7 and are a noted limitation.

Clinician-Administered Measures

The primary measure of MDD symptom severity was the (clinician-rated) Hamilton Depression Rating Scale (HAM-D) [45]. Considered a gold standard means of assessing symptom severity in patients who are depressed, it contains 21 items that are rated on a mixture of 3- and 5-point Likert scales. The first 17 items are summed for the total score, which can range from 0 to 52. Higher scores indicate greater depression severity. The internal consistency of the HAM-D in this sample ranged from $\omega=0.79$ at baseline to $\omega=0.93$ at the 3-month follow-up (question 17 was necessarily omitted from internal consistency calculations due to the absence of variability in responses; all participants received a score of 0 for this "insight" item

["Acknowledges being depressed and ill"]) at all assessment points with the exception of 1 participant at the 3-month follow-up). To evaluate treatment response and remission, we used criteria of HAM-D score reductions of $\geq 50\%$ for treatment response, HAM-D score reductions of $\geq 25\%$ but $< 50\%$ for partial response, and HAM-D scores ≤ 7 to indicate remission [46-48]. An expert rater reviewed 18.9% (20 of the 106 assessments that were ultimately completed) of HAM-D assessments. Inter-rater reliability was excellent (HAM-D: intraclass correlation coefficient (1,1)=0.91).

Self-Reported Measures

Participants completed the following secondary measures of symptoms and functioning at each assessment: (1) The Work and Social Adjustment Scale (WSAS) [49] is a 5-item, self-reported measure of impairment in occupational, social, and family domains. Items are measured on 9-point Likert scales ranging from 0 (no impairment at all) to 8 (very severe impairment). The items are summed for a total score ranging from 0 to 40, where higher scores mean higher functional impairment. The internal consistency of the WSAS ranged from $\omega=0.84$ at baseline to $\omega=0.93$ at the 3-month follow-up. (2) The Quality of Life Enjoyment and Satisfaction Questionnaire-Short Form (Q-LES-Q-SF) [50] is a 16-item self-reported measure of subjective quality of life. Each question is rated on a 5-point Likert scale ranging from 1 (very poor) to 5 (very good). Questions 1-14 are then summed to a total score, and the total score is reported as a percentage maximum possible, such that the final percent score range is 0% to 100%; higher scores correspond to greater ratings of quality of life. The internal consistency of the Q-LES-Q-SF ranged from $\omega=0.84$ at baseline to $\omega=0.90$ at the 3-month follow-up. (3) The PHQ-9 [51] is a self-reported measure of the past week's depression severity. It includes 9 Likert scale items mapping onto *DSM-5* symptom criteria and ranging from 0 (not at all) to 3 (every day). The internal consistency of the PHQ-9 ranged from $\omega=0.70$ at baseline to $\omega=0.89$ at week 8.

Data Analysis

Power Analysis

With 28 participants enrolled, we had $> 80\%$ power to detect pre- to posttreatment effect sizes of $d \geq 1.37$ (very large effect sizes), assuming 30% dropout, a pre- to posttreatment correlation of 0.18, and a doubling of the SD from pre- to posttreatment. The pre- to posttreatment correlation estimate was based on the mean pooled correlation between pretest and posttest HAM-D scores in 14 CBT trials for adult depression [52], and the estimate of the detected effect size was based on a single degree of freedom contrast in a paired means test implemented in SAS for Windows (version 9.4; SAS Institute).

Feasibility and Acceptability

We examined feasibility and acceptability by reporting (1) dropout rates and reasons (defined as participants not completing an end point HAM-D), (2) patient satisfaction (CSQ), (3) patient feedback (uMARS), (4) patient credibility and expectancy ratings (CEQ), and (5) treatment use. We computed means and SDs for the number of app steps completed, the number of days on which participants completed any actions in the app, the

number of messages participants sent their therapist in the app, the number of sessions participants completed with their therapists, and session time spent per patient per week by therapists. For measures collected at least twice (ie, CSQ, CEQ credibility and expectancy, and treatment use), we used generalized linear mixed models with repeated measures to examine if these self-reported ratings changed over time.

Preliminary Efficacy and Secondary Outcomes

Analyses were first completed using our intent-to-treat sample (participants who completed a baseline assessment) and then repeated with our “per-protocol” sample (participants who completed posttreatment assessments and did not change psychiatric medications or begin psychotherapy during the study; $n=24$, 86%). We examined the preliminary efficacy of Mindset for Depression plus brief video-conferencing appointments with a therapist on symptoms and well-being outcomes using mixed model analyses with repeated measures (baseline, mid-treatment, posttreatment, and 3-month follow-up) modeled using an unstructured covariance matrix. We then compared pre- to posttreatment differences using a 2-tailed α of .05 to evaluate preliminary efficacy. We similarly compared pretreatment to end of follow-up estimates to estimate whether

changes remained significant by the end of the follow-up. Means are presented as raw means with SDs, while differences between assessments are presented as model-estimated means with CIs (LSM differences [95% CI]) unless otherwise specified. Effect sizes were calculated as Hedges g_{ave} , which takes the correlation of within-participant scores into account [53]. Analyses were conducted for changes in depression symptoms (HAM-D and PHQ-9), functional impairment (WSAS), and quality of life (Q-LES-Q-SF). All analyses were completed using the SAS software (version 9.4, SAS Institute Inc).

Results

Overview

Study participants ($N=28$) were predominantly female ($n=21$, 75%), White ($n=20$, 71%), and single ($n=19$, 70%), with a mean age of 33.5 (SD 10.9) years. The majority of participants had college or advanced degrees, were employed full time, and came from urban or suburban locations (Tables 2 and 3). Nearly half of the participants ($n=13$, 45%) had one or more comorbid psychiatric diagnoses, and the average duration of MDD was 15.5 (SD 12.7) years.

^dSRI: serotonin reuptake inhibitor.

^eThis included anticonvulsants; no participant reported taking antipsychotics.

Feasibility and Acceptability

Credibility and expectancy scores were moderate to high at pre- and mid-treatment. The ratings did not differ significantly between timepoints. Mean credibility ratings were 18.9 (SD 3.1) at pretreatment and 19.3 (SD 3.8) at mid-treatment (LSM difference 0.4, 95% CI -1.4 to 2.2; $P=.63$; $g_{ave}=0.13$). Mean expectancy ratings were 13.8 (SD 3.3) at pretreatment and 15.0 (SD 5.4) at mid-treatment (LSM difference 1.2, 95% CI -0.7-3.0; $P=.22$; $g_{ave}=0.28$). Of the 28 participants, 2 (7%) dropped out of the study prior to their posttreatment assessment at week 8 (Figure 2): 1 during the first week of treatment and 1 after the midpoint assessment; both participants were lost to follow-up despite repeated contact attempts and neither provided a reason for drop out. One more participant was lost to follow-up after the posttreatment assessment. Among the 26 participants who completed the posttreatment assessment, patient satisfaction was high and did not change significantly from mid-treatment (CSQ total score mean 26.3, SD 4.0) to posttreatment (mean 27.2, SD 3.3; LSM difference 1.0, 95% CI -0.1 to 2.2; $P=.07$; $g_{ave}=0.24$). Conservatively counting the 2 dropouts as not satisfied, 89% (16/28) were very or mostly (9/28) satisfied and 93% (26/28) would recommend the Mindset for Depression program.

With respect to app use and satisfaction, participants reported practicing skills from the app on their smartphone and offline

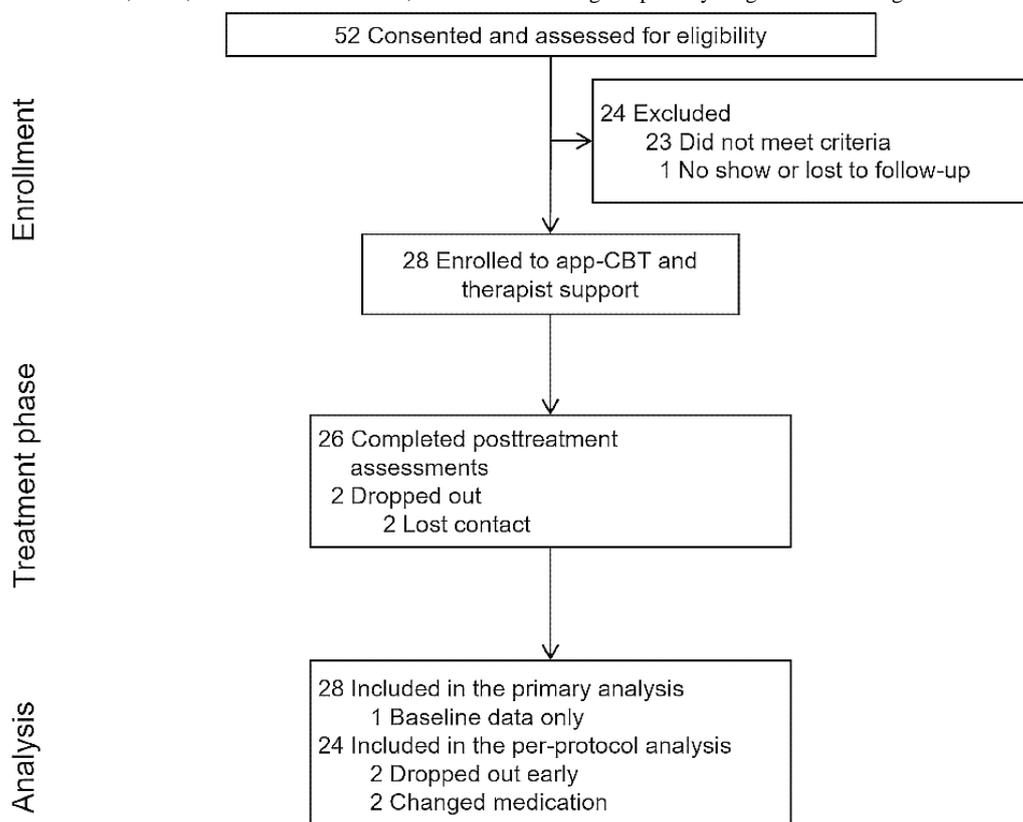

for a median of 50 (IQR 30-60) minutes per week up to mid-treatment and 60 (IQR 30-90) minutes per week between mid- and posttreatment. Based on passively collected app use data ($n=26$), participants accessed the app on 36.8 (SD 10.0) days, completed a median of 7 (IQR 6-8) steps out of 8 steps by the week 8 assessment, and sent a median of 0 (IQR 0-4) between session messages to their therapist through the app. Five participants completed the last assigned step after the week 8 assessment, bringing step completion to a median of 8 (IQR 6-8) by the end of follow-up (3 months), with 58% (15/26) participants completing the final step by then. Participants' overall ratings of the app quality, rated on the 1 (inadequate) to 5 (excellent) scale of the uMARS, was high (mean 4.3, SD 0.4); ratings of the app's functionality (mean 4.5, SD 0.6), aesthetics (mean 4.6, SD 0.4), and information (mean 4.6, SD 0.4) were higher than those of the engagement subscale (mean 3.6, SD 0.6). Participants reported a mean overall star rating of 4.0 (SD 0.5) but were less inclined to endorse that they would be willing to pay for the app (mean 2.5, SD 1.2).

With respect to therapist support, participants attended an average of 7.6 (SD 1.5) of the possible 8 brief sessions, each of which lasted approximately 24.5 (SD 1.1) minutes. In the sessions, therapists mainly covered behavioral strategies (mean 10.9, SD 3.4 minutes), cognitive strategies (mean 6.9, SD 2.7 minutes), psychoeducation (mean 2.5, SD 2.9 minutes), and mindfulness strategies (mean 2.4, SD 1.2 minutes), with only

a little time (<2 minutes on average) spent on explicit motivational strategies, risk management, and technical issues.

Participants had a mean homework completion rate (per therapist report) of 82.7% (SD 13.8%).

Figure 2. Flow of participants through the 8-week open trial of the Mindset Depression app with brief therapist visits on the web for people with a primary diagnosis of major depressive disorder. Reasons for ineligibility include diagnosis of bipolar disorder or severe substance use disorder, PHQ-9 score < 10, past CBT for MDD, acute, active suicidal ideation, and MDD not being the primary diagnosis. CBT: cognitive behavioral therapy.

Preliminary Efficacy and Secondary Outcomes

Over the course of the 8-week treatment, participants’ depression severity decreased significantly on both the clinician-rated (HAM-D: $P<.001$; $g_{ave}=1.47$) and self-reported measures (PHQ-9: $P<.001$; $g_{ave}=1.89$; 4). Concurrently, participants’ self-rated functional impairment decreased (WSAS: $P<.001$; $g_{ave}=1.29$), and their self-rated quality of life increased (Q-LES-Q-SF: $P<.001$; $g_{ave}=1.74$). These changes persisted through the 3-month follow-up, with effect sizes remaining largely the same (Table 4). The results did not differ meaningfully in the per-protocol analyses; HAM-D, PHQ-9, WSAS, and Q-LES-Q scores all improved with statistically significant and large effect sizes (Table 5).

Conservatively counting dropouts as having not responded to treatment, 46% (13/28) participants responded and another 7%

(2/28) partially responded at posttreatment. Regarding remission, and again counting dropouts also as not remitting, 36% (10/28) achieved remission at posttreatment. Based on the per-protocol sample, 54% (13/24) participants fully responded to treatment and 8% (2/24) partially responded to treatment; 42% (10/24) achieved remission by the posttreatment assessment. By the end of follow-up and counting dropouts as not responding and not remitting, 50% (14/28) participants had responded to treatment, and an additional 21% (6/28) of participants had partially responded to treatment; 36% (10/28) participants were in remission. In the per-protocol sample at the end of follow-up and excluding the additional participant lost to follow-up, 61% (14/23) of participants had responded to treatment, and 26% (6/23) of participants had partially responded to treatment; 43% (10/23) participants were in remission at the 3-month follow-up assessment.

Adverse Events and Medication Changes

Overall, 17 out of 28 participants reported a total of 33 adverse events during the 8-week treatment phase of the trial in categories such as psychiatric symptoms (n=21, 64%; eg, increased suicidal ideation, depression, or anxiety, sleep difficulties, and emotional distress), infections (n=6, 18%; eg, COVID-19, shingles, and illness), physical injuries (n=3, 9%), and other (n=3, 9%). All adverse events were identified as either mild (new event that did not interfere with activities of daily living; 25/33, 75.8%) or moderate (new event that posed some

interference or required intervention to prevent interference; 8/33, 24.2%). No serious adverse events occurred in this trial. By assessing how likely it was that reported adverse events were related to treatment, most events were found to be definitely unrelated (19/33, 57.6%), followed by unlikely to be related (5/33, 15.2%) or possibly related (9/33, 27.3%). A waxing and waning course of MDD symptoms and suicidal ideation is common in MDD. However, there were no adverse events indicating significant clinical deterioration in the trial and no principal investigator-initiated withdrawals. Two participants changed psychotropic medications during the

treatment phase: 1 participant increased the dosage of their medication for anxiety and 1 participant discontinued their medication for depression. There were no reported therapy changes during the treatment phase. In the 3-month follow-up phase of the trial, 7 participants reported an additional 10 adverse events in the categories of psychiatric symptoms (4/10, 40%), general disorders (2/10, 20%), and other (4/10, 40%), which were found to be definitely unrelated (5/10, 50%), unlikely to be related (1/10, 10%), and possibly related (4/10, 40%) to treatment. Also during the follow-up period, 5 participants changed psychotropic medications and 3 participants started individual therapy or counseling (non-CBT; for mood or anxiety, and traumatic event or PTSD).

Discussion

Principal Findings

In this study, we examined the feasibility, acceptability, and preliminary clinical impact of Mindset for Depression, an 8-week app-based CBT with therapist support. The results support Mindset for Depression as a viable treatment option for individuals with moderate to severe MDD. Treatment was feasible to deliver in a setting and acceptable to patients who varied widely in age, severity of the symptoms, and other clinical and demographic dimensions, as indicated by high retention rates (27/29, 93%), favorable satisfaction ratings (CSQ), and positive user feedback (uMARS). The results also showed that the treatment was efficacious. There was a significant reduction in clinician-rated (HAM-D) depression severity with a large effect size as well as significant improvement in functioning and quality of life. After just 8 weeks, about half of the participants were rated as treatment responders and a third were in remission, and these changes were maintained throughout the 3-month follow-up. These results are similar to face-to-face psychotherapy [54] and comparable to guided internet-delivered CBTs, notable given the short treatment duration, younger age, and relatively higher severity of the sample, all of which are associated with lower odds of response and remission in digital treatment [55].

Encouragingly, app ratings were above average for mental health apps [56]. Compared to other mHealth for depression or anxiety [57-60] and treatment-as-usual for depression [61], overall treatment satisfaction scores (CSQ) were also excellent. This was achieved despite clinician time that was below typical courses of CBT for depression (8 sessions averaging 24 minutes vs upwards of 20 sessions lasting on average 45-50 minutes) [62]. Indeed, much of the time-consuming didactic content (eg, psychoeducation about the CBT model) was administered by the app through readings, videos, and practice questions, conserving clinician time for more personalized skills' review, practice, and tailoring and addressing risk issues. App usage data were excellent, with most participants reaching the final step by the end of 8 weeks as intended and reporting regularly practicing skills on or off the app each week. Moreover, participants rarely used the messaging function between sessions (eg, seeking additional clarification or encouragement), which would be unbillable clinician time. In this way, Mindset for Depression has the potential to improve the reach of CBT

therapists and hopefully reduce treatment gaps, particularly for underserved communities [63,64].

These results are important because the high cost and limited availability of trained clinicians are major barriers to the dissemination of traditional psychotherapy [65]. Our findings add to an emerging literature demonstrating the potential of guided smartphone-based CBT to mitigate these challenges. However, although numerous seemingly efficacious therapist-supported digital treatments have been created for depression [10], few are available outside of research settings or integrated into a health care system [25]. Created in collaboration with an industry partner to accelerate the dissemination pipeline and allow for ongoing technical maintenance and improvements, Mindset for Depression is commercially available and poised to be truly scalable and successful in real clinical settings. Setting it apart, Mindset for Depression was collaboratively developed with a design team, clinicians, and people with lived experience as well as rigorously applied user interface and experience best practices for mobile platforms. Critically, "users" in the user-centered design process included both patients and clinicians. This approach aligns clinical and engagement incentives so that one is not delivered at the expense of the other and yields an easy to use, streamlined, and effective treatment program. Concretely, this translated to pacing content (delivering or unlocking intervention components in a stepwise manner to encourage practice and mastery of concepts and skills that build on one another), shorter activity lengths, creating a professional and approachable tone, and inclusion of feedback loops. As standardized content is delivered via the app in each step, supporting clinicians are able to prioritize personalizing treatment and use their specialized skillsets, such as addressing unique barriers to motivation, engagement, or response. Critical next steps would be to directly evaluate the program and its readiness to scale in larger scale effectiveness trials and real-world settings.

The results also provide important guidance for improving the program. First, participant feedback (eg, uMARS engagement subscale) indicates that increased customization and interactivity could improve the app's appeal. This is consistent with the larger literature showing user preferences for apps with such features and negative reactions to apps whose content is repetitive and not personally relevant [66]. Although most participants shared positive views of the Mindset app, including indicating that they would recommend the app to friends, there was a mixed response regarding their willingness to pay for the Mindset app. It is unclear to what extent this reflects (1) that this question was asked after treatment and thus patients no longer felt the need to use the app; patients were meant to complete all therapeutic content within the 8-week treatment period; (2) a gap between what patients find beneficial and what they are willing to pay for; other studies have similarly found a reluctance to pay for mental health apps [66,67]; or (3) whether the app and concurrent therapist support were experienced as critically linked, and thus the app alone was not as valued. Indeed, half of participants indicated weekly brief sessions were the exact right amount of therapist contact and only 2 would have preferred less contact. Resolving this question will be necessary for developing a commercially sustainable

implementation plan. Moreover, future iterations would benefit from broadening outcomes of interest. For example, beyond reducing symptoms of depression or other mental health concerns, an optimal intervention would also foster positive emotions and thriving and perhaps target common comorbidities, such as sleep difficulties or substance use. These outcomes should be captured in future studies and additional treatment components integrated as appropriate.

Limitations

The study has limitations that should be considered. First, the study has the inherent limitation of an open trial. Without a control group, we cannot conclusively determine that the treatment causes improvements in symptoms. Future controlled large-scale trials are needed. Second, the patient sample was self-selected, recruitment platforms were diverse, and our study therapists were trained in the use of digital therapeutics. Thus, patient and clinician stakeholders might have been biased toward individuals who are motivated by app-based therapy. Future research in real-world clinical settings is warranted. Third, although the large proportion of White women in the sample is consistent with past work and higher MDD prevalence and rate of treatment seeking in women [10], greater representation of patients with other racial and gender identities would strengthen

our conclusions and ongoing treatment improvements. Fourth, we had adequate power to detect moderate to large treatment effects; a larger replication is needed to explore moderators and mediators, which are important for tiered care models. Finally, a longer follow-up period and health economics metrics would be required to see the full time and cost-savings potential of Mindset for Depression.

Conclusions

Mindset for Depression offers flexible app-led psychoeducation, skills practice, and support to patients with complementary clinician guidance to promote sustained engagement, monitor safety, and tailor treatment further to individual patient needs. The findings show that Mindset for Depression is a feasible, acceptable, and efficacious tool for adults with MDD. The hope is that such a program could be one cost-effective solution to barriers to psychotherapy dissemination and significantly increase access to evidence-based care. Although these initial results are very promising, more work remains to personalize the amount of therapist support and dose of treatment individuals receive to optimize treatment and increase rates of response and remission. The next steps include testing Mindset for Depression in a fully powered randomized controlled trial as well as the real-world clinical settings in which it is deployed.

Acknowledgments

The research was supported by Koa Health. Investigators from Massachusetts General Hospital (MGH) (SW, EEB, KHB, JLG, and HW) developed the Mindset app in collaboration with technologists and designers from Koa Health via a user-centered, iterative design approach. The investigators from MGH were responsible for the study design and the execution of the study. Koa Health supported the technical activities related to the development and deployment of the app. Koa Health had no role in the recruitment of participants and had no access to data during the trial. The sponsor was able to make minor edits to the draft of the paper. HW was supported in part by the National Institute of Mental Health of the National Institutes of Health under award number K23MH119372. KHB was supported in part by the National Institute of Mental Health of the National Institutes of Health under award number K23MH120436. Abstract

Background: Major depressive disorder (MDD) is a global concern with increasing prevalence. While many evidence-based psychotherapies (EBPs) have been identified to treat MDD, there are numerous barriers to patients accessing them. Virtual reality (VR) has been used as a treatment enhancement for a variety of mental health disorders, but few studies have examined its clinical use in treating MDD. Behavioral activation (BA) is a simple yet effective and established first-line EBP for MDD that has the potential to be easily enhanced and adapted with VR technology. A previous report by our group explored the feasibility and acceptability of VR-enhanced BA in a small clinical proof-of-concept pilot. This study examines the clinical efficacy of a more immersive extended reality (XR)–enhanced BA (XR-BA) prototype. This is the first clinical efficacy test of an XR-BA protocol.

Objective: This study examined whether XR-BA was feasible and efficacious in treating MDD in an ambulatory telemedicine clinic.

Methods: A nonblinded between-subject randomized controlled trial compared XR-BA to traditional BA delivered via telehealth. The study used a previously established, brief 3-week, 4-session BA EBP intervention. The experimental XR-BA participants were directed to use a Meta Quest 2 (Reality Labs) VR headset to engage in simulated pleasant or mastery activities and were compared to a control arm, which used only real-life mastery or pleasant activities as between-session homework. The Patient Health Questionnaire (PHQ)–9 was the primary outcome measure. Independent-sample and paired-sample *t* tests (2-tailed) were used to determine statistical significance and confirmed using structural equation modeling.

Results: Overall, 26 participants with MDD were randomized to receive either XR-BA (n=13, 50%) or traditional BA (n=13, 50%). The mean age of the 26 participants (n=6, 23% male; n=19, 73% female; n=1, 4% nonbinary or third gender) was 50.3 (SD 17.3) years. No adverse events were reported in either group, and no substantial differences in dropout rates or homework completion were observed. XR-BA was found to be statistically noninferior to traditional BA ($t_{18,6}=-0.28$; $P=.78$). Both the XR-BA ($t_9=2.5$; $P=.04$) and traditional BA ($t_{10}=2.3$; $P=.04$) arms showed a statistically significant decrease in PHQ-9 and clinical severity from the beginning of session 1 to the beginning of session 4. There was a significant decrease in PHQ-8 to PHQ-9 scores between the phone intake and the beginning of session 1 for the XR-BA group ($t_{11}=2.6$; $P=.03$) but not the traditional BA group ($t_{11}=1.4$; $P=.20$).

Conclusions: This study confirmed previous findings that XR-BA may be a feasible, non-inferior, and acceptable enhancement to traditional BA. Additionally, there was evidence that supports the potential of XR to enhance expectation or placebo effects. Further research is needed to examine the potential of XR to improve access, outcomes, and barriers to MDD care.

Introduction

Background

Major depressive disorder (MDD) is a global concern with increasing cases worldwide [1]. Depressive disorders are the most significant contributors to nonfatal health loss worldwide, with a 37.9% increase in their economic burden from 2010 to 2020 [1,2]. MDD is associated with suicide, which is one of the leading causes of death in young adults. Although many evidence-based psychotherapies (EBPs) for MDD exist, less than 1 in 4 people in low- to middle-income countries receive these treatments [1]. Thus, creating solutions for access to care is a priority in the treatment of MDD.

Due to its simplicity and efficacy, behavioral activation (BA) is one of the most widely used first-line EBP for MDD [3]. The behavioral theory underpinning this intervention postulates that depression is due to an avoidance pattern of increasingly less frequent engagement in pleasurable or mastery activities [3,4]. BA provides the tools for reversing this pattern through intentional scheduling of and engaging in positive and mastery activities. Despite BA's usefulness and effectiveness, few patients with MDD ever obtain access to BA due to barriers and obstacles such as physical limitations, financial constraints to accessing activities, social isolation, mental health stigma, or a lack of trained providers [5,6].

Extended reality (XR) is a term that is used to describe all current and future immersive technologies, including virtual reality (VR) and augmented reality. XR is becoming increasingly popular, with approximately 1 in 5 consumers in the United States using it in 2020 and an estimated 70.8 million people in the United States using it at least once per month in 2023 [7]. Immersive technologies such as VR are being used to solve multiple barriers to mental health care, such as improving access to content not readily accessible in real life (IRL). The use of VR to enhance the treatment of anxiety and trauma disorders has been reported on for the past 3 decades owing to its ability to easily and reliably provide controlled cue desensitization [8].

While there is a preponderance of support illustrating XR's efficacy in enhancing EBP and reducing barriers to care, surprisingly few clinical studies have examined its use directly in populations with MDD [8,9]. While several studies have examined the use of VR to treat mood disorders, to our knowledge, only 1 clinical trial focusing on using VR-enhanced BA (VR-BA) in a population with MDD has been completed to date [9,10]. This previous feasibility study, completed by our group, observed evidence of improvement in MDD outcomes using VR to simulate pleasant activities during a brief BA intervention [10].

This study is an extension of our previous VR-BA feasibility study and remains in line with the international working group's methodological framework for developing the design, implementation, analysis, interpretation, and communication of trials of novel VR behavioral health treatments [11]. We

iterated our previous VR-BA prototype based on pilot-testing and feedback to a more immersive, embodied, and autonomous XR prototype (XR-enhanced BA [XR-BA]) using a commercially available Meta Quest 2 (Reality Labs) VR headset. On the basis of user feedback, we made the XR-BA protocol identical to traditional in vivo or IRL BA by allowing patients to freely decide which XR pleasant activities to engage in rather than being restricted to a list of curated pleasant experiences. This allowed for a more personalized customization and a higher sense of autonomy by users and mirrors the elements associated with traditional BA. It also more closely mimics traditional BA by refraining from confining participants to preselected VR choices. While the devices were not Health Insurance Portability and Accountability Act-compliant at this time, participants were informed of the potential privacy risks associated with Meta potentially tracking their use. However, the authors and the institutional review board considered this risk akin to that of traditional BA, where activities can be observed by others or tracked through purchases. Furthermore, no mental health-specific data were collected on the device.

This study went beyond examining simple feasibility and tested the clinical efficacy of XR-BA compared to traditional BA. We specifically examined whether XR-BA is efficacious in reducing clinical depressive symptoms and shows noninferiority to traditional BA delivered without VR in an ambulatory MDD sample.

Objectives

The first aim of this study was to test the safety and feasibility of our newest prototype (XR-BA) using an embodied and interactive VR headset to engage with maximum free choice during a brief BA protocol guided by a telehealth clinician. It was hypothesized that XR-BA would be safe, feasible, and acceptable for outpatients with MDD receiving remote care.

The second aim of this study was to examine the efficacy of XR-BA compared to that of a traditional brief BA protocol for MDD. We predicted from prior work that XR-BA would not be inferior to traditional brief BA in reducing symptoms of MDD as measured using the Patient Health Questionnaire-9 (PHQ-9). The decision to compare XR-BA to a traditional BA protocol rather than a sham VR control was because engagement with VR itself can be considered a pleasant activity within BA, and thus could be a confounding variable within a sham control. Thus, with traditional BA being the gold EBP standard with known efficacy, it seemed a more meaningful comparison. If XR-BA can be as efficacious as traditional BA and more accessible to those with barriers to IRL pleasant activities, then it may prove to be an impactful enhancement to treatment.

Methods

Recruitment

Recruitment took place remotely via Zoom (Zoom Video Communications)-delivered telehealth sessions between

December 19, 2022, and July 24, 2023. The trial was registered on ClinicalTrials.gov (ID NCT05525390).

Participants were recruited locally via study flyers posted in the Stanford School of Medicine Department of Psychiatry and Behavioral Sciences located in Palo Alto, California, United States. The description of the study was also electronically listed on Stanford University's website for currently recruiting studies, ClinicalTrials.gov, and Craigslist. Without solicitation, a private web-based company called *Power* included our study on its website and connected participants with this study without any formal agreement, consent, or payment from our research group.

The inclusion criteria were as follows: age of ≥ 18 years; ability to speak English; and meeting of the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, criteria for MDD. The exclusion criteria were as follows: substance use disorder in the previous year, diagnosis of any psychotic or bipolar I disorder, seizure in the previous 6 months or untreated epilepsy, current suicidal urges or intent, current nonsuicidal self-injury or parasuicidal behavior, changing psychotherapy treatment within the last 4 months before study entry, or changing psychotropic medication within 2 months of study entry. This study offered no compensation for participation.

The initial screening procedure consisted of 2 steps: an initial phone screening and a face-to-face Zoom intake session. During the initial phone screening, callers were assessed for preliminary eligibility using the Patient Health Questionnaire-8 (PHQ-8) and a brief screening questionnaire and were given the opportunity to ask questions about the study ([Multimedia Appendix 1](#)). If the initial eligibility criteria were met, as determined by the answers to the questionnaire and a PHQ-8 score of ≥ 10 , potential participants were securely emailed a consent form to read, review, and sign at their leisure [[12](#)] ([Multimedia Appendix 2](#)). Potential participants were informed that they could reach out to the clinician with any questions before signing the consent form. After potential participants securely returned their signed consent forms, a Zoom intake session was held to determine complete study eligibility and obtain demographic information ([Multimedia Appendix 3](#)). Complete study eligibility was determined using the clinician-administered Mini-International Neuropsychiatric Interview [[13](#)]. The previously published case report and feasibility study provide further details [[10,14](#)].

Enrollment and Randomization

When a participant met the full study eligibility criteria and was enrolled to take part in the study, they were randomly assigned to 1 of the 2 study arms in a single-blind fashion using permuted

blocks of 4 in sealed envelopes. Participants were notified of their randomization outcome via secure email before session 1.

Procedure

A clinical psychologist met with each participant for 30 to 50 minutes once per week for 4 sessions over Zoom to administer a brief BA therapy protocol. At the beginning of each session, all participants were verbally administered the PHQ-9. If item 9 was endorsed, a risk assessment was conducted in real time, and safety measures were taken in accordance with the risk. Both arms followed the protocol for brief BA based on the guidance of the published literature [[15,16](#)]. No participants were provided with a stipend for activities. All sessions followed the previously established protocol detailed in the case report and feasibility study [[10,14](#)].

Experimental Arm (XR-BA)

The XR-BA participants were shipped a VR Meta Quest 2 headset before the first session with a prepaid return label. This headset has a resolution of 1832×1920 pixels; support for a 60-, 72-, and 90-Hz refresh rate; and room scale [[17](#)].

The Meta Quest 2 headsets did not have any software preloaded or prechosen. XR-BA participants were provided with an XR activity list similar to the Pleasant Events Schedule from traditional BA. The items included in the list were determined by asking subject matter experts to provide quality activity choices based on the categories provided within the Meta Quest 2 headset. While the list included different category options and ideas from those within the Meta Quest 2 headset, the clinician clarified that participants could choose any activity offered within the headset even if it was not included in the list ([Multimedia Appendix 4](#)) [[18](#)]. In between each session, participants were asked to complete ≥ 4 XR activities per week and 1 post-XR questionnaire pertaining to all completed XR activities from the week to assess spatial presence, simulator sickness (tolerability), and technology acceptability ([Multimedia Appendix 5](#)). This questionnaire was sent out to the participant and returned to the clinician via a secure email.

Control Arm (Traditional BA)

The participants in the control group followed the same protocol as those in the XR-BA arm except that they were not provided with a VR headset, were emailed the Pleasant Events Schedule, were asked to choose and complete ≥ 4 activities IRL, and were not administered the post-XR questionnaire.

The previously published case report and feasibility study provide more details [[10,14](#)]. The study timeline is shown in [Figure 1](#).

Measures

The feasibility, or the degree to which XR could successfully be integrated into the brief BA protocol, was measured by commenting on qualitative barriers to use observed. Barriers were assessed by rates of dropout, adverse events, number of times the headset was used, and level of presence experienced in the headset [11]. The level of presence was obtained via participant reports using a Likert scale of 0 (*not at all*) to 4 (*very strongly*) for each question; with 3 questions, there was a possibility of yielding a score between 0 and 12.

The acceptability of the XR-BA treatment was measured via participant reports using the Technology Acceptance Model, with the agreement choices on a Likert scale ranging from 0 (*strongly disagree*) to 4 (*strongly agree*) for each question; with 3 or 4 questions per category, there was a possibility of yielding a score between 0 and 12 or 0 and 16, respectively.

The tolerability of the XR-BA treatment was measured via participant reports using the Simulator Sickness Questionnaire (SSQ), with the agreement choices on a Likert scale ranging from 0 (*no more than usual*) to 3 (*severely more than usual*); with 16 items, there was a possibility of yielding a score between 0 and 48.

The efficacy of the XR-BA treatment was measured via participant reports using the PHQ-8 and PHQ-9, with the agreement choices on a Likert scale ranging from 0 (*not at all*) to 3 (*nearly every day*); with 8 or 9 questions, there was a possibility of yielding a score between 0 and 24 or 0 and 27, respectively.

The previously published case report [14] provides a more in-depth description and background of the following measures: demographic questionnaire, Mini-International Neuropsychiatric Interview, PHQ-8, PHQ-9, presence scale, Technology Acceptance Model, and SSQ.

Of note, agitation (ie, the brief agitation measure) was not used as a measure of tolerability in this study. In addition, unlike the previous study, the number of times the headset was used was not determined from the device itself; rather, it was obtained via participant self-report.

Statistical Analyses

Overview

This study was a 2-arm nonblinded between-participant randomized controlled trial (RCT) testing the feasibility and efficacy of using XR-simulated activities compared to IRL pleasurable or mastery activities during a brief BA intervention for MDD. The Holter critical number in structural equation modeling (SEM) with the analysis of moment structures (AMOS; version 28.0; IBM Corp) [19] was used to determine whether a sample size of 26 would be needed to disprove the model if it were incorrect.

Feasibility

The average total presence for intention-to-treat (ITT) participants and protocol completers was calculated. The average presence experienced was also calculated as a percentage by dividing the average score by 12 (the maximum score). The number of questions in each category determined the outcome

range (either 0-12 for 3 questions or 0-16 for 4 questions). The average percentage of acceptance was also calculated by dividing the average score by the maximum score within the outcome range. To determine the degree of acceptance, as labeled on the scale, the average score was then scaled back depending on the number of questions. For example, the “Perceived Usefulness” category included 3 questions, yielding a potential range of 0 to 12, so an average score of 10 would be divided by 3 to assess the degree of acceptance (in this case, it would yield a score of 3.33, which would correlate to “agree” on the Likert scale). Physical tolerability of the VR headset was assessed via participant reports using the SSQ, which was broken down by symptom and used a Likert scale ranging from 0 (*no more than usual*) to 3 (*severely more than usual*) for each item. The percentage of physical intolerability was calculated by dividing the average scores by the highest potential score (48).

Efficacy

To assess the clinical efficacy of the XR-BA treatment compared with the traditional BA treatment group, the participants’ depression scores were measured using the PHQ-8 from the initial phone screening and the PHQ-9 from the 4 session time points. Independent-sample *t* tests (2-tailed) were used to compare the means between the 2 groups, and paired-sample *t* tests (2-tailed) were used to compare the means within each group. In addition, SEM AMOS was used to confirm the results because of its ability to compare competing models using nested tests, compare parameter estimates across groups, and estimate missing data models using full-information maximum likelihood [19-21]. SEM is widely used in the social sciences and was chosen for this study given its ability to adeptly manage missing data and exhibit greater statistical power compared to conventional multiple regression analyses [22], which was

important given this study’s relatively low sample size. The chi-square statistic was used to evaluate model fit [23]. Changes in chi-square values relative to changes in *df* (chi-square difference tests) were used to compare nested models. These results were also confirmed using traditional linear growth models [24].

Ethical Considerations

Ethics approval was obtained from the Stanford University institutional review board (protocol 66488) and participants provided informed consent before beginning the study. Participant data were deidentified and participants were informed of the potential privacy risks associated with Meta potentially tracking their use. No mental health-specific data were collected on the device. Participants were not compensated for participation.

Results

Participant Demographics

The sample consisted of 26 adults (mean age 50.3, SD 17.3 y; *n*=6, 23% male; *n*=19, 73% female; and *n*=1, 4% nonbinary or third gender), with 21 (81%; mean age 47.9, SD 17.7 y; *n*=5, 24% male; *n*=15, 71% female; and *n*=1, 5% nonbinary or third gender) completing the full protocol. The Holter critical number in SEM AMOS was used to determine that a sample size of 26 would be needed to disprove the model if it were incorrect. There was no significant difference in age ($t_{23,6}=1.34$; $P=.19$) or sex ($t_{23,4}=0.71$; $P=.49$) between the groups.

Figure 2 shows the CONSORT (Consolidated Standards of Reporting Trials) diagram, and Table 1 provides additional participant demographic information.

XR-BA Prototype Feasibility

The completion rates were 77% (10/13) in the XR-BA arm and 85% (11/13) in the traditional BA arm. No participants reported any serious adverse events. The participants in the XR-BA arm used the headset, on average, slightly less than suggested (encouraged a minimum of 12 times), with the completer average being 12 (SD 2.67) and the ITT participant average being 11.18 (SD 3.71). Only 8% (1/13) of the participants did not submit a post-XR questionnaire during 1 week of treatment. This participant reported that she did not use the headset during that week due to being busier than usual with work deadlines and feeling physically ill.

The average total presence rating of the ITT XR-BA participants was 68% (8.1/12; SD 2.5%), whereas the average rating of all the XR-BA completers was 71% (8.5/12; SD 2.2%). The participant who gave the lowest presence rating (3.7/12, 31%, SD 1.15%) shared that “tactile” sensations, such as feeling the sun on her skin, were important to her, and consequently, the VR did not feel immersive. Participants who completed the protocol on average indicated progressively higher levels of presence each subsequent week (Figure 3), although statistical significance was not analyzed.

Figure 3. Headset use and post-extended reality questionnaire results by week among protocol completers.

XR-BA Acceptability

Overall, the participants who completed the protocol were “neutral” or “agreed” with the VR treatment being acceptable, with an average rating of 2.8 (SD 0.21; where 2=neutral and 3=agree) on the Likert scale and 71% (37/52) acceptability (Table 2). The participant who gave the lowest acceptability rating (26.7/52, 51%) described that the learning curve of the headset and the discomfort from the weight of the headset made VR less enjoyable. Participants who completed the protocol indicated a higher level of perceived usefulness of

VR on average after each subsequent week of use (Figure 3). Between the conclusion of week 1 and the beginning of session 2 and the conclusion of week 3 and the beginning of session 4, participants who completed the protocol reported a lower level of desire to continue using the headset after treatment on average (Figure 3). While participants were provided with the XR activity list (Multimedia Appendix 4), there were certain activities from the list that participants specifically mentioned enjoying, such as YouTube 360° videos (8/13, 62%), *Tripp* (5/13, 38%), *Liminal* (5/13, 38%), *Beat Saber* (2/13, 15%), and *Painting* (2/13, 15%).

Table 2. Extended reality–enhanced behavioral activation acceptability.

	Perceived usefulness ^a (0-12; 3 items), mean (SD)	Perceived ease of use ^a (0-12; 3 items), mean (SD)	Attitudes toward use ^b (0-16; 4 items), mean (SD)	Intention to use the technology ^a (0-12; 3 items), mean (SD)
Completer average	8.4 (2.2)	7.7 (2.6)	11.7 (2.6)	9.2 (1.9)
ITT ^c average	8.1 (2.3)	7.5 (2.5)	11.1 (3.0)	8.4 (3.3)

^aDomains comprising the Technology Acceptance Model (higher numbers indicate greater acceptability). Perceived usefulness, perceived ease of use, and intention to use the technology comprised 3 items with a range of 0 (*strongly disagree*) to 4 (*strongly agree*) for each item.

^bAttitudes toward use comprised 4 items with a range of 0 (*strongly disagree*) to 4 (*strongly agree*) for each item.

^cITT: intention to treat.

XR-BA Tolerability

Physical tolerability was determined using the SSQ. Possible responses for the 16 items ranged from 0 (*no more than usual*) to 3 (*severely more than usual*). Lower numbers indicate greater tolerability. The average overall physical tolerability of those who completed the protocol and the ITT participants was 92% (44/48) and 92% (44.4/48), respectively. *Eyestrain* was the most common symptom of physical intolerability. *Burping* and *increased salivation* were the least common symptoms of physical intolerability, with 8% (1/13) of the participants endorsing burping after week 1 of headset use and 8% (1/13) of the participants endorsing increased salivation after week 1 of headset use. The participant who endorsed relatively higher overall average simulator sickness symptoms (rating of 17/48) compared to other participants experienced most of these symptoms after the first week (rating of 30/48) of headset use. This participant shared that the headset felt uncomfortable and heavy on her head and she experienced symptoms of nausea when she was immersed in any activity that had a quick-moving image. Upon trying other activities within the headset, such as the slower-moving *Liminal* and YouTube 360° videos, this participant's symptoms reduced to a rating of 4 out of 48. Overall, participants who completed the protocol experienced a decrease in simulator sickness symptoms between the conclusion of weeks 1 and 3 on average (Figure 3).

Clinical Efficacy

Participants in both study arms showed a 4-point decrease in PHQ-9 scores between sessions 1 and 4, with participants in the XR-BA arm experiencing a 4.4-point decrease and participants in the traditional BA arm experiencing a 3.7-point decrease. There was no significant difference in improvement in PHQ-9 scores between the study arms ($t_{18,6}=-0.28$; $P=.78$; Table 3).

Table 3. Independent-sample *t* test—extended reality–enhanced behavioral activation (XR-BA) versus traditional behavioral activation (BA) and test of significance of the difference between the 2 groups.

	XR-BA (n=10), mean (SD)	Traditional BA (n=11), mean (SD)	<i>t</i> test (<i>df</i>)	2-sided <i>P</i> value
Difference between PHQ-8 ^a at intake and PHQ-9 ^b at session 4	7.40 (5.54)	5.27 (6.07)	-0.84 (19)	.41
Difference between PHQ-9 at session 1 and PHQ-9 at session 4	4.40 (5.66)	3.73 (5.37)	-0.28 (19)	.78

^aPHQ-8: Patient Health Questionnaire–8.

^bPHQ-9: Patient Health Questionnaire–9.

Protocol completers in the XR-BA arm went from an average of moderately severe (15.8, SD 2.86; phone intake) to moderate (session 1: 12.8, SD 3.46; session 2: 10.6, SD 4.14; session 3: 10.5, SD 4.81) to mild (8.4, SD 3.72; session 4) symptoms of depression. The average decrease of 7.4 points on the PHQ-9 between the initial phone screening and session 4 was statistically significant ($t_9=4.2$; $P=.002$) and represented a clinically significant change in severity level from *moderately severe* to *mild* (>5) [25] (Table 4).

Participants in the traditional BA arm remained at an average of moderately severe (16.0, SD 3.38) between the phone intake and the beginning of session 1 (14.5, SD 3.50), and their symptoms of depression decreased to moderate (10.7, SD 4.63) by session 4. This average decrease of 5.3 points on the PHQ-8 and PHQ-9 between the initial phone screening and session 4 was also statistically significant ($t_{10}=2.88$; $P=.02$) and represented a change in clinical severity from *moderately severe* to *moderate* (Table 5).

There was a significant decrease in PHQ-9 scores between the phone intake and the beginning of session 1 in the XR-BA group ($t_{11}=2.6$; $P=.03$) but not in the traditional BA group ($t_{11}=1.4$; $P=.20$). These results indicate that participants in the XR-BA arm showed a significant decrease in PHQ-9 scores even before the treatment began.

To determine whether the participants showed a further statistically significant decrease in PHQ-9 scores between the beginning of sessions 1 and 4, paired-sample *t* tests were run. These results illustrated that participants in both the XR-BA ($t_9=2.5$; $P=.04$) and the traditional BA ($t_{10}=2.3$; $P=.04$) arms experienced a significant decrease in PHQ-9 scores between the start and end of the study (Tables 4 and 5).

Table 4. Paired-sample *t* test (2-tailed)—testing the significance of extended reality–enhanced behavioral activation participants’ average Patient Health Questionnaire scores between various time points (n=13).

	Pretest assessment		Posttest assessment		<i>t</i> test (<i>df</i>)	2-sided <i>P</i> value

Discussion

Feasibility

The results of this study provide evidence that XR-BA in this MDD telehealth treatment setting was a safe, feasible, tolerable, and acceptable modification to a brief BA protocol. The attrition rate of 23% (3/13) of the participants in the XR-BA arm of the study is comparable with that of other VR studies [26,27], lower than that of many RCTs of internet-based interventions for depression [28], and lower than that of a small-sample pilot RCT exploring exercise as a treatment for depression [29]. Importantly, no participant in the XR-BA treatment arm dropped out of the study because of serious adverse events, and no serious adverse events were reported throughout the study.

While participants in the previous VR-BA study completed on average more VR activities than recommended, the participants in this study did not meet their total recommended headset use of ≥ 4 activities each week. This was due to many participants reporting that the headset was difficult to use and it feeling like an overwhelming task to learn. Participants remarked that they would have used the headset more often if they had increased familiarity. In this vein, participants reported that the headset

became more enjoyable and useful over time, which aligns with research that states that the easier to use the device, the more acceptable it is to users [30]. When working with people unfamiliar with VR, future prototypes of VR-BA may want to opt for designs that allow for simplicity, preloaded experiences, decreased choices, and rapid onboarding skill acquisition.

Participants noted several barriers and XR challenges that may have impacted their attempts to use this modality for BA and mood improvement. The learning curve for using the headset device was surprisingly burdensome. Our previous VR-BA prototype chose a simpler, less immersive headset preloaded with activity choices, but this study chose to use a more immersive and interactive headset with higher quality and range of choices of pleasant and mastery activities. This increase in variety and autonomy to simulate traditional BA came with an increasing cost to the user, with each novel experience entailing unique and new technical XR challenges and requiring new skills. This observation aligns with research indicating that it is important to learn *how* to use VR before learning *in* VR [31]. Spending time teaching participants how to use the XR headset was contraindicated in a research study due to the creation of a confound when compared to traditional BA. Yet, in practice

and outside of clinical trials, it may be necessary to do so at this time when technical onboarding to commercial headsets is still complex and challenging for the average person. However, the challenges of onboarding may just as likely provide an opportunity to engage in a mastery or pleasant activity when struggling and finally gaining access to the XR headset and may actually attenuate BA with the focus on this acquisition of onboarding skills.

One participant noted that the ability to choose any activity on the headset led to “decision paralysis,” an interesting juxtaposition to the previous study, which had a limited selection of 37 preselected videos and where feedback stated a desire to have more activity options. While activity ideas were provided, when using XR for activity engagement, it may be helpful to provide an even more detailed database of activity options similar to the list of adult pleasant activities [32].

Considering participant feedback from the previous study that noted that the requirement to complete a post-VR questionnaire after each use was a hindrance and burden, this study only asked participants to complete 1 post-XR questionnaire a week. While only 20% (1/5) of the participants in the previous study completed a post-VR questionnaire for each VR activity, all participants in this study (13/13, 100%) completed a post-XR questionnaire during the weeks in which they used the device. Participants in this study subsequently did not comment on the administrative burden of completing the post-XR questionnaire; however, they did acknowledge that having all the tracking and scheduling accessible via the web or through an app would make it more convenient for them to remember and complete all the required tasks.

Participants in this study rated their presence as higher on average than participants in the previous study, a finding that is consistent with research suggesting that achieving a strong sense of presence is more influenced by interactivity than by realism [33]. Participants noted feeling so present while using the headset that they made comments such as the following: “[it was] good to be able to go elsewhere [in VR] since I don’t have a car,” “it is nice to be able to take a break from my kids and be present at home, but not be,” and “I was so immersed in the VR that I lost track of time.” In addition, presence ratings increased week to week on average, consistent with participant reports that the more familiar they became with the device, the more immersed they felt.

The acceptability ratings in this study were comparatively lower than those recorded for the device used in the previous study. Nevertheless, a noteworthy observation from this study is that acceptance levels in the domains of *Perceived usefulness* and *Attitudes toward use* exhibited an average increase between the conclusion of week 1 and the beginning of session 2 and the conclusion of week 3 and the beginning of session 4. It would be intriguing to extend the study timeline and ascertain whether this trend of escalating acceptance continues, potentially surpassing the ratings for the simpler headset. It would be equally fascinating to explore whether the gradual rise in acceptance over time corresponds to more substantial improvements in mood over the same period. This is particularly relevant considering that some participants mentioned that they

would have used the device more frequently if they had not perceived the learning curve as a hindrance. Furthermore, participants qualitatively indicated that the *Intention to use the technology* rating was lower given the cost and lack of affordability of the Meta Quest 2 headset.

The participants rated the protocol as largely physically tolerable, and no participants dropped out because of adverse effects. While the ratings of physical tolerability were the same (92%-93%) between the 2 studies, the participants in this study qualitatively reported more simulator sickness. Participants particularly noted that they found the Meta Quest 2 headset itself to be “heavy” and “uncomfortable” on their faces. In addition, consistent with the research on simulator sickness, participants noted that they experienced more symptoms of simulator sickness while partaking in activities with a faster-moving image compared to those with a slower-moving image [34,35]. However, also aligned with previous research, participants quantitatively and qualitatively reported a habituation effect where their simulator sickness symptoms largely decreased over time [35]. All participants reported that their symptoms were quickly resolved upon removal of the headset and did not persist.

While this study expanded upon the previous study by increasing the sample size and using a more immersive, interactive headset that offered a wider range of activity options, it would be interesting to conduct a similar study that also uses a mobile app to decrease the administrative burden for providers and patients and streamline the homework process. It is postulated that the focus on homework in BA is essential for successful treatment outcomes. Research has demonstrated that homework completion is significantly related to a decrease in symptoms [36]. Specifically, the behavioral task of completing pleasant activities contributed most strongly to decreasing symptoms of depression [36]. Hence, addressing barriers to completing homework tasks is pivotal for optimizing treatment results.

Given that participants in the previous study noted decreased headset use due to administrative constraints and that participants in this study independently expressed the value of a tracking and reminder app for homework compliance, the next crucial phase involves evaluating whether implementing a mobile app that consolidates scheduling and activity tracking can enhance homework completion rates. This, in turn, could potentially lead to more accurate and consistent homework adherence, thereby further reducing depressive symptoms and enhancing mood, ultimately maximizing the effectiveness of treatment outcomes.

Finally, this study solely used XR as a method of engaging in BA. In subsequent studies, it would be interesting to conduct the therapy in VR for both arms rather than over Zoom. Given that telehealth has become increasingly popular, it would be fascinating to note the feasibility, acceptability, and tolerability of conducting the entire session in VR. It would also be interesting to measure how this may affect the effectiveness of the intervention.

Efficacy

The XR-BA protocol was found to be noninferior to a brief BA protocol for MDD in this small study. Participants in both the traditional and XR-BA arms experienced a statistically significant reduction in depression symptoms between the initial phone screening and session 4 and between sessions 1 and 4, as well as significant reductions in clinical severity between the initial phone screening and session 4.

Only the XR-BA arm showed a statistically significant decrease in symptoms between the phone screening and session 1. Given the unblinded nature of this study, this is not surprising. These results may indicate that participants in the XR-BA arm had an enhanced expectancy or placebo effect due to the novelty or implicit beliefs surrounding technology and mental health treatment. The novelty of the treatment and anticipation that it would be helpful may have led to increased levels of hope and a decrease in depressive symptoms [37,38]. It was observed that the participants who learned that they were randomized into the XR-BA arm expressed more excitement than those who were randomized into the traditional BA arm.

While our previous study suggested the possibility of a greater reduction in symptoms of depression among participants in the VR-BA arm compared to the traditional BA arm, this study did not demonstrate any such superiority as symptom reduction was not statistically or clinically different between the groups. The noninferiority of XR-BA may be attributed to both the positives and negatives of using VR, as noted by participants. Similar to the previous study, participants shared that they found VR to be “novel,” using VR showed them that they could enjoy activities again, and VR inspired them to engage in real-life activities. The latter fact was true among both participants who found VR to be a positive experience (ie, watching a YouTube 360° video of a beach inspired them to visit the beach in person) and a participant who did not enjoy VR because of preferences for tactile experiences and consequently made an increased effort to go outside to feel the sun on their skin. Many participants also noted that the XR-BA helped improve their mood by taking them to a new place in an immersive way, thereby increasing their attention and decreasing distraction, allowing for a fully mindful experience in the present moment.

The finding that XR-BA was as efficacious in reducing symptoms of MDD as a brief traditional BA protocol is critical. Patients can use VR to improve their mood if they encounter barriers to engaging in activities IRL. Participants commented that “VR is easier and more convenient than having to go places,” “I have been able to visit a few places I have always wanted to travel, so I noticed being so absorbed [by the places],” “VR has a larger realm of possibilities. In the real world I need to check hours [that events are occurring/open] and the weather,” and “I would recommend [using VR] to a friend if they didn’t want to do therapy,” which qualitatively supports the notion that VR can help decrease barriers to in-person activity engagement. These statements further corroborate the previous study’s suggestion that clinicians may be justified in using VR as a first step in BA for patients who may not have access, motivation, or desire to engage in activities IRL.

Limitations

This study aimed to recruit and enroll 40 participants, and recruitment took place remotely via Zoom-delivered telehealth sessions between December 19, 2022, and July 24, 2023. The study ended recruitment in July 2023 given that the necessary number of participants to yield a powered result had been enrolled. Although many of the enumerated findings are promising, this study has several limitations. First, the quantitative and qualitative measures were subjective and completed by the participants. Participants in both the XR-BA and traditional BA arms self-reported their completed activity and mood scores, which may have introduced inaccurate reporting. Specifically, there were no objective measures used to evaluate XR experiences, which resulted in participant self-report of the activities chosen and length of time in XR, which many participants did not document in the moment, leading to potentially inaccurate reporting. In addition, although the PHQ-9 is a standard self-report measure, the questions were read aloud for participants to answer rather than being delivered in a standard written format. This method may have resulted in less accurate reporting if the participants felt inclined to respond in a certain way.

Furthermore, as there were no official follow-ups, it is unknown whether the mood gains that the participants reported were long-lasting. This study had a relatively short duration. As mentioned previously, participants remarked on the learning curve of the headset, and both qualitative and quantitative data illustrated that the headset became more acceptable and tolerable each week. Thus, in a longer trial, participants may experience greater mood gains as they become more familiar with the headset. In addition, a participant in the XR-BA arm of the study was unable to use the headset between sessions 2 and 3 owing to both a heavy work week and being physically ill. This participant expressed sadness about this outcome and a desire to expand the study timeline to have more time with the headset. Furthermore, the study’s short duration may have led to mood changes due to factors external to the study, such as a relatively heavy or light work week or an illness. Finally, many participants expressed that there were few free trials or options within the XR headset. Some participants reported that they would be more willing to purchase activities if they were able to keep the headset or if the study were longer so that they had more time with their purchase. Overall, participants in both study arms expressed a desire to lengthen the study timeline and noted that the 3-week, 4-session protocol felt too short.

Another limitation was the nonblinded nature of the study. Participants randomized into the XR-BA arm expressed greater excitement than those randomized into the traditional BA arm, which may have led to an initially greater decrease in depressive symptoms on the former. Further studies should invest in a system of double blinding to confirm these results.

Finally, as in our previous study, recruitment was a large obstacle. Although the goal was to randomize 40 participants with MDD into either of the study arms, only 26 participants were randomized because other potential participants were excluded based on ineligibility, declining to participate, or being lost to follow-up. It is notable that other VR and depression

studies have had similar or smaller sample sizes [39,40]. It is important to recognize that this could underscore an inherent challenge in depression studies, where health state and conditional altruism are large contributing factors to participation interest [41]. In addition, the small sample size hindered our ability to address other interesting research questions, such as whether different subtypes or severity of MDD would yield different effects from the treatment. For example, would individuals with more severe MDD respond better or worse to XR-BA than those with a milder case compared to traditional BA? These are questions that would need to be answered in a study with a larger sample size. Moreover, given the diverse nature of the disorder, the findings might not universally apply to all those dealing with symptoms of depression.

Conclusions

The findings of this study support our previous report that using XR as a substitute for IRL pleasant and mastery activities in a brief BA protocol for individuals diagnosed with MDD is feasible, acceptable, and tolerable. This remained true even when using a more difficult and interactive headset that posed technical and physical challenges.

This study also expanded on our feasibility trial to perform the first known efficacy trial of XR-BA. This study demonstrated that XR-BA may not be inferior to traditional BA as it was equally and statistically efficacious in improving symptoms of depression in an MDD sample as measured using the PHQ-9.

It also suggested that XR-BA may have enhanced the placebo or expectation effects of BA treatment.

The results of this study demonstrate that it may not be unreasonable for clinicians to suggest the use of VR-simulated pleasant activities to patients when delivering BA as VR-simulated pleasant activities may offer solutions to some of the common problems and barriers encountered when using BA. When deciding on a clinical approach, professionals may need to weigh the advantages and disadvantages of using simpler versus complex headsets. Given that this study and the previous VR-BA study both illustrate clinical effectiveness and that the feedback on the previous study's preloaded headset was more favorable compared with this study's software-agnostic Meta Quest 2 headset, it could be concluded that a simpler device would be preferred by patients at this time. Furthermore, despite this study providing the opportunity for participants to choose among a multitude of VR options, the most commonly chosen VR activity was YouTube 360° videos largely given its simplicity and lack of cost. Regardless of the hardware or software specifications, this study supports the notion that the use of VR may enhance mood in those living with MDD when used in conjunction with individual therapy delivering BA principles and protocols. More research on the implementation of such an approach is needed to understand how to most effectively leverage this technology in depressive disorders.

Future and more extensive controlled studies may want to explore further whether XR can increase expectation or placebo effects during MDD treatments or have other enhancing qualities to the delivery of BA for MDD.

Abstract

Background: As depression is highly heterogenous, an increasing number of studies investigate person-specific associations of depressive symptoms in longitudinal data. However, most studies in this area of research conceptualize symptom interrelations to be static and time invariant, which may lead to important temporal features of the disorder being missed.

Objective: To reveal the dynamic nature of depression, we aimed to use a recently developed technique to investigate whether and how associations among depressive symptoms change over time.

Methods: Using daily data (mean length 274, SD 82 d) of 20 participants with depression, we modeled idiographic associations among depressive symptoms, rumination, sleep, and quantity and quality of social contacts as dynamic networks using time-varying vector autoregressive models.

Results: The resulting models showed marked interindividual and intraindividual differences. For some participants, associations among variables changed in the span of some weeks, whereas they stayed stable over months for others. Our results further indicated nonstationarity in all participants.

Conclusions: Idiographic symptom networks can provide insights into the temporal course of mental disorders and open new avenues of research for the study of the development and stability of psychopathological processes.

Introduction

Background

Different lines of research have established the heterogeneous nature of the etiology, clinical presentation, and treatment outcomes of depression [1-4], thus demonstrating a need for new ways to conceptualize and investigate the disorder. This is indicative of a broader issue across specific psychiatric diagnoses. The widespread evidence of substantial heterogeneity within diagnostic labels has increased the awareness of the need for more individualized research on mental disorders [5]. Although clinical psychology has a long tradition of interest in the individual, most studies in clinical psychology rely on nomothetic, cross-sectional data [5]. However, several theoretical arguments [6-8] and empirical studies [9] have shown that findings generated on a between-person basis are often not applicable to within-person processes, calling into question the extent to which cross-sectional studies are relevant for the understanding of individual clinical cases. Recently, the emergence of new theoretical approaches [10], statistical methods [11], and options for the collection of longitudinal data [12] have led to a surge in empirical studies of within-person, idiographic processes in clinical psychology [5].

Idiographic modeling of psychopathology has several possible advantages compared to group-level models. Owing to its potential to provide insights into temporal processes, an idiographic approach using longitudinal data could inform clinicians and researchers about the dynamics of psychological processes *of an individual* in a specific context [13], which is closely linked to clinical practice [14]. In combination with a focus on experiences in everyday life, idiographic models could lead to an improved understanding of mechanisms that influence the development and trajectory of mental disorders. During treatment, idiographic models could potentially be used to provide data-informed feedback to patients and therapists [13], develop personalized psychotherapy interventions [15], or design mobile interventions that are tailored to the individual [16].

To study such within-person processes, researchers use experience sampling methods to collect many observations per individual over time, also known as intensive longitudinal data [17]. Then, various forms of time series models can be used to investigate the relationships among multiple variables across time. Results of these models are often depicted as networks of variables that interact with one another. Then, these can be interpreted in accordance with the network approach of psychopathology that conceptualizes disorders as causal systems of mutually interacting symptoms [11,18]. Networks based on cross-sectional data have become very popular in the past few years, particularly in research on depression [19]. However, the so-called dynamic networks based on longitudinal data are especially promising for the network approach, as they both potentially allow insights into how disorders emerge from the interplay among individual symptoms over time and because they can reveal individual differences in symptom associations. Idiographic network models have, for example, been used to explore individual symptom patterns in different psychiatric disorders [20,21], including depression [22], to investigate

psychotherapy processes [23] or to identify individualized treatment targets in eating disorders [24].

However, due to implicit assumptions of commonly used statistical methods, these patterns are typically modeled as static over time [25]. This approach restricts the investigation of change processes that can be of central interest to researchers and clinicians [14,26]. Therefore, most previous studies have not been able to investigate whether and how individual symptom networks change over time (for an early exception, refer to the study by Wichers and Groot [27]). For example, psychotherapists who are using daily diary data of their patients might be interested to examine whether the association between stress at work and subsequent depressive mood changes during therapy, as their patients might be incrementally able to handle stress better. This development would be difficult to account for when using typical models. In addition to this issue, experience sampling studies are often interested in variables that may change very fast, such as perceived stress or mood, and thus commonly follow individuals for a short time, often 1 or 2 weeks [28]. This study duration may be inappropriate for constructs such as depressive disorders, as it might miss slow changes developing over a longer time span, therefore incorrectly assuming that associations among symptoms are stable over time. We aimed to investigate the possibilities of circumventing these limitations by using recently developed methods for the estimation of time-varying models for psychological applications [25,29]. So far, this approach has not been used with time series data of multiple clinical cases.

Objective

In this study, we applied time-varying network modeling to daily self-report data of patients diagnosed with recurrent depressive disorder to explore the idiographic course of depression over several months and to gain insight into the stability or instability of individual symptom networks of depression. In addition to 2 daily depressive core symptoms, namely anhedonia and feeling down, we included daily summaries of sleep duration, rumination, and the quality and quantity of social interactions as all these aspects have been hypothesized to interact in depression. We chose these items to gain multifaceted insight into the course of depression while limiting ourselves to a few variables for the demonstration and application of the chosen modeling technique. An in-depth theoretical background discussion regarding the selection of variables is provided in [Multimedia Appendix 1](#) [25,29-58].

To justify the necessity of time-varying modeling, which is a more complex and data-intensive approach, we first tested whether the data-generating process of each individual in the time frame of our study was time varying by using a recently proposed hypothesis test [25]. Given the nonstationarity of participants' time series, there were 2 main exploratory goals for this study. First, we aimed to construct individual networks for every patient to model the temporal associations among all variables on a day-to-day basis. Second, we wanted to explore the temporal dynamics of the individual course of depression by investigating changes in the network structure over time. To evaluate the initial indicators of trustworthiness of these models for use in the assessment of individual patients, we further aimed

to assess the stability of estimates, prediction errors, and variance explained. The results of this study provide new insights into the time-varying nature of depression and highlight the usefulness and limitations of new statistical approaches to capture these temporal dynamics.

Methods

Transparency and Openness

This was, in part, a secondary analysis of the data previously analyzed by Lorenz et al [30] on the idiographic association between sleep and depression. Our analyses were preregistered after data collection and before secondary data analysis using the template for preregistration of experience sampling studies [59]. The preregistration and all code for the analyses can be accessed through Open Science Framework [60]. All deviations from the preregistered protocol are explained in detail in [Multimedia Appendix 1](#).

Ethical Considerations

The study was approved by the ethics committee of the University of Leipzig (258/17-ek). Participants who completed the data collection process were reimbursed €250 (approximately US \$280) for their efforts for each study phase, implying a maximum individual financial compensation of €750 (approximately US \$840). They could also keep the mobile phone that was provided to them for the study.

Procedure

Data used in this study were collected as part of the research project, Sensor-Based System for Therapy Support and Management of Depression (STEADY). The overarching aim of the project was the creation of a sensor-based system for individuals with depression, integrating data from smartphones and wearable and stationary sensors to monitor the course of their disorder using self-assessments and physiological and behavioral markers. The data for this study were collected during a feasibility study of the STEADY system. The STEADY smartphone app was installed on a mobile phone that was provided to the participants for the completion of self-report protocols.

Data collection for the feasibility study was split into 3 consecutive study phases between 2017 and 2019, and they did not differ in their self-report protocols. An overview of all self-report questionnaires administered before, during, and after the study phases is provided in the preregistration. Participants were also given wrist-worn fitness trackers and stationary sleep sensors to collect passive sensing data. These data were not included in the analyses due to their questionable data quality. Within the smartphone app, participants were able to fill morning and evening logs. They were asked to complete them directly after waking up and shortly before going to bed, respectively. Morning logs were available from 3 AM to 3 PM, whereas evening logs were available from 3 PM to 3 AM.

Several precautionary measures were undertaken to assist in using the app and to prevent the occurrence of missing data, such as monthly visits to the study center and phone calls.

Participants

Participants were recruited in cooperation with the Department of Psychiatry and Psychotherapy (University of Leipzig Medical Center, Germany). Potential participants were informed about the study by their treating physicians. If they indicated interest, they were contacted by a staff member of the study center, who conducted the formal examination of inclusion and exclusion criteria. If the individual was found to be eligible, written consent for participation was obtained from them. During the initial diagnostic screening, invitees were inquired about sociodemographic information and their medical history in a semistructured interview. The Structured Clinical Interview for Diagnostic and Statistical Manual of Mental Disorders–4 [61] (in its German translation [62]) was used to assess psychiatric diagnoses. The Inventory of Depressive Symptomatology, Clinician Rated (IDS-C) [63] (in its German translation [31]) was used by trained raters to assess current depressive symptom severity.

Inclusion criteria were the following: having a diagnosis of a recurrent depressive disorder; having a current depressive symptom level of at least 14 points on the IDS-C; currently being treated professionally for depression; being aged at least 18 years; and living near the research center of the German Depression Foundation in Leipzig, Germany, to accommodate regular in-person appointments. Individuals were excluded if they had severe somatic disorders; displayed acute suicidal behavior; were pregnant or in the lactation period; had electronic implants; or experienced the following psychiatric comorbidities: borderline personality disorder, schizophrenia, alcohol or drug addiction, or schizotypal and delusional disorders. For this study, we prespecified that participants should have at least 130 days of data and <30% missingness for any variable. Of the 25 total participants, we included 20 (80%) individuals in our analyses. A detailed description of the sample is provided in the following sections.

Measures

Pre-Post Assessment of Depressive Symptom Levels

The IDS-C [63] was used to describe depressive symptom levels before and after the data collection period. It was assessed before and after daily data collection and during some of the monthly visits, but data from only 1 questionnaire each, before the start and after the end of an individual time series, was used in this paper. The IDS-C consists of 30 items that inquire about a range of depressive symptoms, of which 28 items (scored from 0-3) were included in this paper. Items of the IDS-C are weighted equally and combined into a sum score ranging from 0 to 84, where a cutoff point of 13 was originally proposed to identify individuals with symptoms [63]. The IDS-C has been evaluated psychometrically in different populations, including individuals with depression, in both its original version and its German translation [32].

Daily Diary Measures

A variety of self-report questions was used in the morning and evening protocols. As preregistered, we chose a subset of all self-report variables for the following reasons: theoretical relevance for depression, assessment on a continuous scale,

sampling frequency, frequency of missingness, and a general preference for sparsity for our estimation method. In total, 6 daily items were used in this study: loss of interest or joylessness, feeling down or depressed or hopeless, rumination, quantity of social contacts, quality of social contacts, and sleep duration (refer to [Multimedia Appendix 1](#) for the wording).

The first 2 items represent depressive symptoms resembling the items of the Patient Health Questionnaire–2 [64] and are listed as core symptoms in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* [65]. For this study, these items were reframed to inquire about a single day. They were described as *anhedonia* for the first item and *feeling down* for the second item. The quantity and quality of social contacts were also assessed using a visual analog scale, where participants could indicate how many contacts they had and how they felt about these social contacts. All these items were assessed in the evening logs. Total sleep time was assessed in the morning logs. Participants were asked about when they went to bed and when they got up in the morning. The time spent in bed was calculated by the app, and participants were then asked how much of this time they spent sleeping. The items used in this study have not been psychometrically evaluated but were specifically created for the STEADY app. In addition to daily questions, some of the participants provided qualitative information regarding significant life events during monthly visits to the study center.

Data Preparation and Statistical Analysis

Overview

The software environment R (version 4.1.1; R Foundation for Statistical Computing) [66] was used for all analyses in the study. Version control information and the R code for all analyses can be accessed through the Open Science Framework repository connected to this project [60]. All variables in the data set were treated as continuous variables.

Missing Data

Owing to the long data collection period, several participants had many blocks of consecutive data separated by an extended period of missingness. To obtain the single longest time series for each participant, we searched for the longest phase without item-wise missing data for >7 consecutive days and discarded the remaining data. We chose a maximum window of consecutive missingness as we did not want to impute several consecutive missing data points. A detailed workflow for handling missing data is available in the preregistration. We performed item-wise missing value imputation using the Kalman filter, which has been shown to perform well in a previous simulation study of idiographic network analysis [33]. We used the Kalman filter from the R package, *imputeTS* [67], in its default setting.

Statistical Analysis

Time-Varying Vector Autoregression

Vector autoregressive (VAR) models are time series models that can be used to investigate the relationships among multiple variables at a given lag size. For example, in a VAR model of lag 1, the value of a variable at a given time point is regressed

on the value of itself (known as autoregressive effect) and all other variables (known as cross-lagged effects) at the previous time point. As mentioned in the *Introduction* section, these models assume stationarity, meaning that the parameters of the model are assumed to be constant over time, which may not be appropriate for many research questions. Different techniques have been applied to explicitly account for time-varying parameters in psychological time series in the past, mostly focusing on univariate or bivariate associations [23,68–70]. Recently, a new approach for estimating time-varying VAR models based on kernel smoothing has been developed and tested in a simulation study [25,29]. Using VAR models with kernel smoothing allows the estimation of parameters that change over time and choosing between models with different degrees of flexibility to vary over time.

We used time-varying VAR models as implemented in the R package, *mgm* [29], to estimate idiographic models with a default lag size of 1 for reasons of parsimony. Further details about the method and our implementation of the model are available in [Multimedia Appendix 1](#) and in the papers by Haslbeck et al [25] and Haslbeck and Waldorp [29]. To obtain the time-varying parameters, local VAR models are estimated at several equidistant estimation points and then combined. In these local models, observations closer to a specific estimation point are weighted more strongly than observations farther away. The kernel weighting used to achieve this is characterized by its bandwidth, which determines the number and weights of observations included in the estimation. We have described and visualized the resulting models as dynamic networks. These comprise *nodes* (representing variables) and *edges* (representing the temporal associations among variables). The networks were visualized using the R package, *qgraph* [71].

Bandwidth Selection

Bandwidth selection represents a bias-variance trade-off [72], where smaller bandwidths lead to highly local estimates and faster changes. Large bandwidths >1 lead to an estimation that is increasingly similar to the results of estimating a stationary model [25]. To select an appropriate individual bandwidth, several candidate bandwidths were compared using a time-stratified, 5-fold, cross-validation scheme. Then, we selected the bandwidth that minimized the root mean squared error (RMSE) across the test sets. Details about the bandwidth selection scheme and an exploratory analysis of the robustness of selection are available in [Multimedia Appendix 1](#). A visual illustration of the difference between bandwidths of different sizes is provided in [Multimedia Appendix 1](#).

Model Estimation

Using the selected bandwidth, parameter estimates for every estimation point were then obtained via regularized regression using the *least absolute shrinkage and selection operator* (lasso) [73]. The lasso is a regularization technique that shrinks parameter estimates while possibly setting some of them to 0. The choice of regularization parameters is explained in [Multimedia Appendix 1](#). As the lasso is sensitive to different variances, we z-transformed all the variables before all the analyses. Following the simulation study by Haslbeck et al [25], our final model was estimated using 20 equally spaced

estimation points. We distinguished the term estimation point from the term time point, which refers to a single daily observation.

Stability and Predictability

To gain insight into the stability of the parameter estimates, we used a block bootstrap scheme to obtain bootstrapped sampling distributions. We further computed the proportion of explained variance (R^2) and RMSE as prediction errors for each variable at each estimation point. To accomplish this, we used the weighted method of forming a prediction error as implemented in the *mgm* package. The R^2 values for all participants at all estimation points are available in [Multimedia Appendix 1](#).

Stationarity Hypothesis Test

To test whether the data-generating process of the time series of an individual was stationary, we implemented a significance test as proposed by Haslbeck et al [25] to test the null hypothesis that the process was stationary. Details about the test are available in [Multimedia Appendix 1](#).

Results

Sample Characteristics

The 20 included participants (n=13, 65% women) had a mean age of 44.4 (SD 11.6; range 26-67) years during screening. Data were available for 274 (SD 82.4; range 154-539) days (ie, time points) on average. In the selected time series of participants, 5.53% of the data were missing. Further information about the missing data structure is provided in [Multimedia Appendix 1](#). Of the 20 participants, 18 (90%) were German citizens, 1 (5%) had dual citizenship, and 1 (5%) had a different nationality. Of the 20 participants, 11 (55%) had completed the general higher education entrance qualification. On average, IDS-C values decreased from 26 before the start of the time series to 22.9 afterward. Of the 20 participants, 18 (90%) took antidepressant medication and 18 (90%) currently or previously underwent psychotherapeutic treatment. More information about every participant is provided in [Table 1](#).

Table 1. Sample characteristics.

ID ^a	Sex	Age range (y) ^b	Time series length, n	Missingness (%) ^c	IDS-C ^d score before EMA ^e data collection	IDS-C score after EMA data collection	Bandwidth
1	Female	40-45	311	12.6	24	10	0.45

Stationarity Tests

The test for stationarity led to the rejection of the null hypothesis for all participants (20/20, 100%), meaning that we rejected the hypothesis that the data-generating process of an individual time series was stationary. The results for all participants are available in [Multimedia Appendix 1](#). These results provided us a first indication of the necessity of using a time-varying approach for our data.

Case Studies

Overview

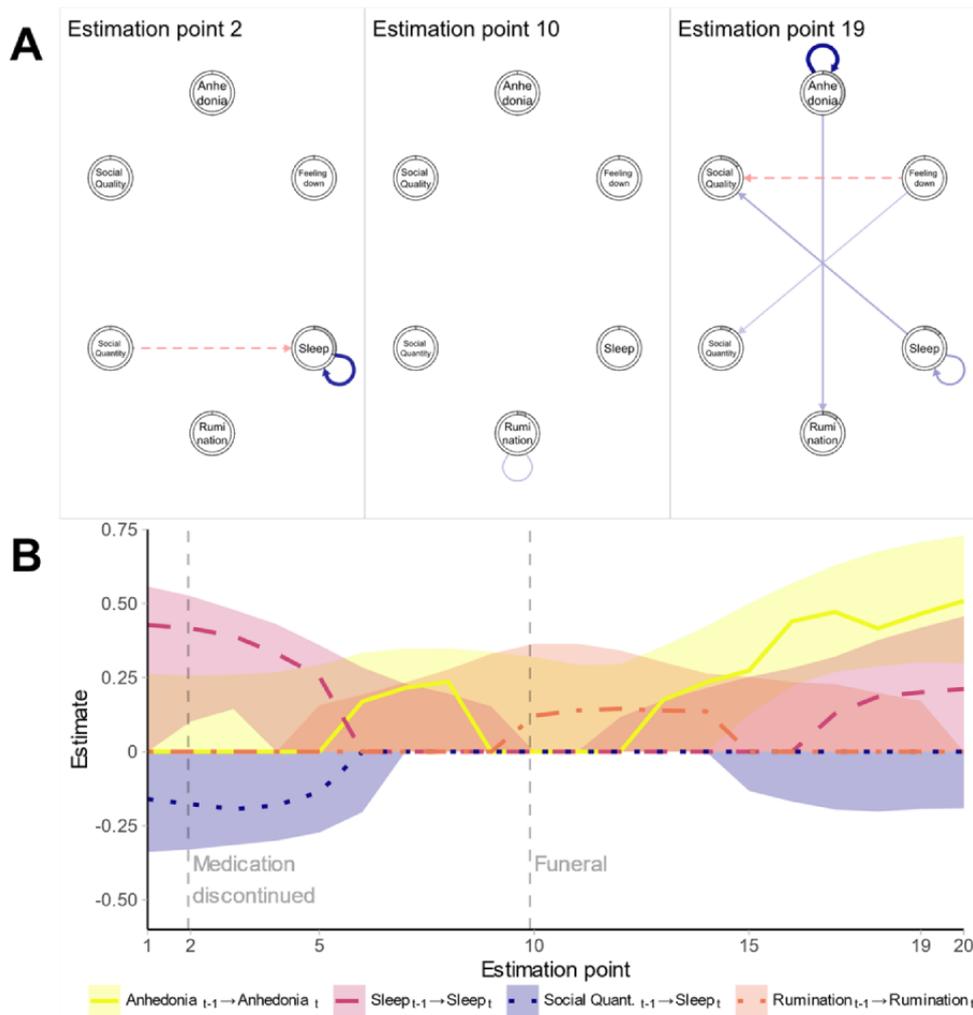

In the following sections, we have presented the individual results of 2 participants (participants 6 and 11). Participant 6 was chosen because she provided qualitative information about crucial life events during her time series, whereas the network structure of participant 11 changed alongside a reported

improved depressive symptomatology over time. We have presented individual networks at estimation points 2, 10, and 19 to showcase models at the beginning, in the middle, and at the end of the time series. We chose to present the 3 edges with the highest intraindividual variability. We have included a case study of participant 2 in [Multimedia Appendix 1](#) to showcase the potential shortcomings of the method that we used.

Participant 6

Participant 6 was a German woman in her 60s, in partial retirement, with a comorbid anxiety disorder. She started multiple antidepressant medications in the year before the study began. She also had previously undergone several psychotherapeutic treatments, and she underwent psychotherapy at the beginning of data collection. A bandwidth of 0.12 was selected for her time series with a final length of 301 days. Her results are visualized in [Figure 1](#).

Figure 1. Results for participant 6: (A) networks at estimation points 2, 10, and 19; (B) time-varying parameters.

The networks at estimation points 2, 10, and 19 (corresponding to days 17, 143, and 285) are displayed in [Figure 1A](#). Width and saturation of edges in the networks were scaled with respect to an arbitrary maximum of 0.5 for all participants, as approximately 80% of all absolute non-0 edge weights were below this threshold. Time-varying parameters are shown in [Figure 1B](#). Estimates at the end of the time series need to be interpreted with caution as fewer data are available for that

period. Effects are sorted based on the extent of variability over time in all plots—the effect with the highest variability is plotted in yellow, the effect with the second-highest variability is plotted in violet, and the effect with the third-highest variability is plotted in blue. The autoregressive effect of rumination in orange was added irrespective of its extent of variability over time.

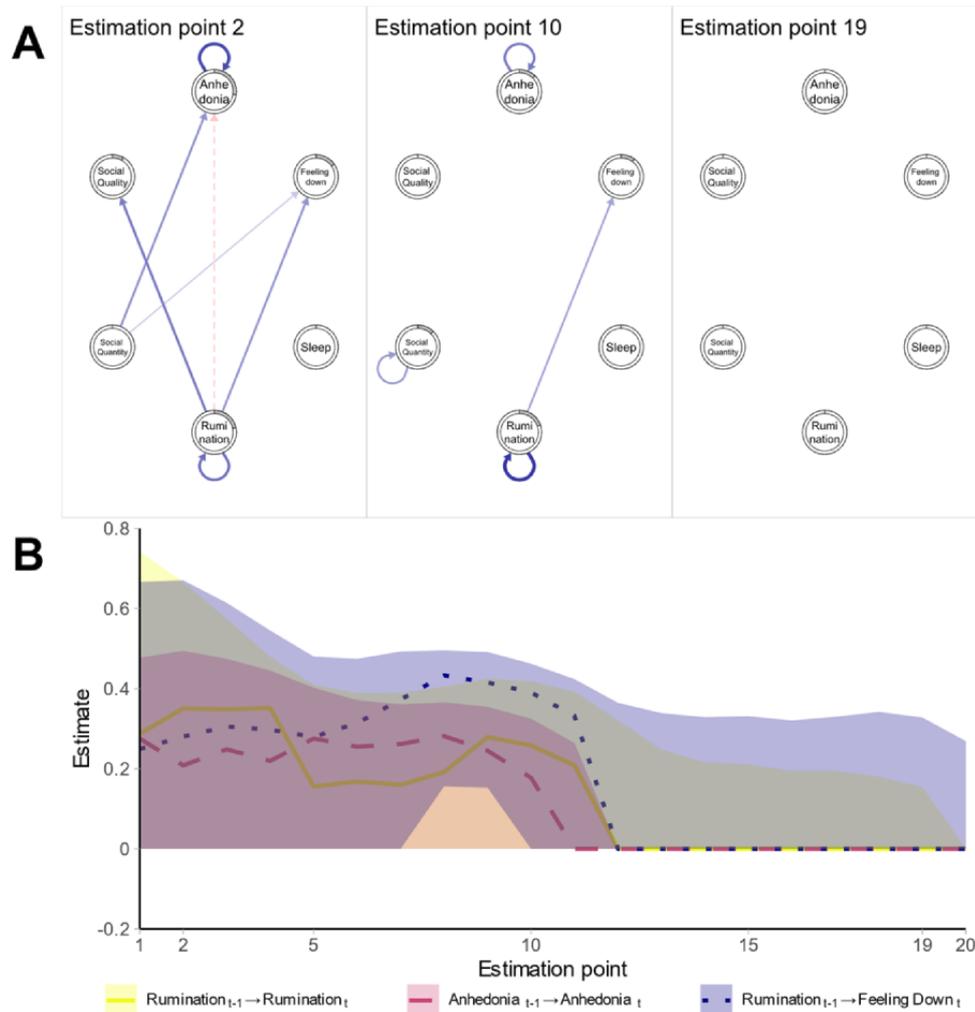

Immediately before the start of the time series, the participant experienced panic attacks, and the dosage of her medication was increased. A few days before the second estimation point (approximately 32 days after the beginning of the time series), she started to phase out her medication, in other words, she continuously reduced the dosage. Both the negative cross-lagged effect from the quantity of social contacts on sleep and the positive autoregressive effect of sleep subsequently disappeared. As self-report sleep involves a different time interval (night) than the remaining measures that summarize the day, the cross-lagged effects including sleep are only interpretable in an asymmetric fashion. In this example, social contacts had an effect on sleep during the subsequent night. Shortly before the 10th estimation point, the participant reported that she visited a funeral and worried about a friend of hers. After that, an autoregressive effect of rumination was detected, which can be interpreted as a prolonged tendency to stay in a ruminative thought process. No more qualitative information about life events was available after this time point. As with many other participants, the bootstrapping results, which we did not include in this paper to keep the plot from being very visually cluttered, indicated a substantial uncertainty of point estimates. This implies that the specific numerical results of an association should be interpreted with caution, as they are likely unstable.

At the end of the time series, the network of participant 6 was relatively strongly connected, with a strong autoregressive effect

of anhedonia. Feeling down was positively associated with the quantity of next-day social contacts but negatively associated with their perceived quality. Her IDS-C sum score increased from 34 to 40 from the beginning to the end of the time series, indicating a worsening of her symptomatology. The average R^2 value averaged over all items and estimation points was 0.113, reflecting many estimation points with almost no associations, which we observed for many participants with smaller bandwidths. R^2 was lowest in the middle of the time series and highest at the end. While the networks of these participants were estimated to be empty at many estimation points, the remaining networks changed very fast over time such that most estimated edges were present only for a short time. In some cases, edges even became inverted within a few estimation points, such that the association between 2 variables was positive at one estimation point and negative at another.

Participant 11

Participant 11 was a self-employed German man in his 40s, who was prescribed an antidepressant medication to treat his depression. He did not previously access any psychotherapeutic services. His time series spanned 204 days, and a bandwidth of 0.12 was selected for his data. Again, the estimated networks and visualization of 3 parameters over time are presented in [Figure 2](#).

Figure 2. Results for participant 11: (A) networks at estimation points 2, 10, and 19; (B) time-varying parameters.

The networks at estimation points 2, 10, and 19 (corresponding to days 12, 97, and 193) are displayed in Figure 2A. Time-varying parameters are shown in Figure 2B. The y-axis in this plot is different from that in Figure 1 to accommodate the large width of the bootstrapped sampling distribution.

At the start of the time series, the network of participant 11 was strongly connected. The effect of rumination on depressive symptoms diverged in the beginning, with a negative effect on next-day anhedonia and a positive effect on feeling down. Both anhedonia and rumination showed strong autoregressive effects at the beginning of the time series. This indicates a resistance to change for these variables, meaning that if a larger deviation from their expected value occurs, it takes longer for these variables to return to their “normal” values. Over time, most of these effects became weaker and ultimately disappeared, whereas only autoregressive effects and a positive association of rumination with next-day feeling down remained. At some estimation points, a weak, positive autoregressive effect of both social variables and a positive effect of quality on the quantity of next-day social contacts emerged (not depicted in this paper). In the end, the network of participant 11 became empty, which was also observed in other participants (such as participants 1, 5, and 18). In addition, depressive symptomatology, as measured using the IDS-C, decreased from 19 to 9, which is an improvement to what typically would be judged as a subclinical

symptom level. The average R^2 value over time points and variables was 0.228. It decreased toward the end, reflecting the empty networks estimated at the end of the time series. All the bootstrapped sampling distributions around the point estimates pointed toward a strong instability of the point estimates, showing that the interpretation of point estimates warrants caution.

Model Quality

In addition to focusing on the individual associations among variables and their change over time, we investigated model fit indices and the raw distribution of variables to check the overall quality of our models and possible violations of assumptions. The RMSE and R^2 values were computed for every variable of each participant at all time points. Averaged over all participants, the mean RMSE was 0.865 (SD 0.111), and the mean R^2 value was 0.235 (SD 0.181). Participant 9 showed the best fit, with an RMSE of 0.714 and an R^2 value of 0.486, whereas participant 3 showed the worst fit, with an RMSE of 0.972 and an R^2 value of 0.054. Overall, this indicates large differences in model fit among participants, with some models showing very poor fit, whereas others had a relatively good fit to the data. There are many potential reasons for these differences, such as overfitting or underfitting of the models or characteristics of the data that

violate the assumptions of the model such as strong nonnormality or abrupt changes.

For 30% (6/20) of the participants, we observed strong floor or ceiling effects in at least 1 item, commonly in either core depressive or social contact items, with the relative frequencies of maximum or minimum scale values exceeding 50%. As these highly skewed data violated the model assumptions, we chose not to interpret the resulting networks of these participants further. However, participant 6 also showed a ceiling effect for the first depression item, as she answered “all the time” for approximately 54.8% (165/301) of the days. Nevertheless, we chose to present her results, as none of the other items were affected, and she provided more relevant qualitative information than any other participant.

Discussion

Principal Findings

The goal of this study was to model the idiographic temporal dynamics of depressive symptoms and other variables associated with depression using daily diary data to gain insight into the temporal dynamics of the disorder. Therefore, we used a recently developed modeling technique that allows for the estimation of time-varying parameters. Both the results of our hypothesis tests and the bandwidth selection procedure provided evidence of substantial changes over time for most participants and thus supported the use of a technique that accounts for these dynamics. We described our results as networks of mutually influencing variables and highlighted the changes in the connections among them over time for exemplar participants. Our results showed extensive variation over time for some participants and marked variability among the networks of different individuals, whereas the bootstrap results suggested the general instability of point estimates.

Individual networks showed temporal associations that might be useful for clinical interpretation and use in self-monitoring contexts. A positive autoregressive effect of rumination, which was present for some estimation points for participants 6 and 11, is sometimes termed as ruminative inertia [74]. Becoming stuck in rumination might be a relevant cognitive mechanism that explains the negative influences of rumination on depression [74]. The contrasting effect of rumination on both depressive symptoms for participant 11 at some estimation points highlights the notion that certain aspects of rumination could also be adaptive for this individual at some times and could therefore differentially impact depressive symptoms. Regarding participant 6, observing a positive effect of feeling down on next-day social quantity at the same time as a negative effect on next-day social quality at the end of her time series could be interpreted as seeking more social contacts after days when she felt depressed, possibly as a remedy or coping strategy, but still being less able to enjoy them or shape them positively.

These person-specific relationships could then be translated into a treatment context by discussing them with the patient or by using them as hypothesis-generating models for potential intervention targets [75]. In addition to specific temporal associations, node-wise summary measures such as node

centrality or predictability have been discussed as potential indicators of the relevance of a certain symptom and, subsequently, as potential guides for intervention targets [24,26]. Time-varying networks provide a potential advantage over time-invariant networks in that they could be leveraged for just-in-time adaptive interventions [76]. For example, if the increase of a certain symptom or behavior strongly predicts increased depressive symptomatology, such information could be used to generate personalized interventions. We have discussed the statistical issues and potential solutions related to this topic in the following sections.

As evident in the provided examples, the results of bandwidth selection and in our hypothesis tests, we observed a strong variation in parameter estimates over time, which highlights the substantial variability of symptom interrelations within a person over the course of their depression. This is consistent with the results obtained by Howe et al [70], who found strong intraindividual variation in the networks among different mood states of participants over time. As they discussed, this finding indicates that when associations among symptoms are not time invariant, interventions based on an analysis of symptom-level associations that do not take this variation over time into account might be suboptimal. This could be especially relevant for the development of personalized, just-in-time adaptive interventions, which aim to provide personalized interventions at the right time. For example, if the quantity of social contacts showed a negative predictive association with depressive mood at some point but a positive one at another, an intervention to increase social activity might not always be beneficial. Thus, our results again reinforce recent calls for the use of network analysis methods that are equipped to detect variation over time [26] to better understand the dynamic nature of mental disorders. Additional qualitative information, as we presented for participant 6, could provide important information to interpret the changes in parameters over time and thus increase the clinical utility of the method.

The general decrease in the number and strength of next-day associations alongside an improvement in depressive symptomatology, which was evident for both participant 11 and other participants not shown in this paper, lends itself to an interpretation from a dynamical systems perspective about depression. The idea that individuals with more strongly connected depressive symptoms are more susceptible to ending up in a depressive state (put forth by Cramer et al [77]) has been investigated in various populations and contexts [78]. The time-varying approach used in this study could provide an interesting, new perspective on these issues [25]. The exemplars presented in this paper are not meant to provide any substantial evidence on the general question of the role of network connectivity in mental disorders. Decreased connectivity was, for example, also observed for participant 18, whose symptoms worsened slightly.

Although we can draw interesting insights from individual networks and their change over time, results for participants with a small bandwidth (refer to [Multimedia Appendix 1](#) for a detailed case study) stand out because parameters changed fast and many networks were empty. While it is possible that the symptomatology of these individuals changes quickly and that

no days, weeks, or months are alike, there are various other, at least equally plausible reasons for these results. These include the possibility of fundamental issues with assessment, such as the inappropriateness of our measures or inaccurate responses [79]. Irrespective of its root cause, the nature of these results can hamper the usefulness of this method. We have discussed the possible technical solutions to this issue in [Multimedia Appendix 1](#), but general issues with power and interpretability remain notwithstanding.

These considerations point to a more general question: in which contexts can time-varying models be useful? Simulation results have shown that time-varying models can outperform stationary ones even at a low number of observations of approximately 50, under certain conditions [25]. Thus, in principle, these models are both applicable to research, where one may be interested in finding specific time-varying phenomena and clinical contexts, where change over time may be interesting information as feedback for clinicians or patients. To make them useful in the latter case, choosing an appropriate context where gradual change is to be expected is important. In the case of changes due to major life events reported by participants, time-varying models that can accommodate abrupt changes might be an appropriate choice [80]. As time-varying techniques need a large amount of data, the proper selection of a limited number of variables is crucial. The need for a large number of observations per individual can be easier to achieve with passively collected data, such as from fitness trackers or smartphone data. When a large amount of data are available and there is a lack of theoretical knowledge about the form of relationships among variables, time-varying models might prove to be especially useful. In summary, when sufficient data can be collected and some gradual change among variables is to be expected and is of interest, time-varying models can shine.

However, although idiographic network models and time-varying subtypes are promising approaches, their clinical utility has not yet been established [81]. In general, idiographic network models have only been applied to clinical practice in small pilot studies [82]. Models that use purely data-driven approaches based on data from a single individual have several limitations, as they can ignore clinical judgment and can be difficult to estimate and interpret properly [34,83]. These issues can be counteracted by integrating clinical knowledge [83] or information from other individuals into individual networks [33,84]. These potential drawbacks of a purely idiographic approach may seem contradictory to the information in the Introduction section, where the nomothetic-idiographic divide and the advantages of the latter were emphasized. Instead of adopting an either-or perspective, highly person-specific approaches with intensive data collection such as those presented in this paper can still be crucial to provide individual feedback and to detect phenomena that would be obscured with less granular methods, thus serving as building blocks for nomothetic studies that aim to generalize these results.

Strengths and Limitations

Our study had several considerable strengths. We used an innovative modeling technique to explicitly model time-varying parameters in symptom networks. The combination of long

individual time series with relatively few missing data and the low number of variables, which is desirable for the performance of the presented method, was conducive to the quality of estimation. Furthermore, our detailed preregistration and open code provide transparency for other researchers.

However, the psychological processes that we are interested in are complex and can occur on a variety of timescales, and our assessments of those processes are affected by measurement error [85,86]. Therefore, our models should be interpreted with several caveats in mind. In general, estimated effects are strongly dependent on which variables are present or absent in the network [87], implying that the inclusion of more depressive symptoms would possibly change our results. Furthermore, the results of parameter estimation crucially depend on the chosen sampling frequency [88] and the subsequent lag choice [17]. Regarding measurement, the use of single items to assess psychological constructs has psychometric disadvantages [14] and may obfuscate the inherent heterogeneity of what likely should not be considered as homogenous constructs (refer to the paper by Bernstein et al [35] for the example of rumination). Moreover, the specific items used in this study were not previously assessed for validity or reliability.

A large number of empty or very sparse networks point to two further limitations of our method. In general, idiographic network models often experience power problems [33], which are further exacerbated in the power-hungry estimation of time-varying networks. Relatedly, regularization techniques decrease sensitivity and prohibit the construction of conventional CIs (refer to the paper by Williams et al [89] and Williams [90] for a discussion regarding lasso in network estimation).

Future Directions

There are multiple avenues for further studies. First, applied researchers can use time-varying VAR models in scenarios where substantial change can be expected and is of core interest, and repeated intensive assessment is feasible to better understand the temporal development of mental disorders. Second, building on its potential clinical use, further methodological research into the estimation method used in this study could provide more information on best practices regarding modeling options. Third, we observed the potential utility of qualitative information as context for time series data. Thus, further studies could investigate best practices regarding the collection and integration of qualitative information into intensive, longitudinal designs and analyses.

Conclusions

Attempts to develop personalized models of psychopathology have become increasingly refined in recent years. While there have been large advances regarding the modeling of interindividual variation, studies of variation within individuals with high temporal resolution have lagged. We have made a step forward in this direction by explicitly modeling individual changes in the associations among depressive symptoms over time. Pronounced within-person variation in our results highlights the importance of investigating the temporal dynamics of symptoms and their interplay over time.

Abstract

Background: The Feeling Good App is an automated stand-alone digital mobile mental health tool currently undergoing beta testing with the goal of providing evidence-informed self-help lessons and exercises to help individuals reduce depressive symptoms without guidance from a mental health provider. Users work through intensive basic training (IBT) and ongoing training models that provide education regarding cognitive behavioral therapy principles from a smartphone.

Objective: The key objective of this study was to perform a nonsponsored third-party academic assessment of an industry-generated data set; this data set focused on the safety, feasibility, and accessibility of a commercial automated digital mobile mental health app that was developed to reduce feelings associated with depression.

Methods: The Feeling Good App development team created a waitlist cohort crossover design and measured symptoms of depression and anxiety using the Patient Health Questionnaire-9, Generalized Anxiety Disorder-7, and an app-specific measure of negative feelings called the 7 Dimension Emotion Slider (7-DES). The waitlist cohort crossover design divided the participants into 2 groups, where 48.6% (141/290) of the participants were given immediate access to the apps, while 51.4% (149/290) were placed on a 2-week waitlist before being given access to the app. Data collected by the Feeling Good App development team were deidentified and provided to the authors of this paper for analysis through a nonsponsored university data use agreement. All quantitative data were analyzed using SPSS Statistics (version 28.0; IBM Corp). Descriptive statistics were calculated for demographic variables. Feasibility and acceptability were descriptively assessed. All participants included in the quantitative data were given access to the Feeling Good App; this study did not include a control group.

Results: In terms of safety, there was no statistically significant change in suicidality from preintervention to postintervention time points ($t_{288}=0.0$; $P>.99$), and there was a statistically significant decrease in hopelessness from preintervention to postintervention time points ($F_{289}=30.16$; $P<.01$). In terms of acceptability, 72.2% (166/230) of the users who started the initial 2-day IBT went on to complete it, while 34.8% (80/230) of the users who started IBT completed the entirety of the apps' 4-week protocol (150/230, 65.22% dropout rate over 4 weeks).

Conclusions: This study is the first reported proof-of-concept evaluation of the Feeling Good App in terms of safety, feasibility, and statistical trends within the data set. It demonstrates a feasible and novel approach to industry and academic collaboration in the process of developing a digital mental health technology translated from an existing evidence-informed treatment. The results support the prototype app as safe for a select nonclinical population. The app had acceptable levels of engagement and dropouts throughout the intervention. Those who stay engaged showed reductions in symptom severity of depression warranting further investigation of the app's efficacy.

Introduction

Background

Depression is a highly prevalent illness that affects approximately 280 million people worldwide [1]. Depression leads to varying degrees of functional impairment and distress [2]. Depression is most often treated through pharmacological intervention, psychotherapy, or neuromodulation with varying efficacy [3]. Suicide is the second leading cause of death in the United States among individuals aged between 10 and 14 years and 25 and 34 years, the third leading cause of death among individuals aged between 15 and 24 years, and the fourth leading cause of death among individuals aged between 35 and 44 years [4,5]. There are approximately 2 times as many suicides (45,979) in the United States as there are homicides (n=24,576) [4]. In pre-COVID-19 times, only 56.8% of people diagnosed with major depressive disorder obtained care. For those who reach out for help, it is estimated that only 37.5% receive minimally adequate treatment or evidence-based psychotherapies [4]. Untreated mental health issues have immense negative effects, from the psychological and physical impacts on the individual to increased health care use costs and loss of productivity that impact communities, societies, and economies [5,6]. Depression is the world's leading cause of disability, and despite various known and effective treatments, >75% of people in low- and middle-income countries receive no treatment [7]. Many individuals with depression are unable to receive effective treatment for a variety of reasons including due to a lack of resources [2], barriers to access such as systems without enough trained providers, and concerns about privacy and stigma. Providing accessible scalable services at low cost is imperative in combating the global mental health crisis.

Mobile smartphone apps and internet-based treatments present a tremendous opportunity to increase the accessibility of mental health care due to their ability to scale and reduce other barriers to entry [8,9]. A meta-analysis from Serrano-Ripoll et al [10] examined existing app-based interventions for reducing depressive symptoms and found that most of these apps significantly reduced symptoms, with moderate effect sizes (0.51) and significantly larger efficacy in more severe cases. There are a variety of publicly available mobile apps for depression that demonstrate clinically significant decreases in depression. Many interventions use a mixed model of automated multimedia and guided interventions to treat symptoms of depression. These interventions, which use both user-guided material as well as clinician support (nurse-moderated and therapist-guided), are shown to be effective, yet they are limited in their practicality and scale, as they rely heavily on clinician support [11-15]. There is also substantial literature into the efficacy of self-guided apps to treat symptoms of depression and anxiety, with many of the publicly available apps based in basic psychoeducation, mindfulness, and cognitive behavioral therapy (CBT). CBT and mindfulness-based apps, interventions

that typically range from 4 to 12 weeks, show significant reductions in symptoms and symptom severity from baseline [16-23].

With >10,000 mental health apps in the market, the choices are overwhelming, and knowing how to evaluate and choose a high-quality app is important. One potential danger in the development and innovations surrounding mental health mobile app-based solutions for depression is that they can be distributed without scientific evidence supporting their treatment techniques [10]. A recent study by Larsen et al [24] showed that in the description of the top 73 mental health apps, 44% used general scientific language such as *evidence-based treatment* while only 2 apps cited low-quality primary evidence and 1 app included a citation to published literature [24]. Differentiating between an app being based in evidence (ie, informed and including principles of evidence-based treatments) and being evidence based (ie, research demonstrating the app is efficacious) is crucial for both app developers and consumers alike [25]. Often, obtaining high-quality evidence is challenging given the cost of industry and academia collaboration in the form of sponsored projects. These projects often occur after the app has been developed and do not leave room for academic or clinical input into industry design during the translational process.

A challenge for mobile mental health solutions is whether an effective app is actually being used. In assessing the usability of a mobile mental health app, one of the primary criteria is adherence. Baumel et al [8] showed that in a study of 100,000 downloads of mental health apps, the median retention rate after 15 days was only 3.9%. In a review of randomized controlled trials of smartphones apps targeting depressive symptoms, Baumel et al [8] found a mean dropout rate of 26.2% that increased to 47.8% when accounting for publication bias. While digital tools with no human interaction have shown to be similarly effective compared with traditional face-to-face treatment, dropout rates are more than twice as high (33% dropout with no interaction) when compared with 11% dropout rates in apps with human interaction [8].

As many conventional evidence-based therapies make the leap to incorporating technology and mobile app use into their dissemination processes, evaluating the efficacy and use of these innovations by independent clinician researchers is crucial. Our group set out to evaluate such a mobile app based on a very popular and common therapy from Dr David Burns' *Feeling Great*, a self-help CBT book for depression by the Feeling Good Corporation. The Feeling Good App being developed is a smartphone app based upon the principles of Testing Empathy Assessment Methods CBT (TEAM-CBT) [26-29]. TEAM-CBT differs from traditional CBT in four key ways: (1) T=testing, frequent ecological momentary assessment of how users feel in the here-and-now (as opposed to the past 2 weeks) is used to track progress as well as relapses between classes; (2) E=empathy, the use of a variety of validation techniques to make the user feel cared about and understood; (3) A=address

resistance, the identification and reduction of motivational process and outcome resistance that nearly always interferes with recovery from depression and anxiety; and (4) M=methods, the use of dozens of techniques that draw from multiple schools of therapy. The techniques are chosen based on the type and categories of problem the user is struggling with. Although TEAM-CBT therapy itself has never been clinically tested, it is considered an evidence-informed therapy incorporating a myriad of evidence-based techniques into its practices.

The current Feeling Good App prototype does not require human intervention and is entirely automated. The current digital TEAM-CBT-based intervention consists of (1) intensive basic training (IBT), which spans 1 to 2 days and interactively teaches principles of cognitive therapy, and (2) ongoing training modules (OTMs) designed to integrate prior lessons and challenge automatic thoughts and core beliefs over 3 to 4 weeks. These training modules include a variety of TEAM-CBT techniques and interactive quizzes to reinforce learning.

Objective

To begin the process of rigorously testing the efficacy, usability, and scalability of this digital mental health intervention, we engaged in a third-party, nonsponsored proof-of-concept analysis of this company's data set. The electronic data were reportedly generated from an internally blinded randomized waitlist crossover trial. This trial's goal was to inform both the app development and help determine whether the technology warranted more resource-intensive sponsored research by academic clinical scientists. This form of research may serve as a model for initial low-risk engagement by academia and industry with minimal conflicts of interest.

The data set was collected during several days of individual digitally delivered intensive basic TEAM-CBT training followed by 4 weeks of additional content to help users challenge distorted thoughts and core beliefs. Using a randomized waitlist crossover data set of a beta test run by and provided to us by the Feeling Good App development team, we examined the safety, feasibility, and acceptability of this digital intervention. In addition, we performed exploratory analyses, examining the evidence for efficacy of this digital app for improving mood symptoms.

Methods

Recruitment

Data were collected by the Feeling Good App Corporation from users who were recruited from a waitlist of several thousand individuals interested in participating in a beta test of a TEAM-CBT mobile app mentioned in one of the Feeling Good podcast episodes hosted by David Burns. A deidentified data set was provided to the Department of Psychiatry and Behavioral Sciences, Stanford School of Medicine, via a nonsponsored data use agreement with Feeling Good App Corporation. The Feeling Good App development team retained ownership of the original data and allowed permission through the data use agreement for the authors to analyze and publish the findings independently. All data for this study were collected by the Feeling Good App development team and not by the authors of

this study. During data collection, authors consulted with the Feeling Good App development team and shared insight on best practices for creating a waitlist crossover cohort design and types of data to collect from users (eg, demographic information, exclusionary criteria, and measures); however, the authors did not have any direct oversight over its collection or means to assess accuracy.

The Feeling Good App was still in development and not commercially available during the study period. All participants were recruited from a waitlist of individuals who had heard of the app from Burns' social media sites and podcast and requested access. An email invitation was sent to waitlist members, and to those who responded to the email invitation, a consent for use of deidentified data in research and a screening form were emailed. Screening information was collected using a Google Survey. Screened respondents were included if they were aged >18 years, were fluent in English, had regular access to an iPhone, and had no previous experience with the Feeling Good App. They also indicated a willingness to spend at least 4 hours per day on IBT and 30 minutes per day on OTMs. Participants were excluded if they admitted to ever having a suicide attempt, suicidal urges, or plans, or self-harm behavior engagement or urges to harm others. Participants who indicated "yes" to any of these risk and safety questions were excluded from the study at enrollment and encouraged to seek help from a mental health professional and given resources to do so.

Ethical Considerations

Use and analysis of the data set was approved by the Stanford institutional review board (protocol ID 67718; Palo Alto, CA).

Intervention

After recruitment and screening, participants obtained access to the contents of the app by invitation to download the iOS app onto their Apple device by the app developers. Participants were then given access to the Feeling Good App, version title "Basic Training Release 2 RCS," a CBT self-help smartphone app designed to reduce a variety of negative feelings. It was not described as a treatment for any mental disorder or as a substitute for professional treatment, and at sign-up, participants were given resources to pursue professional treatment if desired. The app focused on identifying and modifying negative thoughts and beliefs associated with depression and anxiety and was entirely automated with no human intervention. The app used a 2-phased intervention model, with IBT spanning from 1 to 2 days and then OTMs that required 15 to 30 minutes a day for 4 weeks. The IBT contained modules on cognitive distortions, positive refraining, and relapse prevention and provided psychoeducation in the cognitive behavioral model of mental health disorders. The OTMs taught user strategies to challenge and change distorted thoughts and beliefs.

Participants were randomly assigned to an immediate start (IS) group or a waitlist control (WC) group in a crossover design. This study did not include a true control group, as all participants used the Feeling Good App and were included in the data set. Randomization was conducted using the percentage rollouts randomization feature in a software called LaunchDarkly [30]. The IS group was asked to select a day when they could devote

4 hours to the app for 2 consecutive days to start IBT and were given access to the app. The WC group was also asked to select a day to start IBT after a 4-week waiting period. Each week, participants completed self-report measures. Participants were assessed frequently throughout the beta test, but for this analysis, only four time points were reported: (1) *preintervention time point*, baseline at recruitment from the app waitlist; (2) *start of basic training (SBT)*, at the start of IBT; (3) *end of basic training (EBT)*, completion of IBT; and (4) *postintervention time point*, at the end of ongoing OBT and 4 weeks after SBT.

Measures

Overview

At the preintervention time point, all participants completed a survey that provided information about the app as well as complete demographic information. The preintervention information was gathered using a Google Survey that was securely collected and monitored by the Feeling Good App development team by their report. All other measures were collected electronically through the digital app. When participants were recruited from the waitlist at SBT, they completed a variety of self-report measures, including the Patient Health Questionnaire-9 (PHQ-9), the Generalized Anxiety Disorder-7 (GAD-7), and 7-Dimension Emotion Sliders (7DES). At EBT, participants completed the 7DES. At the postintervention time point, participants completed the PHQ-9, GAD-7, and 7DES. According to the Feeling Good App development team, users interacted with the service via browser at the time they applied to be in the beta test and in the app during the duration of the beta test. During that time, the information the users sent to the Feeling Good App servers was encrypted over HTTPS. The Feeling Good App servers stored information in a Postgres database. The connection between the servers and the database was encrypted. The database application was hosted in a private stack that did not allow connections except from application servers. The database used encryption at rest so that if an attacker was able to obtain the

database, they would not be able to access the underlying information. In addition, all identifying information, such as names and email addresses, was encrypted by the application server, so that in the event an attacker was able to access the database they would not be able to match any data to user identities. All data were deidentified before being transferred securely via Box to the authors.

Demographic Measures

Demographic information gathered at sign-up included age, gender, income, marital status, education, and race. Clinical information was gathered from all participants, which included current engagement in psychotherapy or psychotropic medication (at sign-up). All demographic data were collected using a Google Survey at sign-up.

Safety

During the preintervention screening, any participants who indicated a “1” or higher on item 9 of the PHQ-9 (“Thoughts that you would be better off dead or of hurting yourself in some way”) were excluded from the beta test and given resources for support. The preintervention screening also included 4 questions: “Have you ever made a suicide attempt in the past?” “Have you ever struggled with suicidal plans or urges?” “Have you ever engaged in self-harm behaviors, like burning yourself, cutting yourself, and so forth?” “Do you sometimes have urges or plans to harm others?” Any individuals who responded positively to these questions were excluded and given resources for support. No other safety data collection or monitoring was performed.

Qualitative Feedback

Throughout the beta test, qualitative feedback was collected at the end of every exercise (58 times in total for each individual who completed the full intervention) where participants were asked (1) “What did you like least or find upsetting?” and (2) “What did you like the best?” (Figure 1). Qualitative feedback was not reviewed by the development team until after the conclusion of the study.

PHQ-9 Scale

The PHQ-9 [31] is a self-assessment tool that evaluates the degree to which one is experiencing each of the symptoms of depression. This tool uses a Likert scale ranging from 0 to 3 (*not at all to nearly every day*) to measure the severity of depression [31]. Summed scores range from 0 to 27, with higher scores indicating greater symptom severity. The PHQ-9 has strong construct validity and reliability as a measure of depression symptom severity [31,32]. Responses were collected via Google Survey during sign-up, and all subsequent responses were collected within the app.

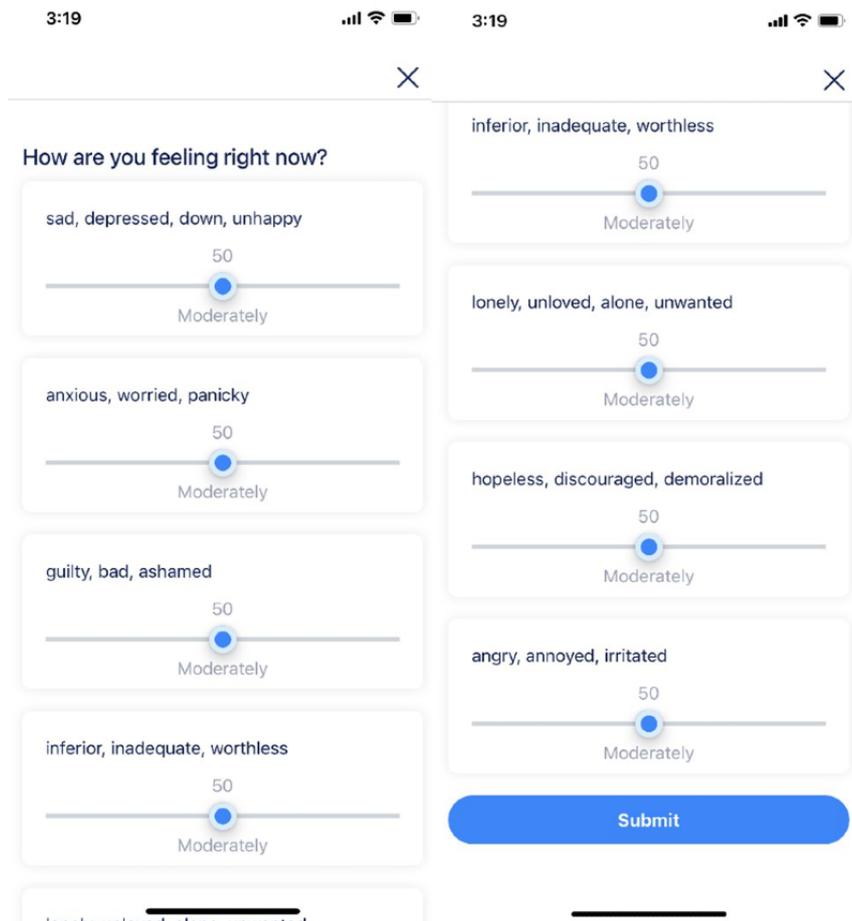

GAD-7 Scale

The GAD-7 [33] is a widely used, freely available self-assessment tool that evaluates the severity symptoms of GAD. This tool uses a Likert scale ranging from 0 to 3 (*not at all to nearly every day*) to measure the severity of anxiety symptoms. Summed scores range from 0 to 21, with higher scores indicating greater symptom severity. The GAD-7 has strong validity [33,34], internal consistency and convergent validity [34,35], and validity as a screening measure for symptom severity [36]. Responses were collected via Google Survey during sign-up, and all subsequent responses were collected within the app.

7DES Scale

The Feeling Good App was designed to produce and track extremely rapid changes in mood. As a result, conventional scales such as the PHQ-9 are not able to measure these types of rapid changes since they ask about the last 2 weeks. Developed for the purpose of the app, the 7DES scale is an ecological momentary assessment [37], which asks users to evaluate on a scale from 0 to 100 the extent to which they are experiencing the indicated negative feelings (Figure 2). These sliders allow for specific report of symptoms, as they change throughout the use of the app. Participants were prompted with the question of “How are you feeling right now?” and asked to move a slider (scale of 0 to 100) to reflect their experience of the following emotions: anger, anxiety, depression, guilt, hopelessness, inferiority, and loneliness. Participants were also asked to complete a single prompt slider rating their current happiness (happiness slider). Participants were prompted with “How happy are you right now?” and provided a 0 to 100 slider to respond (Figure 2). This study examined the data of the full-scaled 7DES-depression (7DES-d) of the 7DES; the anxiety scale (7DES-anxiety) of the 7DES; as well as data from the 5 emotion scales most commonly associated with depression (7DES-composite; depression, guilt, hopelessness, inferiority, and loneliness). Before our analysis, this data set showed that the reliability of this scale at the start of the app was 0.94. The 7DES scale is highly correlated to the PHQ-9 measure ($r=0.67$; $P<.001$). All 7DES responses were collected within the app.

Figure 2. Screenshot of 7-Dimension Emotion Sliders within the app.

Data Analysis

All quantitative data were analyzed using SPSS Statistics (version 28.0; IBM Corp). Descriptive statistics were calculated for demographic variables. Feasibility and acceptability were descriptively assessed using the engagement diagram and dropout tables.

Safety was assessed via qualitative and numerical reports provided by Feeling Good App Corporation team developers. Safety was measured quantitatively in 2 ways. First, we directly measured suicidal ideation using item 9 from the PHQ-9, which asks about the frequency of suicidal thoughts over the past 2 weeks. In addition, we measured suicidal ideation indirectly by using the hopelessness slider from the 7DES, which asks about the user's current feelings of hopelessness. Past research has shown that hopelessness independently predicts suicidal ideation, even when controlling for depression [38,39]. Therefore, we were able to assess safety both directly and indirectly, analyzing changes over time using repeated measures ANOVA.

Efficacy was evaluated using repeated measures ANOVA, which identified changes over time (SBT to postintervention) and by group (IS and WC). The PHQ-9, 7DES-d, and 7DES-composite scores were used to measure depression, while the GAD-7 and 7DES-anxiety scores were used to measure anxiety. Finally, we tested whether baseline characteristics of participant demographics predicted intervention response for both the IS and WC groups by running univariate ANOVA, where the demographic variables were moderators for changes in 7DES scores.

Results

Overview

The demographic variables of age, gender, race and ethnicity, highest level of education, income, marital status, current engagement with therapy, and current engagement with psychopharmacology were used. Descriptive statistics were calculated for each group using chi-square test. As shown in Table 1, there were no statistically significant differences between groups for any demographic variable.

Table 1. Demographics by group.

Characteristics	Immediate start group (n=141)	Waitlist control group (n=149)	Chi-square (<i>df</i>)	<i>P</i> value

Safety

Overall, 207 (40.2%) out of 515 individuals were excluded at screening for suicidality endorsing suicidal urges, suicidal thoughts, and past suicide attempts. For participants of the intervention, on item 9 of the PHQ-9 (“Thoughts that you would be better off dead or of hurting yourself in some way”), there was not a statistically significant change in scores from the SBT to postintervention time point ($t=0.0$, $P>.99$). Although users with suicidal thoughts were excluded from the study at the initial evaluation, at the start of app use, 10 (3.4%) of the 290 users endorsed a 1 (several days over the past 2 weeks) on item 9, while 2 (0.7%) of the 290 users endorsed a 2 (more than half the days). At the end of the intervention, 1 (0.3%) user endorsed

a 1 (several days) and 1 (0.3%) user endorsed a 2 (more than half the days).

Throughout the beta test, qualitative feedback was collected at the end of every exercise (58 times in total) where participants were asked “What did you like least or find upsetting?” Qualitative feedback was monitored, and no participants reported endorsed safety concerns throughout the entirety of the beta test. In addition, we measured changes in hopelessness from the 7DES. There was a statistically significant decrease in hopelessness from the SBT to the postintervention time point in both groups ($F_{289}=30.16$, $P<.001$), and there was not a statistically significant difference in the hopelessness change between the IS and WC groups ($F_1=1.78$, $P=.18$; see [Table 2](#) for engagement rates and [Figure 3](#) for changes in hopelessness).

Table 2. Engagement rates from preintervention to postintervention time point.

Feasibility and Acceptability

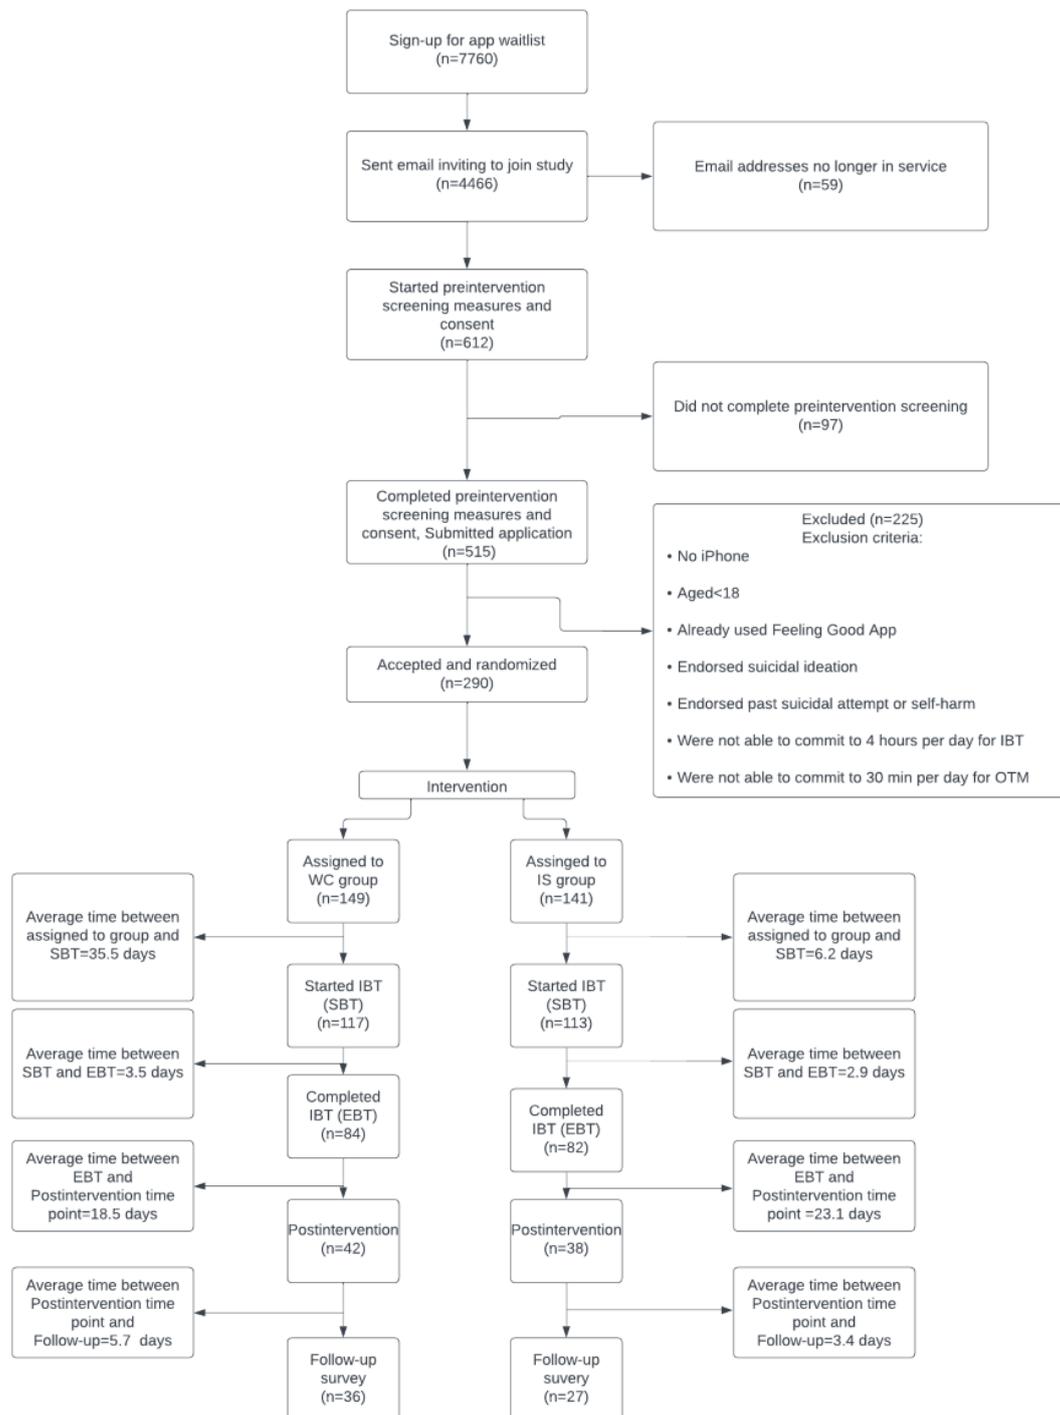

Overview

Invitations to join the study were sent to 4466 individuals who were randomly chosen from beta test waitlist using the percentage rollouts feature on LaunchDarkly. Of those who were invited to join the study, 612 (13.7%) individuals accepted the preintervention screening measures. Overall, 515 individuals completed the preintervention screening process, and 225 were excluded from participation.

An initial group of 290 individuals were enrolled to participate in the study and completed preintervention screening measures and consent forms. Of them, 141 (48.6%) participants were randomly assigned to the IS group and 149 (51.4%) participants were assigned to the WC group. Furthermore, 113 (80.1%) participants who were assigned to the IS group and 117 (78.5%) participants in the WC group started IBT. Initial enrollment dropout rates for the IS group were 19.9% (28/141) and 21.5%

(32/149) for the WC group. Data were not collected about the reason for dropout. Moreover, 27% (38/141) of participants in the IS group completed the postintervention survey, while 28.2% (42/149) of participants in the WC group completed the postintervention survey. A total of 223 participants started IBT, 166 (74.4%) participants completed IBT, and 80 (35.8%) participants completed OTMs. Dropout rates from SBT to EBT were 27.4% (31/113) for the IS group and 28.2% (33/117) for the WC group. From the EBT to postintervention time point, the IS group had a dropout rate of 54% (44/82), while the WC group had a dropout rate of 50% (42/84). Over the 4-week period that users engaged with the app, there was a total dropout rate of 66.4% (75/113) for the IS group and 64.1% (75/117) for the WC group. In total, of the 290 participants who were randomly assigned to groups, 166 (57.2%) users completed IBT, while 80 (27.6%) users completed the 4-week OTMs (see [Table 2](#) for engagement rates and [Figure 4](#) for CONSORT [Consolidated Standards of Reporting Trials] diagram).

Figure 4. Engagement diagram. IBT: intensive basic training; IS: immediate start; OTM: ongoing training module; WC: waitlist control.

Qualitative Feedback

Qualitative feedback, gathered at the end of each exercise throughout IBT and OTMs, was reviewed to identify content-based themes. One prominent theme that emerged pertains to users’ expectations and engagement with the app’s structure and pacing. Some users expressed satisfaction with its user-friendly interface, while others raised concerns about its usefulness in addressing intricate psychological challenges. This theme underscores the significance of aligning app design with users’ diverse needs and preferences. Many users expressed appreciation for the app’s educational value, finding tremendous benefit from the lessons, tools, and techniques offered. However,

the theme of personalization resonates strongly in users’ comments, highlighting their desire for content tailored to their unique experiences.

Technical glitches and functional concerns represent another notable theme. Users’ reports of technical issues underscore the need for rigorous quality assurance to ensure smooth app functionality. This theme also emphasizes the critical role of seamless user experiences in maintaining engagement and fostering positive change in how they are feeling. Furthermore, users’ reflections on the app’s engagement dynamics revealed its potential to evoke hope and encourage proactive self-care behaviors. Users shared hopeful sentiments about their ability

to apply learned techniques from the app into their daily life, and many users looked forward to a commercial release of the app to share with others.

Some users highlighted areas where the app’s pacing and content may not fully align with their preferences, suggesting the need for dynamic content delivery strategies that accommodate varying user needs. One area of concern for many users was the time commitment expected for the completion of the IBT portion of the modules. Results from the data analysis showed that the IBT brings forth some of the most foundational and persistent decreases in symptoms although users report difficulty in committing to the app’s daily requirements of multiple hours.

Upon completing the beta test, many users reflected on the personal growth and positive changes that they experienced throughout both IBT and OTMs. Users expressed a sense of pride and accomplishment and shared how they found the app to be incredibly effective in solidifying their understanding of CBT concepts and skills. Many users reported anticipating using the app again in the future, signaling a desire to continued engagement among users.

Efficacy

PHQ-9 Scale

We examined the possible effect of the Feeling Good App intervention on depression scores as measured by the PHQ-9, a standardized measure of depression. Using a repeated measures ANOVA, we found that there was a statistically significant within-groups effect of time, where mean depression scores measured by the PHQ-9 decreased from sign-up to 4 weeks later ($F_{197}=31.30, P<.001$). In addition, there was a between-group effect ($F_1=19.88, P<.001$). As shown in Figure 5, the IS group saw significant changes ($P<.001$) on the PHQ-9 scores over 4 weeks, while the WC group did not ($P=.20$).

We then used repeated measures ANOVA to assess changes in PHQ-9 scores from the SBT to the end of the app intervention for both groups. There was a statistically significant difference in PHQ-9 scores from the SBT through the end of the app intervention ($F_{78}=43.680, P<.001$). Figure 6 shows the change over time for each group, where the WC group saw significant reductions ($P<.001$) in PHQ-9 scores after starting the app intervention.

Figure 5. Change in Patient Health Questionnaire-9 (PHQ-9) scores over 4 weeks. IS: immediate start; WC: waitlist control.

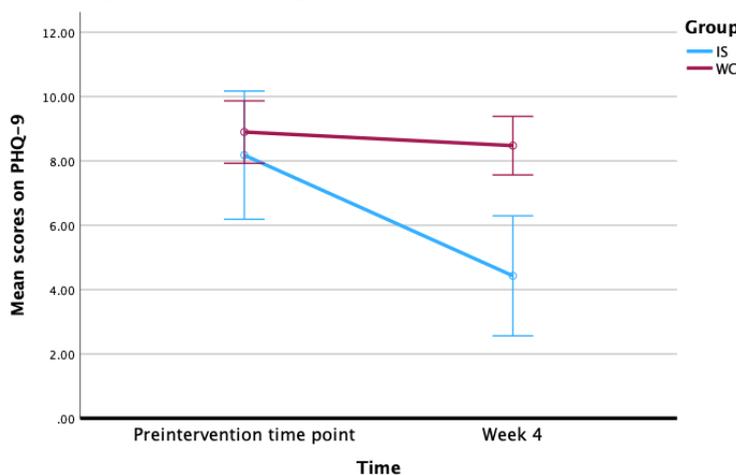

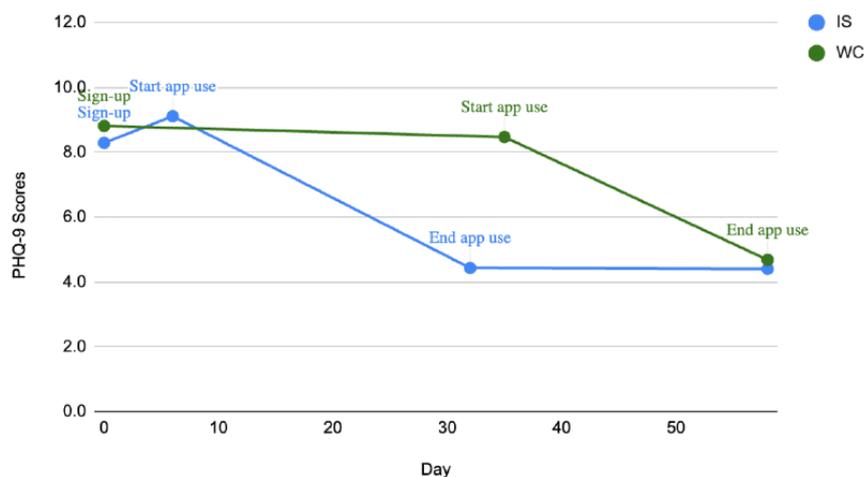

Figure 6. Changes in Patient Health Questionnaire-9 (PHQ-9) from the start of basic training (SBT) to postintervention time point. IS: immediate start; WC: waitlist control.

7DES Scale

In the exploratory analysis, we examined the effect of the Feeling Good App intervention on depression scores as measured by the novel 7DES-d and 7DES-depression measure composite. These slider scales provide information about the severity of current depression symptoms. A repeated measures ANOVA was conducted to measure the changes in depression scores from the SBT to postintervention time point. To account for the participant dropout, analyses for change in time excluded participants who did not complete the measures at both time points. There was a statistically significant change in depression scores throughout the use of the app, where the 4-week Feeling Good App had a statistically significant effect on the 7DES-d ($F_{78}=30.508$; $P<.001$) and 7DES-composite ($F_{78}=34.36$; $P<.001$).

Bonferroni adjustment pairwise comparisons were used to measure the change in depression scores between each time point. Table 3 describes the score changes on the 7DES-composite and 7DES-d scores across the intervention period. On the basis of these results, we can conclude that the reductions in depression scores on the 7DES scale occurred during IBT and were maintained throughout the app intervention for both groups. We then measured whether this change over time was different between the groups. In the repeated measures ANOVA, there was not a statistically significant interaction between time and group ($F_{78}=0.81$; $P=.44$). Therefore, the group

did not impact the changes over time in depression scores, where both the IS and the WC groups saw significant ($P<.001$) decreases in depression scores. Figures 7 and 8 show the change over time by group.

We also conducted a repeated measures ANOVA to measure the changes in scores on the GAD-7 over time. We found that there was a significant within-participants change over time ($F_{78}=38.99$; $P<.001$) and a nonsignificant between-participants effect of group ($F_1=0.64$; $P=.53$). Using Bonferroni adjustment pairwise comparisons, we found that there was a statistically significant reduction in GAD-7 scores from SBT to postintervention time point for both the IS (mean change 21.14, $P<.001$) and WC (mean change 17.78, $P<.001$) groups (Figure 9).

We then measured how the participants' anxiety changed over time as measured by the 7DES-anxiety. Using a repeated measures ANOVA, we found that there was a significant within-participants change based on time ($F_{78}=50.58$; $P<.001$) and that there was not a significant between-participants effect of group on this change ($F_1=1.03$; $P=.37$). Bonferroni adjustment pairwise comparisons were used to measure the change in 7DES-anxiety scores between each time point. There was a statistically significant difference on the 7DES-anxiety from the SBT to EBT for both IS (mean change 15.92, $P<.001$) and WC (mean change 20.00, $P<.001$) groups (Figure 10).

Table 3. Score changes on the 7-Dimension Emotion Sliders (7DES)-composite and 7DES-depression (7DES-d) over time.

Measure	Change across time	P value
7DES-composite		
SBT^a to EBT^b		
IS ^c	-13.71	<.001
WC ^d	-17.29	<.001
EBT to postintervention time point		
IS	1.26	>.99
WC	0.27	>.99
7DES-d

Demographics as Moderators

Finally, we examined the effect of demographic variables on changes in depression scores on the 7DES over time. A univariate ANOVA was used to examine the effect of moderator variables on depression change scores. There were not statistically significant interactions between depression change scores from SBT to EBT and age ($F_{56}=1.11$; $P=.35$), gender ($F_2=0.02$; $P=.89$), race ($F_9=0.69$; $P=.63$), income ($F_8=0.80$; $P=.60$), education level ($F_5=0.97$; $P=.43$), marital status ($F_7=1.80$; $P=.13$), current therapy engagement ($F_1=0.22$; $P=.64$), or use of psychopharmacological medications ($F_1=0.10$; $P=.76$).

Discussion

Principal Findings

This study is the first academic and reported proof-of-concept evaluation of the Feeling Good App in terms of safety, feasibility, and initial reports of efficacy. It demonstrates a feasible and novel approach to industry and academic collaboration in the process of developing a digital mental health technology translated from existing evidence-informed treatment. This study may be able to serve as a model for future low-risk, low resource-intensive, minimal conflict-of-interest pathways to conduct initial nonsponsored research with various stakeholders. The results support the initial Feeling Good App prototype as most likely safe for users, having acceptable levels of engagement throughout the length of the intervention and

evidence of use correlating with significant decreases in symptoms of depression and anxiety for those with moderate to low levels of clinical symptoms of depression.

The qualitative and quantitative measures of safety demonstrated evidence that this app is generally safe to use when excluding users with current safety concerns before use. Safeguards such as providing resources to individuals who indicated any amount of suicidal ideation on the PHQ-9 and encouraging all users to report concerns of safety allowed for users to proceed with the app without significant safety concerns arising throughout the duration of study. Further consideration of safety for users must be considered as the app moves toward commercial use. These may include protocols in place for allowing those with current or past safety concerns to use and benefit from the app since suicidal behaviors and parasuicidal are unfortunately common in those with mood disorders.

Measures of acceptability demonstrate varying points at which users cease use of the app, indicating that improving the app's engagement could benefit its widespread usability. App-based mental health tools are often affected by high dropout rates, particularly those that target depression symptoms. Dropout rates for these depression symptom apps tend to fall approximately 47.8%, and apps with smaller samples and more individualized feedback have lower rates on average than larger, generalized samples [34]. Dropout rates in the Feeling Good study can be considered after basic training, when a large percentage of total improvement has already taken place or at the end of the study and follow-up, which would put it above those reported average dropout rates. The dropout rates through the EBT for both groups combined were 28%, which can be attributed to the IBT's high engagement value and low-time commitment of 1 to 2 days. Over the 4-week period that users engaged with the app, there was a total dropout rate of 66% for the IS group and 64% for the WC group. Further app development may want to focus on improving this dropout, as it is a common problem currently with all forms of treatment for depression and especially for automated digital app- or web-based treatments.

The qualitative data analysis illuminates several salient content-based themes that underscore the multifaceted nature of users' experiences with the mental health app. These themes encompass users' expectations, personalization needs, technical functionality, and engagement dynamics. The findings underscore the importance of user-centered design in creating effective digital mental health interventions. The themes identified suggest the potential for integrating advanced personalization techniques, such as artificial intelligence algorithms, to enhance the app's relevance and resonance with individual users.

Retrospective analysis of this industry-generated existent data set demonstrates a statistically significant ($P < .001$) reduction in depression scores on the PHQ-9 from the beginning of the app to the end of the initial training and to the end of the ongoing modules. However, it is important to note that the cohort was not recruited from a clinical setting, and the mean scores before and after were indicative of mild to moderate depressive symptoms. This study does not fulfill the requirements of a true

efficacy study, rather it includes initial statistical impressions interpreted from the data set. The initial training took place over just 2 days, representing the possibility of rapid improvement. Scores from the 2 groups were not significantly ($P = .41$) different at the start of the intervention, so the delayed reduction in depression scores for the WC group aligned with their completion of the app, indicating that changes over time were attributed to app use.

Each of the scales from the 7DES (anger, anxiety, guilt, loneliness, inferiority, and hopelessness) saw significant ($P < .001$) reductions throughout the duration of the initial training. These reductions were maintained through the end of ongoing modules and the users' time using the app. There were no significant reductions between the end of the initial training and the end of the ongoing modules, suggesting the possibility that the app has the potential to maintain decreased depressive and negative emotions feelings over time.

Reductions as seen through the depression slider 7DES specific to the app were consistent with reductions on the PHQ-9, a popular well-validated assessment tool for depression symptoms. This may support efforts and further exploration of this measure to verify whether it is a clinically and ecologically momentarily valid and reliable measure to be used.

These findings of reduced PHQ-9 and 7DES scores represent potential for this app to help individuals reduce symptoms of depression and associated factors of anger, anxiety, guilt, loneliness, inferiority, and hopelessness. These findings should be further investigated in future studies due to the clinical importance of an app that can help individuals increase their mental well-being.

Individuals from the WC group did not see a significant ($P = .20$) reduction of depressive feelings during the 4-week waiting period. This was surprising, as many times during studies of WCs, there were some improvements seen before beginning an intervention, which may represent expectation, regression to the mean or passage of time, and increased hope for improvement. Research on WC design shows highly variable effects, which depend on the characteristics of sample being studied [40]. One explanation for this lack of waitlist expectation effect in our analysis may be some type of selection bias such as dropout from those individuals who felt their mood improved during the waiting period and chose not to participate. While reasons for dropping out at assignment were not collected, dropout may have been due to remission of symptoms, lack of desire to engage with the program, or technological barriers.

Limitations

Inherent in any clinical research is the risk of selection bias. The app is currently available by sign-up and is likely reaching audiences familiar with the work of Dr Burns. This bias toward individuals with knowledge related to CBT and psychotherapy may have a moderating effect on the reduction of negative feelings. Future research should take place in naturalistic settings with data from more representative populations perhaps in clinical populations or across cultural and diverse demographic contexts worldwide. The app is not publicly accessible through the Apple App Store and is only available to individuals who

are invited to participate in the beta version of the app. With the intention to provide resources at a low cost, these findings should consider the accessibility associated with the app's current stage of development. In addition, the study population was not a clinical population and showed only moderate severity levels of depression per PHQ-9.

This study occurred over a relatively short period with few follow-up data. One of the primary themes within the qualitative feedback was users indicating a desire to continue to use the skills and lessons provided by the app in the future. Further studies could examine the impact of these modules at a consistent time period beyond the completion of the initial training.

Completion of the Feeling Good App involves active attention and effort, and individuals' progressions and effort through the completion of the app were not monitored within this analysis. The app can request its users to engage mindfully but cannot account for potential lapses in attention that result in not engaging with the product in its intended context. User retention and engagement are critical to the success of a mobile app-based intervention. While the development team is capable of monitoring engagement, these data were not analyzed in our study. Further research should aim to examine the relationship between time spent in app and modules completed to determine the potential relationship with symptom reduction.

The participants in this study were all given the Feeling Good App and associated assessments, so this study did not include a control group. Future studies that explore the app and its efficacy should compare the users with a control group that is not given access to the app.

Privacy issues were not evaluated, and further assessment of this app using the American Psychiatric Association's evaluation

model and guidelines is encouraged and should include accessibility, privacy, security, clinical foundation, engagement style, and therapeutic goal [41].

Finally, the data analyzed were generated from an industry partner, and there was no way to ensure the data's accuracy by a third party. Further design and clinical testing will need to have the data collection occur by a third party to improve the level of evidence needed to establish efficacy and effectiveness.

Conclusions

The following are the summarized conclusions of this study:

- A low-risk, resource-sparing, nonsponsored, and unfunded collaboration between industry and academia is feasible and can occur during the development of an evidence-informed digital mental health app.
- The Feeling Good App in its current form was found acceptable and feasible to deliver to mild to moderately depressed users familiar with TEAM-CBT in a nonclinical setting.
- Safety appears reasonable but may need improvements in assessment, monitoring, and contingency management. Some safeguards are currently in place, while some safety improvements, such as monitoring for suicidal ideation, are needed with commercial use and with clinical populations.
- Acceptability: high dropout scores compared with other apps indicate some improvement in engagement needed.
- Although not designed to test efficacy, this study indicates that those who stay engaged with the Feeling Good App had significant ($P < .001$) reductions in the severity of depression symptoms.
- Evidence of feasibility and efficacy thus far supports further testing and development of this app by a third party using a prospective randomized controlled trial.

Conflicts of Interest

None declared.

Abstract

Background: There is evidence from meta-analyses and systematic reviews that digital mental health interventions for depression, anxiety, and stress-related disorders tend to be cost-effective. However, no such evidence exists for guided digital mental health care in low and middle-income countries (LMICs) facing humanitarian crises, where the needs are highest. Step-by-Step (SbS), a digital mental health intervention for depression, anxiety, and stress-related disorders, proved to be effective for Lebanese citizens and war-affected Syrians residing in Lebanon. Assessing the cost-effectiveness of SbS is crucial because Lebanon's overstretched health care system must prioritize cost-effective treatment options in the face of continuing humanitarian and economic crises.

Objective: This study aims to assess the cost-effectiveness of SbS in a randomized comparison with enhanced usual care (EUC).

Methods: The cost-effectiveness analysis was conducted alongside a pragmatic randomized controlled trial in 2 parallel groups comparing SbS (n=614) with EUC (n=635). The primary outcome was cost (in US \$ for the reference year 2019) per treatment response of depressive symptoms, defined as >50% reduction of depressive symptoms measured using the Patient Health Questionnaire (PHQ). The secondary outcome was cost per remission of depressive symptoms, defined as a PHQ score <5 at last follow-up (5 months post baseline). The evaluation was conducted first from the health care perspective then from the societal perspective.

Results: Taking the health care perspective, SbS had an 80% probability to be regarded as cost-effective compared with EUC when there is a willingness to pay US \$220 per additional treatment response or US \$840 per additional remission. Taking the wider societal perspective, SbS had a >75% probability to be cost-saving while gaining response or remission.

Conclusions: To our knowledge, this study is the first cost-effectiveness analysis based on a large randomized controlled trial (n=1249) of a guided digital mental health intervention in an LMIC. From the principal findings, 2 implications flowed, from the (1) health care perspective and (2) wider societal perspective. First, our findings suggest that SbS is associated with greater health benefits, albeit for higher costs than EUC. It is up to decision makers in health care to decide if they find the balance between additional health gains and additional health care costs acceptable. Second, as seen from the wider societal perspective, there is a substantial likelihood that SbS is not costing more than EUC but is associated with cost-savings as SBS participants become more productive, thus offsetting their health care costs. This finding may suggest to policy makers that it is in the interest of both population health and the wider Lebanese economy to implement SbS on a wide scale. In brief, SbS may offer a scalable, potentially cost-saving response to humanitarian emergencies in an LMIC.

Introduction

In the last decade, Lebanon registered an influx of around 1 million Syrian displaced people [1], in addition to approximately 0.5 million unregistered refugees. They are at considerable risk of developing mental disorders such as depression, anxiety, and posttraumatic stress disorder and often in need of mental health services [2]. Meanwhile, Lebanon's own population suffered from a series of overlapping humanitarian and economic crises (ongoing political turmoil, hyperinflation, the COVID-19 pandemic, the Beirut port blast), which undermined population mental health [3] and exacerbated the pressure on Lebanon's already overstretched health care system. As a result of these emergencies, Lebanese health care workers have been put under immense pressure, and many sought to leave the country to work overseas [4].

Considering the crises-related needs, transformations were required in line with Lebanon's national mental health strategy, in which one of its objectives was to scale-up digital self-help programs for priority conditions such as depression, anxiety, and posttraumatic stress in a cost-effective way [5]. To this end, the World Health Organization (WHO) helped to develop, test, and implement a guided e-mental health intervention for depression among Lebanese citizens, displaced Syrians, and other people residing in Lebanon [6-10]. The intervention is called Step-by-Step (SbS) and can be downloaded on digital devices. SbS consists of 5 sessions based on evidence-based psychological treatments, primarily behavioral activation. It is delivered with the aid of nonspecialist helpers trained and supervised to provide participants with guidance via messaging or by phone [6].

Elsewhere, we demonstrated that the SbS intervention is effective in reducing depression, anxiety, and posttraumatic stress and in improving personal and social functioning and subjective well-being in Lebanese citizens, Syrians, and other populations residing in Lebanon [11,12]. The objective of this

paper was to report on the cost-effectiveness of offering the effective SbS intervention in Lebanon. This study is among the first to evaluate the cost-effectiveness of scaling up a response to crises using a digital intervention in low- and middle-income countries.

Methods

Study Design

The study was designed as a cost-effectiveness analysis alongside a pragmatic randomized controlled trial with 2 parallel groups comparing SbS with enhanced usual care (EUC) with assessments at baseline (t0); 8 weeks post baseline (t1), which was after completion of the intervention; and 20 weeks post baseline (t2), hence 3 months after conclusion of the intervention. A study protocol [10], pilot study [8], and feasibility trial [9] have been published, and effectiveness studies showed positive clinical effects on depression, disability, and symptoms of anxiety and posttraumatic stress [11,12].

Ethics Approval

The WHO (ERC.0002797) and Saint Joseph's University in Beirut (CEHDF862) Ethical Review Committees provided medical ethics approval.

Participants

Participants were Lebanese citizens, displaced Syrians in Lebanon, and other people residing in Lebanon. Participants were recruited via social media, online advertisements, and outreach activities. Participants could download the SbS app for iOS and Android or visit its web version, which provided information about the intervention and the study and included a screener for eligibility. To be included in the study, participants had to (1) be aged 18 years or older, (2) reside in Lebanon, (3) be able to speak and understand Arabic or English, (4) have access to a device connected to the internet, (5) score higher than 10 on the Patient Health Questionnaire (PHQ-9) [13] for depressive symptom severity, and (6) score higher than

16 on the World Health Organization Disability Assessment Scale Schedule-12 (WHODAS) for impaired functioning [14]. The exclusion criterion was imminent risk of suicide, in which case the participant received psychoeducation and was directed to the national suicide prevention lifeline. Consenting participants who fulfilled the inclusion criteria were invited to complete the baseline questionnaire. As an incentive, those who completed the questionnaires received a US \$20 phone credit.

Randomization and Masking

Eligible and consenting participants were randomized to either the SbS intervention or EUC using automated permuted block randomization with a 1:1 allocation ratio within blocks of random length between 2 and 8. Randomization was stratified for nationality: Syrians in Lebanon versus Lebanese citizens and other people residing in Lebanon. The randomization algorithm was built into the SbS app and was not accessible by the research team.

Interventions

SbS was a guided digital health intervention to alleviate symptoms of depression, anxiety, and posttraumatic stress [6]. The intervention was based on evidence-based therapeutic techniques. The main therapeutic technique was behavioral activation with additional psychoeducation, stress management, positive self-talk, gratitude practice, reinforcing social support, and relapse prevention [6]. Weekly support to users was provided by phone or messaging by trained nonspecialists called “e-helpers” [9]. The e-helpers were trained over 5 days and continued to receive weekly group supervision by a clinical supervisor as well as individual supervision when needed [11,12]. e-Helpers could only begin their job after passing a competency examination subsequent to the completion of their training. Using a treatment fidelity checklist [11], fidelity checks found minor deviations from the treatment plan, such as when e-helpers skipped practice activities or did not go through the story with users fully [11].

EUC consisted of a psychoeducational message on the SbS app (similar to the first SbS session) and a list of primary health care centers available in different areas in Lebanon. Staff in these health centers were trained in screening, detecting, and managing mental health conditions [15].

Outcome Measures

The central outcome was the PHQ-9 [13]. The PHQ-9 is a 9-item instrument measuring severity of depression, with a cutoff score >10 indicating moderate to severe depression, which has also been validated in Lebanon [16]. For clinical and economic interpretation, the PHQ-9 was converted to treatment response and remission. Response was defined as an improvement of at least 50% between t0 and t2 in depressive symptom severity as measured by the PHQ-9. Remission was defined as a participant’s PHQ-9 score below 5 at t2 [17].

Resource Use and Costs

Questionnaires

Costs stemming from health care uptake and productivity losses were collected using a Lebanese Resource Use questionnaire that was based on both the Trimbos and iMTA (Institute of Medical Technology Assessment) Cost questionnaire for Psychiatric illness (TiC-P) [18], which has good reliability and validity [19], and the cross culturally validated Client Service Receipt Inventory (CSRI) [20] adapted and piloted for use in Lebanon [9]. The Lebanese Resource Use questionnaire was programmed into the SbS app as a self-report questionnaire.

All costs are expressed in US \$ for the year 2019 when the study was carried out and when, according to the World Bank, the average exchange rate for US \$1 was LBP 1507.50.

Cost of SbS

In the year 2019, the personnel cost of offering SbS amounted to US \$59,520 (consisting of the gross annual salaries of a 0.2 full-time equivalent [FTE] clinical supervisor, 1 FTE coordinator, 1 FTE senior e-helper, and 2 FTE e-helper). The annual nonpersonnel cost of offering SbS was US \$62,800 (US \$36,000 for hosting, maintaining, and periodically upgrading the digital intervention; US \$14,800 for renting the office, equipment, and overhead; and US \$2000 for advertising). The total personnel and nonpersonnel costs of operating SbS was therefore US \$59,520 + \$62,800 = \$122,320. SbS can serve 4700 users in a year. Therefore, the per-user costs of SbS was US \$122,320/4700 = US \$26.

Cost of EUC

People randomized to EUC received an online psychoeducational message derived from the first session of the SbS intervention. They also received a list of primary health care facilities with nonspecialized staff trained in the Mental Health Gap Action Programme [15]. The per-user cost of this online message was next to nothing (US \$0.01) and was ignored in the subsequent analyses.

Cost of Health Care Utilization and Productivity Costs

Table 1 reports the cost prices per unit health care, such as a visit to a general practitioner, session with a psychologist, or day in a mental ward.

Costs can be regarded from the health care perspective and from the societal perspective. Taking the health care perspective, only the direct medical costs were considered, stemming from the contacts of participants with health services. Costs were evaluated first from the health care perspective and second from the broader societal perspective, thus adding the costs stemming from productivity losses to health care costs. Productivity losses occur when a person stays absent from work (absenteeism) as well as when a person does not feel well, tries to work anyway but is less productive (presenteeism), resulting in work cutback.

Base Case Analysis

The health economic evaluation was conducted in agreement with the Consolidated Health Economic Evaluation Reporting

Standards (CHEERS) 2022 guideline for trial-based economic evaluations [22]. The costs are reported in US \$ for the reference

year 2019. The study's time horizon was 20 weeks (ie, 5 months).

With a sample size of 1136, the study would be powered to detect a standardized mean difference of medium size ($d \geq 0.50$) between the conditions, as statistically significant at $\alpha \leq 0.05$ (2-tailed) and a power of $(1 - \beta) \geq 0.90$ while accounting for an expected dropout rate of 70%, which is typical for self-help interventions [23]. The study was powered to evaluate a clinical depression-related outcome but not for a health economic evaluation for which costs are typically associated with large standard errors. In other words, in this study, we could statistically test effect differences but not cost differences. Instead, health-economic inferences were not based on statistical hypothesis testing but on probabilistic medical decision-making techniques.

At each assessment (t_0 , t_1 , and t_2), cost data were collected retrospectively from the last 4 weeks. Cumulative costs over the full trial duration of 20 weeks were computed using linear interpolation among the t_0 , t_1 , and t_2 assessments. Incremental costs and incremental effects were computed as the difference of the cumulative costs and effects between the conditions. The incremental cost-effectiveness ratio (ICER) was computed as the cost difference over the effect difference: $ICER = (C_1 - C_0) / (E_1 - E_0)$, where C and E are costs and effects and the subscripts 1 and 0 refer to the SbS and EUC conditions, respectively. The ICER is interpreted as the additional costs for gaining a treatment response and remission.

For intention-to-treat analysis, missing PHQ-9 scores were imputed using regression imputation. The regression imputation model included 2 types of predictors: predictors of outcome (societal costs, PHQ-9, gender, age, education, and WHO-5 Wellbeing as measured at t_0) and predictors of missingness (randomization status, partner status, employment status, and WHODAS-12 at t_0). The first set of predictors was included for predictive accuracy of the outcome, and the second type was included to better satisfy the missing-at-random assumption [24]. After imputation, the PHQ-9 score was converted into treatment response and remission.

To simultaneously evaluate both incremental costs and effects, seemingly unrelated regression equations (SURE) models were

used. In the SURE model, baseline costs were included to adjust for a baseline imbalance because EUC had higher baseline costs than SbS. Since cost data were nonnormally distributed, nonparametric bootstraps (2500 times) were used for the SURE models. The bootstrapped SURE models helped to create 2 figures: (1) the ICER plane on which the simulated ICERs are plotted and (2) the acceptability curve. We return to these figures and their interpretation in the Results section.

Sensitivity Analysis

The base case analysis had treatment response and depressive remission as outcomes. It was first conducted from the health care perspective, then it was repeated from the societal perspective. Missing observations due to dropout were imputed using regression imputation. In a preplanned sensitivity analysis, the base case analysis was repeated using multiple imputation with chained equations (MICE) using predictive mean matching to impute missing observations [25]. This was done to see how robust the results were under varying imputation strategies. All analyses were carried out in Stata 17.0 [26].

Results

Participants

Recruitment of the participants started December 9, 2019, and ended on July 9, 2020. In this 7-month period, 3042 persons were assessed for eligibility, 1676 met the inclusion criteria, and 1249 were randomized: 614 to SbS and 635 to EUC. Figure 1 shows the flow of participants through the trial.

At t_1 , dropout was 64.2% (394/614) in the SbS group and 51.5% (327/635) in the EUC group. At t_2 , these rates increased by an additional 24 and 43 participants, respectively, such that total dropout became 68.1% (418/614) in the SbS group and 58.3% (370/635) in the EUC group. Total dropout in the whole sample was 788/1249, or 63.1%. As indicated, a 70% dropout has to be expected in digital self-help interventions [23].

The demographic, clinical, and economic characteristics of the participants are listed in Table 2. It appears that randomization led to an even distribution of these variables over the conditions; however, societal costs appeared somewhat higher in the EUC group than the SbS group (Table 2).

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) flowchart. t0: baseline; t1: 8 weeks post baseline, which was after completion of the intervention; t2: 20 weeks post baseline.

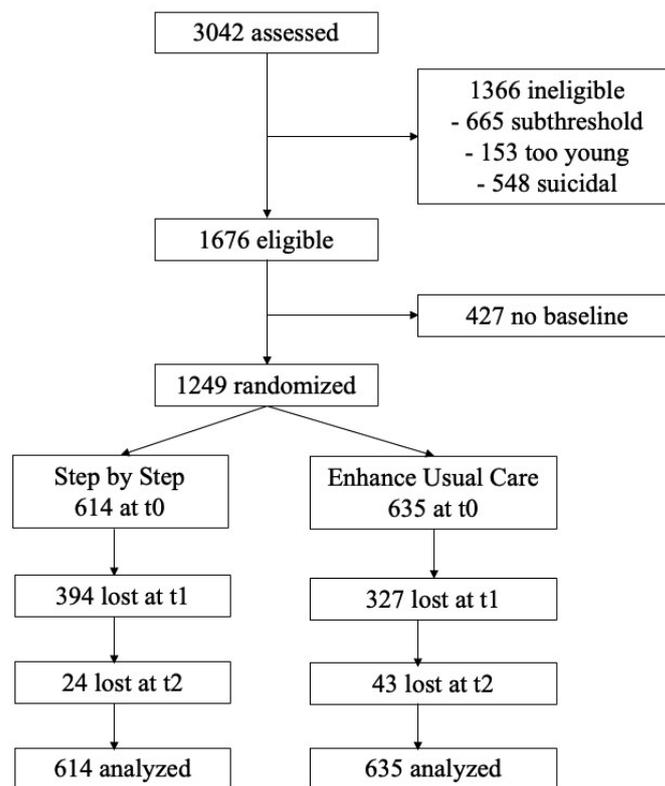

Table 2. Characteristics of the sample at baseline (N=1249).

Cumulative Costs

Table 3 describes the costs in the last 4 weeks at the t0, t1, and t2 assessments and how these costs accumulated over the full 20-week period. Missing cost data at t1 and t2 due to dropouts were imputed; the per-user cost of SbS was not included.

Table 3 shows that the mean health care costs fluctuated per participant slightly over time. The cumulative health care costs

were virtually the same in both groups (US \$241 [SbS] vs US \$243 [EUC]). However, the cumulative productivity costs ended up being lower with SbS (US \$151) than with EUC (US \$202), indicating that SbS helped to reduce productivity losses. This is also mirrored in the mean societal costs that were US \$443 with EUC and US \$393 with SbS. A detailed breakdown of health care and productivity costs is provided in Table S1 in [Multimedia Appendix 1](#).

Table 3. Per-participant costs in US \$ over time by condition, not including US \$26 Step-by-Step (SbS) costs (N=1249).

Base Case Analysis

Incremental Costs

Taking the health care perspective, including the SbS costs of US \$26 per recipient, the bootstrapped incremental health care costs averaged US \$28 (95% CI -\$22 to \$78), suggesting that SbS costs somewhat more than EUC, but this was not statistically significant (bootstrap SE=25.44, $z=1.10$; $P=.27$). For context, US \$28 would buy a single session with a psychologist in Lebanon in 2019.

Taking the societal perspective, the incremental costs averaged US -\$24 (95% CI -\$85 to \$37), suggesting a small cost reduction favoring SbS over EUC, which was not statistically significant (bootstrap SE=31.15, $z=-0.76$; $P=.45$).

It is worth noting that there is a discrepancy between the incremental cost as seen from the health care perspective (US \$28) and the incremental costs as seen from the societal perspective (US -\$24). The cost reduction that comes into view when taking the societal perspective must be related to the greater productivity (less absenteeism and less presenteeism) among the recipients of SbS.

Incremental Effects

The incremental response rate was 0.23 (95% CI 0.18 to 0.27) favoring SbS in a statistically significant way (bootstrap SE=0.022, $z=10.24$; $P<.001$).

The incremental remission rate was 0.06 (95% CI 0.031 to 0.085) favoring SbS over EUC and was statistically significant (bootstrap SE=0.014; $z=4.20$; $P<.001$).

ICER Response: Health Care Perspective

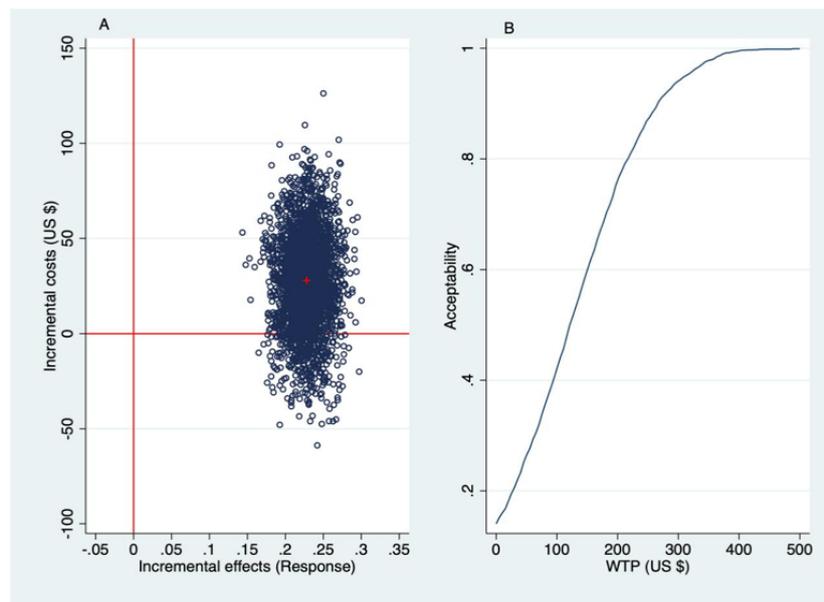

Dividing the incremental health care costs of US \$28 by the incremental response rate of 0.23 gives an ICER of US \$28/0.23=\$122. Thus, SbS costs US \$122 more than EUC per

treatment responder. It should be noted that the ICER of US \$122 is an average and is surrounded by uncertainty, as depicted in Figure 2.

Figure 2A shows the uncertainty around the mean ICER as a scatter of simulated ICERs over the ICER plane. The ICER plane is divided into 4 quadrants, denoted North East (NE), North West (NW), South West (SW), and South East (SE). Of the bootstrapped ICERs, 86% appear in the NE quadrant of the ICER plane, indicating an 86% probability that better effects are obtained by SbS albeit for higher costs than EUC. The remainder of the simulated ICERs appear in the SE quadrant, indicating that health gains are achieved by SbS while cost reductions occurred compared with EUC. Thus, SbS generates a greater health gain albeit for more costs than EUC.

This begs the question about how much one is willing to pay to gain an additional treatment responder. The acceptability curve (Figure 2B) is now key to decision-making. The acceptability curve plots the probability that the intervention is deemed cost-effective (ie, acceptable) on the Y axis (range 0.00-1.00) against various willingness-to-pay (WTP) levels to gain a response on the X axis (range US \$0-\$500). If there is no WTP to gain an additional response (WTP=US \$0), then there is a 14% probability that SbS is acceptable from a cost-effectiveness point of view (because 14% of the simulated ICERs appeared in the SE quadrant). Similarly, the SbS intervention has a 50% probability of being regarded as acceptable if society would be willing to pay US \$122 per PHQ-9 response (because ICER=US \$122 to gain an additional responder). Assuming a decision-maker would like to have a greater than 50% certainty and instead seeks an 80% probability for acceptability, it follows that the WTP for gaining a treatment responder must be about US \$220 (ie, the WTP at which the acceptability curve meets the 80% probability level of acceptability).

Figure 2. Health care perspective: incremental costs per additional Patient Health Questionnaire (9-item version) responder shown in a (A) cost-effectiveness plane and (B) acceptability curve (2500 bootstraps). WTP: willingness to pay.

ICER Response: Societal Perspective

The base case analysis with treatment response as the primary outcome was repeated taking the societal perspective. The incremental effect is as before: a 0.23 greater probability of treatment response with SbS than with EUC but with an incremental societal cost of $-\$24$ (negative cost, hence cost reductions). The fact that societal costs are lower than the health care costs can only be explained by greater productivity of the participants after having received SbS. Absenteeism (and associated costs) may have been reduced because more SbS recipients returned to work than those who received EUC. In addition, a greater proportion of people who received SbS became more productive (ie, less presenteeism).

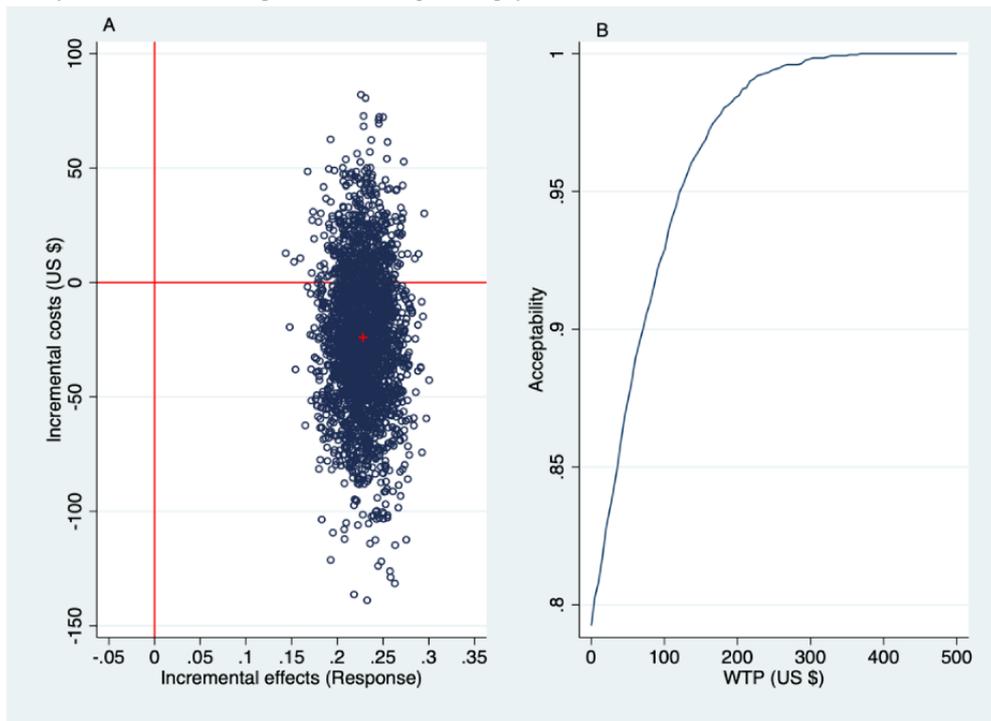

The incremental cost per additional treatment responder was also negative ($\text{US } -\$24/0.23 = -\105); therefore, the ICER is said to be “dominant,” because better effects are obtained for less cost with SbS than with EUC. [Figure 3](#) presents the outcomes.

[Figure 3A](#) depicts the scatter of simulated ICERs. Of these, 21% appear in the NE quadrant, indicating 21% likelihood that

the SbS intervention had better effects albeit for higher costs than EUC. However, a more substantial 79% of the simulated ICERs are in the SE quadrant, which is indicative of a 79% probability that gaining a treatment response with SbS is associated with cost reductions compared with EUC; hence, SbS is deemed “dominant” (ie, represents the more favorable treatment option compared with EUC from a cost-effectiveness point of view). Now, there is no need for a decision maker to review the acceptability curve because, in the context of cost savings, any WTP threshold has become irrelevant. Nonetheless, a look at the acceptability curve (in [Figure 3B](#)) shows that, at $\text{WTP} = \text{US } \0 , the likelihood of acceptability is 0.78 (78%), increasing to 0.95 (95%) at a WTP of US \$110.

In sum, taking the health care perspective, SbS has an 80% likelihood to be regarded as cost-effective when there is a WTP of US \$220 for an additional PHQ-9 response. However, taking the societal perspective, SbS is associated with a cost reduction and hence “dominant.” To reiterate, the cost reduction as seen from the societal perspective indicates that people become more productive (lesser absenteeism and presenteeism) after receiving SbS.

Figure 3. Societal perspective: incremental costs per additional Patient Health Questionnaire (9-item version) responder shown in a (A) cost-effectiveness plane and (B) acceptability curve (2500 bootstraps). WTP: willingness to pay.

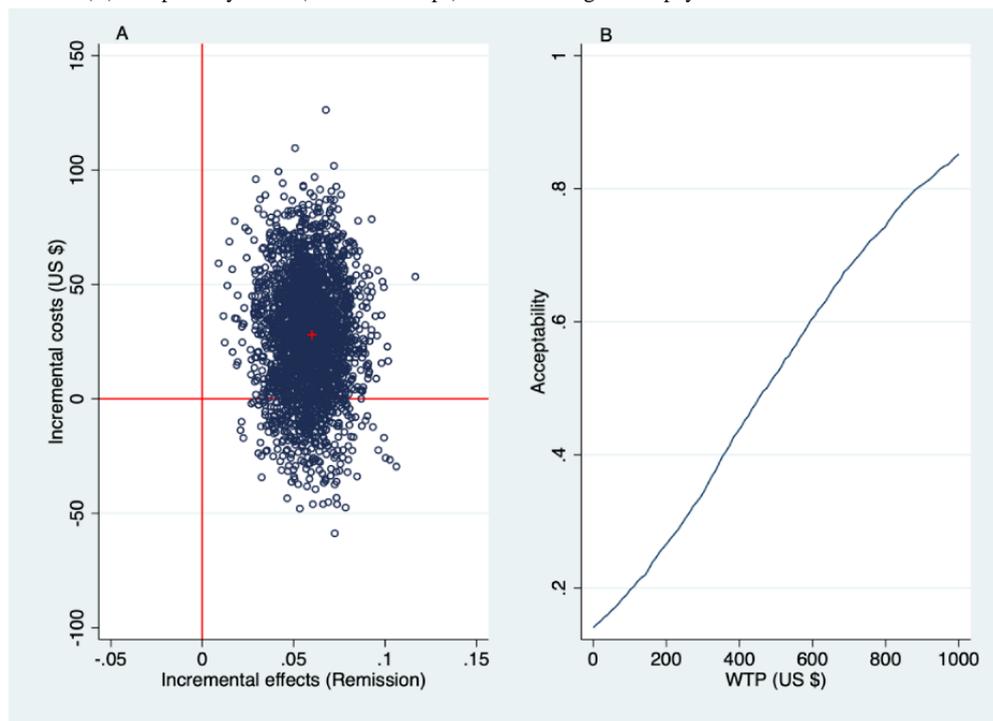

ICER Remission: Health Care Perspective

The base case analysis was repeated for the secondary outcome, remission. The incremental health care costs remained the same as before, at US \$28. The remission rate achieved was higher by 0.058 (95% CI 0.031-0.085) with SbS than with EUC, which was statistically significant (bootstrap SE=0.014, $z=4.20$; $P<.001$). Division of the incremental health care cost by the incremental remission rate gives US \$28/0.058=\$474. Thus, to achieve a remission with SbS costs more than with EUC, by \$474. [Figure 4](#) presents the results.

Since achieving a remission with SbS costs more than with EUC, the acceptability curve needs to be reviewed for decision-making. At WTP=US \$0, there is a 14% probability that SbS is deemed to be acceptable from a cost-effectiveness point of view (because 14% of the simulated ICERs appeared in the SE quadrant). At WTP=US \$474, the acceptability reached the 50% probability level (because the ICER=US \$474 for health care costs per remission). Should a greater than 50% certainty be required for decision-making in health, say, acceptability at the probability level of 80%, then it follows from [Figure 4](#) that the required WTP threshold is about US \$840 per remission.

Figure 4. Health care perspective: incremental costs per additional Patient Health Questionnaire (9-item version) responder shown in a (A) cost-effectiveness plane and (B) acceptability curve (2500 bootstraps). WTP: willingness to pay.

ICER Remission: Societal Perspective

Looking at remission and taking the societal perspective, the incremental costs are negative (US -\$24), indicating a cost reduction (due to fewer productivity losses after receiving SbS). This implies the SbS intervention dominates EUC as the more cost-effective treatment option as seen from the wider societal perspective.

Sensitivity Analysis

Table 4 summarizes the outcomes from the base case analysis (incremental costs per response and per remission based on regression imputation) and compares these with those from the sensitivity analysis (MICE using predictive mean matching).

Taking the health care perspective, Table 4 shows that the ICER is US \$121 per responder in the base case analysis (US \$101 in the sensitivity analysis) and US \$474 per remission in the base case analysis (US \$141 in the sensitivity analysis).

When taking the societal perspective, SbS was dominant relative to EUC because costs will be saved in both the base case analysis and sensitivity analyses.

Overall, the sensitivity analyses produced results that were fairly similar to the base case analysis but produced a higher remission rate (0.163) relative to the base case analysis (0.058). The estimate of 0.058 can only be interpreted as a small but positive incremental effect of SbS on remission. The estimate of 0.163 is still indicative of a small but positive incremental effect of SbS on remission, and our previous conclusion would not alter in any material way. All in all, the sensitivity analysis produced similar or roughly similar outcomes as the base case analysis. This is important because the study was subject to an expected, but large, dropout; therefore, it is important to assess if the results did not crucially depend on one or another imputation technique but that different imputation techniques indeed produced similar results.

Table 4. Base case and sensitivity analyses.

Analysis, perspective, and outcome	Incremental costs (US \$)	Incremental effects	ICER ^a cost (US \$) or effect	ICER distribution, %			
				NE	NW	SW	SE

^aICER: incremental cost-effectiveness ratio.

Discussion

Principal Findings

The health-economic evaluation of SbS versus EUC was conducted from 2 perspectives: the health care perspective and the societal perspective. The evaluation showed that the distinction between both perspectives is important. After all, SbS turned out to be associated with additional costs than EUC when seen from the health care perspective but was associated with cost savings as seen from the more encompassing societal perspective, apparently because the health care costs were more than compensated by the greater productivity of the people who received SbS instead of EUC. To be precise, taking the health care perspective, SbS had an 80% probability to be regarded as cost-effective compared with EUC when there was a WTP of US \$220 per additional treatment response or US \$840 per additional remission. Taking the more encompassing societal perspective, SbS had a more than 75% probability to be cost-saving while gaining treatment response or remission. Access to evidence-based mental health care in Lebanon is limited due to insufficient resources and infrastructure. Digital mental health interventions offer promising alternatives to address this issue, particularly for vulnerable populations like displaced people and those affected by conflict [11]. In addition, stigma surrounding mental health services discourages individuals from seeking help. To address this, interventions like SbS offer remote support, allowing mental health patients to seek private assistance without fear of negative perceptions [27].

Limitations

Our study was not without limitations. First, the findings may have been affected by the high dropout rate. Here, it should be

noted that high dropout rates were expected, as these are usually associated with digital self-help interventions [11,12,23,28,29]. In the power calculation, we therefore accounted for the high dropout. In addition, different imputation techniques for missing data produced similar results, attesting to the robustness of our findings despite the high dropout rate. Nonetheless, dropout may have influenced the study's outcomes.

Second, no clinical diagnostic interviews were used to assess depression status. Nevertheless, the PHQ-9 is a reliable instrument and was transformed in clinically relevant metrics such as treatment response and remission using well-established cutoffs.

Third, unit cost prices were mostly based on tariffs and reflected the price levels of the year 2019, which are likely to differ from current price levels in Lebanon where inflation is high.

Fourth, the effects were assessed at 3 months postintervention. Although the effects were maintained over that period, new studies are required to assess longer-term effectiveness and cost-effectiveness of digital self-help interventions and to assess the need to perhaps invite participants to return to SbS, for example after a depressive relapse.

Finally, decision-making based on a health-economic evaluation must consider that there are no universally agreed-on WTP thresholds for gaining a treatment response and remission. Ultimately, it is up to national policymakers what they consider good value for money, which may depend on factors such as the need for health care in the population, possibilities for sustained funding, and likely budget impacts in addition to medical-ethical and equity considerations.

Our study also has some notable strengths. In low- and middle-income countries, resources, expertise, and infrastructure for mental health care research, including health-economic

evaluations, are limited [30]. This is one of the larger randomized trials in mental health in a low- to middle-income country and one of the very few studies to assess the cost-effectiveness of a guided, digital self-help intervention for treatment response and remission in such a context. Furthermore, the fact that the study was able to recruit 1249 participants during the COVID-19 outbreak demonstrates the high demand for a low-threshold intervention like SbS.

Comparison With Prior Work

In terms of clinical outcomes, SbS significantly reduced symptoms of depression, anxiety, and posttraumatic stress and improved functioning [11,12]. These findings were consistent with meta-analytic evidence that digital health interventions for depression offered with some guidance, like SbS, are effective in generating beneficial clinical outcomes [31]. A health-economic evaluation of Syrian refugees in Turkey compared a group-based guided self-help course for stress management with EUC and demonstrated a 97.5% probability of cost-effectiveness at a WTP of US \$2802 for gaining a quality-adjusted life year [32].

Regarding the cost-effectiveness of guided digital interventions, Mitchell et al [33] performed a systematic review of 27 economic evaluations of internet-based psychological interventions for anxiety disorders and depression and found that 81% of the internet-based treatments were cost-effective. More recently, Rohrbach et al [34] conducted a systematic review and meta-analysis of 37 trial-based economic evaluations of digital health interventions for people with mental disorders compared with care as usual or “no intervention.” They observed that online therapies for mental disorders were more effective at generating health gains for similar costs as usual care across

a range of mental disorders. All in all, our results appear consistent with available evidence in indicating that guided digital self-help has a high probability to be regarded as cost-effective when compared with care as usual. However, it should be noted that the reviews and meta-analyses were based on studies conducted in high-income countries, whereas our study presents evidence from a middle-low income country facing a series of overlapping humanitarian and economic crises.

Conclusions

The SbS intervention, in addition to having a statistically significant and clinically meaningful effect on depression, anxiety, and stress-related disorders [11,12], had a more than 75% probability of being cost-saving as seen from the societal perspective.

Taking the health care perspective, SbS is associated with additional costs that are acceptable when there is a WTP of US \$220 to achieve a treatment responder or US \$840 for gaining a remission. In short, this study shows that digital health can be seen as cost-effective or even cost-saving compared with usual care. Apart from its cost-effectiveness, digital care can bring additional benefits because it can be accessed 24/7 from any location without the need to travel to health services and with less fear of stigma. This can be particularly relevant when access to routine care is hampered.

Throughout crises, health care systems are frequently overburdened, the health care workforce health is affected, and access to specialists for support is limited. In such a context, a digital self-help intervention with limited guidance appears to offer a promising and cost-effective approach to respond to humanitarian crises in low-resource settings such as Lebanon.

Acknowledgments

Step-by-Step (SbS) was developed by the World Health Organization in collaboration with the National Mental Health Programme of the Ministry of Public Health in Lebanon, Freie Universität Berlin, and University of Zurich. The authors acknowledge, with many thanks, the contributions from the Primary Health Care department at the Ministry of Public Health in Lebanon, Dr Randa Hamadeh and Imad Haddad; the directors of the primary care centers who provided unit cost price data; and the National Mental Health Programme and SbS team of Perrine Posbic, Nour Kik, Ahmad Akar, Gaelle Fahed, Layal Hamze, Maria Hayek, Sally Khoury, Yara Hasbany, Jihane bou Sleiman, Ghida Anani, and Charbel Zgheib. The authors alone are responsible for the views expressed in this article, and they do not necessarily represent the views, decisions, or policies of the institutions with which they are affiliated.

Fondation d'Harcourt and Research for Health in Humanitarian Crises (R2HC, managed by Elrha) funded this research. The research was conducted using an open-source software platform established by Freie Universität Berlin. The development of the SbS software platform was funded by the EU H2020 STRENGTHS project, European Union's Horizon 2020 Research and Innovation Programme Societal Challenges under grant agreement No 733337. The funders of the study had no role in study design, data collection, data analysis, data interpretation, or writing of the report. The opinions expressed in this paper are those of the authors and do not necessarily represent the decisions, policies, nor views of the organizations they serve or of the funder. Abstract

Background: Cognitive symptoms are an underrecognized aspect of depression that are often untreated. High-frequency cognitive assessment holds promise for improving disease and treatment monitoring. Although we have previously found it feasible to remotely assess cognition and mood in this capacity, further work is needed to ascertain the optimal methodology to implement and synthesize these techniques.

Objective: The objective of this study was to examine (1) longitudinal changes in mood, cognition, activity levels, and heart rate over 6 weeks; (2) diurnal and weekday-related changes; and (3) co-occurrence of fluctuations between mood, cognitive function, and activity.

Methods: A total of 30 adults with current mild-moderate depression stabilized on antidepressant monotherapy responded to testing delivered through an Apple Watch (Apple Inc) for 6 weeks. Outcome measures included cognitive function, assessed with 3 brief n-back tasks daily; self-reported depressed mood, assessed once daily; daily total step count; and average heart rate. Change over a 6-week duration, diurnal and day-of-week variations, and covariation between outcome measures were examined using nonlinear and multilevel models.

Results: Participants showed initial improvement in the Cognition Kit N-Back performance, followed by a learning plateau. Performance reached 90% of individual learning levels on average 10 days after study onset. N-back performance was typically better earlier and later in the day, and step counts were lower at the beginning and end of each week. Higher step counts overall were associated with faster n-back learning, and an increased daily step count was associated with better mood on the same ($P<.001$) and following day ($P=.02$). Daily n-back performance covaried with self-reported mood after participants reached their learning plateau ($P=.01$).

Conclusions: The current results support the feasibility and sensitivity of high-frequency cognitive assessments for disease and treatment monitoring in patients with depression. Methods to model the individual plateau in task learning can be used as a sensitive approach to better characterize changes in behavior and improve the clinical relevance of cognitive data. Wearable technology allows assessment of activity levels, which may influence both cognition and mood.

Introduction

Background

Major depressive disorder (MDD) is a debilitating condition and the leading cause of disease burden worldwide [1,2]. MDD is characterized primarily by low mood, or reduced interest and pleasure in daily activities [3]. Cognitive deficits are a substantial problem in patients with MDD, with reported impairments in a range of domains, including processing speed, attention, executive function, learning, and memory [4-6]. Despite impaired cognition being widely reported, further studies using objective neuropsychological measures are required [7].

Self-Assessment of MDD

MDD is typically assessed using retrospective self-report, where patients reflect on their experiences over a period of days or weeks. However, this method of reporting is subject to a variety of memory distortions [8,9], and depression itself is linked to impaired recollection, memory bias, and overgeneralization [10]. A direct comparison between retrospective recall and repeated real-time assessments has shown negative emotional biases in patients with depression [11,12] which persist beyond the depressive episode in a subset of patients [13]. Various explanatory factors have been proposed, such as the number of previous episodes and demographic factors, but overall results have been inconsistent [14].

If patients' recollections correspond poorly with their actual experiences, this is likely to distort our understanding of disease course and treatment response [15]. Discrepancies between objectively measured cognitive function and patients' self-report have been demonstrated, with the latter being influenced by depressed mood [16-18]. This may be true even in cases of significant cognitive impairment, where self-reported cognitive function is associated with subjective complaints of depressive symptoms but not objective cognitive outcomes [19]. Hence, it is plausible that self-reported and objective assessments are measuring different cognitive capabilities, with objective measures needed to reveal underlying cognitive function.

Results from cognitive tests may also vary in relation to within-individual differences, including dietary effects and sleep-wake cycles [20,21]. These variances can make it difficult to differentiate clinically meaningful change from measurement error [22]. Higher frequency sampling is thought to generate more stable and reliable estimates of constructs of interest [22], by reducing state effects on punctual relationships, which can obscure the signal in study interventions, and by narrowing the margin of error [23].

Real-Time Measurement of Cognition, Mood, and Activity

Advances in portable technology have enabled the precise, unobtrusive recording of real-time psychological, behavioral,

and physiological measures. Higher frequency assessments in the context of everyday life can identify real life changes that are associated with clinical improvement [24], improve sensitivity for detecting change [25] and help to identify shifts in depressive symptoms [26]. Additionally, this approach allows for the characterization of the temporal relationship of symptoms over time in relation to changes in an individual's behavior and environmental influences [27,28] creating a profile of the dynamic relationships between cognitive function, psychological processes, and biological processes of an individual [29].

However, this approach also has important implications for sampling strategy and data analysis. Diurnal changes in mood and affect have been reported in individuals with depression, where negative symptoms are more prevalent in the morning [30] and increased positive affect is seen later in the day [31,32]. Further, research indicates cognitive function follows the same pattern as daily changes in mood, with worse performance in the morning and better performance in the evening on a range of cognitive measures, including memory, attention, and psychomotor speed [33]. In the general population, more positive and less negative moods are typically seen on weekends, with improvements starting on Fridays [34], while more activity, measured by higher step counts, is noted during weekdays in comparison with weekends [35,36]. To account for the complexity of these fluctuations and how patients themselves may experience depression, novel data collection methods, such as ecological momentary assessments, are a promising opportunity to address this gap. Current scientific literature is mostly laboratory-based. Although ecological momentary assessment studies have shed light on various aspects of the disease, such as rumination and emotion reactivity [37], however, less is known about the relationship between cognition function and mood in MDD.

Goal of This Study

Here we examine data from a 6-week feasibility study of daily cognitive, mood, and activity assessment in adults with mild-to-moderate depression stabilized on antidepressant treatment. Previously, in this same sample, we demonstrated excellent compliance with daily cognitive and mood assessments on a smart watch and good agreement with validated full-length cognitive and self-report measures [38]. High adherence rates were found (95%) with no deterioration over the course of the study. Adherence was not associated with depressive symptoms or cognitive functioning.

In this study, we aim to optimize methods for analyzing high-frequency longitudinal data and characterize relationships between cognition, mood, and activity data in order to facilitate future intervention studies. This study aims to examine (1) longitudinal changes in mood, cognition, activity levels, and heart rate over 6 weeks; (2) diurnal and weekday-related changes; and (3) the cooccurrence of fluctuations between mood, cognitive function, and activity.

Methods

This was an observational study aimed at characterizing longitudinal patterns in cognition, mood, and activity in patients with MDD over 6 weeks with high-frequency assessment enabled by a wearable device.

Participants

Full recruitment details have previously been reported by Cormack et al [38], who demonstrated the feasibility of high-frequency testing for a prolonged period of 6 weeks in participants with depression. In brief, participants were recruited for a primary psychiatric diagnosis of MDD with mild to moderate depression (as defined by Patient Health Questionnaire [PHQ]-9 scores between 5 and 15, inclusive). They were recruited through a patient recruitment company with links to primary care providers and patients with depression groups. Participants aged between 18 and 65 years, inclusive, who were able to read and understand English, were eligible for participation. Individuals were excluded if they had a personal history of another psychiatric disorder (except nonprimary anxiety); mental, neurological, or neurodegenerative disorders; or substance abuse or dependence. In total, 30 participants with MDD receiving antidepressant monotherapy treatment were enrolled.

Measures

Cognitive function and mood were assessed with the Cognition Kit app (joint venture between Ctrl Group and Cambridge Cognition), loaded onto the Apple Watch (high-resolution touch-screen watch), and paired with an iPhone. Participants were asked to wear study equipment between 8 AM and 10 PM for 6 weeks. This duration was chosen as it is the time it typically takes for the improvement in mood to be seen following the start of administration of the antidepressant medication.

Prompts for cognitive assessment were given 3 times daily (morning, afternoon, and evening). Cognitive function was assessed with the Cognition Kit N-Back test, which has shown sensitivity to impairments in MDD [39]. Research suggests that n-back task performance is a marker of cognitive function, including aspects of working memory, task switching, and attention [40]. During test administration, 9 symbols randomly selected from a pool of 227 were presented briefly, one at a time, over 30 trials. Participants were asked to respond when any symbol was the same as the one presented 2 trials previously. The primary outcome measure was d-prime (the ratio of hits [correct detection of an n-back match] to false alarms [response during no match]). Under the current implementation of the paradigm, values of d-prime range from -3.33 to 3.33. Test-retest reliability of high frequency testing using n-back d-prime is 0.8 in a mixed sample of participants with neurodegenerative disease, immune-mediated inflammatory disorders, and healthy controls [41]. Each assessment took 30 seconds to complete, after which participants were shown their test score.

Prompts for mood assessment were given up to twice daily (afternoon and evening), with no prompt delivered in the

evening if participants had completed the assessment in the afternoon. Mood was assessed with the following three questions adapted from the PHQ-2 and Perceived Deficits Questionnaire: How much have the following problems bothered you over the past day? (1) Lack of interest or pleasure in doing things; (2) Feeling down, depressed, or hopeless; and (3) Trouble concentrating on things (eg, newspapers or television). Responses were coded on a 4-point scale of severity of symptoms (1=no problem to 4=greatly). Responses were summated to provide a summary mood score. The PHQ-2, a short, validated form of the PHQ-9, has high accuracy and sensitivity to depression [42].

Total daily step count and average heart rate, measures associated with depressive symptom severity, [43,44], were acquired passively through the Apple Watch. The Apple Watch has been found to be a reliable and valid tool for assessing heart rate variability and is extremely accurate as a daily step count [45,46]. Similarity the n-back test has been previously used in wearable technology studies that incorporated high-frequency testing, demonstrating its feasibility [38,47].

Procedure

Participants attended the study site, where researchers introduced the devices and tasks to participants, who were given the opportunity to practice using the software and hardware and ask questions. Testing was completed in the following 6 weeks (42 days), with data uploaded to secure study servers when transfer through Wi-Fi or roaming was possible. The study was completed with a home visit at 6 weeks, during which study hardware was returned.

Daily assessments were completed as part of a larger test battery, including full-length rating scales, and cognitive tests, and a semistructured qualitative interview, as described previously [38].

Statistical Analysis

Data Cleaning

Data were harmonized by defining the first study day as the first day in which participants responded to assessment prompts for cognitive and mood assessments. Earlier days, only passive data were excluded from analyses. For activity and heart rate measures, non-wearing days (defined as days with <100 recorded steps [48,49], or where no heart rate was recorded) were excluded from the analyses (25 observations out of 1160).

Response frequency within each 1-hour period collapsed across days (eg, 6 AM-6:59 AM, 7 AM-7:59 AM, and 8 AM-8:59 AM) was examined separately for mood and d-prime to identify periods with sparse data. One-hour periods with $n < 25$ assessments overall were excluded. This left n-back data from 6 AM-11:59 PM ($n=29$ observations dropped) and mood data from 12 noon until 5:59 PM ($n=98$ observations dropped). For all included 1-hour periods, there were between 41-287 data points available (mean 182 mood, 180 n-back assessments per 1-hour period).

Change Over Time

Since outcome measures are sampled repeatedly, hierarchical models are required to account for observations nested within individuals [50]. Random effects of participants with random intercept and random slope were applied to all models to control for between-participant variability, allowing the intercept and regression coefficient to vary between participants [51]. Model parameters were estimated using maximum likelihood, and model fits were compared with model likelihood ratios. This allowed the direct comparison of models with different fixed-effect structures using chi-square analysis and the selection of the best-fitting model. Diagnostic tests included examination of the normality of residuals and their spread for each predictor variable.

Raw data were transformed using log and square root transformations into normally distributed data as appropriate. A series of longitudinal mixed-effects models examined change in each outcome measure over the 6-week duration of the study to identify time-related trends in outcome measures. Each outcome measure was designated as the response variable, and a fixed effect of time-on-task was specified. Intercept-only models and linear, quadratic, and cubic trends of time-on-task were examined. For unequally spaced timepoints (cognitive assessment or mood), a continuous autoregressive correlation structure was applied. For summated daily indices (step count or heart rate), a first-order autoregressive covariance structure was used.

Diurnal and Weekday Effects

Fixed effects of diurnal variation or weekday were examined by appending these as additional predictors (fixed effects) to the best-fitting models. The time of day was treated as a continuous variable. Weekday was dummy coded from 1 to 7 (1=Monday to 7=Sunday). As in previous work, the quadratic and linear fixed effects of time of day and day of week were examined [32]. For measures with variation both in time-of-day and day-of-week (d-prime and mood), models first examined the effects of time-of-day and then incorporated weekday effects.

Characterizing Individual N-Back Learning Curves

N-back learning curves were characterized following previously described methods [52]. This includes (1) the “starting point,” the level at which performance begins; (2) the “asymptote,” the theoretically best score achievable toward which task performance tends with unlimited assessments; (3) the “slope,” the rate at which learning occurs; and (4) the “learning rate,” how quickly a prespecified level of performance is reached.

Intercepts extracted for each participant from the best-fitting mixed model for change over time using the analysis steps described above were implemented as individual starting points. These were subtracted from d-prime at each assessment occasion to provide a baseline-adjusted d-prime. As in previous work, the data were smoothed [53] by applying a 3-assessment moving average to the data series, corresponding to the typical number of assessments per day.

For each individual participant, nonlinear regression was used to fit an inverse curve ($Y=a-(b/X)$), yielding personalized

estimates for a (asymptote, the theoretically best score achievable: as $X \rightarrow \infty$, $Y \rightarrow a$) and b (slope) for baseline adjusted d-prime (Y) over each consecutive n-back assessment (X). A 90% learning rate was defined as the number of trials required by each individual participant to reach 90% of their potential beyond their starting point ($Y=0.9a$ when $X=10*b/a$) [52]. The stable maximum d-prime was calculated for participants by summing their asymptotes and intercepts.

Exploratory correlations of individual asymptotes and slopes were completed with summary measures from mood and activity assessments. The data were first examined for normality, and parametric and nonparametric correlations were completed as appropriate.

Covariation of Fluctuations With Mood

Fluctuations over time were quantified using random effects. Residuals derived from the best-fitting hierarchical models described above, regressing out significant effects of time-on-task (to control for practice effects), diurnal effects, or weekday effects as relevant to each outcome measure. Residuals reflect the deviation of each individual from their own slope at each moment in time (better or worse, or higher or lower), quantifying the difference between each observation and what would be statistically expected. Since all measures, with the exception of d-prime, reflected overall daily measures, mean daily residuals for d-prime were computed by averaging d-prime residuals for each day, providing a consistent time scale for covariation analyses. Hierarchical models were used to examine covariation between measures. All models specified a first-order autoregressive covariance structure and random intercepts. Diagnostic tests included examination of the normality of residuals and their spread for each predictor variable.

A step-by-step approach was taken to examine the covariation of mood with d-prime and other assessment domains. First, a mixed model was used to predict fluctuations in mood based on fluctuations within all other domains (fixed effects: d-prime, activity, and heart rate). Next, the direction of causality was examined using a time-lagged approach. Analyses examined whether the fluctuations in mood were predicted by fluctuations in the predictor variable on the previous or following day. Only outcome measures that were significant predictors in concurrent covariation analyses were taken forward and included in the lagged models.

Analyses were repeated after excluding the period during which 90% of n-back learning took place (computed from individual participant learning curves), with the exception of participants who showed no significant slope where all data were included. This helped to identify correlation between measures after the influences of task learning were minimized. Where significant associations with mean daily d-prime fluctuations were seen, analyses were repeated when constrained only to days in which 3 n-back assessments were available. This aimed to test whether covariation between d-prime and mood was affected by regression to the mean (where days with fewer n-back assessments are likely to show greater variability).

Ethical Considerations

The study was reviewed and approved by the Proportionate Review Sub-Committee of the Wales Research Ethics Committee at Swansea University (17/WA/0042) and performed in accordance with the current version of the Declaration of Helsinki. All participants provided written informed consent before being enrolled.

Results

Sample Characteristics

The final sample (N=30) included 19 women and 11 men, aged between 19 and 63 years (mean 37.2, SD 10.4 years). All participants received antidepressant monotherapy and had been on their current medication for an average of 9.9 (SD 9.5 months; range 0.4-94.3). Current medications included selective serotonin reuptake inhibitors (n=20), serotonin and norepinephrine reuptake inhibitors (n=5), tricyclic antidepressants (n=4), and serotonin antagonists and reuptake

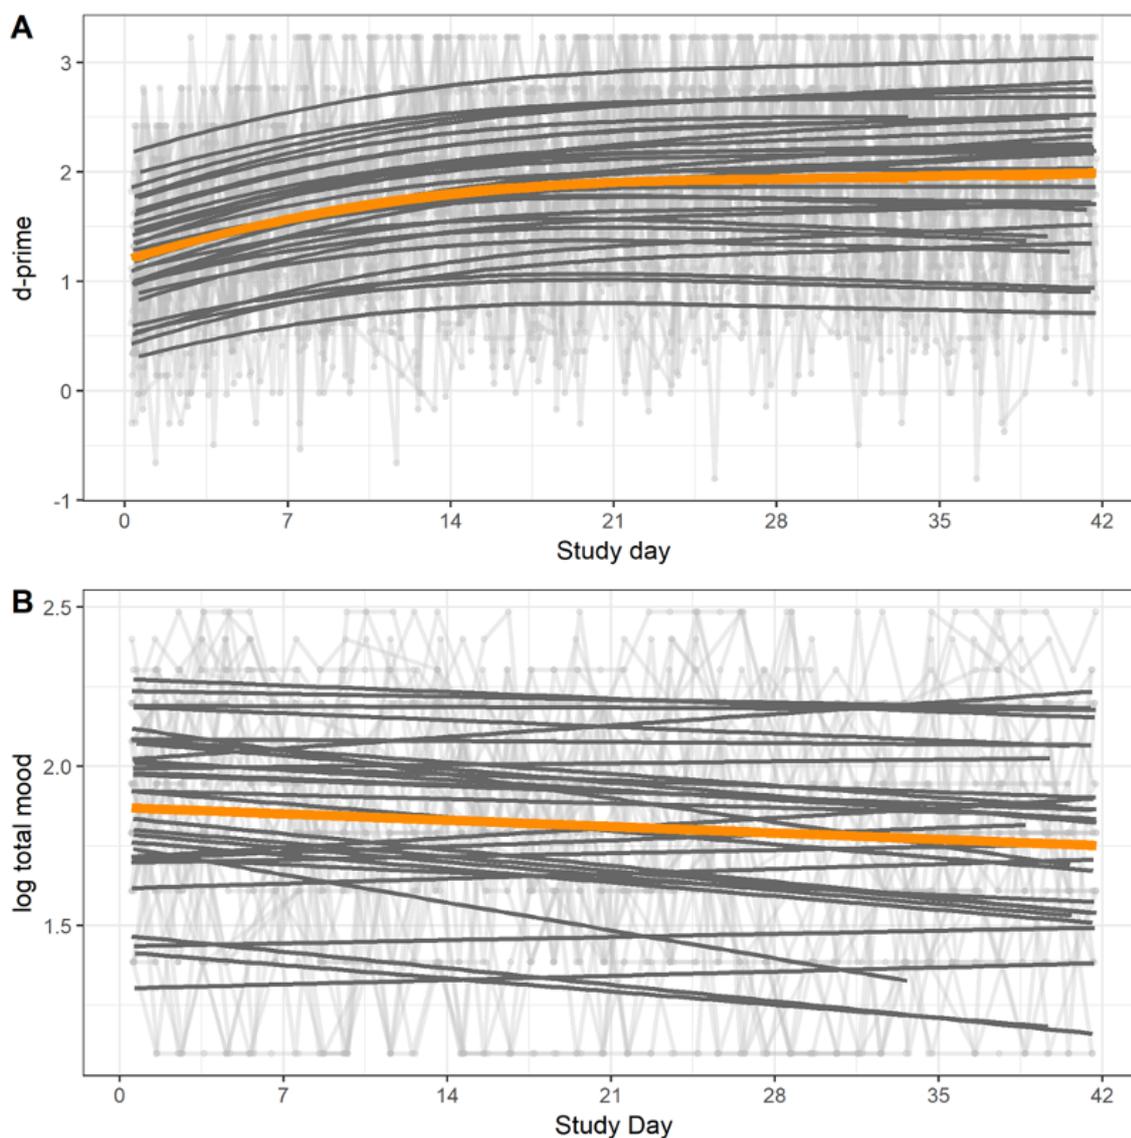

inhibitors (n=1). The mean depression symptom severity as measured by the PHQ-9 was 9.1 (SD 3.1; range 5-15).

Modelling Changes in Mood, Cognition, Activity Levels, and Heart Rate Over 6 Weeks

Model selection statistics and resultant model parameters are presented in Table S1 in [Multimedia Appendix 1](#). A cubic trend provided the best fit for change in cognitive performance over 6 weeks. Similarly, a linear trend provided the best fit for within-subjects change in mood over 6 weeks, in which depressive symptoms showed a subtle reduction over the course of the study. Heart rate and activity levels showed no overall change over time.

Data for d-prime and mood are presented in [Figure 1](#). Here, individual daily scores (light gray lines) are shown alongside fitted random effects (bold gray) and the fitted fixed effect (orange). This illustrates the variability across participants in the direction and magnitude of change over the 6 weeks and the remaining variability from these model fits.

Figure 1. Change over study duration (A) in d-prime (up to 3 daily) is shown on the y-axis, with higher scores equating to better performance and (B) total mood as reflected by the y-axis (higher scores equate to a more depressed mood): random effects (bold gray lines), fixed effects (orange lines), model fits, and individual scores (pale gray lines) for individual participants.

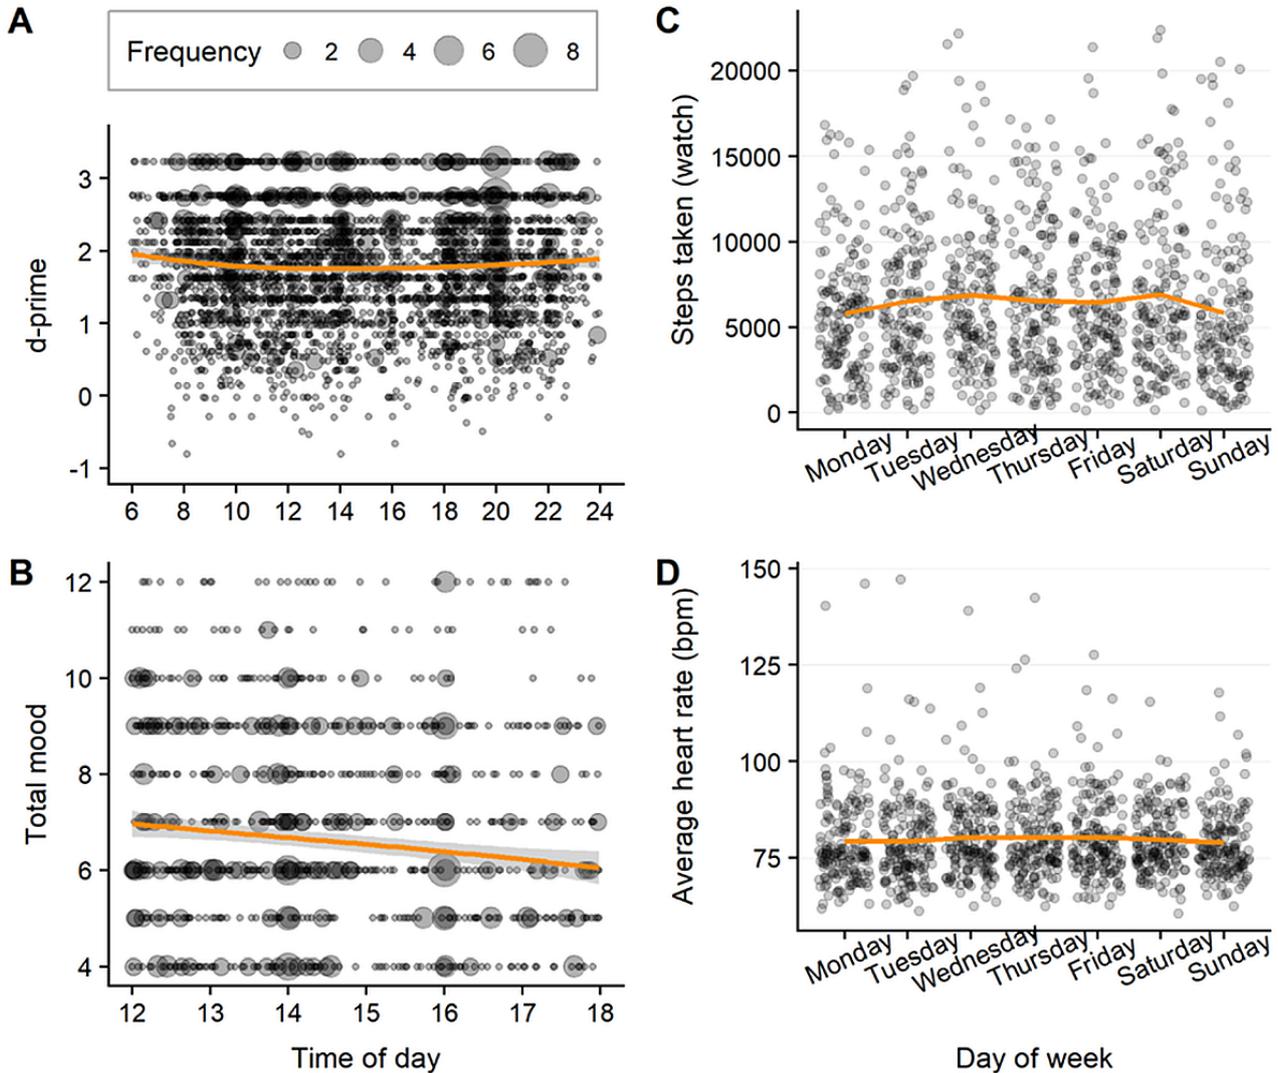

Diurnal and Weekday-Related Changes

D-prime showed a significant quadratic effect of time-of-day, with better performance seen first thing in the morning and later at night (Figure 2A; time-of-day: estimate=-0.02, SE 0.01; $t=-2.33$; $P=.02$; time-of-day: estimate=0.001, SE 0.0006; $t=2.48$;

$P=.01$). The model including time-of-day improved model fit (fit statistics: Akaike information criterion [AIC]=5952.15, Bayesian information criterion [BIC]=6019.10, likelihood ratio $\chi^2=6.16$; $P=.01$). No significant linear or quadratic effect of the weekday was observed ($P\geq.15$).

Figure 2. Diurnal and weekday effects in data: (A) Bubble chart of d-prime over time-of-day from early morning until midnight with loess regression line, with higher scores showing better performance; (B) bubble chart of total mood over time-of-day from noon until evening with loess regression line, with higher total mood denoting more severe depressive symptoms; (C) total steps taken over weekdays with mean line; and (D) average heart rate (beats per minute) over weekdays with mean line.

Mood showed a subtle improvement over the course of the day, which did not reach significance thresholds and did not improve model fit (Figure 2B; time-of-day: estimate=-0.01, SE 0.006; $P=.06$; model fit statistics: AIC=436.22, BIC=476.20, likelihood ratio=3.55; $P=.06$). The effects of day-of-week were also not significant ($P\geq.14$).

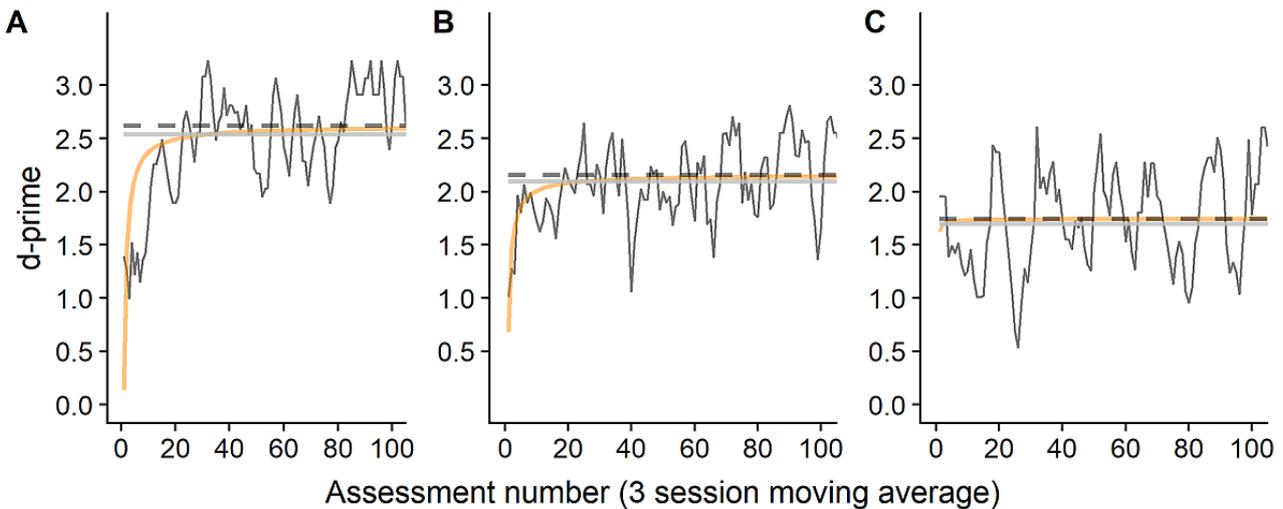

Significant changes in activity and heart rate were also found over weekdays (Figure 2C-2D). Step counts were lower at the week onset and end (weekday: estimate=3.52, SE=1.50; $t=3.52$; $P=.004$; weekday: estimate=-0.64, SE 0.17; $t=-3.66$; $P=.003$). As expected, including these quadratic weekday effects improved model fit (fit statistics: AIC=10131.19, BIC=10166.41, likelihood ratio=-5058.60; $P=.002$). Similarly, heart rate showed a subtle quadratic effect of weekday with lower heart rates recorded on week onset and end (weekday: estimate=0.01, SE=0.006; $t=1.96$; $P=.05$, weekday: estimate=-0.002, SE=0.0008; $t=-1.98$; $P=.05$), with improved

model fit (AIC=-2312.81, BIC=-2272.56, likelihood ratio=3.91; $P=.05$).

Characterizing the N-Back Learning Curve

An adequate fit of the inverse learning curve model was seen for 27 out of 30 participants of whom estimates for both slope and asymptote were significant (minimum $t=2.18$; $P<.04$). In participants with adequate fit, 90% learning rates were reached after an average of 22.4 assessments (range 13-31), occurring after a mean of 10 days (range 6-24). Participants with data showing poor fit displayed a flatter trajectory and lower slope over the period of assessment than those with a better fit (Figure 3). Stable maximal d-prime was seen at a mean of 1.94 (range 0.74-2.93), with 4 individuals having maximums within the top quintile of positive n-back scores (at 2.59 and above) and no participants with 95% CIs incorporating the highest possible score.

Figure 3. Examples of individual learning curves (dark gray lines), and inverse curves for n-back performance (orange line; $y = \text{asymptote} - (\text{slope}/x)$) over period of assessment. Asymptotes are shown in black dashed lines, while 90% learning rate is shown in pale gray. Subjects A (slope=2.48) and B (slope=1.47) show moderate and adequate fit for the inverse curve, while a poor fit is seen for subject C (slope=0.12).

A total of 3 participants did not show a learning effect over the period of assessment, characterized by a nonsignificant slope. These participants performed overall above chance in n-back assessments (mean scores between 0.9 and 1.7), indicating adequate understanding of test objectives but no clear learning pattern.

Learning slope and asymptote correlated moderately with one another ($\rho = 0.70$, 95% CI 0.39-0.84; $P < .001$), but neither slope nor asymptote correlated with the intercept (minimum $P = .40$). Correlational analysis examining the relationship between learning parameters and mean mood and activity during the monitoring period revealed no significant association between learning slope or asymptote with mean mood ($\rho = -0.07$ to 0.05 ; minimum $P = .74$), but a significant association emerged with mean activity (slope: $\rho = 0.44$ [0.05-0.75]; $P = .02$; asymptote: $\rho = 0.45$ [0.08-0.68]; $P = .02$).

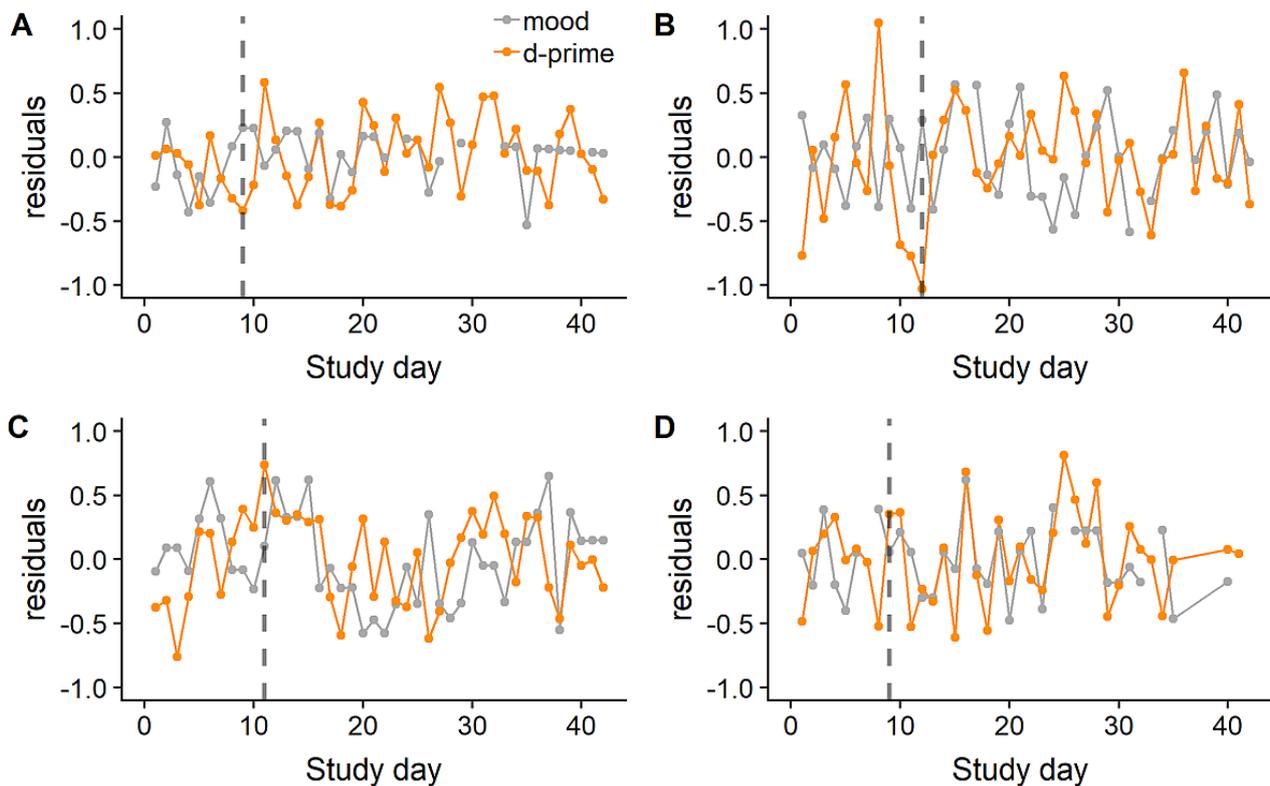

Covariation of Fluctuations Between Mood, Cognitive Function, and Activity

When examining the full assessment period, mood fluctuations did not significantly covary with fluctuations in daily heart rate ($t = 1.2$; $P = .23$), or d-prime ($t = -1.8$; $P = .07$). However, daily mood fluctuations were seen with concurrent fluctuations in step count (estimate = -0.001 , SE 0.0004; $t = -3.93$; $P < .001$), with a relatively higher levels of activity associated with relatively better mood. Examining the direction of these effects using

lagged models for the entire assessment period revealed that increased step count the day before was associated with better mood on the following day (previous day activity residual: estimate = -0.001 , SE 0.0004; $t = -2.40$; $P = .02$). However, a relatively more positive mood did not predict increased activity on the following day ($t = -0.49$; $P = .62$).

Fluctuations between outcome variables and mood were reexamined after excluding the period during which 90% n-back learning rates were reached. Daily fluctuations in d-prime (estimate = -0.06 , SE 0.02; $t = -2.51$; $P = .01$) and activity (estimate = -0.002 , SE 0.0005; $t = -3.50$; $P < .001$) were associated with fluctuations in mood (Figure 4 shows individual examples of covariation of mood with d-prime). The covariation of mood with heart rate was nonsignificant ($t = 1.74$; $P = .08$). Estimates and significance levels remained similar after restricting analyses to days where all 3 n-back assessments were available (d-prime: estimate = -0.07 , SE 0.03; $t = -2.57$; $P = .01$; activity: estimate = -0.002 , SE 0.0005; $t = -4.42$; $P < .001$). Taking a lagged approach, but after excluding the learning period, increased step count was again associated with better mood on the next day (estimate = -0.001 , SE 0.0005; $t = -2.00$; $P = .05$). However, a relatively more positive mood did not predict an increased step count on the following day ($t = -0.34$; $P = .73$). This approach also indicated that relatively higher d-prime scores were not associated with better mood on the previous or following day (t range = 0.61 to -0.77 ; P range = 0.44 to 0.72).

Figure 4. Covariation of daily mood residuals and mean daily d-prime residuals before and after 90% learning level reached (denoted in dashed line) for 4 participants. Note that mood residuals are inverted, so that higher residuals denote better outcomes for both mood and n-back performance.

Discussion

Principal Results and Comparison With Previous Work

This study characterizes high-frequency assessments of mood, cognition, and activity levels over a 6-week period in patients with MDD. By modelling individual learning curves from cognitive testing, we show that, after excluding an initial learning period, Cognition Kit N-Back test performance shows sensitivity to daily fluctuations in mood. The n-back test showed rapid early performance improvement followed by more incremental learning as participants neared a stable performance level, a trend that is replicated from previous findings for mean daily data in this sample [38]. This pattern is similar to that seen in laboratory-based cognitive assessments [53,54] and in practice effects identified during higher-frequency mobile cognitive assessments completed over 1 week of testing [22,55]. Participants completed 90% of task learning after a mean of 22 assessments (approximately 10 days after study onset). All participants achieved this level of improvement after 31 assessments (23 days). As such, a 10-day run-in before the introduction of any intervention may help to reduce the majority of learning effects in this n-back task, and subsequent performance can be referenced relative to an individual's learning plateau as a proxy for baseline. Careful consideration of learning effects may be particularly important in intervention studies examining temporal associations between symptoms and accurate digital phenotyping [56]. As such, after the removal of learning effects, the association between mood and n-back performance can be objectively measured with a brief 3-times daily assessment. After excluding the initial learning period

from the analysis, we found that better mood was associated with higher n-back scores on measurements taken on the same day. This approach demonstrates a potential method to “baseline” individual performance in high-frequency assessments after their learning plateau is reached in order to disentangle clinically meaningful relationships between mood and cognition. The absence of a significant relationship between mood and n-back performance during the learning period could be attributable to the development of specific learning strategies applied by participants during the learning phase [57,58] that obscure the relationship between mood and cognition.

Indeed, experimental studies have shown better cognitive performance when a positive mood is induced [59-61], although findings are not always consistent (eg, Nusbaum et al [62]). In the case of the latter study [62], this may be due to an examination of cognitive flexibility as opposed to working memory, as these may have distinct underlying mechanisms contributing toward overall cognitive performance [63]. Working memory impairments in patients with depression have been widely observed and are associated with the number of hospitalizations and the overall prognosis [64,65]. Performance in this domain is associated with negative symptom severity, including lack of motivation and apathy [66], in addition to positive valence [60]. In this study, changes may represent longer-term improvements in response to existing treatment regimens or may reflect the natural history of remission and fluctuating symptom levels commonly reported in depression [67]. It has been suggested that enhanced patient understanding of mood and mood changes over time may help to improve depressive symptoms and their management [68,69]. Whether

these methods themselves have an impact on mood over time requires further clarification [70].

When examining diurnal and weekday effects, participants showed modestly better cognitive test performance early in the morning and late at night, with a slight decrease in function throughout the middle parts of the day. These findings are in agreement with the reported “afternoon slump” in cognition in healthy adults [71]. Neither diurnal nor day-of-week effects on mood were seen, in contrast to previous reports [31,34]. However, in broad agreement with previous research [35,36], we identified day-of-week effects for activity levels as measured by step count and similar patterns in mean heart rate. Step counts showed a quadratic effect of day of week, with lower counts registered at the beginning and end of each week. These findings highlight the importance of carefully considering the timing of assessments to ensure consistency in data sampling and control trends in data over time. Longer-term trends in mood data independent of any treatment effects highlight the importance of adequately controlling for subtle overall trends in time in future interventional studies, ideally using a randomized design and a placebo-controlled comparison group. Using a multilevel modeling approach, we were able to examine whether mood fluctuated synchronously with other measures of interest over time. We identified covariations in mood and activity levels, in keeping with a body of research showing improvements in depression symptoms with exercise [72,73], or simple walking interventions [74]. Our results show that a relatively increased mood was associated with a relatively increased step count on the previous day (but not the following day), which indicated that the beneficial effects of exercise on well-being may well be protracted [75].

Limitations

While associations between activity levels (step count), mood, and cognition were identified, step counts are likely to have

been influenced by wearing patterns [38], thereby reducing the reliability of the data. The summarized daily step counts also fail to elucidate whether activity was acute or prolonged, vigorous, or light, and the exact timing of activity changes in relation to mood and cognitive assessments. Accelerometers can help to continuously monitor activity, and concurrent GPS and travel diary information has been found to help to classify and identify the duration of walking [76]. Previous studies have examined associations between physical activity on mood in assessments triggered through GPS distance tracking [77,78], a method that could be used to refine the timing and accuracy of activity assessments in this context. Additionally, since this study focused on patients with mild-to-moderate MDD who volunteered for participation, it is unclear whether the results would generalize to patients with different clinical severity.

Conclusions

This study indicates the importance of incorporating objective measures of cognitive testing and provides insight into fluctuations in mood and cognition in patients with MDD. The feasibility of remote high-frequency testing in MDD is promising for future research in this field and has important implications for clinical interventions. While these methods can be used to monitor nuanced fluctuations between mood and cognition in a real-life setting, they may also be useful as a treatment tool. Understanding objective cognitive function in depression may also be used to target patients’ acceptance of their objective difficulties in cognition and may be particularly relevant for interventions such as CBT and mindfulness [79]. Overall, while assessments of activity need to be further refined and improved, the effects of step count on mood and cognition support the concurrent capture of data on activity, which may be an important contributor to variations in mood and changes in cognition in everyday life in patients with depression.

Conflicts of Interest

SS is an employee of Takeda Pharmaceuticals, the sponsor of the research. LC was an employee of Takeda Pharmaceuticals USA, Inc, at the time of study. JK and FC are employees at Cambridge Cognition. The other authors have no conflicts to declare.

Multimedia Appendix 1

Final model selection and model parameters for daily assessment outcomes over 6-week period.

Abstract

Background: Suicide is a leading cause of death worldwide. Journalistic reporting guidelines were created to curb the impact of unsafe reporting; however, how suicide is framed in news reports may differ by important characteristics such as the circumstances and the decedent's gender.

Objective: This study aimed to examine the degree to which news media reports of suicides are framed using stigmatized or glorified language and differences in such framing by gender and circumstance of suicide.

Methods: We analyzed 200 news articles regarding suicides and applied the validated Stigma of Suicide Scale to identify stigmatized and glorified language. We assessed linguistic similarity with 2 widely used metrics, cosine similarity and mutual information scores, using a machine learning-based large language model.

Results: News reports of male suicides were framed more similarly to stigmatizing ($P < .001$) and glorifying ($P = .005$) language than reports of female suicides. Considering the circumstances of suicide, mutual information scores indicated that differences in the use of stigmatizing or glorifying language by gender were most pronounced for articles attributing legal (0.155), relationship (0.268), or mental health problems (0.251) as the cause.

Conclusions: Linguistic differences, by gender, in stigmatizing or glorifying language when reporting suicide may exacerbate suicide disparities.

Introduction

Background

Suicide is a leading cause of death in the United States, claiming over 48,000 lives in 2021 [1]. Rates of suicide and self-harm are significantly different for males and females. In 2021, US

age-adjusted suicide rates were higher among males (22.8/100,000) than females (5.7/100,000) [1]. However, reported rates of nonfatal self-harm in 2020, the most recent year for which such data are available, were higher among females (189.4/100,000) than males (123.8/100,000) [2].

Gender and Suicide

The observed gender disparities in suicide death rates between males and females are echoed in gender differences in other suicide-related behaviors such as ideation, attempts, and mechanisms [3]. Women have higher rates of lifetime suicidal ideation [4] and suicide attempts [5]. Wang et al [3] also report that men experience higher rates of suicide likely due to the increased lethality of the mechanism. Circumstances of suicide, or negative life events that precipitate suicide-related behavior [6], also vary among men and women according to the analysis of suicides in the National Violent Death Reporting System [6]. For example, previous analysis correlates negative financial and employment circumstances with increased male suicides in 2009 [7]. Suicide-related behavior is therefore highly gendered, and research that seeks to inform understanding and prevention of suicide must consider gender as a layer of analysis. While we acknowledge the call for expanded US research on gender differences across all suicide-related behaviors [8], this study includes gender as an essential layer of analysis to understand reports of suicide deaths.

Unsafe Media Reporting about Suicide

Unsafe news reporting is among many risk factors that contribute to suicide [9]. For example, studies have shown that sensationalized reporting, including that of celebrity suicides, is positively correlated with a rise in suicides [10,11]. Other research has shown that specific characteristics of news coverage, for example, descriptions of an epidemic or suicide myths, may also shape population-level effects on suicide [12]. However, the need to better understand how specific language in framing suicide news shapes its perception is ongoing. In particular, one critical research need is to better elucidate the differences in unsafe reporting by gender when considering the differences in suicide-related behavior. While discussions of all suicide-related behavior are likely subject to unsafe reporting, this study aligns with the focus of existing work examining unsafe media portrayals of individual suicide deaths in particular.

Stigma and Glorification in News Reports

The suicide reporting guidelines detail best practices for news organizations to safely report suicides and generally focus on content that should not be included, such as the mechanism or specific location of suicide [13]. However, assessing subtle nuances about how suicide may be discussed or framed in other harmful ways is more challenging. In this study, we explore two particular ways of framing suicide in news reports, which are stigmatizing and glorifying descriptions.

Although elucidating the precise language that stigmatizes or glorifies suicide is challenging, researchers have developed the validated Stigma of Suicide Scale (SOSS) [14], which helps to linguistically define these constructs as detailed below. The SOSS furthers research in this area by measuring specific words and how they may stigmatize or glorify perspectives. The scale reports a list of words that can be used to further understand, identify, and explore such framings. For example, “shallow,” “pathetic,” and “immoral” are associated with stigmatizing perspectives (ie, those perspectives that ascribe a negative

attitude or perception toward those who die by suicide). Similarly, “understandable,” “brave,” and “motivated” are associated with glorifying perspectives (ie, those perspectives that seek to normalize suicide) [14].

Identifying Problematic Framing

Carefully framing suicide deaths in the news media is essential as the language people use shapes perceived reality [15] and can influence suicide-related behavior [12]. Previous articles on suicide reporting have mostly focused on assessing the degree of explicit adherence to elements of the suicide-safe reporting guidelines [16]. While recent articles have applied machine learning and natural language processing to suicide news, they have largely focused on using these techniques to automate identifying more structured elements present in the suicide reporting guidelines [13]. Thus, in this research, we aim to develop natural language processing methods to measure and explore the more nuanced problematic framings of suicide using stigmatizing or glorifying language. Furthermore, we explore such framings by gender and by the circumstance of suicide. We pose two main research questions: (1) how does the overall framing of suicide differ by gender identity? and (2) how does such framing differ by gender when considering the specific circumstance of suicide?

Methods

Data Collection

Data for this study were comprised of news articles from All the News [17], a leading benchmark data set used in the field of computer science and natural language processing-based news research; the public availability of the data set allows for independent validation of results by the academic community and facilitates transparent head-to-head comparison of different natural language processing approaches. The data set includes 143,000 publicly accessible articles published by 15 print and digital American publications, from 2015 to 2017. Articles included in this data set are in English and come from publishers across political alignments. Examples of publishers include the New York Times, CNN, Washington Post, Breitbart, Fox News, BuzzFeed News, and others [17]. We identified articles from this data set relevant to suicide using suicide-related keywords previously curated by public health experts [18]. Previous research has used the All the News data set for identifying political polarization [19], differences between human- and machine-generated news [20], and news recommendations [21]. We randomly sampled 800 suicide-related articles, in English, and excluded 600 articles mentioning homicide-suicide, suicide bombings, suicide attempts, suicide euphemisms, and fictional portrayals of suicide [22], such as those illustrated in fictional books, television, and movies, as these classifications in media are researched differently in suicidology. In total, 200 articles met the inclusion criteria of mentioning a real-life suicide death not involving the homicide of another person and constitute the data set in this study.

Qualitative Methods

We used 2 coders for a deductive approach to annotate article mentions of gender and circumstances of the suicide to answer

our research questions. We derived our definitions of circumstances from Chancellor et al's [23] validated annotation scheme of risk factors for suicide. Chancellor et al [23] developed the scheme using social media data of 200 Reddit community posts from r/SuicideWatch with a focus on construct validity. This scheme offers a formal technique to identify clinical suicide-related information in lay contexts.

Quantitative Methods

Framing—Stigma of Suicide Scale

As noted above, we derived the frames of stigmatization and glorification from the SOSS study [14]. This validated scale consists of linguistic descriptors of suicide. To derive the scale, Batterham et al [14] used principal component analysis of survey results from the public, rating 80 one-word descriptors of someone who dies by suicide to produce a list of words associated with stigmatization and glorification of suicide. The SOSS includes a third frame of isolation or depression (ie, “unhappy,” “depressed,” and “sad”), which we briefly report in this study but do not focus on the subsequent analyses as we found no discernable differences between genders, perhaps because depressed mood is a common symptom preceding suicide [24], and such language can be applied generically.

Linguistic Representation of the Stigma of Suicide Scale

To get a comprehensive linguistic representation of stigmatizing and glorifying language as represented by the SOSS, we used natural language modeling techniques instead of relying on lexicon-based approaches that restrict themselves to finding exact matches of a fixed set of keywords. We adopted language modeling techniques to better capture linguistic context and nuanced writing style, considering semantic and syntactic relationships between words and phrases in sentences [25,26]. Existing research has shown that such context-based approaches outperform lexicon-based ones on natural language understanding tasks [27,28]. We used the keywords identified by Batterham et al [14] for stigmatization and glorification to generate vector representations for each frame. Vector representations are large numerical representations of text used in natural language processing, and the numerical representations help identify other words that tend to co-occur or lie in the vicinity of particular words of interest. We used Bidirectional Encoder Representations from Transformers (BERT; Google) [29] along with their relevant extracted synonyms using WordNet (Princeton University) [30], a large English database containing synonymous groups (synsets) of nouns, verbs, adjectives, and adverbs. BERT is a leading large language model that is pretrained on billions of documents from the internet and encodes text to generate word-embedding representations for all the words or phrases associated with a SOSS dimension. Adding representations of synonyms strengthens the semantic representation of SOSS dimensions. After this addition, we manually examined the dictionaries to remove irrelevant words captured by WordNet. We calculated Cohen κ to assess interrater reliability (IRR) for each SOSS dimension. Finally, we averaged the relevant individual word embeddings to generate the final vector representation of each SOSS dimension.

Representation of News Articles

We generated a unique vector representation for each news article in our data set to answer research question 1 and to analyze how suicide is framed using the SOSS dimensions. We again used BERT, programmed in Python (Python Software Foundation) using Hugging Face transformers [31], to extract a sentence-level embedding representation for each news article. This allowed us to capture nuanced attributes such as context, framing and writing style, and the relationship between words in a sentence. Note that we did not aggregate the individual embeddings of all the words present in a news article to generate its linguistic representation. Sentence-level BERT embeddings ensured that we captured relevant dependency between words used in the news article. As a result, each news article was characterized using a vector representation to compare it against the SOSS dimension embeddings.

Suicide Framing Based on the Axis of Gender

We analyzed how suicide is framed in the news based on the victim's identified gender by comparing the embedding representation of each news article with the 3 vectors of the 3 SOSS dimensions (stigmatization, glorification or normalization, and isolation or depression). We adopted the cosine similarity scoring framework, as used in previous work [32], to score each article in our data set against the SOSS dimensions. These cosine similarity scores range from -1 to 1, where a higher positive score represents a stronger alignment between a news article and the corresponding SOSS dimension.

Further, we divided all the articles into groups based on the annotated gender identity of the victim. Toward inclusive representation of gender identity in our analysis, we annotated for cisgender, where one's gender identity aligns with their assigned sex, and transgender, where one's gender identity does not align with their assigned sex [33]. This resulted in the ultimate formation of 2 groups corresponding to the most represented gender identities in our data set, which are female and male. Note that some news articles made references to multiple victims. To handle such cases, articles mentioning same-gender identity victims were treated as reporting a single female or male death, and those with mixed-gender mentions were processed by manually extracting relevant text for each victim, respectively, to inform the analysis.

Ethical Considerations

The study did not meet the criteria for institutional research board review as it did not involve interactions with human or other living subjects, private or personally identifiable data, or any pharmaceuticals or medical devices [34]. The data set is comprised only of public, open-source news articles. While this data set is public, widely used, and institutional research board exempt, all possible care was taken to ensure the results of this study were communicated sensitively and safely given the context of suicide.

Results

Overview

A total of 221 real-life suicide deaths were reported from the 200 articles. We identified almost 70% (68.4%, 153/221) of these deaths to be cisgender male, 28.4% (64/221) cisgender female, and 0.4% (1/221) were identified as transgender male. Less than 2% (3/221) of deaths were reported without specifying the decedent's gender. The main analysis focused on articles reporting suicide deaths of cisgender men and women due to the underrepresentation of noncisgender identities in the sample. This paper targets the circumstances of suicide, more than one

of which can be attributed to a single death and characterizes them in the results that follow.

Circumstances of Suicide

In total, 153 male decedents in our study had 159 circumstances and 64 female decedents had 75 circumstances (Table 1). We found 21 unique circumstance types among our sample of articles. Analyses described in this paper characterize the top 7 circumstances (Table 1) that occurred most frequently, which are (1) unspecified (n=60), (2) legal problem (n=41), (3) explicit statement of mental health symptoms or diagnosis (n=38), (4) social or relationship problem (n=35), (5) physical health problem (n=33), (6) financial or job problem (n=19), and (7) preceding suicidality (n=13).

Table 1. Summary of top 7 circumstances of suicide by gender annotated in 200 news articles.

Gender	Unspecified, n (%)	Legal problem, n (%)	Mental health symptoms or diagnosis, n (%)	Social or Relationship, n (%)	Physical health, n (%)	Financial or job, n (%)	Preceding suicidality, n (%)	Full sample, n
Cisgender men	35 (22)	31 (19.5)	29 (18.2)	21 (13.2)	24 (15.1)	10 (6.3)	9 (5.7)	159
Cisgender women	24 (32)	9 (12)	8 (10.7)	13 (17.3)	8 (10.7)	9 (12)	4 (5.3)	75
Transgender ^a	0 (0)	0 (0)	0 (0)	1 (100)	0 (0)	0 (0)	0 (0)	1
Unspecified ^a	1 (25)	1 (25)	1 (25)	0 (0)	1 (25)	0 (0)	0 (0)	4

^aExcluded from additional analyses due to underrepresentation in the data set.

Framing Suicide by Gender

The distributions in Figure 1 illustrate the proportion of articles reporting a male (orange) or female (blue) suicide death with linguistic overlap with each SOSS attitude of stigma, isolation or depression, and glorification. In Figure 2, and subsequent figures, dotted lines represent mean cosine similarity scores across the 2 genders that are male (orange) or female (blue). The isolation or depression frame is excluded from the remaining analyses as no difference occurred in cosine similarity. Cosine similarity measures how similar 2 vectors

are with increasing values representing increased similarity. A Mann-Whitney *U* test revealed that articles reporting male suicide deaths contained statistically significant more linguistic overlap with the stigma attitude on average than papers reporting female suicide deaths ($P<.001$). Such articles reporting male deaths also contained statistically significant more linguistic overlap with the glorification attitude on average than articles reporting female suicide deaths ($P=.005$). We found no statistically significant difference in the average linguistic similarity between papers reporting male or female suicide deaths ($P=.07$) regarding the isolation attitude.

Figure 1. Illustration of the relationship between research questions and analysis.

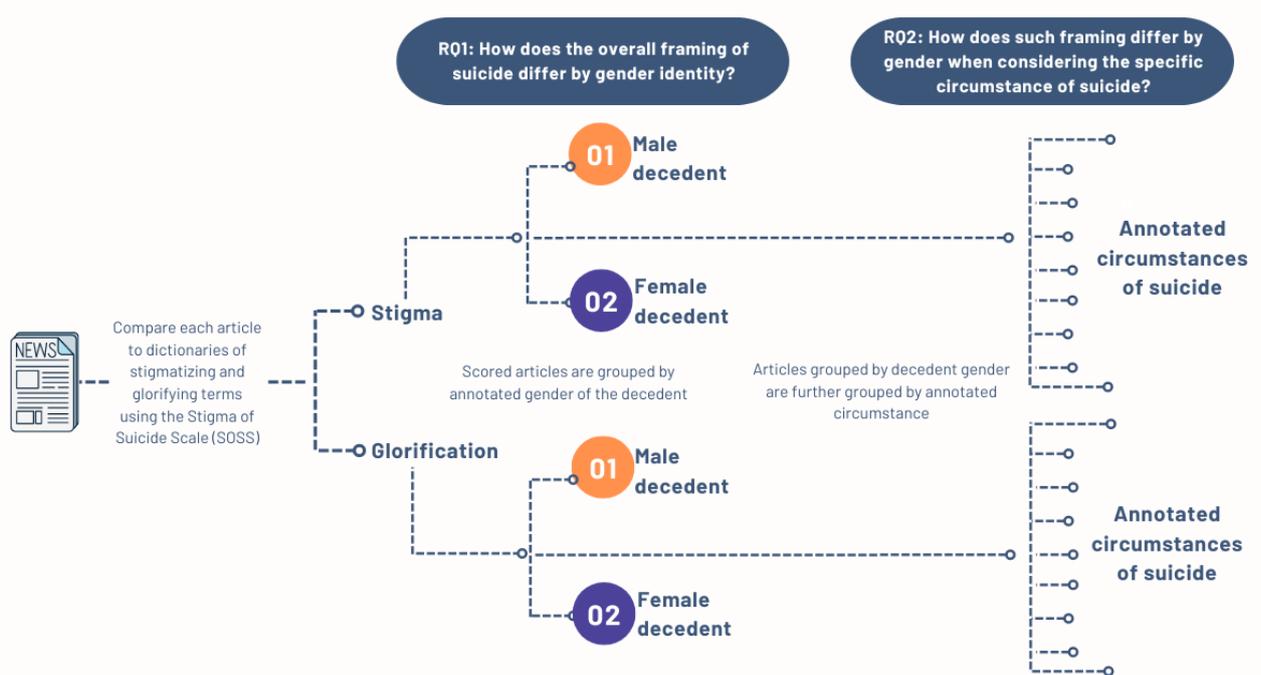

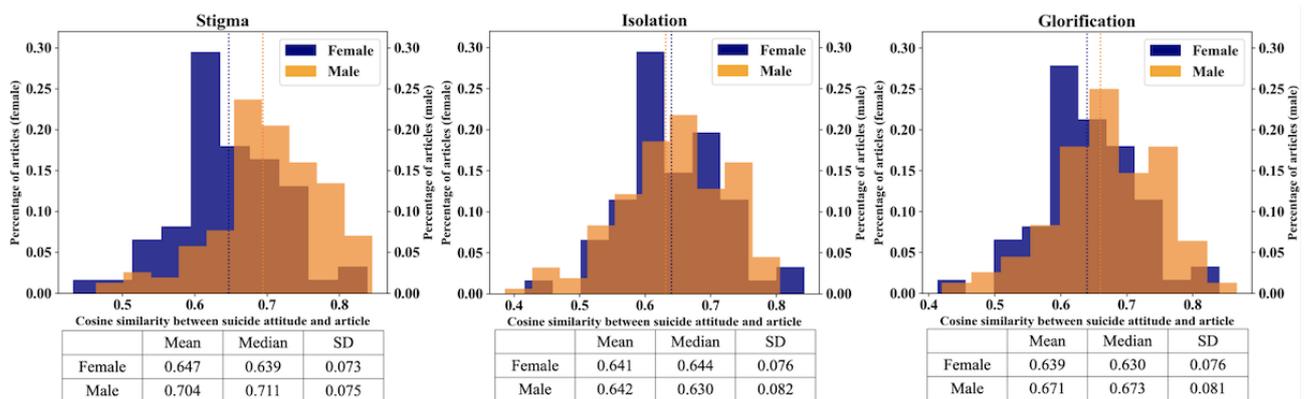

Figure 2. Percentage distribution plots of cosine similarity scores by gender compared to the Stigma of Suicide Scale dimensions.

Assessing IRR using Cohen κ for each SOSS dimension demonstrated acceptable reproducibility, $\geq 75\%$, between coders with scores of 0.84, 0.89, and 0.94 for stigma, isolation or depression, and glorification, respectively. Assessing IRR using Cohen κ for decedent gender and circumstance demonstrated acceptable reproducibility ($\geq 75\%$) between coders with a score of 0.81.

Framing Circumstances of Suicide by Gender

We reported mutual information (MI) scores, which are widely used in the information theory literature, to determine differences by gender in stigmatizing or glorifying language as used under a particular circumstance of death. MI is an indicator

of similarity (score farther from 0) or dissimilarity (score closer to 0) between two distributions [35]. In Table 2, the MI scores compare articles reporting male and female suicides to the stigma and glorification of SOSS attitudes for the 7 most frequently reported circumstances in the sample. Regarding stigmatizing language, reports of male and female suicide deaths were least similar when attributed to a legal problem (0.155), a social or relationship problem (0.268), or when no circumstance is described (0.312). Regarding glorification language, reports of male and female suicides were least similar when attributed to a legal problem (0.132), an explicit statement of mental health symptoms or diagnosis (0.251), or a physical health problem (0.320).

Table 2. Mutual information scores between male and female suicide deaths by circumstance. All the News data set—United States, 2015–2017. The closer the score is to 0, the less mutual information is present between the groups.

Circumstance	Stigma MI ^a	Glorification MI
Unspecified	0.312 ^b	0.578
Legal problem	0.155 ^b	0.132 ^b
Explicit statement of mental health symptoms or diagnosis	0.421	0.251 ^b
Social or relationship problem	0.268 ^b	0.522
Physical health problem	0.443	0.320 ^b
Financial or job problem	0.349	0.849
Preceding suicidality	0.343	0.441

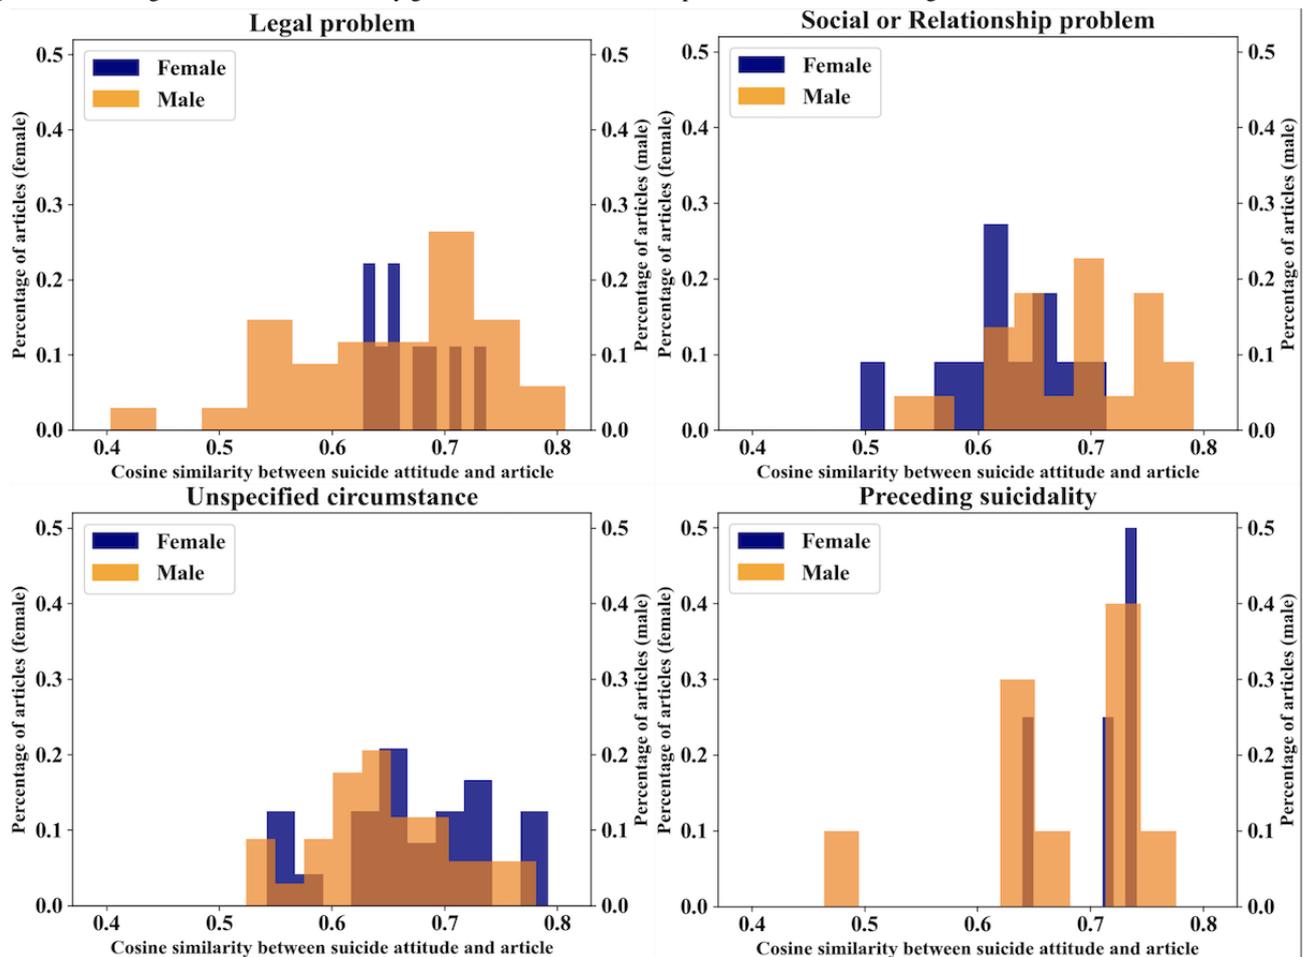

^aMI: mutual information.

^bCircumstance with the least linguistic similarity between males and females for the stigma and glorification frame is further characterized in the text.

Article similarity to the stigma attitude for the circumstances with the greatest difference in MI is displayed in Figure 3. Mean cosine similarity measurement revealed that reports of female suicides attributed to a legal problem (0.671) or without any circumstance specified (0.673) were more linguistically similar

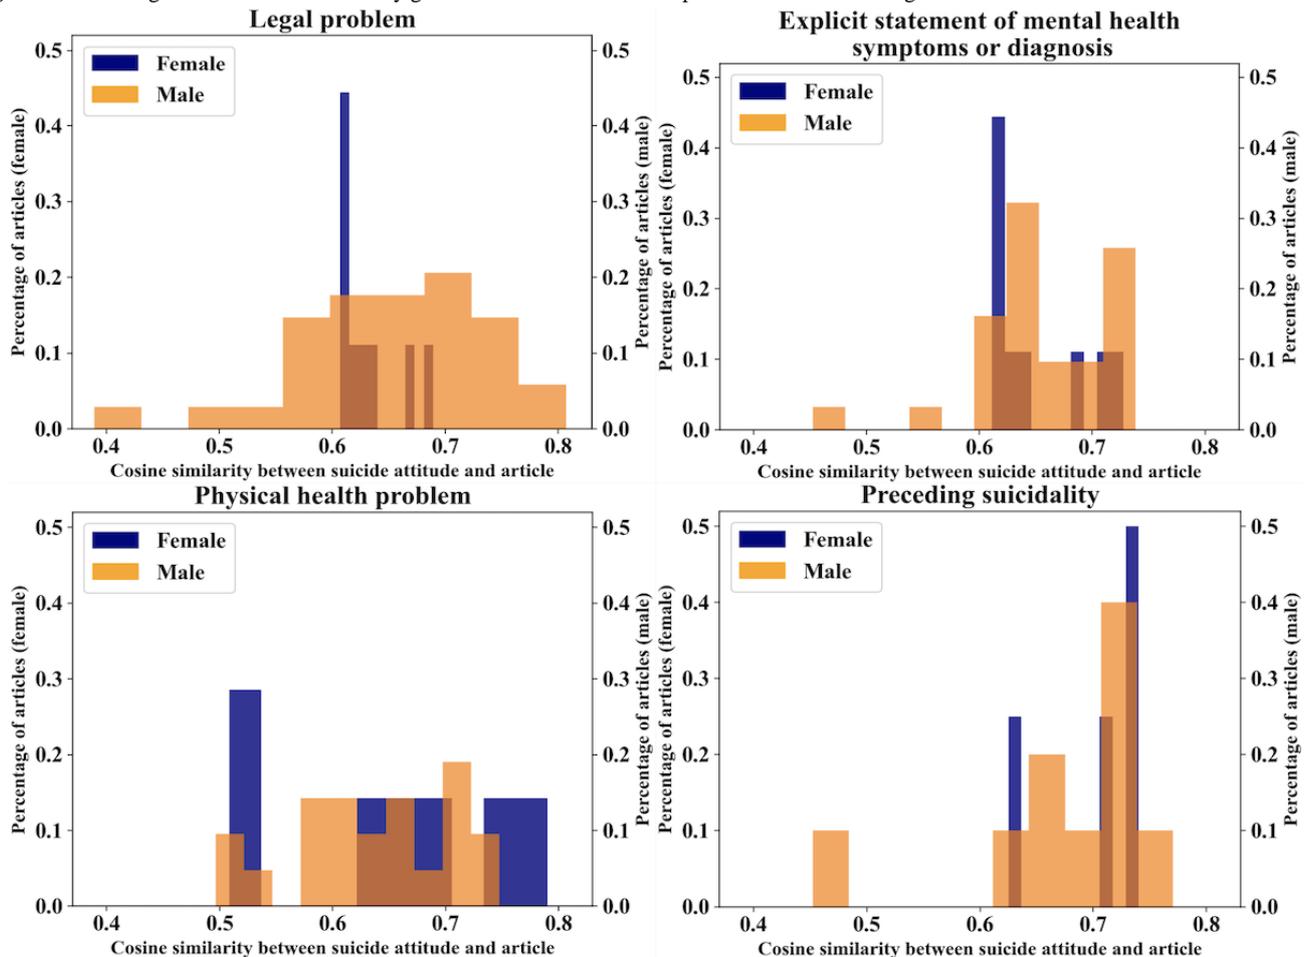

to stigmatizing framing than reports of male suicides attributed to the same circumstances (Figure 3). However, male deaths attributed to a social or relationship issue (0.682) had greater linguistic similarity to stigmatizing framing than reports of female deaths of the same circumstance (0.624).

Figure 3. Percentage distribution of articles by gender and circumstance compared to the attitude of “stigma”.

Similar results hold for the circumstances with the least MI by gender regarding the glorification attitude. On average, reports of male suicides attributed to a legal problem (0.654), mental health symptom or diagnosis (0.657), or a physical health

problem (0.639) were more linguistically similar to the glorification attitude than those reporting female suicides (Figure 4).

Figure 4. Percentage distribution of articles by gender and circumstance compared to the attitude of “glorification”.

Suicidality had the fourth lowest MI score for both the stigma (0.343) and glorification (0.441) attitudes. The difference between the distributions of articles for this circumstance was less than the other circumstances; the linguistic similarity of reports of these suicides both to the stigma (Figure 3) and glorification (Figure 4) attitudes was higher than for other circumstances, regardless of decedent gender. The average cosine similarity to the glorification attitude for the suicidality circumstance was 0.702 for females and 0.656 for males in Figure 4. The average cosine similarity to the stigma attitude for suicidality as a circumstance was 0.708 for female deaths and 0.671 for male deaths.

Discussion

Key Findings

This study describes the reported gender of decedents and the circumstance of suicide in news articles and provides evidence that linguistic framing differs by both gender and circumstance.

Our comparison of SOSS attitudes in news articles revealed that descriptions of male suicides, on average, had higher linguistic scores for stigmatization and glorification than female suicides. This finding is important considering the observation that males die by suicide at higher rates than females in the United States, largely as a consequence of the greater use of firearms in suicide attempts [3]. Stigmatizing language, which can reduce help-seeking behavior [36], and language that

glorifies or normalizes suicide acts [37], which may induce suicide-related contagion [38], are thereby concerning aspects of media reporting on suicide. This merits further attention as part of efforts to reduce high rates of suicide among males and other populations in need.

Circumstances of Suicide and Stigmatizing Language

We used MI scores to identify differences in stigmatizing and glorifying language by gender and circumstance, discerning for which groups these differences were most pronounced. The scores indicated that the greatest differences, by gender, in stigmatizing language were those that discussed a legal problem, social or relationship problem, or no specified circumstance.

Language in reports of female deaths attributed to legal problems had higher linguistic similarity to attitudes of stigma than reports of male deaths of the same circumstance. However, the inverse was true for male deaths attributed to a social or relationship problem. The proportion of articles in our sample attributing legal and social or relationship problems as circumstances to each gender is opposite of the proportions of disclosed circumstances in the National Violent Death Reporting System [6]. Increased stigmatizing language in reports of women experiencing legal problems and men experiencing relationship problems may be attributed to their perceived deviation from social norms [39]. Reports of female deaths not attributed to any circumstance were more linguistically similar to the stigma attitude than reports of male deaths—demonstrating the presence

of discernable stigmatizing language even without specifying the circumstances of suicide. This shows that reporting suicide in more general details, per the safe reporting guidelines, may not eliminate stigmatization when framing death.

Circumstances of Suicide and Glorification Language

Similarly, when examining attitudes of glorification, news articles contain different language when reporting suicide deaths of men and women. We observed the greatest differences in language reflecting attitudes of glorification in articles that attributed death to a legal problem, explicit statement of mental health symptom or diagnosis, or a physical health problem. Specifically, reports of male deaths attributed to these problems had higher linguistic similarity to attitudes of glorification than those of female deaths for the same circumstances. Identifying these circumstances as being prone to using glorifying language for male suicide decedents may offer insights into areas where greater disparity exists in safe reporting by gender for more focused education among news organizations and their staff. For example, a correlation study of the SOSS used for this analysis indicates that male gender among respondents is correlated with decreased suicide literacy and increased stigma and glorifying attitudes of those who die by suicide [40]. As a 2021 study finds a greater stigma of suicide among medical professionals compared with the public [41], news publishers should consider education to increase suicide literacy among journalists.

Again, it should be noted that for a sizeable minority of deaths (22% for males and 32% for females), there was no specified circumstance. This may partly reflect the effect of the safe suicide reporting guidelines, which advise against oversimplifying or speculating the reason for the suicide [13]. Still, we find that harmful language persists in the absence of unsafe details.

Shoring Up Safe Reporting of Suicide

This work brings light to the knowledge about the potential hazards of new reports of suicide beyond existing safe reporting guidelines. Current guidelines encourage the omission of specific details from journalistic reporting of suicide deaths such as method, location, or personal details of the decedent [13]. The relationship between adherence to safe reporting guidelines and suicide prevention is well established [16,42,43]. However, our findings suggest that stigmatizing and glorifying framing, facilitated by harmful language, persists in news reports of suicide regardless of adherence to safe reporting guidelines. This is especially exhibited by the presence of such language even when a circumstance is not attributed to the suicide death (Figure 3). Previous work highlights that stigmatizing and glorifying language has implications on public perceptions of suicide [44-47] and prevention strategies of help-seeking [36,37]. Yet, strategies to mitigate such language in the reporting of suicide deaths could be expanded upon in contemporary guidelines [13].

In response to this gap, we call on future work to investigate the relationship between guideline adherence and harmful framing in news reports of suicide deaths and all other suicide-related behaviors. Such investigation informs the

extension of existing journalistic guidelines to include unsafe language. The use of computational approaches in this study illustrates the feasibility of this task. Such methods may support the development of tools to detect the harmful language in news reporting of suicide as demonstrated in a similar recommendation of 3 models of artificial intelligence tools to improve adherence to safe reporting guidelines [48] as a key prevention strategy.

Additional Implications

Although gender minorities experience elevated risk and rates of suicide [9], our data do not allow us to discern if news media reports of suicide reflect these disparities or to compare reporting language between them. Gender minorities were underrepresented in this sample of suicide reports in the news even when the information was available. Existing research that explores suicide and gender focuses on risk factors for men and women [49]. This focus may be influenced by limited disclosure of nonconforming gender identity or default reporting of sex assigned at birth, often precluding public health surveillance [49]. Facing the same challenge, this work explored framing language in news reporting across all gender identities. Still, the absence of these identities in news reports prevents a complete understanding of stigmatizing language in these populations.

Our analysis revealed an unexpected finding. While we did not detect a discernable difference, by gender, in the linguistic similarity to stigma or glorification regarding the circumstance of preceding suicidality, reports of suicide attributing to this circumstance displayed greater similarity to both stigmatizing and glorifying attitudes compared with reports attributed to other circumstances. This suggests that a history of suicidal behavior is often reported in an unsafe way.

Limitations

Limitations of this study include its sample size, our capacity to describe or account for the audience consuming news from the venues analyzed from this American outlet-focused data set, the age of the articles, and the lack of availability of some sociodemographic attributes in annotated articles, all of which may preclude generalizability of the findings. Although the study team intended to annotate for age, race, and occupation in addition to gender, recognizing that identity is intersectional, these details were largely unavailable to inform the analysis, possibly due to adherence to the safe reporting guidelines. Although gender was available in the sample, gender minorities were underrepresented. Considering larger and more diverse corpora of news may allow for deeper analysis based on an intersectional lens.

Conclusions

Previous studies have investigated stigma and framing in news reports of suicide [47] or have focused on specific stigmatizing suicide terms [50]; however, this study examined suicide reporting language using a state-of-the-art natural language processing approach and revealed important differences by gender, and particularly stigmatizing and glorifying language for specific circumstances.

Safe reporting and messaging following a suicide is an important approach that can be used to lessen harm and reduce the future risk of suicide [51]. Journalistic adherence to media guidelines can prevent imitative suicide [42]; however, further opportunities exist to understand which elements of language, such as the 2 on which we focused in this study, are the most impactful [52]. While information management strategies such as those prescribed by the safe reporting guidelines seek to prevent harmful suicide reporting [53], actual efficacy and

fidelity of adherence may differ based on the sociodemographic characteristics of the decedent, such as gender. The subtle, yet harmful framing of who experiences suicide in news media might influence prevention, intervention, and help-seeking behaviors [36], particularly among already disparaged or marginalized populations. Identifying sociodemographic differences in such framing supports the need to further understand suicide disparities and develop tailored stigma reduction strategies.

Acknowledgments

This project was supported, in part, by an appointment to the Research Participation Program at the Centers for Disease Control and Prevention (CDC) administered by the Oak Ridge Institute for Science and Education through an interagency agreement between the US Department of Energy and CDC. JCF, SM, and MDC were supported through a National Institutes of Health grant 1R01MH117172. The findings and conclusions in this paper are those of the authors and do not necessarily represent the official position of the CDC.

Authors' Contributions

JCF performed conceptualization, data curation, and methodology, and wrote the original draft. SM contributed to formal analysis, methodology, writing, and visualization. NL wrote, reviewed, and edited this paper. AC provided writing, reviewing, and editing expertise. EK provided writing, reviewing, and editing expertise in addition to data curation. SAS supervised the writing, reviewing, and editing. MDC conceptualized, supervised, acquired funding, and contributed to writing, reviewing, and editing this paper.

Abstract

Background: Identifying individuals with depressive symptomatology (DS) promptly and effectively is of paramount importance for providing timely treatment. Machine learning models have shown promise in this area; however, studies often fall short in demonstrating the practical benefits of using these models and fail to provide tangible real-world applications.

Objective: This study aims to establish a novel methodology for identifying individuals likely to exhibit DS, identify the most influential features in a more explainable way via probabilistic measures, and propose tools that can be used in real-world applications.

Methods: The study used 3 data sets: PROACTIVE, the Brazilian National Health Survey (Pesquisa Nacional de Saúde [PNS]) 2013, and PNS 2019, comprising sociodemographic and health-related features. A Bayesian network was used for feature selection. Selected features were then used to train machine learning models to predict DS, operationalized as a score of ≥ 10 on the 9-item Patient Health Questionnaire. The study also analyzed the impact of varying sensitivity rates on the reduction of screening interviews compared to a random approach.

Results: The methodology allows the users to make an informed trade-off among sensitivity, specificity, and a reduction in the number of interviews. At the thresholds of 0.444, 0.412, and 0.472, determined by maximizing the Youden index, the models achieved sensitivities of 0.717, 0.741, and 0.718, and specificities of 0.644, 0.737, and 0.766 for PROACTIVE, PNS 2013, and PNS 2019, respectively. The area under the receiver operating characteristic curve was 0.736, 0.801, and 0.809 for these 3 data sets, respectively. For the PROACTIVE data set, the most influential features identified were postural balance, shortness of breath, and how old people feel they are. In the PNS 2013 data set, the features were the ability to do usual activities, chest pain, sleep problems, and chronic back problems. The PNS 2019 data set shared 3 of the most influential features with the PNS 2013 data set. However, the difference was the replacement of chronic back problems with verbal abuse. It is important to note that the features contained in the PNS data sets differ from those found in the PROACTIVE data set. An empirical analysis demonstrated that using the proposed model led to a potential reduction in screening interviews of up to 52% while maintaining a sensitivity of 0.80.

Conclusions: This study developed a novel methodology for identifying individuals with DS, demonstrating the utility of using Bayesian networks to identify the most significant features. Moreover, this approach has the potential to substantially reduce the

number of screening interviews while maintaining high sensitivity, thereby facilitating improved early identification and intervention strategies for individuals experiencing DS.

Introduction

Background

Improving the identification and management of depression in primary care remains a global challenge. A meta-analysis has revealed that in primary care, approximately 50% of patients with depression receive diagnoses, while around 15% acquire treatment [1]. While screening for depressive symptomatology (DS) holds significance, it alone falls short of being effective [2].

When evaluating individuals with DS, one approach involves the use of screening tools to determine who may require treatment and further investigation. Among these tools, the 9-item Patient Health Questionnaire (PHQ-9) is a widely used, self-administered questionnaire [3].

In certain scenarios, mental health information (such as the PHQ-9) may not be available, whereas other health or behavioral information that can be linked to an increased risk of depression may be abundant. Examples of such data are demographics, medical history, lifestyle indicators, and socioeconomic status. In such scenarios, it may be useful to leverage the available data to identify individuals likely to have DS such that these individuals can be targeted proactively for interventions. This proactive strategy has the potential to provide necessary support and care before symptoms escalate or result in severe consequences.

Data-driven approaches using machine learning offer an appealing opportunity to design better prescreening methodologies, particularly within primary care settings. Machine learning algorithms can identify patterns in the data that may not be obvious to human experts [4-6].

In many studies involving machine learning models, insights beyond the model development phase are not provided. The results usually provide a simple *Yes* or *No* for the presence of depression, usually operating as “black boxes” with an absence of transparency in the decision-making process [7,8]. There is a lack of understanding as to which features are most important in predicting DS.

There are instances where machine learning models offer some level of explainability [9-12]. However, the insights generated by these models often only consider the predictive power of the predictors. While this approach can help identify the most impactful predictor, it does not provide a probabilistic measure, which is essential for dealing with uncertainty. The use of probability-based measures in machine learning models can

provide clinicians with a more nuanced understanding of an individual’s likelihood of experiencing depression.

Moreover, most machine learning models developed for detecting DS fail to provide applications on how to use the models effectively [13-16]. These studies do not develop practical tools to help users benefit from the machine learning models, focusing solely on the model development process. To encourage the use of machine learning models in clinical practice, it is essential to develop machine learning models that are designed with the end user in mind. This includes creating tools that can help practitioners effectively integrate the model into their practice.

The current literature on the use of machine learning models for predicting DS lacks a comprehensive integration of explainability and transparency to identify the important features associated with DS using only general health and socioeconomic data and in the absence of tools such as the PHQ-9 or any other depression-related features. In addition, there is a shortage of practical applications using machine learning to support clinical practice. In our proposed method, we aim to address these gaps.

Objective

The first objective of this study is to establish a replicable prescreening proof-of-concept methodology for the detection of individuals with DS. Using solely general health and socioeconomic data, we aim to demonstrate the potential for such data in identifying individuals who might benefit from further screening. The second objective is to enable the identification of the most influential predictors with probabilistic insights into their importance, all based on the same general health and socioeconomic data. The third objective is to develop a tool that enables specialists to use the benefits of the methodology in their practice.

This paper’s structure comprises a *Methods* section detailing data preparation, the feature selection technique, and probabilistic insight extraction. It introduces a machine learning algorithm and its applications. The *Results* section presents cleaned data sets, chosen features, the most influential predictors, and the performance of the models and showcases the models’ utility in a practical scenario. The *Discussion* section concludes by summarizing findings, acknowledging limitations, and discussing implications.

Methods

Overview

Our proposed methodology for developing a machine learning model to assess people with DS was applied to 3 distinct Brazilian data sets. The first, known as the PROACTIVE data set [17], comprised individuals aged ≥ 60 years residing in socioeconomically deprived areas of Guarulhos city. The participants were registered in 20 primary care clinics in Guarulhos and were approached, according to a randomly ordered list, for a DS screening interview conducted either in person or via phone using a personalized app [18].

The other 2 data sets, Pesquisa Nacional de Saúde (PNS) 2013 and PNS 2019 [19], resulted from a Brazilian national health survey that assessed individuals aged ≥ 18 years in different sociodemographic groups and health behaviors. The surveys were conducted in 2013 and 2019 using a household approach where they applied stratified sampling.

All 3 studies used the PHQ-9, which is a 9-item questionnaire that serves as a screening tool for assessing DS. All questions are related to the previous 2 weeks, with responses to each question scored from 0 to 3, where 0 means “Not at all” and 3 means “Nearly every day.” The PHQ-9 cut-off score commonly used for DS is ≥ 10 [20-22], and we used this to create a binary classification target for the machine learning model. Summary statistics of the sociodemographic data and the prevalence of DS are presented in Tables S1, S2, and S3 in [Multimedia Appendix 1](#) for the PROACTIVE, PNS 2013, and PNS 2019 data sets, respectively.

Ethical Considerations

The PROACTIVE trial received approval from the Comitê de Ética em Pesquisa Faculdade de Medicina da Universidade de São Paulo and authorization from the Guarulhos Health Secretary (number 2.836.569). The Brazilian National Health Ethics Research Committee of the Brazilian National Health Council approved the PNS 2013 (number 328.159) and PNS 2019 (number 3.529.376) surveys. Anonymized versions of the PNS 2013 and PNS 2019 surveys are publicly available for download and analysis. All participants provided informed consent.

Data Preparation

First, we randomly divided each data set into training (70%) and test (30%) sets. The development of the models is performed using the training data set with the test data set strictly used to test the performance of the created models on data not yet seen. Next, we created our response variable by summing the recorded responses of all the PHQ-9 score items for each participant and recording a 1 when the total sum was ≥ 10 and 0 otherwise. We only included participants who answered all 9 items, and the respondents were aged ≥ 18 years.

We dropped all features from the data sets related to depression, as our aim was to solely use data readily available in health platforms, such as general health and socioeconomic information. We also dropped features and patients with more than 20% missing values [23] and features with just 1 level in

the responses obtained. Furthermore, we categorized all numeric features with more than 30 levels into 4 bins by quartiles (25, 50, 75, and 100).

We then transformed all features into ordinal numbers. To address any remaining missing values, we adopted an approach discussed in the study by Enders [24] by creating a new missing class and assigning it a value of 0. This choice was based on the fact that not all features had a value of 0 and that 0 is a value close to the range of the feature values. This also facilitates model development, as the standardization process that we applied after the missing imputation step is less sensitive when the range values are close to each other. Standardization is applied to ensure that all features have a similar scale, which helps in comparing the importance of different features and improving the model’s overall performance [25].

Feature Selection

The development of a machine learning model generally involves selecting relevant features to be used as inputs. A total of 1 approach to this task is constructing a Bayesian network (BN), which is a directed acyclic graph composed of nodes and edges. In this context, nodes represent the features and the directed edges represented by arrows illustrate the relationships among them [26].

BNs have been successfully applied in different scenarios, such as feature selection [27-29], model prediction [30-32], and providing insights for decision-making [33-36]. Moreover, a BN is a useful tool for visualizing and interpreting complex relationships between features. This enables the identification of critical features and their impact on the outcome.

BNs can be constructed using two primary methods, namely (1) manual node definition and edge direction [37] or (2) learning through data [38,39].

In our approach, we apply the Incremental Association Markov Blanket algorithm to learn the BN from data [40]. The Markov blanket (MB) of a node X, represented by MB(X), is characterized by its parents (nodes that have arrows pointing toward X), children (nodes that receive arrows from X), and spouses (nodes with arrows leading to children of X, yet not linked to X).

To evaluate the confidence level of the BN learned from the data, we used a bootstrap approach [41] by generating 1000 samples of the BN. We then computed the probabilities of having an edge between every pair of nodes (X_i, X_j ; known as strength) and the probabilities of having a directed edge from X_i to X_j and from X_j to X_i (known as direction) [42]. To construct our final BN, we selected the edges with a strength of 50% and higher [43] and set their direction to correspond with the majority of the bootstrap models.

Subsequently, we conducted another test to assess the strength of the BN by performing an independence test between every pair of nodes using mutual information [44]. We used an independence test because it can investigate whether 2 features are statistically independent, implying that the occurrence or value of 1 feature does not influence the other. If the test yielded

insufficient evidence of nonindependence ($P \geq .05$), then that edge was removed from the network.

Conventionally, in the literature [45,46], BN-based feature selection is predominantly performed using the MB of the outcome of interest. However, we also tested the efficacy of using all the features connected to the outcome by a path (we call this All-path-features). A feature was considered part of this path if it was possible to reach the outcome node by traversing the edges and nodes in between, regardless of the directions of the edges. Therefore, we tested 2 scenarios of the model: 1 using All-path-features in the path and another using only the MB of the outcome.

BN Parameter Learning

Once the BN structure is constructed, it is possible to assess the relationships between the features. These relationships are probabilistically expressed through conditional probability distributions (CPDs) [47]. The process of estimating the CPD is known as parameter learning. The CPD specifies the probability distribution for each node given its parents. To estimate the CPD, we used the Bayesian method [48]. The Bayesian method is a powerful tool for estimating the CPD, as it takes into account both prior knowledge and observed data.

In this study, we computed the CPD table of the outcome node given its parents. The parents represent the features on which our outcome is conditionally dependent, and the CPD table provides the probability values of having DS for different combinations of parent values. We examined the combinations of parent values that exhibited the most discriminatory power when considering individuals with DS.

The data preparation, construction, and parameter learning of the BN were implemented using R 4.2.2 with libraries bnlearn, parallel, and base. R is freely available open source software (R Foundation for Statistical Computing).

Training of Prediction Models

In the training phase of model development, particularly in a classification problem with 2 classes, it is common practice to oversample the minority class [49-51]. This is because by oversampling the minority class, we can improve the model's ability to learn from both classes and achieve better overall performance.

For the development of the models, our approach applied stochastic gradient descent (SGD), which is a widely used optimization algorithm in machine learning. The objective of SGD is to minimize an error function through an iterative process where the model's parameters are updated at each step until the algorithm converges. SGD is known for its scalability [52], stability, and robustness [53] and has shown good performance across different domains [54-56].

One of the drawbacks of using SGD is that finding the optimal combination of hyperparameters for each data set can be challenging. We used BayesSearchCV from Python's skopt package, which applies both Bayesian optimization and 5-fold cross-validation to evaluate each model's performance [57]. The selection of the optimal hyperparameter set for each data set was done by selecting the configuration that yielded the

highest area under the receiver operating characteristic curve (AUC-ROC) metric.

The study focused on tuning 3 hyperparameters: the loss function, penalty term, and α coefficient. The loss function characterizes the relationship between the model's predictions and the actual values. A total of 3 types of loss functions were examined: Hinge, Modified Huber, and Log [58,59].

The penalty term corresponds to a regularization technique aimed at enhancing the model's generalization capability. In addition, the α coefficient, a positive value, controls the level of regularization applied. In this study, 3 types of regularization for the penalty term were considered: L1 [60], L2 [61], and elastic net [62].

To explore the effect of the α coefficient on regularization, a range of values from 0.000001 to 1,000,000 were used.

Evaluation of the Models

We evaluated the models using two scenarios: (1) All-path-features and (2) the MB of the outcome, as mentioned in the *Feature Selection* section. For each scenario, we used the best set of hyperparameters discussed in the *Training of Prediction Models* section.

To validate each model, we once again applied 5-fold cross-validation on top of the cross-validation for hyperparameter tuning explained in the previous section. For each fold, we recorded the threshold that optimized both sensitivity and specificity simultaneously determined by the Youden index. Afterward, by averaging the thresholds obtained from the folds, we analyzed the metrics of AUC-ROC, sensitivity, and specificity. In addition, we calculated the mean and SD of these metrics across the folds. Sensitivity, specificity, and AUC-ROC were chosen as evaluation metrics to assess the performance of the models, given their advantages in the screening process.

To assess the performance of each machine learning model, we used the test data, which was set aside during the data preparation stage. We used sensitivity, specificity, and AUC-ROC to assess the performance of the model, applying their respective thresholds calculated according to the previous paragraph. Then, we compared the results to those obtained from the training data. By comparing these results, we gained insights into the model's generalization capabilities and its performance on new and unseen instances.

The model development was implemented in Python 3.7.7 using packages SGDClassifier, CalibratedClassifierCV from sklearn, and BayesSearchCV from skopt. Python is freely available open source software (Python Software Foundation).

Application of the Models

Having identified the most important features and created a model to use these features to predict DS for each data set, the next step was to analyze how the models can help target people with DS and what benefits they offer. To this end, we used the test data, which were previously only used to evaluate the performance of the models, to illustrate the relationship between the reduced screening interviews that can be obtained by

selecting screening participants based on the developed model and the sensitivity and specificity of the overall screening methodology.

To illustrate the benefits of using these models for selecting screening participants, consider a specific cohort with a DS prevalence of 10%. If we were to screen this cohort randomly, in a study with 100 participants having DS, 1000 individuals

would need to be screened. From a public health perspective, 10 individuals would need to be screened for every identified individual.

To assess the effectiveness of the models, consider a scenario where we need to screen 40 individuals using a random approach (Figure 1). For a 10% DS prevalence, we would identify 4 people having DS.

Figure 1. Example of a random screening list. DS: depressive symptomatology; P(DS): probability of having depressive symptomatology.

ID	DS	P(DS)									
1	No	0.02	11	No	0.06	21	No	0.43	31	No	0.71
2	No	0.06	12	No	0.22	22	No	0.38	32	No	0.05
3	No	0.12	13	No	0.22	23	No	0.24	33	No	0.14
4	No	0.22	14	No	0.04	24	No	0.16	34	Yes	0.97
5	No	0.01	15	Yes	0.53	25	No	0.08	35	No	0.28
6	No	0.09	16	No	0.44	26	No	0.08	36	No	0.37
7	No	0.08	17	No	0.22	27	Yes	0.68	37	No	0.15
8	No	0.13	18	No	0.12	28	No	0.27	38	No	0.49
9	No	0.09	19	No	0.19	29	No	0.22	39	No	0.02
10	Yes	0.86	20	No	0.18	30	No	0.05	40	No	0.48

The models developed by our approach can be used to prioritize the individuals with the highest risk of DS for screening. This is because the model provides a probability score for each individual having DS. Hence, by ordering the cohort by this probability, and screening individuals in order of decreasing the probability of DS, the screening process is expected to be much more efficient.

A ranked list example is illustrated in Figure 2. If we use our models and start to screen individuals from 1 to 10, after

screening 5 individuals (based on the probability score of having DS given by our models with a threshold >0.5), we would expect to identify 4 true positives (TPs) who have DS and 1 false positive (FP) who does not have DS. To identify 4 individuals with DS using our models, it would be necessary to screen a total of 5 people. Therefore, by using our models and screening only 5 people, we achieve the same outcome as screening 40 people randomly, representing a reduction of 87.5% in screening interviews.

Figure 2. Example of a ranked list provided by the models. Class=comparing predictions with observed values. DS: depressive symptomatology; FP: false positive; P(DS): probability of having depressive symptomatology; TN: true negative; TP: true positive.

ID	Rank	DS	P(DS)	Class
34	1	Yes	0.97	TP
10	2	Yes	0.86	TP
31	3	No	0.71	FP
27	4	Yes	0.68	TP
15	5	Yes	0.53	TP
38	6	No	0.49	TN
40	7	No	0.48	TN
16	8	No	0.44	TN
21	9	No	0.43	TN
22	10	No	0.38	TN

We can measure the reduction in number of screening interviews. This value will provide us with a clear understanding of how much the model can save compared with the random screening approach and is illustrated in equation 1:

Where R is the reduction in the number of screening interviews in %, TP is the number of TP cases, FP is the number of FP cases, and DS_i is the prevalence rate of DS.

Another crucial aspect of the developed models is their capability to simulate the relationship between sensitivity and the reduction in screening efforts. For example, suppose a practitioner believes that the achieved sensitivity using the default threshold of 0.5 is insufficient, it is possible to fine-tune the sensitivity by selecting a new threshold. By doing so, the models can calculate the corresponding reduction in screening interviews associated with the adjusted sensitivity value.

Results

Data Preparation

After preprocessing the training data as discussed in the previous section, we were left with 12 out of 33 features and 3854 out of 3961 observations for the PROACTIVE data set. For PNS 2013, we were left with 218 features and 77,376 observations out of the initial 1000 and 155,432, respectively. Similarly, for PNS 2019, we had 254 out of 1087 features and 111,548 out of 205,434 observations.

Despite PNS 2019 having an additional 87 features compared with PNS 2013, the features present in PNS 2013 are also included in PNS 2019. The divergence lies in the 2019 survey, wherein certain questions were broken down into multiple

components. On the other hand, PROACTIVE incorporates distinct features from both PNS 2013 and 2019 data sets.

Feature Selection

We built the BN from data using 1000 bootstrapped samples. We then performed the additional independence test on all the edges as described in the *Feature Selection* section. For the PROACTIVE data set, the connection from HYPERTENSION to AGE was dropped ($P \geq .05$). For PNS 2013 and PNS 2019, no edge had to be removed. The BNs for PROACTIVE, PNS 2013, and PNS 2019, with 12, 19, and 29 features, respectively, are displayed in Figures S1-S3 in [Multimedia Appendix 1](#).

For the PROACTIVE data set, the MB of the outcome node consisted of postural balance problems, shortness of breath, and how old people feel they are. In the PNS 2013 data set, the MB nodes were related to the ability to do usual activities, chest pain, chronic back problems, and sleep problems. Finally, in the PNS 2019 data set, the MB nodes were related to the ability to do usual activities, chest pain, verbal abuse, and sleep problems. Detailed descriptions of these features can be found in Tables S4, S5, and S6 of [Multimedia Appendix 1](#) for PROACTIVE, PNS 2013, and PNS 2019, respectively.

BN Parameter Learning

For each data set, we analyzed the probability of having DS given their MB nodes. As detailed in [Table 1](#) for PROACTIVE, the features of postural balance and shortness of breath each have 2 levels (“Yes” or “No”), and the feature of how old people feel they are has 4 levels, with the minimum being up to 50 years and the maximum being >70 years. In [Table 1](#), we present the probabilities of DS for those not having a postural balance problem, not having a shortness of breath issue, and feeling up to 50 years old, against having both issues and feeling more than 70 years old. All individuals in this data set are aged ≥ 60 years.

Table 1. Probability of having depressive symptomatology in PROACTIVE for 2 example scenarios.

Postural balance ^a	How old people feel they are? ^b	Shortness of breath ^c	P(DS) ^d
No	Up to 50 years	No	0.08
Yes	>70 years	Yes	0.75

^aDo you have problems with postural balance?

^bIn general (or most of the time), how old do you feel?

^cHave you ever experienced shortness of breath while walking, climbing stairs, or with changes in temperature (eg, when it is hot or cold)?

^dP(DS): probability of having depressive symptomatology.

For the PNS 2013 and PNS 2019 data sets, the MB features are binary, with 2 possible values: “Yes” or “No.” Thus, [Tables 2](#) and [3](#) present 2 distinct scenarios, one where all features have

a “Yes” value, and the other where all features have a “No” value.

Table 2. Probability of having depressive symptomatology in Pesquisa Nacional de Saúde 2013 for 2 example scenarios.

Ability to do usual activities ^a	Chest pain ^b	Chronic back problems ^c	Sleep problems ^d	P(DS) ^e
Yes	Yes	Yes	Yes	0.66
No	No	No	No	0.03

^aIn the past 2 weeks, have you been unable to perform any of your usual activities (such as work, school, playing, and household chores) due to health reasons?

^bDo you feel chest pain or chest discomfort when walking on a hill, going up one flight of stairs, or fast walking?

^cDo you have any chronic spinal problems such as chronic back or neck pain, lumbago, sciatica, vertebral, or disc problems?

^dIn the past 2 weeks, have you used any medication to help you sleep?

^eP(DS): probability of having depressive symptomatology.

Table 3. Probability of having depressive symptomatology in Pesquisa Nacional de Saúde 2019 for 2 example scenarios.

Ability to do usual activities ^a	Chest pain ^b	Verbal abuse ^c	Sleep problems ^d	P(DS) ^e
Yes	Yes	Yes	Yes	0.79
No	No	No	No	0.04

^aIn the past 2 weeks, have you been unable to perform any of your usual activities (such as work, school, playing, and household chores) due to health reasons?

^bDo you feel chest pain or chest discomfort when walking on a hill, going up one flight of stairs, or fast walking?

^cIn the past 12 months, has anyone yelled or cursed you?

^dIn the past 2 weeks, have you used any medication to help you sleep?

^eP(DS): Probability of having depressive symptomatology.

The results presented in [Table 1](#) for the PROACTIVE data set indicate that individuals who report postural balance problems, episodes of shortness of breath, and feeling >70 years old have a higher probability of having DS. Specifically, if a person reports all 3 of these symptoms, the probability of having DS is 0.75, which is over 8 times higher than if the person reports feeling <50 years old and having no issues with postural balance or being out of breath.

In both PNS 2013 and PNS 2019, 3 features remained consistent over the 6-year period in both data sets (ability to do usual activities, chest pain, and sleep problems). The only difference is that in PNS 2013, feature chronic back problems as shown in [Table 2](#) is replaced by those related to verbal abuse as illustrated in [Table 3](#). The results reveal that answering “Yes” to all 4 questions results in a probability of having DS of 0.66 for PNS 2013 and 0.79 for PNS 2019. On the other hand, if a person answers “No” to all 4 questions, the probability of having DS is only 0.03 and 0.04, respectively.

Training of Prediction Models

The results obtained from the training process of our models are presented in [Tables 4-6](#) for the 3 data sets. These tables provide the sensitivity and specificity determined by the thresholds of 0.444, 0.412, and 0.472 for PROACTIVE, PNS 2013, and PNS 2019, respectively. Furthermore, they present the AUC-ROC metrics for two scenarios: (1) using All-path features of the BN and (2) using the MB of the outcome.

Each of the 3 tables includes sensitivity, specificity, and AUC-ROC values for 5 folds, which were obtained using a 5-fold cross-validation approach with the best set of hyperparameters, as described in the *Training of Prediction Models* section. These metrics specifically correspond to the validation sets used during the cross-validation process.

Upon analyzing the results across all 3 data sets, we observed consistent outcomes. The mean values of sensitivity, specificity, and AUC-ROC for each fold closely align with the individual values, and the SD is low.

In PROACTIVE ([Table 4](#)), the optimal parameters were determined to be $\alpha=.200$, loss function=modified_huber, and penalty term=L2 for the All-path-features scenario. The MB scenario required a different set of parameters, specifically $\alpha=.0005$, loss function=log, and penalty term=elastic net.

For PNS 2013 ([Table 5](#)), the optimal hyperparameters for model tuning were found to be an α value of .003, hinge loss function, and L2 penalty term for the all-features scenario. The MB scenario yielded an α value of .006, log loss function, and L1 penalty term.

The best parameters for the PNS 2019 ([Table 6](#)) model were $\alpha=.003$, loss function=log, and penalty term=elastic net. The parameters for the MB scenario were $\alpha=.083$, loss function=log, and penalty term=L2.

Table 4. PROACTIVE—sensitivity, specificity, and area under the receiver operating characteristic curve (AUC-ROC) values in 5-fold cross-validation.

Metrics	F1 ^a	F2 ^b	F3 ^c	F4 ^d	F5 ^e	Values, mean (SD)

Evaluation of the Models

The evaluation results of the models on the test data are presented in [Table 7](#). In addition, we provide the metrics obtained from analyzing the entire training data and the mean of the 5-fold cross-validation. It is important to note that the

whole data evaluation approach differs from the 5-fold cross-validation method. Instead of comparing the average metrics across the 5 folds in the validation set as if they were separate models, we assess the overall performance on the complete training data set.

Table 7. Sensitivity, specificity, and area under the receiver operating characteristic curve on test data using All-path-features.

	PROACTIVE	Pesquisa Nacional de Saúde 2013	Pesquisa Nacional de Saúde 2019
Sensitivity			
Training	0.766	0.735	0.708
Cross-validation	0.768	0.736	0.709
Test	0.717	0.741	0.718
Specificity			
Training	0.633	0.737	0.762
Cross-validation	0.632	0.735	0.762
Test	0.644	0.737	0.766
Area under the receiver operating characteristic curve			
Training	0.765	0.806	0.804
Cross-validation	0.763	0.805	0.804
Test	0.736	0.801	0.809

The sensitivity specificity and AUC-ROC metrics obtained from the whole data evaluation, illustrated in [Table 7](#), exhibit consistency with those obtained through the 5-fold cross-validation approach. Moreover, these metrics are not considerably different from the sensitivity, specificity, and AUC-ROC observed in the test data.

[Figures 3-5](#) display the AUC-ROC graph and confusion matrices for PROACTIVE, PNS 2013, and PNS 2019, respectively. The confusion matrix is based on the threshold of each model applied to the test data.

Figure 3. Confusion matrix and area under the receiver operating characteristic curve for PROACTIVE. DS: depressive symptomatology; FN: false negative; FP: false positive; TN: true negative; TP: true positive.

		Real	
		Yes DS	No DS
Model prediction	Yes DS	271 TP 21.7%	310 FP 24.8%
	No DS	107 FN 8.6%	560 TN 44.9%
		378 30.3%	870 69.7%
		Total	Total

In Figure 3, the confusion matrix reveals that out of a total of 581 cases above the threshold (TPs+FPs), 271 cases actually have DS. In addition, there are 107 cases below the threshold that have DS (false negatives). Moreover, the model for the PROACTIVE data set accurately classifies 831 cases (66.6%: TPs+true negatives) out of a total of 1248 cases.

Comparing Figures 4 and 5 with Figure 3, we observe better results. Both figures exhibit higher AUC-ROC values, with 0.801 for PNS 2013 and 0.809 for PNS 2019. In terms of correctly classifying cases, the models achieved a success rate of 73.7% for PNS 2013 and 76.1% for PNS 2019.

Figure 4. Confusion matrix and area under the receiver operating characteristic curve for Pesquisa Nacional de Saúde 2013. DS: depressive symptomatology; FN: false negative; FP: false positive; TN: true negative; TP: true positive.

		Real	
		Yes DS	No DS
Model prediction	Yes DS	1067 TP 5.9%	4411 FP 24.3%
	No DS	373 FN 2.1%	12,336 TN 67.8%
		1440 7.9%	16,747 92.1%
		Total	Total

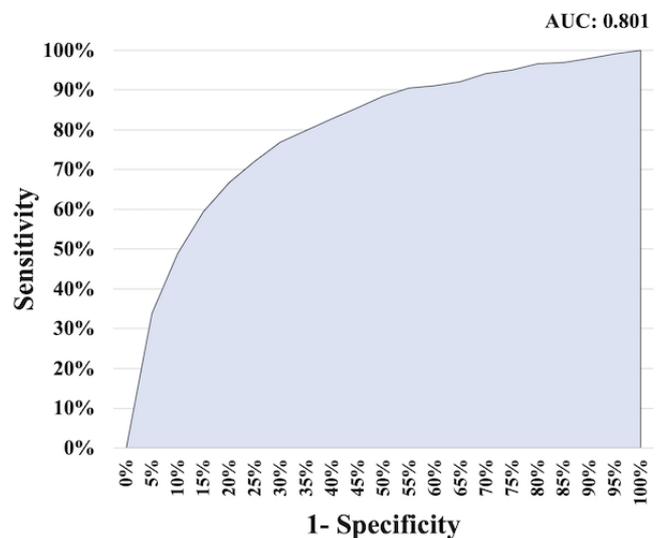

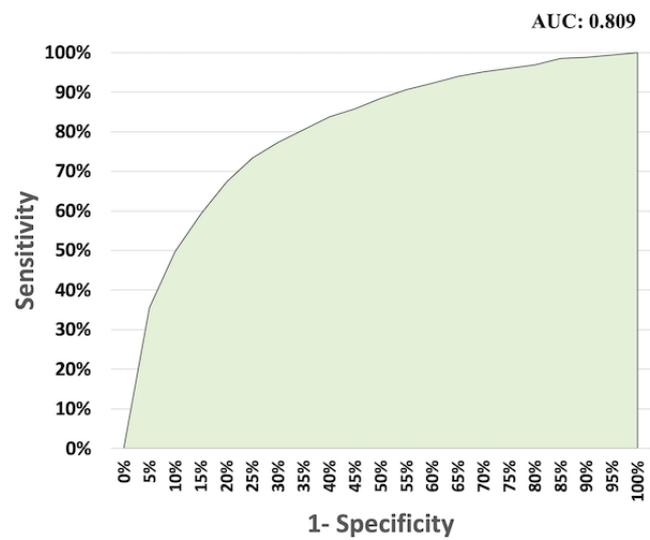

Figure 5. Confusion matrix and area under the receiver operating characteristic curve for Pesquisa Nacional de Saúde 2019. DS: depressive symptomatology; FN: false negative; FP: false positive; TN: true negative; TP: true positive.

		Real	
		Yes DS	No DS
Model Prediction	Yes DS	1908 TP 7.2%	5597 FP 21.1%
	No DS	750 FN 2.8%	18,314 TN 68.9%
		2658 10.0%	23,911 90.0%
		Total	Total

Application of the Models

Our approach offers a high degree of flexibility in terms of adjusting the threshold to suit a desired sensitivity value. To achieve this, we can leverage the test data to simulate the trade-off between sensitivity and screening interviews reduction using equation 1 outlined in the *Methods* section.

The prevalence of DS in the PROACTIVE, PNS 2013, and PNS 2019 data sets is 30.3%, 7.9%, and 10% as illustrated in [Figure 3](#), [Figure 4](#), and [Figure 5](#), respectively. The prevalence of DS in the PROACTIVE data set is more than 3 times that in the PNS data sets. Hence, it is reasonable to expect that both PNS models will exhibit superior performance with respect to screening interviews reduction in comparison to PROACTIVE. This is because when using a random screening approach, a higher prevalence of DS within a particular cohort leads to more efficient identification of affected individuals, as opposed to a cohort with a lower prevalence.

[Figures 6-8](#) illustrate the receiver operating characteristic curves, where the bars on the x-axis represent the reduction in screening interviews as a percentage. These graphs demonstrate the trade-off between the sensitivity and the reduction in screening interviews achieved by using our models.

As an example, according to [Table 7](#), the calculated threshold in the PROACTIVE data set corresponds to a sensitivity of 0.717. In [Figure 6](#), this sensitivity reduces screening interviews by 35%. Furthermore, even when aiming for higher sensitivities, such as 78% or 92%, using the model developed for this data set can still result in reducing interviews by 29% or 17%, respectively.

The key finding is that for any sensitivity above 0.640, using this model consistently outperforms a normal random approach (the screening interviews reduction is higher than 1-sensitivity). This holds even with the high prevalence of DS in this cohort, as demonstrated by [Figure 6](#).

In the case of both PNS models, it is apparent from [Figures 7 and 8](#) that they outperform the PROACTIVE model in [Figure 6](#). Although both models exhibit considerable improvements, the PNS 2013 model demonstrates a slightly better performance than the PNS 2019 model. Specifically, the results indicate that at a sensitivity of 88%, the PNS 2013 model achieves a 40% reduction in screening interviews, while the PNS 2019 model achieves a 39% reduction. The reduction at the same sensitivity level of 88% achieved by the PROACTIVE model is 22%. Furthermore, for both PNS data sets, using our models is always superior to using a random approach.

Figure 6. PROACTIVE—trade-off between sensitivity versus reducing screening interviews. ROC: receiver operating characteristic.

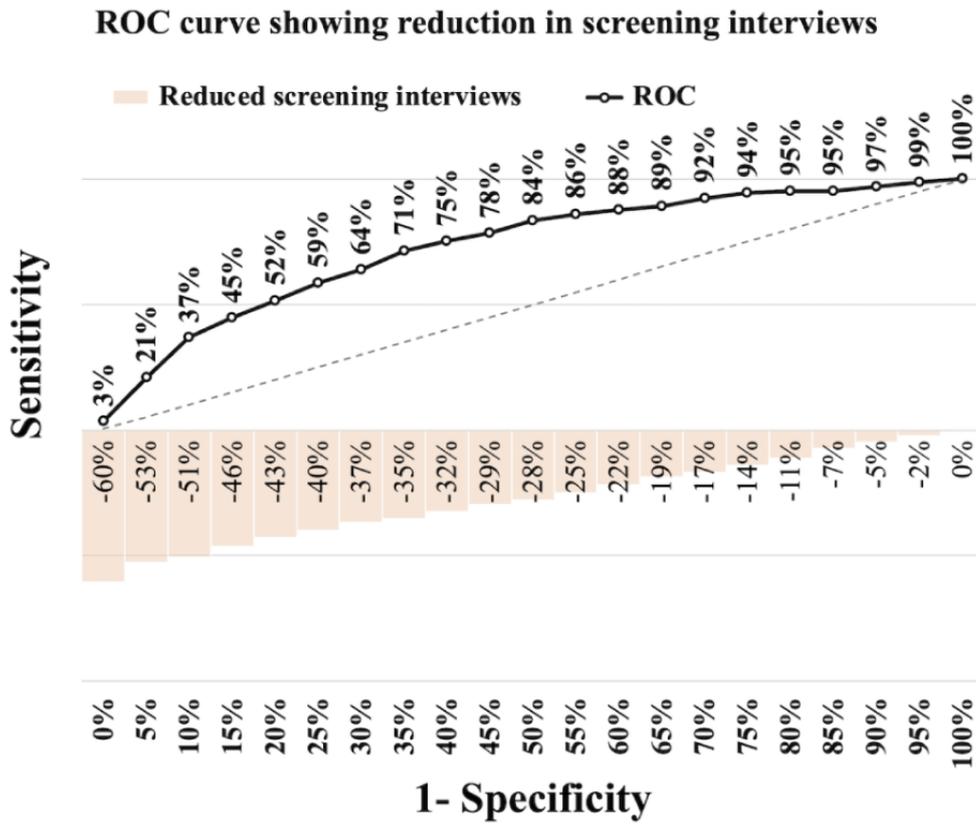

Figure 7. Pesquisa Nacional de Saúde 2013—trade-off between sensitivity versus reducing screening interviews. ROC: receiver operating characteristic.

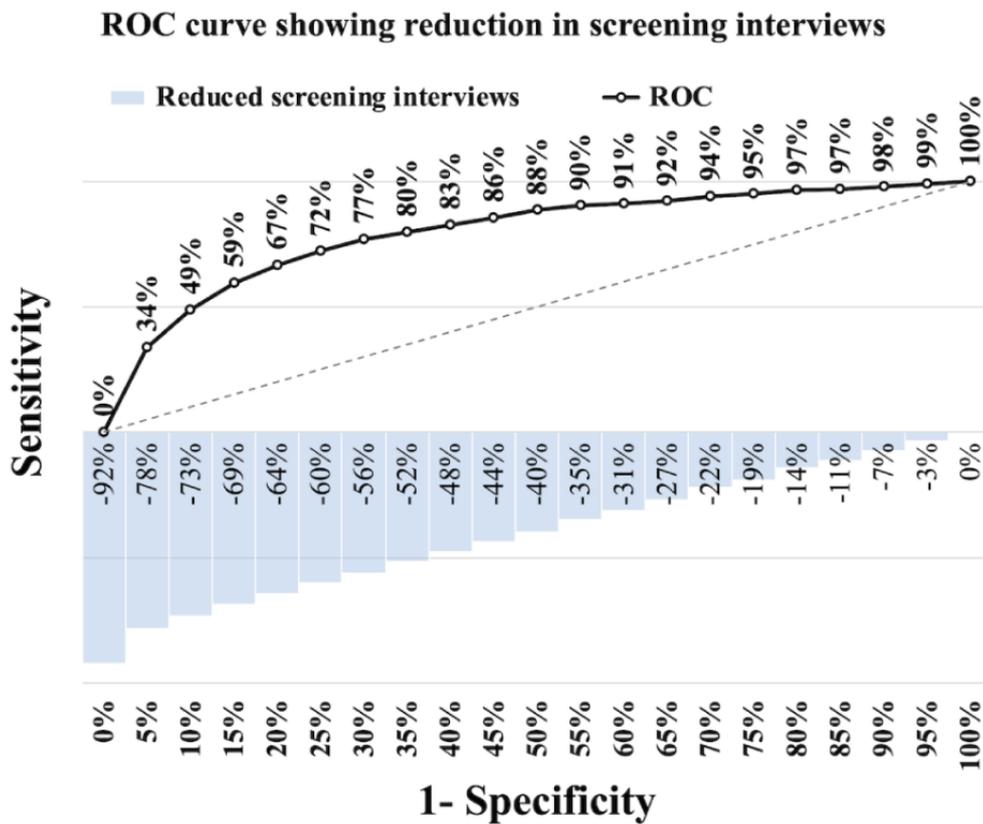

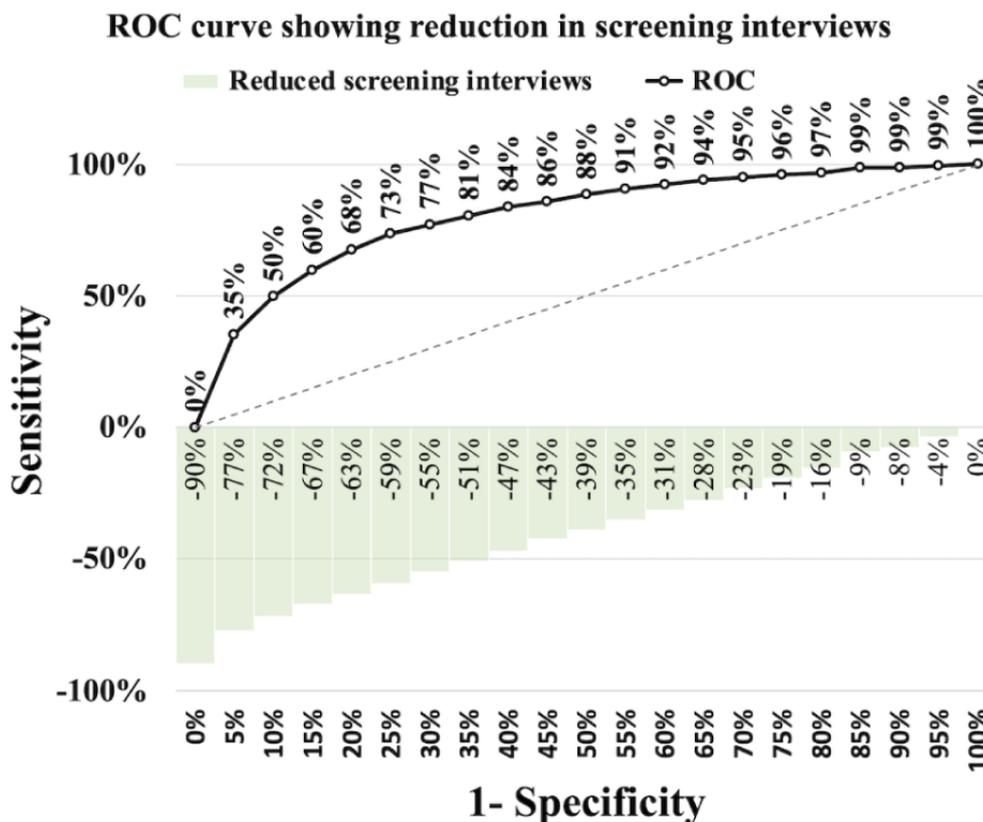

Figure 8. Pesquisa Nacional de Saúde 2019—trade-off between sensitivity versus reducing screening interviews. ROC: receiver operating characteristic.

Discussion

Overview

To enhance the development of our models, we conducted a comparison between 2 scenarios regarding feature selection. In the first scenario, we used All-path-features nodes from our BN, while in the second scenario, we focused on using only the MB of the outcome. By analyzing and contrasting these 2 scenarios, we aim to gain a comprehensive understanding of the impact that including or excluding these specific nodes has on our model.

The results of our analysis consistently showed that using All-path-features from the BN yielded superior outcomes compared with using only the MB of the outcome. Furthermore, we used the test data in the All-path-features scenario to evaluate the performance of the models for each data set. This approach ensures that the model’s performance is assessed in a fair manner using previously unseen data, reflecting its real-world performance.

Using the optimal threshold that maximizes both sensitivity and specificity, determined by the Youden index, can be beneficial. This approach ensures more reliable and accurate diagnoses by minimizing the errors of missing a positive case (false negatives) or incorrectly diagnosing a negative case as positive (FPs).

The PNS 2013 and PNS 2019 data sets stand as valuable pillars of Brazil’s national health data landscape. The models have consistently highlighted 3 features—the ability to do usual activities, chest pain, and sleep problems. This result across a

6-year span underscores these attributes’ robustness as good indicators for detecting DS, thereby offering valuable insights for health care services. However, it is important to reapply the methodology as new data sets emerge to check for patterns and new insights.

Our assessment revealed that both the models trained on the PNS 2013 and PNS 2019 data sets outperformed the PROACTIVE data set model. This can be attributed to the larger sample sizes and lower prevalence rates of DS in the PNS data sets. It is worth noting that the PROACTIVE study exclusively concentrated on individuals aged ≥ 60 years. Larger data sets provide a more diverse representation of the population, leading to improved generalization of the model’s predictions. In addition, the lower prevalence of DS in these data sets implies that a random screening approach would require screening a larger number of individuals to identify those with DS. In this context, the model’s ability to target individuals with a higher probability of having DS can markedly reduce screening interviews.

Despite our emphasis on developing a methodology using general health and socioeconomic data without relying on features related to depression, our approach outperformed studies using similar nondepression-related features. For instance, a study conducted with university undergraduates in Bangladesh used machine learning models to predict depression. The predictors included basic information such as academic year and cumulative grade point average, without using the PHQ-9 or any depression-related information. The models achieved an AUC-ROC ranging from 0.694 to 0.802, sensitivity ranging from 0.32 to 0.53, and specificity ranging from 0.86 to

0.87 [63]. Another study, conducted in Japan, used machine learning to predict depressive symptoms using sociodemographic and biological metabolite information, also without relying on the PHQ-9 or questionnaires assessing depressive symptoms. Their models achieved an AUC-ROC ranging from 0.53 to 0.68 but did not report results for sensitivity and specificity [64].

Principal Findings

Our models exhibit almost the same sensitivity, specificity, and AUC-ROC values when applied to both the training and test data across all 3 data sets. This finding suggests that our approach is capable of generalizing effectively to unseen data, demonstrating its robustness and reliability.

It is worth noting that even when using only the MB, the results obtained were still satisfactory, making it a viable option for reducing the number of questions required to predict DS. Furthermore, the probabilistic measures extracted from the MB of the outcome demonstrated strong discriminatory power. This emphasizes that the features within the MB hold the utmost importance in the model across all 3 data sets.

The output of the models offers a visual representation of the relationship between sensitivities and the associated reduction in screening interviews. This gives health care providers the flexibility to adjust the desired sensitivity of the models according to their specific requirements. Such adaptability enhances the utility of the model as a proof-of-concept in clinical settings, making it particularly beneficial in environments with limited resources.

Limitations

While a PHQ-9 score of 10 or higher can serve as a useful indicator for DS, it should be interpreted in conjunction with other clinical information and within the context of an individual's unique circumstances. If available in the data sets, it would be straightforward with our methodology to predict different outcomes beyond PHQ-9 scores. However, the methodology may require some adjustments in the algorithm.

While our proposed methodology demonstrated good performance in all 3 data sets, it is important to note that there is a possibility of the model not performing well on certain data sets. This could happen if the features in the data set do not have a strong correlation with the outcome or if the prevalence of DS in a specific cohort is high.

The consistent prominence of the same 3 essential features in both PNS 2013 and PNS 2019 is noteworthy, but this information holds relevance primarily within Brazilian primary care settings. Across diverse cultures, different features might emerge as the most important indicators. Furthermore, it is important to consider the potential for these features to dynamically shift in significance over time, depending on the readily available data.

We acknowledge that having access to the readily available data may require obtaining permissions. Despite the data being accessible, various legal and ethical considerations may necessitate obtaining explicit permissions or approvals before its use.

Although the use of BN for feature selection yielded consistent results, it is worth noting that constructing the model using bootstrap can be very hardware demanding. In addition, the feasibility of this approach depends on the size of the data set in terms of the number of features, the range of values of the features, and the number of observations.

Conclusions

We presented a data-driven proof-of-concept methodology for identifying individuals with DS using alternative features beyond common mental health screening questionnaires. This approach was tested on 3 distinct data sets, yielding consistent results that indicate a strong generalization of the methodology for targeting individuals who could benefit from further screening.

Using BNs, we were able to identify the most influential features (ie, the MB of the outcome) and extract insights using probabilistic measures through parameter learning. Our analysis revealed that for the PROACTIVE data set, a study that screened Brazilians aged ≥ 60 years, the most influential features were related to postural balance, shortness of breath, and how old people feel they are. For the PNS data sets, which screened a national sample of Brazilians aged ≥ 18 years, the influential features of the 2013 data set were related to the ability to do usual activities, chest pain, chronic back problems, and sleep problems. In the PNS 2019 data set, the same features were found to be important as in PNS 2013, except for chronic back problems, which were replaced by a feature related to verbal abuse.

Finally, it has been demonstrated through empirical analysis that using the proposed models results in a considerable reduction of the screening interviews (up to 52%) while maintaining a sensitivity of 80%.

Abstract

Australian providers of mental health services and support for young people include private and public allied health providers, government initiatives (eg, headspace), nongovernment organizations (eg, Kids Helpline), general practitioners (GPs), and the hospital system. Over 20 years of research has established that many young people prefer to seek mental health support online; however, clear client pathways within and between online and offline mental health services are currently lacking. The authors propose a Digital Mental Health Practice model of care for youth to assist with digital mental health service mapping. The proposed model offers accessible pathways for a client to engage with digital mental health services, provides clear navigation to access support for individual needs, and facilitates a seamless connection with offline mental health services using a transferable electronic health records system. This future-looking model also includes emerging technologies, such as artificial intelligence and the metaverse, which must be accounted for as potential tools to be leveraged for digital therapies and support systems. The urgent need for a user-centered Digital Mental Health Practice model of care for youth in Australia is discussed, highlighting the shortcomings of traditional and existing online triage models evident during the COVID-19 pandemic, and the complex challenges that must be overcome, such as the integration of diverse mental health care providers and establishment of a robust electronic health records system. Potential benefits of such a model include reduced pressure on emergency rooms, improved identification of immediate needs, enhanced referral practices, and the establishment of a cost-efficient national digital mental health care model with global applicability. The authors conclude by stressing the consequences of inaction, warning that delays may lead to more complex challenges as new technologies emerge and exacerbate the long-term negative consequences of poor mental health management on the economic and biopsychosocial well-being of young Australians.

Introduction

The COVID-19 pandemic highlighted what was already well-established about Australia's mental health system: that demand and ease of access were not being successfully met [1-5], especially for individuals younger than 25 years, who are the most at-risk age group [6,7]. Over the past 20 years, the Australian youth mental health system has slowly transitioned from being fragmented and piecemeal, with poor integration between inpatient and outpatient services, to include online and offline offerings nationally [8]. However, these offerings are not always clearly connected for clients to navigate [1,7] and are often difficult to access in regional and remote areas (especially for young indigenous and marginalized populations of Australia), where online and offline services are seldom integrated or inclusive [9].

Young people are increasingly using the web as the first step in seeking support and information regarding their mental health [10,11]; yet, the digital services currently on offer often poorly integrate with existing offline mental health and hospital systems of care [1,12,13]. There is also a lack of sharing of clients' mental health records between private and nongovernment organization (NGO) providers who offer online support (eg, ReachOut, BeyondBlue, Kids Helpline, and SANE), telephone centric services (eg, Lifeline and Kids Helpline), and traditional face-to-face clinical support (eg, headspace). This is due to several ethical and practical challenges associated with sharing electronic health records (EHRs) in mental health care [14], including issues of interoperability, missing data, privacy and confidentiality concerns, and legal compliance.

Currently, EHRs of young people are typically not part of digital mental health service offerings, with data often only collected upon entrance to determine the level of care required (ie, the

triage stage). This means that when young people later return to online services at differing stages of need, or via a different modality, they often must “start again” with programs or offerings that may no longer suit their needs, rather than being directed to more suitable supports that reflect their prior engagement and the current stage of their mental health journey. Furthermore, the current lack of transferable EHRs between service providers implies that young people often have to retell their story multiple times. This can lead to incomplete patient histories, duplicate assessments, fragmented care, and safety risks associated with delayed or inappropriate treatment [15].

We propose a Digital Mental Health Practice model of care for youth (DMHP-Y) to aid digital mental health service mapping. It provides clear and accessible pathways for a young person to enter a digital mental health system, and then accurately navigate it to access support for their individual needs, beyond initial triage. This model proposes transferable EHRs regarding mental health service use to inform clinicians of historical online and offline service access, including any digital mental health assessments and treatments previously engaged in by a client. This will provide clinicians with essential background information on a patient’s mental health journey to date, assist in decision-making about future assessments and treatments, and facilitate continuity of care.

A Brief Overview of Current Digital Mental Health Practices in Australia

Established in 2006, headspace is an NGO funded by the Australian Government as part of its national approach to service the mental health needs of young people (younger than 25 years) [16]. While headspace has been widely lauded for providing no-gap Medicare access to psychologists under a general practitioner (GP)-referred mental health care plan, the service has been under strain, given its high client demand nationwide [17,18] and the limitations to ongoing mental health management beyond the “Better Access” to mental health Medicare system [19-21]. “eheadspace,” the digital provision of mental health support, was established to provide online resources for young people to connect with mental health information and support through forums, digital tools, and one-to-one counseling via web chat and telephone. While not an emergency service, eheadspace duplicated some of the resources offered by other NGOs’ online services (eg, ReachOut and Kids Helpline), which have also struggled in connecting online resource offerings to offline clinician services (often because clients may choose to contact these services anonymously). Furthermore, the lack of integration between eheadspace and face-to-face headspace services demonstrates the challenges involved in integrating online and offline services, even within the same service environment. Herein lies a major systemic issue: the lack of secure, transferable, digital mental health recordkeeping within and between services [22-24].

Notwithstanding this challenge, new online platforms have emerged in recent years that leverage health ITs (HITs) to integrate digital mental health tools with existing face-to-face mental health services. The “Innowell” platform [25] is a customizable digital dashboard for mental health services,

designed for assessing, monitoring, and managing the mental health of their clients. It collects and reports personal information to clients and their health professionals to promote collaborative and measurement-based care, and offers a range of online clinical content and assessment tools that are made available to clients as determined by their face-to-face mental health service. Another Australian example is Orygen’s “Moderated Online Social Therapy” (MOST) platform [26,27], a free online digital mental health service that young people can connect to following a referral from participating offline services. The MOST model of care is designed to support young people with, and in between, their face-to-face sessions with a clinician, or while they are waiting for care. It offers a range of on-demand digital services, including one-on-one support, self-directed online therapy, and moderated peer-to-peer online social networking.

These 2 platforms reflect emerging models of digital mental health care internationally, which also use HIT to augment face-to-face sessions and facilitate measurement-based care. A notable example from the United States is the “Digital Clinic” [28,29], which uses smartphone apps to augment and extend care at the Beth Israel Deaconess Medical Center in Boston, Massachusetts. This evolving hybrid model of care emphasizes therapeutic alliance, measurement-based care, and shared decision-making between clients and clinicians. A key feature of the model is mindLAMP (Learn, Assess, Manage, Prevent), an open-source app that provides customizable education, assessment, and management tools, and facilitates data sharing with patients and clinician support. mindLAMP can also be used to capture metadata regarding clients’ use of the app, as well as health and physical activity patterns via a smartwatch (eg, step count and heart rate) to enable “digital phenotyping.” Digital phenotyping is a new and evolving multidisciplinary field of science that uses data from smart devices to create a holistic digital picture of behavior and health, and has the potential to augment clinical care at the individual level (eg, by identifying clinically significant behavior changes) [30].

By integrating HIT with existing mental health services, the models described above represent the beginning of a new era of digital mental health service delivery. Something these models have in common is the requirement for clients to first connect with a face-to-face mental health service to access online services. However, young people are often reluctant to seek professional face-to-face help and face barriers to treatment such as cost, stigma, confidentiality concerns, poor mental health literacy, and inaccessibility to or lack of knowledge of resources [31,32]. These factors contribute to an increasing trend for young people to use the web as the first step in seeking support and information regarding their mental health [10,11], usually by typing a text-based query into an internet search engine [12]. Discussions of Rickwood et al’s [33] help seeking model in the context of the online environment emphasize the importance of internet-based resources and interventions in addressing the mental health concerns of young people [34] and ensuring that young people are guided to appropriate services [35]. Reputable digital mental health services that do not require prior face-to-face referrals, such as ReachOut and Kids Helpline, therefore play an important role in early intervention and as

gateway services for young people in Australia who are seeking mental health information and support [34,36,37]. They also provide opportunities for young people to anonymously engage with peers online about mental health concerns, using moderated social media platforms, which itself has been shown to increase the likelihood of seeking formal mental health treatment [38,39]. A DMHP-Y is therefore required to map client-led online help seeking and engagement pathways to and within digital mental health services, and help clients navigate access to support for their individual needs, including seamless connections with offline mental health services.

Considerations in Evidence-Basing a DMHP-Y

Digital mental health approaches are typically evidence-based as stand-alone interventions (eg, apps, video counseling, websites, and forums) rather than as holistic models of care. For a DMHP-Y to be effective and well-used, more research is needed to build an evidence base for the following, in order to inform design decisions that reflect youths' help seeking behaviors and preferences, and the navigation of their mental health journey.

Understand and Monitor Digital Engagement With Mental Health Care Over Time

This is necessary to map how and at what stages of their mental health journey young people engage with the digital mental health system over time, as use of digital mental health information and tools is often not linear. It also needs to be understood why some demographics might be more likely to arrive at a digital mental health service via an internet search, rather than via clinician referral or social networks. Further, in relation to online search words, search engine optimization (SEO) strategies must account for the different search terms individuals use to find information on mental health, given that the vocabulary for mental health help seeking has been shown to differ based on developmental age [40].

Understanding Preferred Digital Tools of Young People for Supporting Their Mental Health

The online support services and modalities offered as part of a DMHP-Y must reflect and keep up with changing preferences and use patterns among young people. For example, there is growing evidence suggesting that young people want to use dynamic social media environments to seek information about their mental health and treatment options, and give and receive peer support from others facing similar mental health challenges [41-43]. While public social media platforms have significant privacy and security risks, recent studies have shown that custom-built social media-based services such as Kids Helpline's "My Circle" (formerly "KHL Circles") can be a safe and effective way for young people to engage in counselor-guided peer support for their mental health [25,44-46]. Next on the horizon is the increasing incorporation of virtual, augmented, and mixed reality technologies into social media, giving rise to the metaverse, which presents both opportunities and challenges for the future of digital mental health treatment and support [47,48]. A future-looking DMHP-Y model of care

must therefore be dynamic enough to adapt quickly as technology and platform preferences continue to evolve, yet ensure that new service offerings are tested and evidence-based before implementation, and user privacy and safety remain the first priority.

Ensuring an Optimum and Inclusive User Experience

It is well established that participatory design research methodologies involving all stakeholders and end users in the design and development of digital mental health systems and interventions are needed to ensure an optimum user experience for clients, clinicians, and other support staff [49,50]. However, further research into understanding individual human factors across different ages, genders, education, locations, abilities, neurotypes, and cultural needs is crucial to providing an inclusive and dynamic experience, leading to better service matching, more engagement, and less dropout from services. Furthermore, all DMHP-Y web content should be created using "universal design" principles to ensure usability by people with the widest possible range of abilities in the widest possible range of situations [51]. For example, Kids Helpline has already adopted a mobile-first approach and has implemented a range of inclusivity features to allow for people with hearing or sight impairment to access their services, such as "voice to text" across all modalities, ensuring that all website text is accessible via screen readers, and that all video content includes subtitles and audio cues. Kids Helpline has also introduced design initiatives to support children and young people with limited access to devices, data, and network coverage.

Ensuring Continuity of Care

As discussed, a DMHP-Y model of care must provide for ongoing connections and transferability of information between online modalities and with offline services via EHRs. The need for and benefits of a transferable EHR should be made clear to clients upon first engagement with a digital mental health system. For example, so that they can easily navigate their mental health journey across modalities (ie, within and between online and offline services) and avoid having to repeat initial onboarding processes in the future. Participatory action research is needed to ensure that such a transferable EHR system is developed on the basis of user-centered design principles so that it meets the needs of both clinicians and clients, and effectively facilitates continuity of care (especially for nonlinear mental health treatment journeys). Once the evidence base for this is established, a standardized EHR system should ideally be implemented nationally across all community and private mental health services to ensure comprehensive and seamless record keeping between online and offline services.

My Health Records (Australia's national digital health record system managed by the Australian Digital Health Agency) provides a case study in how difficult it can be to roll out an EHR system nationally. Challenges include low uptake, incomplete information, and concerns around privacy and security [52]. While it is possible for My Health Records to be used for mental health care, it is currently underused for this purpose, with concerns raised about the inclusion of sensitive and potentially stigmatizing mental health information alongside physical health information [24]. Furthermore, psychologists

and other allied health professionals are excluded from engaging meaningfully with My Health Records, as conformant software is not currently available for allied health practices. My Health Records also does not allow for the inclusion of records of engagement with NGOs' digital mental health services. Therefore, our perspective is that a DMHP-Y model of care requires a national EHR system specifically for mental health, which facilitates the transferring of records between digital mental health services and other health providers. While the considerations are complex and beyond the scope of this paper, any EHR system that seeks to support the mental health journeys of young people needs to include records of engagement with digital mental health services (most of which in Australia, at present, are NGOs and are outside of the health care system).

Proposing a Future-Looking DMHP-Y

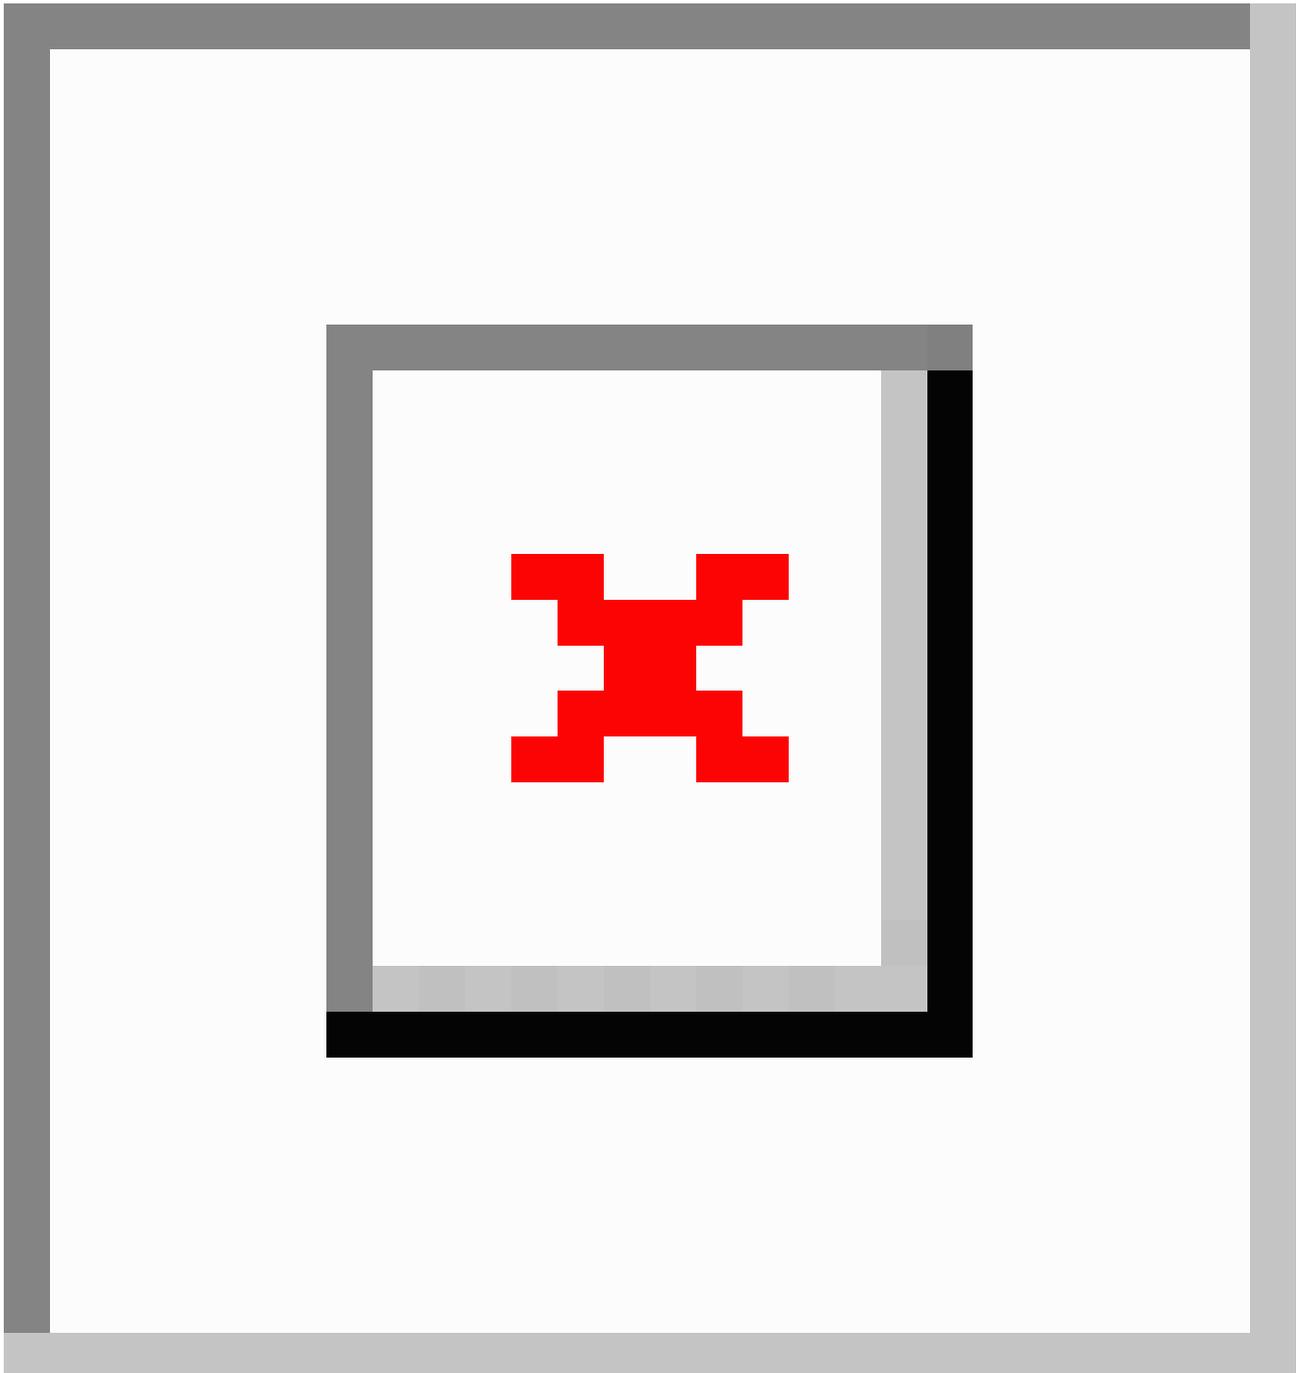

Overview

As outlined, current service provision for youth mental health in Australia offers both offline (eg, headspace and private practice allied health) and online support services (eg, eheadspace, Kids Helpline, and ReachOut). At the time of writing, the only emerging evidence-based digital platforms in Australia connecting clinicians and clients across online and offline service modalities are Innowell [25] and MOST [26,27]. While these models of care provide some basis for the model proposed below in Figure 1, they can only be accessed by clients after obtaining a referral from a participating offline mental health service.

In contrast, the DMHP-Y model of care proposed by the authors is focused on client-led online help seeking and engagement pathways. It aims to provide a map of the client-led engagement pathways that would be possible from the point at which a user first engages with a digital mental health service and is provided with a transferable EHR, regardless of whether they have previously engaged with offline mental health services or how far along their overall mental health journey they might be. While the model proposes that initial access to digital services (with the exception of phone counseling) should be via a common landing point for onboarding, it accounts for there being numerous engagement and re-engagement points (such as following engagement with offline services). The model also accounts for technologies that will change the way we interact online over the coming years, such as the incorporation of natural language processing and other artificial intelligence (AI) modalities, and avatar and social network use in the metaverse. The model presented is, therefore, a future-looking starting point for a model of care that would improve connections between services and transferability of client information, as technological advances and user preferences continue to evolve.

The proposed DMHP-Y model aims for what is herein dubbed the 3 Is of digital mental health care: *inclusivity* (equal access to all), *individuality* (choice based on preferences), and *integrity* (reliable, ethical, and evidence-based care). The 3 Is are addressed, where applicable, across each step of a client's movement through the system of care.

Figure 1. The future-looking Digital Mental Health Practice model of care for youth (version 1.0).

Step 1: First Engagement

This step represents the *individual* journeys and modalities that lead young people to first engage with a digital mental health service. As stated previously, young people often use the web as their first step in seeking support and information regarding their mental health [10,11], usually via a text-based query in an internet search engine, which is the most common help seeking approach among young people aged <25 years [12]. Other potential initial engagement channels include suggested links on websites or social media, recommendations from text-based chat services and social media, as well as clinician referral and word of mouth.

Research on young people's mental health-related search word practices suggests that digital mental health services need to ensure that they can be easily found not only using diagnostic search terms (eg, depression, anxiety, etc), but also using simple affective phrases (eg, sad, scared, or lonely) [40]. SEO strategies also need to account for differences in demographics, ability, neurotype, language, and cultural backgrounds to ensure *inclusivity*. Moreover, ongoing analysis of common search phrases for mental health issues to inform SEO updates is key to a DMHP-Y model remaining a primary online source of help (*integrity*) over less evidence-based or predatory mental health offerings.

Step 2: Landing Page

No matter what leads a potential client to first engage with a DMHP-Y system, they should be directed to a common landing page that quickly explains the service modality options available to them (*individuality*), as well as a clearly identifiable link to “immediate help” (ie, a link to a national mental health crisis line [53]) to reduce cognitive load on what could be a distressed individual (*integrity*). Often, landing pages are cluttered with dense information or vague navigation. Studies clearly show that time spent engaging with a digital platform is directly related to intuitive design and consideration of user digital literacy [54,55]. The design of the landing page is therefore crucial and should not be dictated solely by the service provider but rather be designed in consultation with young people from a diverse range of backgrounds and with differing levels of mental health literacy (*inclusivity*). This is to ensure that the right balance is achieved between the need to provide essential information to the client and the need of the client to progress to an appropriate service quickly and easily. This essential information should include explaining the need for and benefit of creating a transferable EHR to navigate their mental health journey, as the next step in the model may require this for progress into the service.

Step 3: Onboarding and Virtual Triage

The next step is to create a transferable EHR for the client (if they do not already have one) so they can onboard into the DMHP-Y system and complete a mental health screening assessment to inform “virtual triage.” It has been proposed that virtual triage could also leverage AI, specifically natural language processing, which shows promise for adaptation for mental health services [55-58] and is currently being used successfully in corporate operations and retail services. It is not the authors’ suggestion that such a sensitive system and service model be reliant on AI alone, rather, a hybrid model of triage engagement be offered (ie, human and AI), depending on the level of severity of a client upon initial screening. An example of this would be when a client has completed the initial onboarding for an EHR and their mental health screen indicates high levels of distress (addressing *individual* urgent need), they are flagged as such and directed immediately to a human counselor contact (eg, text-based or voice-based, depending on the preference of the client) as the first port of call for immediate triage (ie, *integrity* of priority care). For clients who decline contact with a human counselor, the system may provide them with targeted resources and alternate options for support (*inclusivity*), while flagging their profile within the ecosystem for therapeutic monitoring, follow-up, and support. Clients identified as “severe” at screening can, if required, be directed to emergency services, or referred to community or private mental health services via a contact number or URL for their closest service.

Step 4: Online Support

Once level of care requirements are established, the DMHP-Y model can offer a personalized (ie, *individual* and *inclusive*) menu of text- and voice-based choices from a suite of digital therapies and supports. Low-risk first-time clients may be directed to multimedia psychoeducation, or virtual counselor

sessions can be scheduled in an environment of choice (eg, an initial telecounseling session via phone, web, or metaverse avatar counseling). This initial entrance level of support could also include evidence-based AI chatbots for mental health information [56,58] or asynchronous text-based guidance from counselors [59]. In turn, this would aid them to learn more about their mental health needs and options for individual care, both within the online service and via offline services. With appropriate technology and client consent in place, there is also potential for digital phenotyping to play a role in informing clinical support needs, by integrating data from a client’s smart devices with their engagement trends with the DMHP-Y model over time [30].

For clients who understand their mental health needs (ie, have previously received diagnosis or therapies), the option of self-guided psychoeducation and digital programs, such as cognitive behavioral therapy or acceptance and commitment therapy, may be offered. These forms of digital therapies are evidence-based for clients experiencing depression, anxiety, and stress symptoms and wanting to self-manage [60,61].

Clients who are seeking continuous social support, especially for chronic mental health conditions, may benefit from community engagement via counselor-moderated 24/7 peer-to-peer social networks. This level of ongoing social support has been found to benefit young people in managing their mood and learning new coping strategies, and offers social support outside of specific therapies [26,44-46]. Connecting for peer-to-peer support in counselor-moderated social networks such as Kids Helpline’s My Circle has also been shown to reduce mental health stigma and increase help seeking for mental health issues in the future [44-46]. Kids Helpline’s My Circle is an example of how peer-to-peer social networks can integrate and link directly to other text-based resources such as self-directed online psychoeducation modules, website content, and text-based one-to-one counseling in an easy-to-navigate digital ecosystem. The integration of digital mental health resources and interventions into an ecosystem further allows them to be used strategically and dynamically by digital counselors, by conceptualizing them on dichotomies from low to high intensity (eg, website vs one-to-one text-based counseling) or solo to assisted interventions. For example, clients presenting with “severe” symptomatology who are struggling to see improvements by using self-directed online psychoeducation may conceptually benefit from using higher-intensity and assisted interventions, which may involve online counselors directing them to peer-to-peer support or one-to-one interventions that match their willingness, motivation, and clinical needs.

Offline Support

Though not a “step” in the DMHP-Y model, referral to offline face-to-face support may be deemed appropriate or necessary at any stage of a client’s engagement with a digital mental health service. In this situation, digital counselors should provide “warm referrals” for clients; that is, they should discuss options and gain client consent to introduce them to an offline service. A system for sharing of EHRs must therefore be established between a DMHP-Y model and offline services for seamless

recordkeeping and best-practice care for clients in need of outpatient or inpatient care. This, of course, goes both ways, as clients may transition to digital services having already engaged with offline services. An EHR system for mental health should therefore ideally be implemented nationally across all community, private mental health, and digital mental health services and allow clients who may have an existing EHR established with offline services to connect it to digital mental health services (as many seek digital services themselves rather than via a referral from an offline service).

At the time of writing, there are multiple health record software programs on offer in Australia, but none provide seamless recordkeeping between online and offline services. There are, however, digital mental health services in Australia that seek to connect young people to and from offline services via direct referrals, albeit without fully transferable EHR systems. For example, Kids Helpline connects young people to offline services via warm referrals to community and specialist mental health services and emergency and child protection services where clients are at risk of significant harm. Conversely, as discussed, following a referral from participating offline services, young people can connect to Orygen's MOST platform [26,27] to access online support either while they are waiting for face-to-face care in order to augment their face-to-face sessions or after discharge. It is these types of systems of care that need to be further developed and tested at the national level.

Conclusion

Australia presently overrelies on traditional triage models of care for mental health (eg, hospital emergency departments and crisis support telephone services), which came close to systemic failure during the peak of the COVID-19 pandemic as they struggled to address increased demand for mental health support during the health crisis [62]. Given that the demand for online services is growing despite many digital mental health services currently having a poor evidence base [63], it is now even more necessary to develop a road map, testing phase, and rollout plan for a DMHP-Y model of care for service provision.

User-preferred models for mental health that provide EHRs to enable seamless cross-referrals between online and offline allied health and psychiatric care will reduce pressures on existing mental health providers in Australia and facilitate continuity of care for clients. This will be achieved by maintaining detailed records of the young person's mental health journey—tracking engagement with both clinical treatment and digital support tools—which will allow seamless repeat entrance to both online and offline support when needed. The goal should be for young

people to be able to enter services for support without having to retell their story wherever possible.

The primary challenge is the “start up” phase for a DMHP-Y model of care, which must address four significant hurdles: (1) synchronization of existing systems and models of mental health care, online and offline, across different provider organizations (NGOs, government, private sectors, GPs, and hospitals); (2) establishing a transparent, secure, and agile EHR system for mental health; (3) tracking and managing clients that present within digital systems under multiple identities (eg, due to stigma or privacy concerns); and (4) upskilling mental health workers and professionals in digital health and digital therapy skills to extend evidence-based practices across existing (eg, videoconference counseling) and future technologies (eg, metaverse counseling and AI). Developing a dynamic and future-looking DMHP-Y model of care that incorporates the introduction of new automated technologies such as AI does not imply the loss of quality mental health professional care. On the contrary, a DMHP-Y model of care that incorporates AI facilitates the economic and professional release of clinicians to dedicate time and expertise to clients who are in urgent need of help or require long-term care across hybrid offerings of traditional community face-to-face resources and digital resources.

The investment and development in DMHP-Y models of care will improve services in Australia from “treatment only” to “treatment and user-choice support” systems. In turn, this will (1) alleviate pressure on emergency rooms (which have seen a dramatic increase in mental health presentations over the past decade) [64]; (2) improve online to offline referral practices (and vice versa); (3) better identify and prioritize those who need immediate face-to-face help from those who need ongoing social and psychoeducation support; (4) greatly improve the cost efficiency of the current mental health system in Australia; and (5) pioneer a national model of digital mental health care that is replicable globally.

The most significant risk to our mental health system is inaction. If we do not start implementing changes in digital systems in mental health care at the national level, the knock-on effects of poor mental health care management for young people will continue into adulthood. This will contribute to significant long-term economic and biopsychosocial problems for Australia's population in the future, compounding national health burdens of disability and disease. Moreover, the longer the delay to develop, test, and refine such digital models for mental health services, the more complex the task will become as new technologies and platforms such as AI and the metaverse are introduced at an increasingly rapid pace.

Abstract

Background: Recommender systems help narrow down a large range of items to a smaller, personalized set. NarraGive is a first-in-field hybrid recommender system for mental health recovery narratives, recommending narratives based on their content and narrator characteristics (using content-based filtering) and on narratives beneficially impacting other similar users (using collaborative filtering). NarraGive is integrated into the Narrative Experiences Online (NEON) intervention, a web application providing access to the NEON Collection of recovery narratives.

Objective: This study aims to analyze the 3 recommender system algorithms used in NarraGive to inform future interventions using recommender systems for lived experience narratives.

Methods: Using a recently published framework for evaluating recommender systems to structure the analysis, we compared the content-based filtering algorithm and collaborative filtering algorithms by evaluating the accuracy (how close the predicted ratings are to the true ratings), precision (the proportion of the recommended narratives that are relevant), diversity (how diverse the recommended narratives are), coverage (the proportion of all available narratives that can be recommended), and unfairness (whether the algorithms produce less accurate predictions for disadvantaged participants) across gender and ethnicity. We used data from all participants in 2 parallel-group, waitlist control clinical trials of the NEON intervention (NEON trial: N=739; NEON for other [eg, nonpsychosis] mental health problems [NEON-O] trial: N=1023). Both trials included people with self-reported mental health problems who had and had not used statutory mental health services. In addition, NEON trial participants had experienced self-reported psychosis in the previous 5 years. Our evaluation used a database of Likert-scale narrative ratings provided by trial participants in response to validated narrative feedback questions.

Results: Participants from the NEON and NEON-O trials provided 2288 and 1896 narrative ratings, respectively. Each rated narrative had a median of 3 ratings and 2 ratings, respectively. For the NEON trial, the content-based filtering algorithm performed better for coverage; the collaborative filtering algorithms performed better for accuracy, diversity, and unfairness across both gender and ethnicity; and neither algorithm performed better for precision. For the NEON-O trial, the content-based filtering algorithm did not perform better on any metric; the collaborative filtering algorithms performed better on accuracy and unfairness across both gender and ethnicity; and neither algorithm performed better for precision, diversity, or coverage.

Conclusions: Clinical population may be associated with recommender system performance. Recommender systems are susceptible to a wide range of undesirable biases. Approaches to mitigating these include providing enough initial data for the recommender system (to prevent overfitting), ensuring that items can be accessed outside the recommender system (to prevent a feedback loop between accessed items and recommended items), and encouraging participants to provide feedback on every narrative they interact with (to prevent participants from only providing feedback when they have strong opinions).

Introduction

Background

Recommender systems create personalized recommendations within a specific domain, suggesting items that may be of use to a user and helping quickly narrow down a potentially overwhelming number of options [1]. Recommender systems are used on global platforms such as Netflix—a movie streaming service—which uses other people’s movie ratings to recommend movies, Amazon—an e-commerce company—which uses frequently-bought-together items to recommend purchases, and Pandora—a music streaming service—which uses 450 musical attributes to recommend songs [2].

A range of health care applications for recommender systems have been examined, including the use of recommender systems to suggest prompts for counselors in a suicide prevention helpline chat [3], tailor care preference assessments in nursing homes [4], and identify expert physicians for specific diseases [5].

In this paper, we present an evaluation of NarraGive, the first recommender system for providing web-based recommendations from a collection of mental health recovery narratives.

Lived Experience Narratives

Mental health recovery narratives are a subset of lived experience narratives, which are representations of a person’s experiences of physical or mental health and how that person has lived through and responded to those experiences [6]. The uses of lived experience narratives in health research have been extensively studied but with little focus on *which* narratives people engage with.

Studies have explored the use of lived experiences to encourage people to seek and sustain treatment, such as using narratives to improve health care participation in patients with breast cancer [7], promote smoking cessation in the African American community [8], and promote diabetes self-management [9] and diabetes medication adherence [10]. The use of lived experiences in support groups has also been studied, such as sharing stories in diabetes education in minority ethnic groups [11]. Some studies have provided medical students with narratives to facilitate learning and improve subsequent medical practices, such as using patient stories during practice placements [12] and learning about cancer pathology using narratives of patients who have experienced cancer [13].

Other studies have explored the use of lived experiences as a therapeutic tool for individuals, such as student nurses creating digital stories to challenge the “reality shock” of beginning clinical practice [14], young women telling their stories to reduce stress [15], women with eating disorders accessing recovery stories [16], service users with psychosis watching lived experience videos [17], incarcerated women telling their stories [18], patients with dementia using storytelling as a therapeutic tool [19], adults with diabetes engaging in lived experience support groups to reduce diabetes-related distress [20], painting trees to symbolize periods of one’s life as a starting point for telling a life story to treat depression and anxiety [21], and young people watching digital stories to reduce the prevalence of binge drinking [22].

Lived experience narratives have the potential to be used for a wide variety of purposes and, as a result—as documented previously—are frequently used in interventions. However, so far, the focus of health lived experience-based interventions has been solely on examining the effects of engaging with these narratives, with less focus on which *specific* narratives the participants are exposed to (though a few studies have placed emphasis on providing representative narratives [23] or particularly engaging and high-quality narratives [8]). Thus, while there have been studies evaluating the use of recommender systems in health care settings and, separately, evaluating the use of lived experience narratives, there have not been any lived experience narrative recommender systems developed before this study.

The Problem Being Addressed

This is the first evaluation of a lived experience narrative recommender system. The design of such a recommender system has distinct challenges. For example, narratives are sensitive types of data that impose ethical requirements to protect both the narrator and the recipient. Therefore, the use of recommender systems needs to be informed by considerations about the curation and use of narratives [24–26]. The goal of our evaluation was to develop preliminary evidence to inform the future use and evaluation of recommender systems with lived experience narratives.

The Narrative Experiences Online Intervention

Overview

The Narrative Experiences Online (NEON) study [27,28] evaluated whether having web-based access to people’s real-life stories of recovery from mental illness can be helpful for people

who are experiencing psychosis or other mental health problems. This builds on the evidence base that indicates that receiving recovery narratives can support mental health [27]. In the NEON intervention, participants interact with a web application through which they can access a web-based collection of mental health recovery narratives (henceforth, narratives)—the NEON Collection.

Narrative Characterization

The development of the NEON Collection, including the narrative inclusion criteria, has been reported elsewhere [29]. In brief, recorded recovery narratives were obtained, always with consent, from existing collections and individual donations to the study. Only narratives that could be presented on the web in a single electronic file (eg, PDF, JPEG, and WAV) were included. Within these files, narratives were presented in a range of forms, including prose, poetry, audio recordings, video recordings, individual images, and sequential art. Each was presented by a single narrator only—there were no composite narratives. The narratives were deliberately chosen to be diverse [30]. All narratives in the NEON Collection were characterized using the Inventory of Characteristics of Recovery Stories (INCREASE) [31] to capture 77 different features of the narratives related to narrator characteristics, narrative content, and turning points. While we used selected INCREASE characteristics in our recommender system, the greater breadth of characteristics collected will support future secondary analyses. The trials opened with 348 narratives and closed with 659 narratives available.

Narrative Request Routes

There are 6 ways for participants to request narratives through the NEON intervention, which are internally documented as 1 of 8 request methods.

[Textbox 1](#) summarizes the external and internal narrative request routes.

The NEON intervention home page has buttons corresponding to 4 of the 6 external narrative request routes: “Match me to a

story (recommended),” “Get me a random story,” “Browse stories,” and “My stories.”

The first option uses NarraGive to recommend a single narrative that the participant has not seen before. NarraGive is a hybrid recommender system (meaning that it uses a combination of recommendation strategies [32]) that uses both content-based filtering (recommending narratives based on their content) and collaborative filtering (recommending narratives based on how other participants have rated them) to recommend narratives to participants.

The second option presents a randomly selected narrative that the participant has not seen before.

The third option allows participants to browse narratives grouped into categories based on the narratives’ INCREASE characteristics (Figures S1 and S2 in [Multimedia Appendix 1](#))—some categories are based on the value of a single characteristic (eg, the narrator’s gender is “female”), and some are based on the value of multiple characteristics (eg, a positive narrative, defined as having an “upbeat” tone and an “escape” or “enlightenment” genre; Table S1 in [Multimedia Appendix 1](#)). Not all narratives are accessible through the category option.

The fourth option allows participants to access narratives that they have previously bookmarked or rated highly.

In addition, the internal request routes include whether NarraGive produced the recommendation using content-based filtering or collaborative filtering and whether a narrative selected from the “My stories” page was previously rated highly for hopefulness or manually bookmarked by the participant. One important benefit of having different narrative request routes is to prevent exposure bias, a well-known issue in recommender systems where participants are only presented with a subset of the available items, so they only provide ratings for that subset, with recommender systems unable to distinguish between disliked and unrated items and unknown and unrated items [33]. For example, the “Get me a random story” button might allow participants to access narratives that they would not otherwise be exposed to but that nonetheless may be beneficial.

Textbox 1. Narrative request mechanisms that participants use to access narratives (external routes) and the corresponding logs made by the intervention (internal routes).

External and internal narrative request routes
<ul style="list-style-type: none"> • Participant clicks on the “Match me to a story (recommended)” button <ul style="list-style-type: none"> • Participant accesses a narrative recommended via content-based filtering. • Participant accesses a narrative recommended via collaborative filtering. • Participant clicks on the “Get me a random story” button <ul style="list-style-type: none"> • Participant requests a random narrative. • Participant clicks on the “Browse stories” button and selects a narrative <ul style="list-style-type: none"> • Participant makes a category-based request for a narrative. • Participant clicks on the “My stories” button and selects a narrative <ul style="list-style-type: none"> • Participant requests a narrative that they have rated as hopeful. • Participant requests a narrative that they have marked as a favorite. • Participant uses the intervention for the first time and is presented with their first narrative <ul style="list-style-type: none"> • Participant accesses their “first” narrative. • Participant clicks on a narrative from a Narrative Experiences Online (NEON) communication <ul style="list-style-type: none"> • Participant accesses the suggested narrative in a reminder message aimed at prompting them to use the NEON intervention.

Narrative Feedback

After a participant has accessed a narrative through any request route, they are presented with 5 feedback questions (Table 1), and their responses to these questions are time-stamped and logged. The focus (hope, similarity, learning, and empathy) is based on the NEON Impact Model [29] developed through a systematic review [34] and qualitative [35] and experimental studies [36]. The measurement approach has been previously validated [29]. To maximize response rates, the first question is marked as compulsory. The other 4 questions are marked as optional, and the participant has the choice to answer either all or none of the optional questions. A set of 5 response values (for the 1 compulsory and 4 optional questions) forms a single rating, as does a single response value for the compulsory

question. Ratings with optional questions answered are also referred to as optional ratings. Table 1 shows the questions, answer options, and numerical ranges (not visible to participants) of the questions and whether they are mandatory.

If a narrative is rerated, this overrides the previous rating (but the time-stamped logs of previous ratings are not deleted).

One benefit of recommender systems requiring a rating for each narrative is that this helps minimize selection bias, which occurs when participants are allowed to choose whether to rate the items, leading to ratings that are typically biased toward higher or more homogeneous ratings [33,37]. Selection bias is a well-known problem in recommender systems relying on explicit data.

Table 1. Questions, answer options, numerical ranges, and mandatory nature of narrative response data.

Question	Answer options	Range	Mandatory
How hopeful did the story leave you feeling? (hopefulness)	“Less hopeful than before,” “no change,” “a bit more hopeful,” and “much more hopeful”	-1 to 2	Yes
How similar was the storyteller to you? (similarity to the narrator)	“Not at all,” “a bit,” “quite a lot,” and “very much”	0 to 3	No
How similar was the storyteller’s life to your life? (similarity to the narrative)	“Not at all,” “a bit,” “quite a lot,” and “very much”	0 to 3	No
How much did you learn from the story? (learning)	“Not at all,” “a bit,” “quite a lot,” and “very much”	0 to 3	No
How emotionally connected did you feel with the story? (empathy)	“Not at all,” “a bit,” “quite a lot,” and “very much”	0 to 3	No

The NarraGive Recommender System

NarraGive is a hybrid recommender system. It uses one content-based and 2 collaborative filtering algorithms to allow for comparison of performance of the 3 algorithms using 2 distinct approaches to inform this new field of lived experience narrative recommendation. NarraGive was assembled using the Simple Python Recommendation System Engine library (SurPRISE; version 1.1.1; Nicolas Hug) for Python (version 3.6 and above), integrating implementations of filtering algorithms provided in these libraries [38]. NarraGive does not recommend previously requested narratives, types of narratives that a user has previously blocked, or individual narratives that a user has blocked.

The content-based filtering algorithm is based on the SurPRISE implementation of the k-nearest neighbor (kNN) algorithm. Although kNN is traditionally used as a collaborative filtering algorithm, NarraGive used an adapted version to measure the similarity between narratives, in which it uses their INCREASE characteristics to cluster together narratives in “neighborhoods” and recommend to participants unseen narratives that are similar to their other highly rated narratives. Narrative similarity is assessed using selected INCREASE characteristics, consisting of the INCREASE sections on narrator characteristics, narrative characteristics, narrative content, and turning points.

The selected collaborative filtering algorithms are the SurPRISE implementations of the singular value decomposition (SVD) and, to support comparison, SVD++. A broad introduction to these 2 algorithms is provided in the work by Hug [39]. These aim to capture the latent factors that determine how much a participant likes a narrative. NarraGive ran these 2 algorithms and selected the narrative with the highest predicted rating. Thus, the 2 algorithms served as distinct subsystems, so this evaluation will analyze the 2 subsystems separately to compare them. For the purposes of collaborative filtering, similarity between users is assessed using the demographic items collected in a “personal profile” created at first use and containing items describing participant demographics and format preferences. [Multimedia Appendix 2](#) provides details on all items in the profile.

When making a narrative recommendation, narrative feedback ratings are weighted (with a hopefulness rating twice as influential as each of the individual optional ratings) and combined. This was due to the underlying theory that we developed on narratives making an impact on recipients, which emphasized hope creation as the most critical mechanism. When a participant requests a narrative from NarraGive, it internally generates 1 list per algorithm of the 10 narratives with the highest predicted rating. It then presents the highest-scoring narrative of these 30 to the participant. The participant is not shown the predicted rating, other internally generated narratives, or which of the 2 filtering mechanisms was used to generate the recommendation.

The NEON Trials

The NEON intervention has been evaluated in 3 pragmatic randomized controlled trials with different populations. The NEON trial (ISRCTN11152837; N=739) is a definitive trial for

people with experience of psychosis. The NEON for other (eg, nonpsychosis) mental health problems (NEON-O) trial (ISRCTN63197153; N=1023) is a definitive trial for people experiencing any other type of mental health problem. The NEON-C trial (ISRCTN76355273; N=54) is a feasibility trial with people who informally care for people experiencing mental health problems, which is not within the scope of this study. The NEON intervention was identical in all 3 trials. A separate instance of NarraGive was used for each trial, and there was no pooling of narrative feedback or recommendations among the 3 trials.

Aims and Objectives

The aim of this study was to analyze the 3 recommender system algorithms used in NarraGive to inform future interventions using recommender systems in this new field of lived experience narrative recommendations. An evaluation of the impact of the NEON intervention using NarraGive has been reported elsewhere [40]. This study did not aim to provide an indication of NarraGive’s viability but rather to inform the development of future lived experience narrative recommender systems and guide design choices on collaborative versus content-based filtering algorithms.

The objectives were as follows:

1. To describe participant characteristics and patterns of narrative requests and feedback.
2. To evaluate the algorithms used in NarraGive by comparing collaborative-based and content-based narrative recommendations to inform future implementation approaches.

Objective 1 was addressed using data from the intervention version of NarraGive, and objective 2 was addressed using data from the final evaluated version.

Methods

Overview

An evaluation of NarraGive was conducted using data from the NEON and NEON-O trials, structured using the framework for evaluating recommender systems (FEVR), which was developed through a review of recommender system evaluation work [41]. The FEVR defines a set of components intended to guide the design of a recommender system evaluation.

After the NEON trials closed, logging files describing interactions with trial procedures and the NEON intervention were downloaded for analysis. These files included trial allocation, baseline demographic characteristics, personal profiles, narrative characteristics, narratives that the participants requested and the corresponding internal narrative request route, and participants’ ratings. All log entries were time-stamped.

Ethical Considerations

The NEON study trial protocol and an update have been published elsewhere [27,28]. Ethics approval was obtained in advance of trial start from a UK National Health Service Research Ethics Committee (Leicester Central Research Ethics Committee; 19/EM/0326). All participants provided web-based

informed consent for the use of their data for research purposes, and all study data were pseudonymous, with each participant's data linked by a unique ID. Some participants were compensated (£20 [US \$25.59] vouchers) for some data collection rounds, as described in our trial protocol.

Participants

The NEON trial included participants who (1) had experience of psychosis in the previous 5 years, (2) had experience of mental health-related distress in the previous 6 months, (3) resided in England, (4) were aged ≥ 18 years, (5) were capable of accessing or being supported to access the internet on a PC or mobile device or at a community venue, (6) were able to understand written and spoken English, and (7) were capable of providing web-based informed consent.

The NEON-O trial included participants who (1) had experience of mental health problems other than psychosis in the previous 5 years, (2) had experience of mental health-related distress in the previous 6 months, (3) resided in England, (4) were aged ≥ 18 years, (5) were capable of accessing or being supported to access the internet on a PC or mobile device or at a community venue, (6) were able to understand written and spoken English, and (7) were capable of providing web-based informed consent. It excluded participants eligible for the NEON trial.

Our study included participants from the NEON trials' intention-to-treat samples [27].

Sample Size

Both trials were powered on the mean item score for the 12 subjective items in the Manchester Short Assessment of Quality of Life (MANSA) as collected at baseline and the 52-week follow-up [42], and hence, the sample size was chosen on this basis.

For the NEON trial, a total sample size of 684 was chosen to provide 90% power to detect a minimal clinically important effect size (Cohen d) of 0.27 (SD 0.9 [43]; power=90%; $P=.05$), allowing for 20% attrition. The planned analyzable sample size was 546.

For the NEON-O trial, the SD of the MANSA scores for the study population was estimated from baseline data provided by the first 350 enrolled participants (see the study by Rennick-Egglestone et al [27] for the rationale). A total sample size of 994 was selected to provide 90% power to detect a minimal clinically important effect size (Cohen d) of 0.27 (SD 0.94; power=90%; $P=.05$), allowing for 40% attrition, which was estimated from the completion rates for interim data. The planned analyzable sample size was 596.

Both trials recruited their planned samples and were allowed to overrecruit ($N=739$ for the NEON trial and $N=1023$ for the NEON-O trial). The final attrition rates were 23.5% (NEON trial) and 44.8% (NEON-O trial).

Evaluation Framework

Table 2 describes the FEVR components that were selected to define the evaluation.

Table 2. Framework for evaluating recommender systems (FEVR) components defining the NarraGive evaluation.

FEVR component	Brief description
Evaluation objectives	
Overall goal	<ul style="list-style-type: none"> To evaluate whether the recommender system NarraGive supported participants in finding helpful narratives
Stakeholders	<ul style="list-style-type: none"> Participants in the NEON^a and NEON-O^b trials' ITT^c samples
Properties	<ul style="list-style-type: none"> Prediction accuracy, usage prediction, diversity, coverage, and unfairness across participants
Evaluation principles	
Hypothesis or research question	<ul style="list-style-type: none"> Objective 1: To describe participant characteristics and patterns of narrative requests and feedback Objective 2: To evaluate the NarraGive recommender system by comparing collaborative-based and content-based narrative recommendations
Control variables	<ul style="list-style-type: none"> Randomized data set that is split 75:25 between the training set (to train the algorithms) and the testing set (to evaluate the metrics)
Generalization power	<ul style="list-style-type: none"> Use of real-world data from participants with mental health problems; limited due to variation in system use
Reliability	<ul style="list-style-type: none"> Cross-validation with repeated initialization of collaborative filtering algorithms
Experiment type	<ul style="list-style-type: none"> Offline evaluation
Evaluation aspects	
Types of data	<ul style="list-style-type: none"> Explicit ratings

^aNEON: Narrative Experiences Online.

^bNEON-O trial: NEON for other [eg, nonpsychosis] mental health problems) trial.

^cITT: intention to treat.

Recruitment

Participants were recruited across England from March 9, 2020 (both trials), to March 1, 2021 (NEON trial), or March 26, 2021 (NEON-O trial). The trials used a mixed web-based and offline approach to recruit participants. Recruitment was through paid web-based advertising on mental health websites; promotional messaging distributed by a range of community groups and health care practices; promotional messaging distributed on Facebook, Twitter (subsequently rebranded as X), and Google (with the reach of messages enhanced through payments); media appearances by the central study team; and the work of clinical research officers in 11 secondary care mental health trusts.

Clinical research officers approached participants in person and distributed promotional messaging through local authorized channels such as mailing lists of service users who had

consented to be contacted about research studies. All promotional advertising and messaging conformed to principles approved in advance by the supervising research ethics committee [44].

Registration

All recruitment approaches directed potential participants to a web-based eligibility checking interface that requested responses to a series of questions specified in the trial protocol. All responses were self-rated. No formal diagnosis of a mental health condition was required for participation. Trial allocation was determined through responses, and eligible potential participants were provided with access to a tailored web-based participant information sheet. Participants subsequently completed a web-based informed consent form by providing an email address and optional telephone number.

The consent process was concluded by clicking on a link in an auto-generated email to validate the email address. After confirming consent, participants completed web-based forms to collect baseline demographic and clinical data and were then randomized using a web-based system validated by a clinical trial unit to the intervention or control arm. Demographic items were age (in years), gender (female, male, or other), ethnicity, region of residence, highest educational qualification, lifetime use of primary care mental health services, lifetime use of specialist mental health services, current use of mental health services in relation to psychosis (NEON trial only), main mental health problem in the last month, best description of recovery status, residential status, and employment status.

Intervention arm users gained immediate access to the NEON intervention until trial end (September 22, 2022), whereas control arm users gained access after completing the 52-week follow-up questionnaires and until trial end. Data on NEON intervention use by both intervention and control group users are within the scope of this study.

Analysis

Objective 1: Describe Participant Characteristics and Patterns of Narrative Requests and Feedback

Participant Characteristics

The demographic and clinical characteristics of participants randomized to each trial were described using means and SDs for normally distributed data and counts with percentages for categorical data. Descriptive statistics were calculated for all baseline demographic data items.

Following UK Data Service guidance on statistical disclosure [45], ethnicity responses were grouped into 2 categories (White British and other ethnicity) due to the small number of participants in most ethnicity categories, although recognizing that this could be perceived as a reductive approach to ethnicity data. “Current mental health problem” also comprised categories with low numbers of participants, so relevant rows were shown as “<5” with no percentage, and other rows were shown as “<10” with no percentage to avoid being able to infer other values.

Patterns of Narrative Requests and Feedback

Data on participant narrative requests and narrative feedback were taken from log files and used to calculate per-trial summary statistics for the number of participants, number of participants who requested at least one narrative, number of narratives at the start and end of the trial, number of narratives given at least one rating, number of narrative requests, number of narrative ratings, number of optional ratings, number of ratings per narrative, number of ratings per rated narrative, length of intervention use by participants, and narrative access routes.

While providing feedback on narratives was encouraged, it was possible for the participant to navigate away from the page and not submit any feedback; therefore, the number of narrative ratings may be smaller than the number of narrative requests, so these figures were reported separately.

Statistics for the number of ratings per narrative present 2 sets of figures with different selection criteria: those including only data for narratives that received at least one rating and those including data for all narratives. This breakdown shows how many ratings NarraGive had access to as it could only access rated narratives.

Nonparametric data were presented as medians and IQRs. Category data were presented as counts with percentages.

Objective 2: Evaluate the NarraGive Recommender System by Comparing Collaborative-Based and Content-Based Narrative Recommendations

Overview

The 3 algorithms (kNN, SVD, and SVD++) were trained and tested using all the available data, representing the point in time at which the trials closed. Training an algorithm involves providing it with a set of data that it can use to create predictions for missing data points. Testing an algorithm involves obtaining these predictions and measuring a feature of those predictions.

The results for objective 2 were obtained using the SurPRISE library (version 1.1.3) for Python (version 3.10.7). Only participants who provided at least one rating and narratives that were given at least one rating were included (as SurPRISE uses participant-item rating pairs as the basis for its predictions), which mirrors the information that NarraGive had access to during the intervention.

This study evaluated NarraGive using the metrics outlined in [Textbox 2](#), applied separately to the content-based algorithm (kNN) and the collaborative filtering-based algorithms (SVD and SVD++).

There are 2 types of metrics: metrics that compare predicted ratings with actual ratings (prediction-based metrics) and metrics that measure a feature of the top-n predicted items (feature-based metrics). Prediction-based metrics include prediction accuracy, usage prediction, and unfairness across participants. Feature-based metrics include diversity and coverage. For prediction-based metrics, there is no standard data-splitting strategy [46], so the data set is split into a training set (75%) and a testing set (25%). For feature-based metrics, the entire data set is used as the training set.

NarraGive only used the first 3 sets of ratings (hopefulness, similarity to the narrator, and similarity to the narrative) to inform its recommendations as these 3 questions had been validated in a feasibility study [29] and the remaining 2 questions were added after the feasibility study. Therefore, only the first 3 sets of ratings were used in the evaluation.

The hopefulness ratings were normalized, which in this case involved shifting the ratings to use the same rating scale as that of the 4 optional questions.

The evaluated version of NarraGive presented in this paper used the same training data as the intervention version of NarraGive with 3 minor modifications. First, where the narratives’ INCREASE characteristics were updated during the trials (eg, to correct human error in inputting characteristics), this evaluation only used the final set of uploaded characteristics. Second,

during the intervention, NarraGive filtered out previously requested and blocked narratives. This evaluation included these narratives as the predictions themselves were not influenced by whether a narrative was blocked or previously requested (ie, blocked and previously requested narratives were filtered out after the prediction process in the trial implementation), which could affect, for example, coverage metrics. Third, during the NEON trials, some accounts were removed due to suspected repeat registrations [27]; this evaluation removed all ratings from those participants even though NarraGive may have initially used those ratings.

The logs that were recorded during the intervention did not include NarraGive's internal recommendation lists and instead only recorded the single narrative that was selected to show to the participants. Therefore, using the intervention version of NarraGive would have prevented any comparison of its subsystems and would have allowed for only a limited analysis of its performance as a whole.

The results from objective 1 (about participants and their use of the system) used the data collected from the live intervention, whereas the results from objective 2 (about NarraGive and its subsystems) used the evaluation version of NarraGive.

During a previous feasibility study of NEON (N=25 mental health service users), 465 ratings were collected for the initial

Textbox 2. The 5 metrics for evaluating NarraGive.

Metric and metric category

- Prediction accuracy
 - Normalized mean absolute error
- Usage prediction
 - Mean average precision per participant
- Diversity
 - Intralist diversity
- Coverage
 - Item space coverage
- Unfairness across participants
 - Overestimation of unfairness

Prediction Accuracy

Prediction accuracy is the extent to which a recommender system can predict participant ratings [41]. The root-mean-square error (RMSE) and mean absolute error (MAE) [49] are 2 of the most commonly used metrics for evaluating rating prediction accuracy. The MAE uses the absolute difference between the predicted and true ratings, whereas the RMSE squares this difference, which results in the RMSE penalizing inaccurate predictions more [1].

The intervention was designed to be used over time rather than as a one-off, so the accuracy metric should primarily capture the *overall* accuracy rather than emphasizing occasional large

set of narratives in the NEON Collection [29]. NarraGive had access to these ratings in the NEON and NEON-O trials to reduce the “cold start” problem, where recommender systems perform poorly for new items and participants [1]. The evaluation excluded these ratings to ensure that NarraGive was only evaluated on data collected live during the NEON intervention.

The SVD and SVD++ algorithms were both randomly initialized according to a normal distribution [47], and the 75:25 split between training and testing sets was also random and calculated using NumPy (a package for scientific computing with Python) [48], where “fresh, unpredictable entropy will be pulled from the OS” [48]. To account for the randomness, cross-validation was performed. The data set was split into 4 folds, with a different fold used as the testing set each time, and the SVD and SVD++ algorithms were reinitialized each time. Medians and IQRs were reported.

An additional exploratory analysis was conducted to determine how the accuracy changed over time. For each month between June 2020 and July 2022 inclusive, data up to but not including the first day of each month were used for training and testing, and the accuracy was measured (using the same accuracy metric as for the main NarraGive evaluation).

inaccuracies (ie, an inaccurate prediction off by 2 points followed by a completely accurate prediction should be treated as no worse than 2 inaccurate predictions off by 1 point each), and this is better achieved using the MAE. Because the helpfulness ratings were normalized, the prediction accuracy metric was the normalized MAE (NMAE).

Different variations in the MAE have been reported in the literature. In particular, some versions square root the averaged summation [1], whereas others do not [47,50]. This evaluation uses SurPRISE's in-built MAE calculation, which does not use a square root.

A lower NMAE indicates greater prediction accuracy. For NarraGive, the scale ranges from 0 (greatest prediction accuracy) to 4 (equation 1 in [Multimedia Appendix 3](#)).

Usage prediction

Usage prediction is the rate of correct recommendations in a setting where recommendations are classified as 1 of 2 options: relevant or nonrelevant [41]. An item is relevant to a participant when the participant's rating for it meets a predefined numerical threshold (where the threshold is participant independent and defined per question).

There are 2 common metrics for measuring usage prediction: precision and recall. Precision measures how likely it is that a recommended item is relevant and is defined as the ratio of relevant selected items to the total number of selected items [49]. Recall, conversely, measures how likely it is that a relevant item is selected and is defined as the ratio of relevant selected items to the total number of relevant items [49].

As the length of the recommendation list increases, recall improves, whereas precision worsens [1,49]. The length of NarraGive's internal recommendation list is 10, which is relatively short (compared to, for example, a search engine that recommends tens or hundreds of web pages), meaning that it is impossible to achieve a meaningfully high recall score, so the metric for usage prediction was precision.

As usage prediction is usually used for measuring how relevant a *list* of recommendations is, this evaluation used NarraGive's internal recommendation list (consisting of a 10-narrative list produced using content-based filtering and two 10-narrative lists produced using collaborative filtering). As the participants do not see this list, only metrics that focus on the characteristics of the list as a whole—rather than focusing on the order *within* the list—were used (ie, where the list is treated more like a mathematical set than an ordered list as the ordering beyond the first item does not affect participants), and metrics that exclusively evaluate ranking order were not used.

The analysis of recommender system evaluations by Herlocker et al [49] showed that accuracy metrics can be divided into equivalence classes. One of these classes comprises all metrics that are averaged overall, and one of these classes comprises per-user correlation metrics and the mean average precision per-user metric. To ensure that this analysis of NarraGive captured its performance as widely as possible, a variation of precision that falls into a different equivalence class from that of the NMAE was used, namely, the mean average precision per participant (hereafter, precision).

As the ratings are on a 4-point scale, they need to be converted to a binary scale that classifies recommendations as either relevant or nonrelevant. For optional questions, relevance was defined as “a bit,” “quite a lot,” or “very much.” For hopefulness, relevance was defined as “no change,” “a bit more hopeful,” or “much more hopeful.”

Higher precision indicates a greater proportion of relevant narratives. The scale ranges from 0 (least precision) to 1 (equation 2 in [Multimedia Appendix 3](#)).

Diversity

Diversity measures how varied the recommended items are [41]. The current metrics for diversity [41,50] are intralist diversity (ILD) and variations thereof. ILD was developed by Ziegler et al [51], and variations include the rank-sensitive ILD metric by Vargas and Castells [52]. Similar to usage prediction, because the lists used to calculate diversity came from NarraGive's internal recommendation list and the ILD by Ziegler et al [51] is permutation insensitive (ie, the position of recommendations on the list does not affect the diversity score), this metric was used, with cosine similarity as the distance metric calculated using the narratives' INCREASE characteristics.

The original study defined ILD on a per-list basis (ie, for the recommendation list of one participant). This metric has been expanded in this study to be averaged over all participants' lists to produce an overall ILD value.

The lower the ILD value, the greater the diversity among the recommended items. The scale ranges from -1 (most diverse) to 1 (equation 3 in [Multimedia Appendix 3](#)).

Coverage

Coverage can be split into participant space coverage and item space coverage [41]. Participant space coverage is the proportion of participants who can be provided with recommendations by the recommender system [1]. The threshold for being provided recommendations is low—a participant needs to have rated at least one narrative (which is achieved when they first access the intervention as it is compulsory to provide a response for the first narrative); thus, participant space coverage was not used. A variation of participant space coverage assesses the proportion of participants that can be recommended *high-quality* items (ie, items with a predicted rating above a predefined threshold). This notion of variable quality among participants is addressed more thoroughly using an *unfairness across participants* metric instead.

Item space coverage is the proportion of items that the recommender system can recommend [1]. Ge et al [53] further split item space coverage into prediction coverage and catalog coverage. They defined prediction coverage as the proportion of items for which the recommender system can produce a predicted rating and catalog coverage as the proportion of items that are recommended in a series of recommendation lists. Because there is no predefined limit to when NarraGive can produce a predicted rating for a narrative, prediction coverage was used.

The definition of catalog coverage by Ge et al [53] captures the set of recommended items produced over time for a single participant (ie, the items that would have been recommended to the participant if they had asked for recommendations at that time; this is different from the set of recommended items that the participant requested and was actually presented with over time).

To capture the *overall* coverage, the proportion of narratives that are recommendable is measured, where a narrative is recommendable if, for at least one participant, the narrative appears in NarraGive's internal recommendation list.

Other versions of coverage use only the top recommendation, but as there are more narratives than there are participants, this would upper bound the item space coverage at approximately three-quarters for the NEON trial—total number of recommendations (which is equal to the number of participants who rated at least one narrative as there is 1 recommendation per participant) divided by the number of narratives that were rated at least once. For longer recommendation lists (such as 10), because recommender system algorithms cannot always produce a predicted rating for each item, a participant's list may be less than the desired length. For this evaluation, a length of 10 was sufficient to ensure that the total number of recommendations being considered across all participants was greater than the number of narratives.

A higher item space coverage value indicates greater item coverage. The scale ranges from 0 (lowest item coverage) to 1 (equation 4 in [Multimedia Appendix 3](#)).

Unfairness Across Participants

Unfairness across participants measures whether participants are treated fairly either at the group level (participants in the same group are treated fairly) or at the individual level (participants who are similar are treated fairly) [41].

NarraGive is designed for use in a health care setting—a setting in which protected characteristics such as disability are critical to attend to. It would be crude to stipulate that, for example, all participants should have an equal probability of being recommended a narrative about wheelchair users as this would be far more relevant to some participants than others (and, indeed, a recommender system's entire purpose is to provide *personalized* rather than generic recommendations). As acknowledged by Yao and Huang [54], “in tasks such as recommendation, user preferences are indeed influenced by sensitive features such as gender, race, and age. Therefore, enforcing demographic parity may significantly damage the quality of recommendations.”

Thus, they proposed 4 metrics: value unfairness, absolute unfairness, underestimation of unfairness, and overestimation of unfairness. Value unfairness “occurs when one class of user is consistently given higher or lower predictions than their true preferences.” Absolute unfairness “measures inconsistency in absolute estimation error across user types.” Underestimation of unfairness “measures inconsistency in how much the predictions underestimate the true ratings.” Overestimation of unfairness “measures inconsistency in how much the predictions overestimate the true ratings.”

NarraGive is implemented in a health care context in which the principle of harm avoidance is crucial. Therefore, one of the most important factors to consider is whether NarraGive is recommending potentially harmful narratives to participants. The metric used to measure this aspect is the overestimation of unfairness.

Overestimation of unfairness measures how much NarraGive consistently overestimates the predicted rating of narratives (ie, how often a participant rates a narrative lower than NarraGive expected) within a disadvantaged subset of the participants and compares this to the overestimation in the nondisadvantaged group.

Participants were divided into groups based on their demographic characteristics. The first grouping was by ethnicity as having a minority ethnicity predicts mental health problems [55], and the second grouping was by gender, informed by Sex and Gender Equity in Research guidelines [56].

The disadvantaged group for the gender comparison was defined as either “Female” or “Other.” The disadvantaged group for the ethnicity comparison was defined as “Irish,” “Gypsy or Irish Traveller,” “Any other White background,” “White and Black Caribbean,” “White and Black African,” “White and Asian,” “Any other Mixed/Multiple ethnic background,” “Indian,” “Pakistani,” “Bangladeshi,” “Chinese,” “Any other Asian background,” “African,” “Caribbean,” “Any other Black/African/Caribbean background,” “Arab,” and “Any other ethnic group.”

The baseline demographic information was used for measuring unfairness between participants as the questions were compulsory, so there was higher completeness of the baseline data than of the personal profile as well as greater granularity with the range of possible answers. The overestimation of unfairness is defined according to the study by Yao and Huang [54].

A lower overestimation of unfairness value indicates that there is less disparity between overestimation among disadvantaged participants and among nondisadvantaged participants. The scale ranges from 0 (least unfair) to 4 (equation 5 in [Multimedia Appendix 3](#)).

Other Categories

Zangerle and Bauer [41] detailed 10 categories of evaluation metrics that can be used in the FEVR. Of these, 5 (discussed previously) were used in evaluating NarraGive, and the other 5—ranking, novelty, serendipity, fairness across items, and business oriented—were not used for the reasons described in [Multimedia Appendix 4](#) [33,41,57].

Results

Objective 1: Describe Participant Characteristics and Patterns of Narrative Requests and Feedback

Participant Characteristics

The baseline sociodemographic and clinical characteristics of participants in the NEON (N=739) and NEON-O (N=1023) trials are shown in [Table 3](#).

An exploration of the baseline differences has been reported elsewhere [58].

Table 3. Baseline sociodemographic and clinical characteristics of Narrative Experiences Online (NEON) and NEON for other (eg, nonpsychosis) mental health problems trial (NEON-O) participants.

	NEON baseline (N=739)	NEON-O baseline (N=1023)
Gender, n (%)		
Female	443 (59.9)	811 (79.3)

^cNVQ: National Vocational Qualification.

^dNHS: National Health Service.

^eN/A: not applicable; indicates a question that participants were not asked; in particular, only NEON trial participants were asked about their current use of mental health services.

^fIAPT: Improving Access to Psychological Therapies.

Patterns of Narrative Requests and Feedback

Table 4 shows summary statistics on the participants, narratives, narrative requests, narrative ratings, intervention use length, and narrative request routes.

A histogram of the lengths of intervention use is shown in Figure S1 in Multimedia Appendix 5. In the NEON trial, 12.4% (92/739) of the participants used the intervention only once, whereas in the NEON-O trial, 19.45% (199/1023) of the participants used the intervention only once. Lengths of >400

days were merged to prevent participant identifiability. The lengths of intervention use for the first 30 days are shown in Figure S2 in Multimedia Appendix 5, with participants who only used the intervention once ("single-use participants") removed to show only nonzero time lengths.

Tables 5 and 6 show the number of narrative rating values that each question received for ratings from NEON trial participants.

Tables 7 and 8 show the number of narrative rating values that each question received for ratings from NEON-O trial participants.

Table 4. Number of narrative requests via the content-based filtering internal access route, collaborative filtering internal access route, and all other internal access routes.

	NEON ^a	NEON-O ^b
Participants, n (%)	739 (100)	1023 (100)
Participants who requested at least one narrative	365 (49.4)	562 (54.9)
Participants who requested and rated at least one narrative	284 (38.4)	409 (40)
Narratives at the start of the trial, n (%)	348 (100)	348 (100)
Narratives at the end of the trial, n (%)	657 (100)	657 (100)
Narratives given at least one rating	375 (57.1)	366 (55.7)
Narrative requests, n (%)	3762 (100)	3548 (100)

Objective 2: Evaluate the NarraGive Recommender System

Overview

The best results (per metric per trial) are italicized. Where 2 values are equal, neither was better than the other.

For rating sets, better means that all 6 values (across both trials) were better than the 2 corresponding values for the other 2 rating sets, with *N/A* if no rating set was better.

For algorithms, we identified the filtering approach that was better (if any), comparing the content-based and collaborative subsystems of NarraGive per rating set across both trials. Specifically, if the kNN value was better than both SVD and SVD++ values, then we identified content-based filtering as better. If both SVD and SVD++ values were better than the

kNN value, then we identified collaborative filtering as better. If neither the kNN nor SVD and SVD++ was better than the other, then the value was calculated per trial.

For trials, better means that each of the 9 values was better than the corresponding value in the other trial, with *N/A* if neither trial was better.

Prediction Accuracy

Tables 9 and 10 show the NMAE of the kNN, SVD, and SVD++ algorithms when trained and tested on the hopefulness, similarity to the narrator, and similarity to the narrative ratings using NEON and NEON-O trial data, respectively.

For NMAE, better means lower.

Hopefulness was the better rating set, collaborative filtering was the better approach, and NEON-O was the better trial.

Table 9. Normalized mean average error (NMAE; using Narrative Experiences Online [NEON] trial data).

NMAE (NEON trial)	Hopefulness, median (IQR)	Similarity to the narrator, median (IQR)	Similarity to the narrative, median (IQR)
kNN ^a	0.686 (0.670-0.703)	1.070 (1.059-1.077)	1.150 (1.140-1.153)
SVD ^b	0.650 (0.638-0.664)	1.043 (1.035-1.047)	1.098 (1.076-1.121)
SVD++	<i>0.646 (0.639-0.654)</i> ^c	1.044 (1.038-1.049)	1.099 (1.080-1.120)

MAE Over Time

Multimedia Appendix 6 shows how the median NMAE values changed over time (with an interval of 1 month) for the kNN, SVD, and SVD++ algorithms using “Hopefulness” ratings from NEON trial participants.

Figure 1 shows that the 2 collaborative filtering algorithms were more accurate than the content-based filtering algorithm. As the number of ratings increases (and the IQR decreases), the NMAE stabilizes, which happens for all 3 algorithms at approximately 2000 ratings.

Figure 1. Comparison of the accuracy of the k-nearest neighbor (kNN), singular value decomposition (SVD), and SVD++ algorithms over time. NMAE: normalized mean absolute error.

Other Results

Further analysis of the coverage metric showed that certain narratives were not routinely recommended by NarraGive, as described in [Multimedia Appendix 7](#).

Discussion

Principal Findings

Overview

For the NEON trial, the content-based filtering algorithm performed better for coverage; the collaborative filtering algorithms performed better for accuracy, diversity, and unfairness across both gender and ethnicity; and neither algorithm performed better for precision. For the NEON-O trial, the content-based filtering algorithm did not perform better on any metric; the collaborative filtering algorithms performed better on accuracy and unfairness across both gender and ethnicity; and neither algorithm performed better for precision,

diversity, or coverage. These findings provide preliminary evidence to inform future implementations.

Table 21 shows, for each metric, the filtering method that was better overall (per trial), the filtering method for the best result (per trial), and the trial in which all 9 values were better than those of the other trial. *N/A* indicates that neither trial nor filtering method was better overall. The table also indicates whether the metric was feature based or prediction based.

These results suggest that clinical population may be associated with recommender system performance. The content-based filtering algorithm had the best performance on feature-based metrics, suggesting that collaborative filtering methods may be associated with producing more accurate predictions whereas content-based filtering methods may be associated with recommending a wider range of items.

A low number of ratings for an item (or having only low ratings) can substantially influence how (or *if*) that item is recommended to other participants, as demonstrated by the 3 unrecommendable narratives in NarraGive.

Table 21. Summary of NarraGive evaluation metrics.

Metric	Prediction based or feature based	Better filtering method		Filtering method of best value		Better trial
		NEON ^a	NEON-O ^b	NEON	NEON-O	
NMAE ^c	Prediction	Collaborative	Collaborative	Collaborative	Collaborative	NEON-O
Precision	Prediction	N/A ^d	N/A	Collaborative	Content	NEON
ILD ^e	Feature	Collaborative	N/A	Collaborative	Content	NEON-O
ISC ^f	Feature	Content	N/A	Content	Content	NEON-O
Unfairness (gender)	Prediction	Collaborative	Collaborative	Collaborative	Collaborative	N/A
Unfairness (ethnicity)	Prediction	Collaborative	Collaborative	Collaborative	Collaborative	N/A

^aNEON: Narrative Experiences Online.

^bNEON-O: Narrative Experiences Online for other (eg, nonpsychosis) mental health problems trial.

^cNMAE: normalized mean absolute error.

^dN/A: not applicable.

^eILD: intralist diversity.

^fISC: item space coverage.

Unrecommendable Narratives

Each trial comprised between 1 and 3 ratings for each narrative. This preliminary evaluation only used data from NEON and NEON-O participants (to mirror the data used in the metrics). No rating given by a NEON or NEON-O participant was the highest, and only 1 rating had the optional questions answered (and none of these values were the highest value). The low number of ratings and the low scores given could contribute to the unrecommendableness of these narratives.

NarraGive, and recommender systems in general, often requires that there is a minimum amount of information about a participant or an item before being able to produce recommendations for or about them. In this case, due to

SurPRISE's implementation of recommender system algorithms, the kNN, SVD, and SVD++ algorithms require at least one rating for an item for it to be recommended and at least one rating by a participant for them to be recommended a narrative (to the extent that the recommender system never sees these unrated items and nonrating participants as they are filtered out before being passed to the recommender system).

This means that newly added narratives cannot be recommended immediately—they need at least one participant to access the narrative through another method (such as browsing to it) and then rate it. Consequently, there are other unrecommendable narratives (where unrecommendable in this case means that the recommender system does not have *access* to it in the first place rather than having access to it but not producing it as a

recommendation for any participant). This is known as the *cold start problem*.

Interpretation of Metrics

In the context of NarraGive, diversity is not necessarily better or worse. An earlier substudy of the NEON study showed that there is unlikely to be a universally hopeful narrative [29], so a skew in recommended narratives is not necessarily a flaw.

Similarly, having greater coverage (ie, being able to recommend a greater proportion of available narratives) may not be useful if some narratives are only hope inspiring for a very small subset of participants.

The 2 unfairness metrics (unfairness across participants based on ethnicity and gender) capture 2 types of unfairness but not all. A previous NEON study [29] identified 7 harm minimization strategies for the NEON intervention, which provided the basis for the unfairness metric (ie, that being recommended narratives with a predicted rating that is higher than the resulting rating may be harmful). However, other types of unfairness, such as those based on disability, were not explored.

Relationship to Prior Work

Recommender Systems for Nonnarrative Texts

Several book recommendation systems exist [59-61], but the focus has mostly been on novellike books rather than on health narratives or recovery narratives. In addition, many health recommender systems exist or have been proposed [62-72], but the focus has largely been on physical health and behavior changes rather than on providing desired content, such as enjoyable, useful, or hope-inspiring recovery narratives.

Dimensionality Reduction

The per-trial values for ILD were very similar. One explanation for this is a known phenomenon called the curse of dimensionality, where the increase in the number of dimensions (where the number of INCREASE characteristics represents the number of dimensions) causes a rapid increase in the “volume” that samples can occupy, which increases the data sparsity exponentially [73]. This increase in dimensionality produces effects such as the concentration of measure [74], where distance values converge and the difference between the furthest and the nearest point tends toward 0 [75], effectively making distance-based similarity comparisons meaningless. High-dimensionality problems can occur with as few as 10 dimensions [75], making the 77-item INCREASE measure susceptible to these issues. This may explain why the results for ILD are so similar—they are based on cosine distance. Other distance measures such as the Euclidean distance and correlation are also susceptible to this challenge [73].

One solution is to reduce the dimensionality of the characteristics before analysis through dimension reduction techniques [75] such as principal component analysis or matrix factorization, which retain as much of the original meaning of the data as possible while reducing the number of dimensions to a practical number.

Strengths and Limitations

There are several strengths to this study. First, the NEON and NEON-O trials produced a unique data set of participant ratings, comprising ratings from both mental health service users and non-service users. This data set was suitable for analysis over time and for comparison of content-based and collaborative filtering algorithms.

Second, the numerous narrative request routes helped prevent exposure bias, and requiring a rating for each narrative helped prevent selection bias.

There are also some limitations to this study. This analysis did not consider individual participants’ rating patterns. Further analysis could add participant and item biases, which take into account items’ and participants’ average ratings to find the *deviation* from this average [76], or weight high-data participants (who have provided many ratings) as more informative than low-data participants.

The decision to include “no change” in hopefulness as an indicator of relevance was made to distinguish from actively hope-reducing narratives, but an alternative approach would be to only include those narratives rated as “a bit more hopeful” or “much more hopeful.”

The unfairness across participants metric (overestimation of unfairness) was based on the assumption that overestimated narratives are more likely to be harmful, but it is possible that a participant could rate a narrative highly and still find it harmful and, similarly, rate a narrative as lower than predicted but not find it harmful. The unfairness metrics also did not cover all aspects of unfairness.

Finally, this study is the first evaluation of a recommender system application to lived experience narratives. This is a complex area involving both technical challenges such as the choice of algorithm and ethical challenges such as managing narratives with respect and not just as another form of data. This complexity means that there are no existing standards against which NarraGive can be currently judged, and hence, the comprehensive evaluation presented in this study is primarily intended to be formative for the field rather than evaluative of NarraGive.

Recommendations

There are 6 recommendations for researchers, intervention developers, recommender system developers, and health care professionals.

First, recommender systems with a focus on providing the greatest variety and widest range of content may benefit from using a content-based kNN algorithm, whereas recommender systems with a focus on predicting participants’ ratings most accurately may benefit more from the SVD or SVD++ algorithm. Recommender systems with a focus on both should implement a hybrid model with suitably weighted filtering algorithms.

Second, health care professionals should be aware of the unrecommendability of some items and not rely on recommendations to cover the entire search space.

Third, researchers and intervention developers should carefully decide which feature of the recommender system (ie, variety or accuracy) is most important and optimize the recommender system for a specific feature. Depending on what aspect of a recommender system is most important, different methods exist for optimizing for a specific metric, such as for diversity [43] and unfairness [46].

Fourth, platforms containing a recommender system should include other item access mechanisms (such as being able to browse through items) to prevent feedback loops where participants can only rate items that already have many high ratings while unrated items remain unrated and unrecommended [28]. This helps reduce the number of inaccessible narratives (because if the recommender system is the only access route, any unrecommendable narratives will be entirely inaccessible to participants), and developers could include a “random” access route (in addition to the recommender system access route) that is weighted toward these inaccessible narratives.

Fifth, recommender system developers should actively encourage the rating of new items, such as by suggesting them to participants or having a random button that is weighted toward new narratives. Alternatively, the narratives could be given an initial set of ratings before being published.

Sixth, initial studies should be conducted on proposed recommender systems to find the number of ratings required for the accuracy to stabilize; for NarraGive, this was approximately 2000 ratings. Because clinical population may be associated with recommender system performance, initial

studies should also be used to inform clinical population selection.

Implications for Future Work

Key future questions include whether a single or hybrid recommender system is optimal, a wider consideration of available algorithms and clarification of the rationale for selection, the rationale and timing of training and retraining the algorithm, and the identification of the most important metrics through which algorithmic performance should be evaluated.

For example, future studies investigating the use of recommender systems for recommending narratives could incorporate the similarity between participants and *narratives* by training filtering algorithms to recommend narratives with narrators that are either similar to or different from participants depending on (either implicit or explicit) participant preference.

Conclusions

Clinical population may be associated with recommender system performance. The collaborative filtering algorithms were more accurate and less unfair than the content-based filtering algorithm. Recommender systems are susceptible to a wide range of biases, and it is important to mitigate these by providing enough data for the recommender system to start with (to prevent overfitting), ensuring that there are other ways of accessing items besides through the recommender system (to prevent a feedback loop between accessed items and recommended items), and encouraging participants to provide feedback on every item they interact with (to prevent participants from only providing feedback when they have strong opinions).

Acknowledgments

This study was funded by the National Institute for Health and Care Research (NIHR; personal experience as a recovery resource in psychosis: Narrative Experiences Online Programme [RP-PG-0615-20016]). Abstract

Background: Health care providers and health-related researchers face significant challenges when applying sentiment analysis tools to health-related free-text survey data. Most state-of-the-art applications were developed in domains such as social media, and their performance in the health care context remains relatively unknown. Moreover, existing studies indicate that these tools often lack accuracy and produce inconsistent results.

Objective: This study aims to address the lack of comparative analysis on sentiment analysis tools applied to health-related free-text survey data in the context of COVID-19. The objective was to automatically predict sentence sentiment for 2 independent COVID-19 survey data sets from the National Institutes of Health and Stanford University.

Methods: Gold standard labels were created for a subset of each data set using a panel of human raters. We compared 8 state-of-the-art sentiment analysis tools on both data sets to evaluate variability and disagreement across tools. In addition, few-shot learning was explored by fine-tuning Open Pre-Trained Transformers (OPT; a large language model [LLM] with publicly available weights) using a small annotated subset and zero-shot learning using ChatGPT (an LLM without available weights).

Results: The comparison of sentiment analysis tools revealed high variability and disagreement across the evaluated tools when applied to health-related survey data. OPT and ChatGPT demonstrated superior performance, outperforming all other sentiment analysis tools. Moreover, ChatGPT outperformed OPT, exhibited higher accuracy by 6% and higher *F*-measure by 4% to 7%.

Conclusions: This study demonstrates the effectiveness of LLMs, particularly the few-shot learning and zero-shot learning approaches, in the sentiment analysis of health-related survey data. These results have implications for saving human labor and improving efficiency in sentiment analysis tasks, contributing to advancements in the field of automated sentiment analysis.

Introduction

Background

Sentiment analysis is a field within natural language processing (NLP) that aims to extract sentiments and opinions from text related to specific entities and topics [1], such as people, organizations, events, and places [2]. Specifically, we consider the task of classifying texts as positive, neutral, or negative. Research in this area can occur at different levels of granularity, ranging from a single sentiment for an entire document or for each sentence within it to exploring various aspects associated with each entity, which can be associated with different sentiments [1,3].

Recently, we have witnessed an increase in the use of sentiment analysis to computationally evaluate the attitudes, perceptions, and emotions of social media users regarding the COVID-19 pandemic [4,5]. Most of these works study content from social media platforms such as Twitter, Reddit, and Facebook [6], as social media has been a main platform to express opinions related to COVID-19 in a public manner. Simultaneously, surveys, which refer to data collected from a group of people regarding their opinions, behavior, or knowledge through specifically designed questions, have also been used to investigate the impact of the COVID-19 pandemic. In particular, surveys conducted during the lockdown period in 2020 examined the effects on people's lives, behaviors, and mental health, among other topics [7-9]. Web-based surveys are often semistructured, that is, composed of closed-answer components (eg, different clinical questionnaires) and open-ended questions that allow a free-text answer. Sentiment analysis tools have been applied to the latter to help monitor the attitudes, sentiments, and perceptions of the participants during the pandemic to assist health decision-making [10].

The application of sentiment analysis tools on free-text data obtained from surveys poses challenges for health care providers and researchers in the health domain. This is partly attributed to the fact that most state-of-the-art applications are designed for different domains, such as social media, and there is limited knowledge regarding their performance in survey data. In addition, recent studies have applied the most well-known sentiment analysis tools, including TextBlob [11], VADER (Valence Aware Dictionary and Sentiment Reasoner) [12], and Stanza [13], to analyze health-related content on social media platforms [14-16] and, more recently, in the context of COVID-19 [6,17]. These studies highlighted the need for a more comprehensive evaluation of sentiment analysis tools, as the initial results exhibited a lack of accuracy and yielded inconsistent outcomes [15,16]. The main reason for this discrepancy was the disparity in data sets and the potential sensitivity of the tools to the composition of the data set [16]. Consequently, researchers trained new algorithms tailored to their specific data set.

Two COVID-19 survey data sets were used in this study, both collected by teams from the National Institutes of Health (NIH) and Stanford University. The collected data were used to assess the general topics experienced by the participants during the pandemic lockdown.

Researchers from both institutions aimed to comprehend the general sentiment patterns over time and identify an overall sentiment for events during that period, such as vaccines and the 2020 presidential elections. In both data sets, it was often the case that a complete response contained multiple topics, with many sentences referring to distinct subjects. Thus, this study is focused on the analysis of sentiment at the sentence level. By assessing each sentence independently, subtle shifts in sentiment could be captured, which could potentially be neglected at the document level. Moreover, we thought that an analysis based on sentence level, rather than aspect-based level, was more appropriate, given that our focus was not on the granularity of the various aspects of an entity. For instance, when evaluating different features of an intensive care unit, aspects might encompass ventilators, rooms, staff, nurses, and others. Therefore, the decision to focus on sentence-level sentiment analysis is influenced by practical considerations, our research objectives, and the nature of the survey responses.

In this study, as the first contribution, we analyzed 2 independent survey data sets containing free-text data collected during the lockdown period of the COVID-19 pandemic, with accompanying ground-truth sentiment labels generated by human raters for hundreds of responses. The second contribution involves a comparison of 8 widely used state-of-the-art sentiment analysis tools, which have been frequently and recently used in the health domain [16], on COVID-19 surveys at the sentence level. We demonstrate that performance across tools varies and that there is a complex correlation structure between their predicted polarity scores. The third contribution of this paper is to investigate whether the polarity prediction performance can be improved through few-shot learning on a small labeled data set or zero-shot learning with ChatGPT [18].

Related Work

There are 2 main approaches to performing sentiment analysis: lexicon based and machine learning based. Initial lexicon methods are the simplest rule-based methods and seek to classify the sentiment of a sentence as a score function of the word polarities existing in a dictionary [19-23]. Lexicon-based techniques use mostly adjectives and adverbs to compute the overall sentiment score of a text, for instance, Linguistic Inquiry and Word Count (LIWC) [24], Affective Norms for English Words [25], and SentiWordNet [26]. Dictionaries of lexicons are created either manually or automatically [27,28]. First, a list is generated from a specific domain. Then synonyms and antonyms are added from other existing dictionaries such as WordNet [29]. More sophisticated lexicon-based methods focus on complex rules, such as regular expressions [30,31], instead of simply computing a sentiment score based on word polarities.

Machine learning-based techniques use statistical methods to compute sentiment polarity. The process involves training a classifier on a labeled data set, such as movie reviews or social media posts, and then using the model to predict the sentiment of new, unlabeled data. Obtaining labeled data to train the classifiers is a time-consuming task. Machine learning-based methods often face challenges when processing negative and intensifying statements and can have low performance when applied to different domains, as they rely mainly on the data set

size. The rules proposed in the lexicon-based approaches have also been used to extract relevant features and used as input to machine learning algorithms (eg, naive Bayes, k -nearest neighbors, decision tree, and logistic regression) to predict the sentiment [32-37]. Other machine learning methods are based on deep neural networks (DNNs). DNNs have been successfully used for sentiment analysis, as described in detail by Birjali et al [3], Zhang et al [38], and Yadav and Vishwakarma [39], having achieved state-of-the-art performance on several benchmarks. DNN architectures used include recurrent neural networks [40,41], long short-term memory networks [42,43], and convolutional neural networks [44-46].

More recently, transformers [47] (deep learning architectures) and large language models (LLMs) have gained popularity due to their ability to perform NLP tasks, including sentiment analysis, with remarkable performance. These LLMs have been pretrained on large text corpora using transformers, such as Bidirectional Encoder Representations from Transformers (BERT) [48], Robustly optimized BERT approach (RoBERTa) [49], Embeddings from Language Models (ELMo) [50], Generative Pre-trained Transformers (GPT) [51], and Pathways Language Model (PaLM) [52]. LLMs in sentiment analysis can handle several data types and domains as well as identify patterns and relationships between the semantics of words and phrases that are indicative of sentiment. LLMs for sentiment analysis can also be fine-tuned to specific domains and applications, which usually lead to better results, as shown in previous studies [53-59]. Finally, ChatGPT (OpenAI) [18] has suddenly emerged to produce human-like responses to user inputs. The notable performance of LLMs has led to increased interest in few-shot and zero-shot learning methods using them. Few-shot learning algorithms enable a model to learn from only a few examples, whereas zero-shot learning algorithms can transfer knowledge from one task to another without additional labeled training examples. These approaches have demonstrated comparable or superior performance to prior state-of-the-art fine-tuning methods on various NLP tasks [60-62].

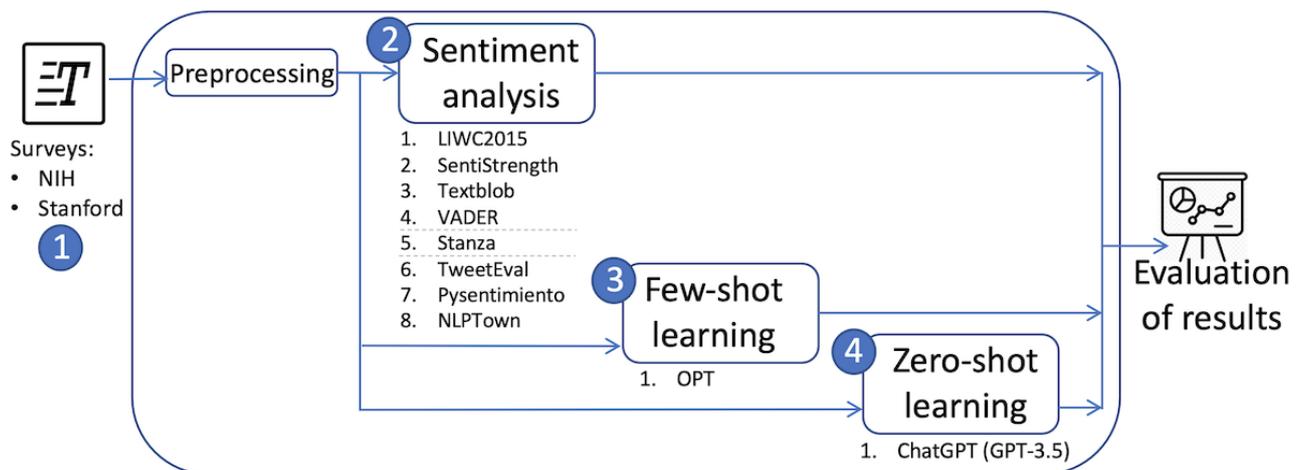

Sentiment analysis has become an increasingly popular technique in the health domain, as noted in the study by Rodríguez-Ibáñez et al [63]. A recent study [64] also found that the main data source for studies on health is social media, such as Twitter and Facebook. This is attributed to advancements in mobile technology and their use as a source in health-related topics, such as finding treatments, sharing experiences and opinions, and addressing public health surveillance issues [65-67]. During the pandemic, we witnessed social media becoming the main forum to express opinions related to COVID-19, which helped authorities to understand and monitor sentiments toward topics related to the pandemic [68-73].

Various studies have proposed new sentiment analysis methods and compared existing tools (eg, TextBlob [74], VADER [12], and Stanza [13]) on topics related to COVID-19, mainly extracted from social media [6,16,17,75-78]. However, to the best of our knowledge, there are no studies that have compared several sentiment analysis tools on health-related surveys—a more structured type of text data than social media posts—that collected knowledge, beliefs, and habits during the COVID-19 pandemic [79-84]. The only study we are aware of that evaluates ChatGPT on various sentiment analysis tasks, comparing it with fine-tuned BERT, is the study by Wang et al [85]. The results demonstrated that ChatGPT exhibited promising zero-shot sentiment analysis ability, achieving performance on par with fine-tuned BERT and state-of-the-art models. However, it fell slightly behind domain-specific fully supervised state-of-the-art models.

Methods

This section presents the data sets used in this study along with our evaluation of sentence sentiment analysis methods, as illustrated in Figure 1. Specifically, we describe the (1) survey data sets, (2) state-of-the-art sentiment analysis tools, (3) few-shot learning with an LLM, and (4) zero-shot learning with ChatGPT.

Figure 1. Workflow of our study for evaluating sentence sentiment analysis using state-of-the-art sentiment analysis tools, few-shot learning with a large language model, and zero-shot learning with ChatGPT over health-related surveys. GPT: Generative Pre-trained Transformers; LIWC2015: Linguistic Inquiry and Word Count 2015; NIH: National Institutes of Health; OPT: Open Pre-Training Transformers; VADER: Valence Aware Dictionary and Sentiment Reasoner.

Data

NIH Data Set

This data set was collected as part of a web-based survey assessing mental health during the pandemic, which started from April 2020 to May 2021. This was a sample of convenience, as participants were recruited from a pool of previous participants in the National Institute of Mental Health and National Center for Complementary and Alternative Medicine studies by advertising on social media and by flyers within the Washington metropolitan area. Participants who signed up completed various questionnaires at baseline, assessing demographics, clinical history, and psychological state [86]. The participants were then sent emails every 2 weeks for 6 months, inviting them to complete 3 of those questionnaires at that time. This latter survey consisted of 45 questions assessing various attitudes, behaviors, and impacts surrounding the pandemic and a single free-response question (“Is there anything else you would like to tell us that might be important that we did not ask about?”). There was a maximum of 13 potential survey (and free) responses per participant. Of the 3655 participants who enrolled in the study, 2497 (68.31%) responded at least once to the free-response item, yielding a total of 9738 item responses. These were composed of 26,411 sentences, which were the data used in this study. The semantic

content of these responses (eg, main topics of concern over time) is available in the study by Weger et al [87].

Stanford Data Set

This data set was collected as part of a web-based survey conducted from March to September 2020 by a Stanford University team. The survey was conducted using a sample of convenience recruited through 3 social media platforms: Twitter, Facebook, and Nextdoor. They could participate by clicking on a survey link in the social media post upon seeing the recruitment materials. The survey comprised 21 questions including demographics and the impact of COVID-19 on individuals’ lives [88]. In this study, we focus on the evaluation of 3 free-text responses to the following questions: (1) “Although this is a challenging time, can you tell us about any positive effects or ‘silver linings’ you have experienced during this crisis?” (2) “What are the reasons you are not self-isolating more?” and (3) “Have you experienced any difficulties due to the coronavirus crisis?” Of the 4582 participants recruited, 3349 (73.09%) responded to at least 1 of the 3 free-text questions, resulting in a total of 7182 item responses. These were composed of approximately 21,266 sentences, which were the data used in this study. The topics and sentiments in these responses are reported in the study by Lossio-Ventura et al [10]. Table 1 presents additional details regarding the NIH and Stanford data sets.

Table 1. Details of the National Institutes of Health (NIH) and Stanford data sets.

	NIH	Stanford
Start of the collection period	April 2020	March 2020
End of the collection period	May 2021	September 2020
Responders, n/N (%)	2497/3655 (68.31)	3349/4582 (73.09)
Response items, n	9738	7182
Sentences before processing, n	26,411	21,266
Sentences after processing, n/N (%)	26,188/26,411 (99.16)	21,035/21,266 (98.91)
Tokens after processing, n	462,518	299,735
Tokens per sentence, mean (SD)	17.66 (11.11)	14.25 (9.74)

Annotation

We created training and test sets for both the NIH and Stanford data sets. These sets were derived from the surveys after completing the preprocessing steps and were used for training, tuning, and the official evaluation.

Training Data Set

We randomly selected 260 sentences, with 130 sentences from each data set. Each subset of 130 sentences was annotated by a different annotator. The annotators were instructed to assign a polarity value of -1 (negative), 0 (neutral), or 1 (positive) to each sentence.

Test Data Set

A total of 1000 sentences were randomly chosen, with 500 sentences selected from each data set [89]. Each set was annotated by 3 separate and independent annotators: A.1, A.2, and A.3 for NIH and A.4, A.5, and A.6 for Stanford. The

annotators were instructed to assess the polarity of each sentence on a scale of -1 (negative), 0 (neutral), or 1 (positive).

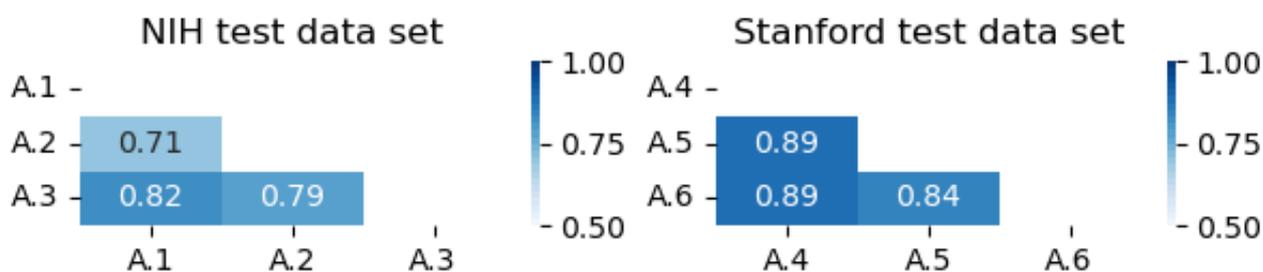

We used a 3-point scale to annotate the data. We then followed a 3-step procedure to determine the final labels, similar to that described in the studies by Nakov et al [90] and Rosenthal et al [91]. First, if all 3 annotators agreed on a label (full agreement), that label was accepted. Second, if 2 of the 3 agreed on a label (partial agreement), that label was also accepted. Third, if there was no agreement, the label was set as neutral (no agreement). Fleiss κ measure was calculated to assess the agreement between the 3 annotators of each test data set. The associated P values were computed to test if the agreement between annotators was substantially better than what would be expected by chance. Further details of the training and test data sets are provided in Table 2. Pearson correlation coefficients were also calculated to evaluate the degree of agreement between each pair of annotators, as shown in Figure 2.

Table 2. Details of the National Institutes of Health (NIH) and Stanford data sets.

	Training (n=130)		Test (n=500)	
	NIH	Stanford	NIH	Stanford
Sentences, n (%)	130 (100)	130 (100)	500 (100)	500 (100)
Negative sentences, n (%)	71 (54.6)	45 (34.6)	223 (44.6)	234 (46.8)
Neutral sentences, n (%)	51 (39.2)	41 (31.6)	232 (46.4)	117 (23.4)
Positive sentences, n (%)	8 (6.2)	44 (33.8)	45 (9)	149 (29.8)
Full agreement, n (%)	N/A ^a	N/A	340 (68)	385 (77)
Partial agreement, n (%)	N/A	N/A	159 (31.8)	112 (22.4)
No agreement, n (%)	N/A	N/A	1 (0.2)	3 (0.6)
Fleiss κ	N/A	N/A	0.6311	0.7572
P value	N/A	N/A	<.001	<.001

^aN/A: not applicable.

Figure 2. Correlation of annotators on the National Institutes of Health (NIH) and Stanford test data sets. A.1, A.2, A.3 represent the 3 independent NIH annotators, while A.4, A.5, A.6 represent the Stanford annotators.

Preprocessing

The survey responses contained personal identifiable information and multiple sentences covering different themes, for example, 2020 presidential elections and COVID-19 vaccines. Therefore, preprocessing steps included splitting responses into sentences, replacing people’s names, suppressing email addresses, and lemmatizing and converting text to lower case.

Sentiment Analysis Applications

We considered popular sentiment analysis applications available on the internet that use rules, machine learning, and fine-tuned LLMs.

Linguistic Inquiry and Word Count 2015

Linguistic Inquiry and Word Count 2015 (LIWC2015) [24,92,93] is a text analysis software that identifies and calculates the frequency of different categories of words in texts, such as pronouns, emotional words, cognitive words, and social words. LIWC2015 seeks to group words into categories that can be used to analyze psycholinguistic features in texts. Researchers in various fields, including psychology, sociology, and computer science, have used LIWC2015 to study a wide range of topics, such as personality, emotional expression, deception, and social interaction. LIWC2015 has also been used in various relevant studies on sentiment analysis. It provides with a summary variable “Tone” that combines positive and negative dimensions (*posemo* and *negemo*) into a single one.

The higher the tone, the more positive it is. The tone ranges from 0 to 100. Numbers <50 indicate a more negative emotional tone. The default LIWC2015 Dictionary contains approximately 6400 words, word stems, and select emoticons.

SentiStrength

SentiStrength is a sentiment analysis tool that assigns scores to words and phrases based on their positive or negative sentiment [94-96]. It calculates an overall sentiment score for the text by combining these individual scores. This tool can provide dual-, binary-, trinary-, or single-scale results. In this study, a single scale ranging from -4 (extremely negative) to 4 (extremely positive) was chosen, with 0 indicating neutral sentiment. SentiStrength uses linguistic and lexicon-based methods. Linguistic methods involve rules and heuristics for identifying sentiment-bearing words and phrases, including cues such as repeated punctuation, emoticons, negations, and capital letters. The lexicon used consists of 2546 terms associated with polarity and intensity. Part of the lexicon was added from General Inquirer, including word roots such as “extrem*” to recognize variants. Training data sets included posts from various platforms such as BBC Forum, Twitter, YouTube, Digg.com, MySpace, and Runners World.

TextBlob

TextBlob is a Python library used in NLP tasks [11,74], such as part-of-speech tagging, sentiment analysis, and noun phrase extraction. TextBlob outputs a polarity score ranging from -1 to 1. A negative score signifies a negative sentiment, a positive

score indicates a positive sentiment, and a score of 0 represents a neutral sentiment. TextBlob includes 2 analysis approaches: a rule-based model and a supervised machine learning naïve Bayes classifier model.

VADER

VADER [12,97] is a rule-based model designed for analyzing sentiment in social media text. It uses 5 rules based on grammatical and syntactical patterns to determine sentiment intensity. These rules involve punctuation, capitalization, degree modifiers, conjunctions such as “but,” and trigram evaluation to identify negations that can affect polarity. VADER was developed and validated using a gold standard list of lexical features, including LIWC, General Inquirer, and Affective Norms for English Words. The model was trained on various data sets, including tweets, New York Times opinions, movie reviews, and Amazon product reviews.

Stanza

Stanza is an open-source Python library that provides several methods for performing NLP tasks [13,98], including part-of-speech tagging, named entity recognition, dependency parsing, and sentiment analysis. Stanza’s sentiment analysis module assigns a positive, negative, or neutral sentiment score (0, 1, or 2, respectively) to each sentence in a given text. Stanza’s sentiment analysis tool is based on a convolutional neural network model using the vectors trained by Mikolov et al [99] on 100 billion words from Google News as well as a combination of lexical and syntactic features. It was trained on large data sets including movie reviews and the Stanford Sentiment Treebank. Unlike other methods, Stanza includes preprocessing of its own (sentence splitter and tokenizer).

TweetEval

TweetEval is a benchmarking platform for Twitter-specific classification tasks [100]. TweetEval consists of 7 NLP tasks: irony detection, offensive language detection, emoji prediction, emotion recognition, hate speech detection, stance detection, and sentiment analysis. Using TweetEval, a common set of evaluation metrics and data set, researchers and practitioners can compare the performance of different models on the same tasks and identify the most effective models for different NLP applications. TweetEval provides a leaderboard for ranking the performance of different models on the sentiment analysis task. The leaderboard is based on the F₁-score. TweetEval returns 3 labels (positive, negative, and neutral) associated with a weight. TweetEval sentiment analysis is based on the RoBERTa model, an LLM based on BERT (trained on 58M tweets), and fine-tuned on the SemEval 2017 sentiment analysis data set (approximately 40,000 tweets) [91].

Pysentimiento

Pysentimiento is an open-source Python library that includes models for sentiment analysis and social NLP tasks, such as hate speech detection, irony detection, emotion analysis, named entity recognition, and part-of-speech tagging, in several languages such as English, Spanish, Portuguese, and Italian [101,102]. The English model for sentiment analysis is based on BERTweet [103], a RoBERTa model, trained on English

tweets and also fine-tuned on the SemEval 2017 sentiment analysis data set [91]. Pysentimiento returns 3 polarity labels per text associated with a weight.

NLPTown

NLPTown [104] is a sentiment analysis application based on a BERT-base-multilingual-uncased model, fine-tuned for sentiment analysis on product reviews for 6 languages (English, Dutch, German, French, Spanish, and Italian), and predicts the sentiment of the review as the number of stars (1-5).

Few-Shot Learning With Open Pre-Trained Transformers Language Models

As mentioned previously, few-shot learning seeks to address the challenge of sentiment analysis when only a small amount of labeled data is available for training. In traditional supervised learning, models are trained on large data sets with many labeled examples. However, in some applications such as sentiment analysis, labeled survey data are scarce or expensive to obtain, making it difficult to train accurate models. In this study, we used the Open Pre-Trained Transformers (OPT) [105], a suite of decoder-only pre-trained transformers ranging from 125M to 175B parameters created by Meta AI. OPT has been used in several applications but has never been applied to sentiment analysis. This model has shown to perform similarly to the GPT-3 [60] on several NLP tasks. The OPT model was built using a data set of 180B tokens. This represents approximately 23% (180B/780B) of the amount of data set tokens used for the Pathways Language Model [52]. The largest OPT model has comparable number of parameters to GPT-3 (175B parameters) [60], although we used all models except for the latter given graphics processing unit limitations. The novelty of OPT is its availability as open source (albeit only for academic research).

Zero-Shot Learning With ChatGPT

Zero-shot learning refers to the use of a model to perform a task for which it has not been explicitly trained. Thus, zero-shot learning for sentiment analysis recognizes and classifies sentiment in text without being explicitly provided with examples of sentiment labels. Instead, the model is trained on related tasks, such as language modeling or machine translation, which enables it to understand the underlying structure of the language and the context in which it is used. In this study, we used ChatGPT (based on GPT-3.5), which has significantly improved the performance of several NLP tasks. GPT-3.5 is a model with 175B parameters created by OpenAI and trained on a vast amount of text data sourced from the internet using both reinforcement and supervised learning techniques. For this paper, we generated a polarity score for each sentence x by asking ChatGPT “What is the sentiment of the following sentence ‘ x .’”

Ethical Considerations

The NIH survey was approved by the Institutional Review Board of the NIH (reference number 20MN085), and all participants provided consent for the study. The Stanford survey was approved by Stanford’s Institutional Review Board (reference number 55436), and all participants provided consent for the study.

All survey data and responses in both the NIH and the Stanford data sets were anonymized and associated with a unique ID. Participants from both studies were not compensated for participating in the surveys.

Results

Evaluation Metrics

To assess the overall performance of the sentiment analysis tools, we evaluated the accuracy, macro *F*-measure, macro precision, and macro recall. Macro evaluation metrics were recommended in the NLP competition SemEval-2017 Task 4 [91].

Preparation of Applications for Evaluation

Harmonization of Applications' Outputs

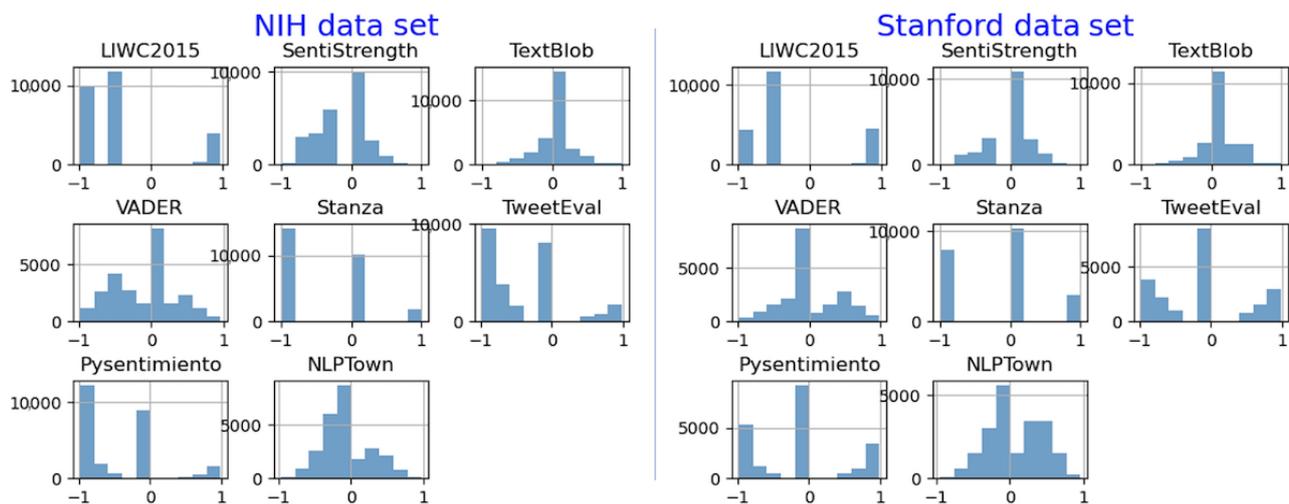

The LIWC2015, Stanza, and SentiStrength applications produce outputs that are measured on distinct scales. LIWC2015

generates a continuous value ranging from 0 to 100; SentiStrength generates an integer score ranging from -4 to 4; and Stanza produces a discrete whole number score of 0, 1, or 2, which correspond to negative, neutral, and positive sentiments, respectively. Therefore, it is necessary to convert these scores to a common range of [-1, 1], as formally defined in equation 1.

$$\text{score}'(x) = 2 \times (\text{score}[x] - \text{score}[x]_{\min}) / (\text{score}[x]_{\max} - \text{score}[x]_{\min}) - 1 \quad (1)$$

The distribution of sentiment scores across all tools is shown in Figure 3. We then classify all negative values as negative sentiment, all 0 values as neutral, and all positive values as positive sentiment. It is important to note that the VADER application uses a slightly different classification approach, considering a score ≤ 0.05 to be negative, a score between -0.05 and 0.05 to be neutral, and a score ≥ 0.05 to be positive.

Figure 3. Distribution of sentiment scores across all applications on the National Institutes of Health (NIH) and Stanford data sets. LIWC2015: Linguistic Inquiry and Word Count 2015; VADER: Valence Aware Dictionary and Sentiment Reasoner.

Fine-Tuning for Few-Shot Learning

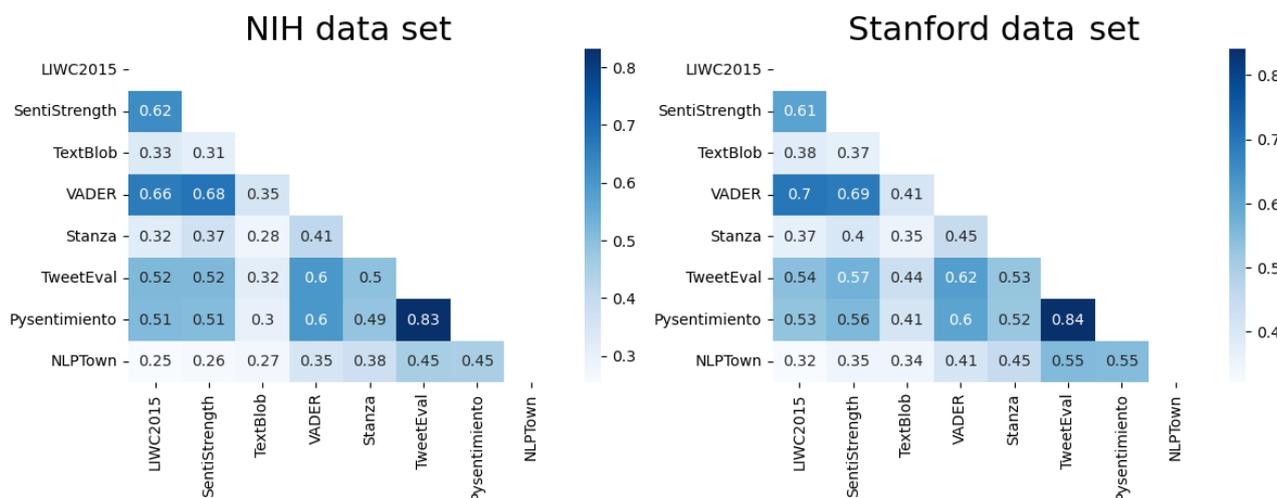

We used few-shot learning using our small amount of training data to fine-tune the OPT models, rather than training them from scratch. For this experiment, the training data set was split into 85% (110/130) for feeding the model and 15% (20/130) for validation. Given the memory constraints, we considered only OPT 125M, 350M, 1.3B, and 2.7B. We performed a hyperparameter search to optimize the performance of the model on sentiment analysis. We considered learning rate=[3×10^{-4} , 1×10^{-4} , 3×10^{-5} , and 1×10^{-5}], batch size=[4, 8, 16, and 32], number of epochs from 1 to 7, and the AdamW optimizer. The models that performed the best were OPT-1.3B and OPT-2.7B, using a learning rate of 1×10^{-5} , a batch size of 32, and 5 epochs.

These were the models used to obtain the test set results reported in next subsections.

Experiment 1: Correlation Between the Outputs of Applications

The objective was to evaluate the agreement level among various methods for predicting the sentiments of COVID-19 survey responses. Understanding the methods' agreement or divergence was crucial in determining the reliability and accuracy of predictions, allowing for accurate studies of the relationship between language use and mental health. The Pearson correlation coefficient was used to assess the reliability of the tools, as shown in Figure 4. Disagreement among the methods prompted us to evaluate few-shot learning to obtain high-quality predictions.

Figure 4. Pearson correlation matrix of score applications on the National Institutes of Health (NIH) and Stanford data sets. LIWC2015: Linguistic Inquiry and Word Count 2015; VADER: Valence Aware Dictionary and Sentiment Reasoner.

Experiment 2: Prediction of Sentiment Scores

Tables 3 and 4 show the performance results obtained by all applications, few-shot learning, and zero-shot learning techniques on the NIH and Stanford test data sets, respectively. Both test sets comprised 500 sentences each, as detailed in the Data section. The top 2 performance results are italicized. Of note, a perfect classifier that accurately categorizes all items obtains a value of 1, whereas a perverse classifier that misclassifies all items achieves a value of 0. However, a trivial classifier that assigns all sentences to the same category (positive, negative, or neutral) and a random classifier both have a value of 0.3333.

ChatGPT achieved a significant improvement in sentiment analysis compared with other models through zero-shot learning. On the NIH data set, ChatGPT outperformed few-shot learning (OPT-1.3B and OPT-2.7B) by 6% in accuracy and 7% in *F*-measure. Similarly, on the Stanford data set, ChatGPT showed better results than the OPT-1.3B and OPT-2.7B models, with 6% higher accuracy and 4% higher *F*-measure.

Moreover, to further evaluate the sentiment analysis tools, we used Bayesian analysis, as recommended by Benavoli et al [106], to assess the statistical significance of the performance of the methods. Specifically, we applied the Bayesian signed-rank test [107] to compare the accuracies achieved across multiple data sets. This test quantifies the likelihood of observing the signed ranks of accuracy differences under both

the null hypothesis (indicating no significant difference) and alternative hypothesis (indicating a significant difference). The Bayesian signed-rank test is designed to compare performance over multiple data sets (≥ 2); therefore, we further partitioned the independent Stanford and NIH data sets. Each data set was partitioned into 3 subsets, based on the sentiment label assigned to them, resulting in positive, neutral, and negative subsets for each data set.

This division was influenced by insights from our prior analysis, which highlighted inherent distinctions among sentences associated with positive, neutral, and negative labels. For instance, positive sentences exhibited a preponderance of positive adjectives, whereas negative sentences featured more negative adjectives, and neutral sentences tended to emphasize facts that are characteristic of the neutral category. Therefore, we assumed a degree of independence across subsets within each data set. The heat map diagram in Figure 5 shows the results of our Bayesian analysis, with cells corresponding to row *i* and column *j*. On the left side, “A higher than B” indicates the probability that method *i* performs better than classifier *j*. The center indicates the probability of practical equivalence between methods *i* and *j*. Similarly, on the right side, “B higher than A” indicates the probability that method *j* is better than classifier *i*. These experiments confirmed that ChatGPT performed better than all the other alternatives. The OPT models showed similar performance to methods other than ChatGPT and could be considered as a viable second option.

Discussion

Principal Findings

Our primary objective was to assess various sentiment analysis tools for the purpose of predicting the sentiments of survey responses during the COVID-19 pandemic. Obtaining a thorough understanding of the tools' degree of agreement, as shown in Figure 4, was crucial for determining whether they could be used as surrogates for human labeling. The disagreement between tools led us to try ensemble methods to produce more reliable ratings. Fine-tuned BERT models such as TweetEval and Pysentimiento outperformed the other baseline methods. Fine-tuned methods have the ability to learn domain-specific patterns from text, resulting in better performance than lexicon- and rule-based methods. However, these techniques often require large training data sets to achieve optimal performance, such as the 40k tweet data set used to train TweetEval and Pysentimiento.

As part of the process of determining agreement between tools, we labeled a small data set (260 sentences), which is what prompted us to consider the possibility of using few-shot and zero-shot learning techniques. We then investigated the performance of OPT, which is unexplored in sentiment analysis, for few-shot learning using a small training data set (260 sentences). The OPT-1.3B and OPT-2.7B models surpassed all the baseline methods as well as the fine-tuned BERT models. This highlighted the potential of few-shot learning in dealing with scarce annotated data and the effectiveness of few-shot learning. Although better results could have been achieved with a larger training set, these experiments primarily aimed to investigate the potential of OPT using limited annotated data. The potential is to be able to produce models tailored to specific research applications, with only a small time investment by domain experts. We believe that these models can significantly contribute to the sentiment analysis of health- and clinical-related surveys and can be further fine-tuned with additional data and optimized hyperparameters.

Our investigation also encompassed zero-shot learning with ChatGPT, which exhibited remarkable performance compared with all other models, including few-shot learning with OPT, as presented in Tables 3 and 4. Note that GPT-3.5—the model behind ChatGPT—is trained on related tasks, such as language modeling or machine translation. This enabled it to understand the underlying structure of sentiment-related language and the context in which it is used. Moreover, the necessity for manual text annotations in sentiment analysis tasks makes ChatGPT

and other LLMs particularly attractive. As demonstrated by Ziems et al [108], LLMs can alleviate the workload of human annotators in a zero-shot manner, thereby enhancing the efficiency of social-science analysis. In addition, a study [109] found that ChatGPT outperformed crowd workers in various text annotation tasks, including assessing relevance, stance, topics, and frame detection. These findings suggest that there may be potential in using ChatGPT and other recent LLMs for annotation in clinical NLP and reserving human input for quality control. Sentiment analysis tools based on LLMs, such as ChatGPT, automatically identify relevant features, reducing the need for manual engineering, which is a common requirement in tools such as LIWC 2015 and VADER. In addition, LLMs enable fine-tuning, allowing for potential adaptation to different sentiment analysis tasks (eg, in new domains) without the need for complete retraining. LLM-based tools can also capture longer-range context for more accurate sentiment assessment.

Limitations

There exist several limitations and risks of ChatGPT and other non-open-source LLMs regarding protected health information (PHI). Non-open-source LLMs require sending information to an external server and do not provide transparency into how they handle PHI, making it difficult to assess how the model is processing and protecting sensitive information. They may also have security vulnerabilities that can be exploited to gain unauthorized access to PHI. Note also that LLMs are not specifically designed for sentiment analysis, which may sometimes lead to errors, for instance, subtle sarcasm such as "Oh yes, great job!," context-dependent negation as in "The vaccine was not as bad as I thought," and idiomatic expressions such as "It's a piece of cake." They may encounter difficulties with nuanced health-related terminology and concepts. Therefore, specialized health terminology may require additional adaptation beyond general text fine-tuning, for instance, medical abbreviations and acronyms such as "The patient teared up because of a significant increase in their CD4 count" and "So, my mom's HbA1c levels have improved after insulin therapy." In addition, although several outputs may sound plausible, they may occasionally be incorrect. In our view, the output of LLMs should not be used without a plan for human quality control (eg, via sampling) or mitigation (eg, repeated validation). This is crucial for ensuring the accuracy and reliability of the generated content, as LLMs may produce results that require refinement or correction before dissemination. Moreover, there are constraints on the ability to access ChatGPT via its application programming interface, and this may make it too

costly or time-consuming to do so. Therefore, researchers and health care practitioners might also opt to use an open-source language model for their NLP-related projects, such as OPT, which can be run on site and perform well on sentiment analysis.

Finally, our study focused on using surveys to understand people's feelings, specifically regarding COVID-19, which was a very important topic at the time. Thus, our conclusions apply specifically to discussions about COVID-19 and may not be true for other subjects. In addition, it is important to highlight

that the Stanford data set has an implicit polarity bias: it specifically asks for positive effects ("Although this is a challenging time, can you tell us about any positive effects or 'silver linings' you have experienced during this crisis?") and difficulties ("Have you experienced any difficulties due to the coronavirus crisis?"). The NIH data set poses a single, less-biased question. Therefore, it is crucial to be careful when generalizing our findings beyond the scope of COVID-19 during the studied time frame.

Acknowledgments

The authors would like to thank Kelsey Yeh and Nathaniel Menon, who worked as research assistants in the Social Media Lab at Stanford University, for their assistance in annotating the Stanford test data set. The authors would also like to express gratitude to the many respondents who shared their experiences in both studies. The research reported in this publication was supported in part by the Intramural Research Programs of the National Institute of Mental Health (ZIAMH002922: Principal Investigator JC and ZIC-MH002968: Principal Investigator FP), National Center for Complementary and Integrative Health (ZIA-AT000035: Principal Investigator LA), and National Institute of Arthritis and Musculoskeletal and Skin Diseases (K24AR075060: Principal Investigator EL). The content is solely the responsibility of the authors and does not necessarily represent the official views of the National Institutes of Health.

Data Availability

The test data sets generated and analyzed during this study are deidentified and freely available in the FigShare repository [89]. The source code for fine-tuning the OPT models and using ChatGPT in the experiments conducted in this study is publicly accessible on GitHub [110].

Authors' Contributions

JALV and FP contributed to conceiving the study idea and design. LA and JC led the collection of the National Institutes of Health (NIH) data set, whereas EL led the collection of the Stanford data set. The annotation of the training NIH and Stanford data sets was conducted by RW and AYL, respectively. The annotation of the NIH test data set was conducted by LA, RW, and EPG, whereas AYL and 2 research assistants annotated the Stanford test data set. JALV set up the applications and performed the evaluation. JALV and FP wrote the initial draft and revised the subsequent versions. All authors read, revised, and approved the final manuscript.

Abstract

Background: Technology-based mental health interventions address barriers rural veterans face in accessing care, including provider scarcity and distance from the hospital or clinic. webSTAIR is a 10-module, web-based treatment based on Skills Training in Affective and Interpersonal Regulation, designed to treat posttraumatic stress disorder and depression in individuals exposed to trauma. Previous work has demonstrated that webSTAIR is acceptable to participants and effective at reducing symptoms of posttraumatic stress disorder and depression when delivered synchronously or asynchronously (over 5 or 10 sessions).

Objective: This study explored factors that lead to greater patient satisfaction with webSTAIR, a web-based, coach-guided intervention.

Methods: We analyzed qualitative interview data to identify themes related to patient satisfaction with webSTAIR delivered with synchronous video-based coaching.

Results: Four themes emerged from the data: (1) coaching provides accountability and support, (2) self-pacing offers value that meets individual needs, (3) participants like the comfort and convenience of the web-based format, and (4) technical issues were common but not insurmountable.

Conclusions: We conclude that participants valued the accountability, flexibility, and convenience of tech-based interventions with video-delivered coaching.

Introduction

More than 1.7 million US veterans receive mental health care through the Veterans Health Administration (VHA) annually [1]. However, US veterans underuse mental health care and often experience barriers that impact access, such as provider scarcity [2], distance to clinic [3], inability to take off from work or school, and dependent care responsibilities [4-6]. Veterans living in rural areas make up about 24% of all veterans in the United States [7], and they have similar mental health care needs as urban veterans; however, rural veterans experience access barriers at higher rates [8,9]. Technology-based mental health interventions are a potential solution to address some of the barriers that rural veterans in the United States face.

Technology-based mental health interventions can be accessed from a smart phone or tablet. They range from fully automated to therapist-guided in person or by video, telephone, or SMS text messages [10-13]. Technology-based mental health interventions have demonstrated effectiveness in clinical trials, with moderate-to-high effect sizes [14-17]. However, satisfaction with a treatment plays a significant role in treatment effectiveness. Patient satisfaction with treatment is linked to greater adherence [18,19] and greater perceived improvement in clinical status [20,21]. Even when adherence to treatment is controlled for, satisfied patients benefit more from care than less satisfied patients [22,23]. In mental health settings, a strong therapeutic alliance is linked to greater patient satisfaction [24]. Further understanding of factors that contribute to patient satisfaction is critical to designing future tech-based interventions that demonstrate better engagement and retention and greater clinical benefit [25,26].

Studying satisfaction with mental health treatments is complex. There are a number of variables that can influence patient satisfaction with mental health treatment, such as patient, disease, provider, therapy, and environmental factors (eg, technology-mediated treatments) [22,27,28]. Although many teams evaluate overall satisfaction by collecting survey data and compiling ratings to quantify patients' levels of satisfaction, qualitative data provides a nuanced and contextualized understanding of satisfaction [22]. In 2 recent studies, our team found that having therapist support and the convenience of being able to access treatment on the web contributed to patient satisfaction with technology-based mental health interventions [29,30]. This study uses qualitative interviews with patients who completed an internet-based mental health treatment to explore factors that lead to greater patient satisfaction in such a program. This study builds on previous findings by exploring the benefits of using a coach and the ways web-based formats provide comfort and convenience, as well as increased access in some cases.

Methods

Study Design

webSTAIR is an internet-based intervention adapted from Skills Training in Affective and Interpersonal Regulation (STAIR), a treatment for trauma-exposed individuals with symptoms of posttraumatic stress disorder (PTSD) and depression [31]. The

program was developed to engage rural women veterans, who have been found to be underrepresented in mental health services [32]. However, male veterans were also enrolled if they were interested and met the study criteria. webSTAIR offers 10 web-based modules of self-directed skills training on emotion regulation (eg, emotional awareness, emotional management, and distress tolerance) and interpersonal skills (eg, assertiveness, flexibility, and compassion for oneself and others).

In addition to the asynchronously delivered web-based content, participants were offered 5 or 10 synchronous video coaching sessions, which took place using video-telehealth, after the completion of 1 or 2 modules. Coaches were licensed Veterans Affairs (VA) mental health providers who underwent training in the intervention and attended weekly supervision with a certified STAIR trainer. Sessions with the coach lasted approximately 45-50 minutes and involved reviewing module content, discussing the applicability of concepts in the veteran's life, and strategizing on how to integrate skills into daily practice. The webSTAIR program was delivered as routine care in mental health outpatient clinics at 9 sites serving rural patients within the VHA. The qualitative data presented were collected as part of a naturalistic evaluation of the program.

Recruitment and Sample

Participants in the webSTAIR program were US veterans recruited from 9 VHA facilities across the country that serve rural patients. Referrals were either clinician- or self-initiated. Participants completed the program between September 2018 and March 2020. Eligibility for the study was determined based on an initial telephone screening. Patients were considered eligible if they reported a history of trauma exposure and screened positive on the Primary Care PTSD Screen (PC-PTSD; positive on 3 of 5 items [33]) or the 2-item Patient Health Questionnaire (PHQ-2; positive on 1 of 2 items [34]), indicating clinically significant symptoms of PTSD or depression. The following resulted in ineligibility for enrollment: cognitive impairment or psychosis, mania, primary drug or alcohol abuse, current domestic violence, concurrent trauma-focused treatment, residential care for PTSD within 1 year, or an inability to attend telemental health appointments by video.

Measures and Data Collection

Demographic information for all patients in the program was collected at the initial intake phase of the study. The qualitative data for this study were collected during a 1-time interview conducted following the completion of the webSTAIR program. Patients who completed the program were sent a letter explaining the purpose of the interview and study details. This letter also included a contact number that patients could call to decline participation. All patients who did not actively call to decline were then contacted by study staff and asked if they would like to participate. Study staff made at least 3 attempts to contact participants. Outreach resulted in a response rate of 30%, with 74 participants agreeing to participate. The demographic information of interviewees was linked using a study ID number.

The interview guide was piloted and refined during the pilot intervention phase of the study [30,35]. It contained both

categorical and open-ended questions. One member of the study staff conducted the interview, while 1-2 staff members took detailed notes during the interview. While the study team did not record or transcribe interviews, note-takers were often able to capture responses nearly verbatim. Quotes in this paper are drawn from these notes.

Participants were asked questions about their experience working through the program and about their satisfaction with the intervention. Interviews were conducted by telephone by study staff, including the first author (AHS) and second author (HT), as well as other members of the study team (MW). Interviews lasted approximately 60 minutes. At the conclusion of the interview, the interview notes were consolidated, and the finalized interview notes were entered into a database. Interview protocols were reviewed by the principal investigator's affiliated institutions' institutional review board, designated as "quality improvement."

Data Analysis

Interview data were analyzed using strategies from qualitative content analysis and thematic analysis [36-39]. The interview notes for each participant were entered into a matrix in Microsoft Excel (Microsoft Corp) and organized by interview question. A list of the interview questions used in the analysis for this study can be found in [Multimedia Appendix 1](#). Data coding and analysis were conducted by a master's-level researcher with extensive qualitative experience who also functioned as a

research assistant on the study (AHS) and a postdoctoral nurse trained in qualitative methods (HT). A codebook was developed based on interview guide questions and refined based on emergent findings. The second author (HT) reviewed the codes assigned by the first author, either agreeing or disagreeing. Coders met to resolve any disagreements until consensus was reached. The themes were analyzed and further defined to describe participants' satisfaction with the intervention. The data are presented here by satisfaction with the web-based, coach-guided format of webSTAIR.

Ethical Considerations

Study procedures were reviewed and found to be exempt by the institutional review board for Baylor College of Medicine and Affiliated Hospitals. Data were collected under a quality improvement designation. Participant confidentiality was upheld with the use of a randomized participant ID number.

Results

Sample

The exit interview was completed by 74 participants, the majority of whom were rural (46/74, 62%), White or Caucasian (48/74, 65%), female (42/74, 57%), aged between 35 and 44 years (25/74, 34%), and had some college or a 2-year college degree (32/74, 44%). A detailed list of participant characteristics can be found in [Table 1](#).

Table 1. Participant demographics.

Demographics	Coach 5 (n=43), n (%)	Coach 10 (n=31), n (%)	Total (N=74), n (%)

Themes

Participants responded to categorical questions that they were generally satisfied with the webSTAIR program; that is, the majority of interview participants felt that webSTAIR met their needs and that they would use a similar program again in the future. Four themes emerged from the open-ended responses

and are detailed below: (1) coaching provides accountability and support, (2) self-pacing offers value that meets individual needs, (3) participants like the comfort and convenience of the web-based format, and (4) technical issues were common but not insurmountable. [Table 2](#) presents quotations exemplifying each theme.

Table 2. Domains and illustrative quotes.

Themes	Illustrative quotes
Theme 1: coaching provides accountability and support	<ul style="list-style-type: none"> Because she was so good at bringing back the tools you get out of webSTAIR. Website tells you to apply it, but it's nice to hear it differently and she brings it back to my situation. That was really helpful for me (35-44-year-old White female). Seemed like sessions were the practice/reiteration part. She really provided the application, tying it together and making it stick. Would stress this a lot. It really helped and challenged me. (35-44-year-old White male)
Theme 2: self-pacing offers value that meets individual needs	<ul style="list-style-type: none"> It allowed me to go at my own pace. I had time to consider my answers and think about what I wanted to say. (55-64-year-old White male) When you're meeting in person, you often are bobble heading even if you're not getting what they're telling you. Reading for yourself and being able to go over it and process... gives you time to process. (55-64-year-old mixed-race female) Some lessons needed more time to practice and to mentally digest. I'm still going over them because I printed them out, but I feel like I needed more time... (45-54-year-old White female)
Theme 3: participants like the comfort and convenience of the web-based format	<ul style="list-style-type: none"> I work, helped me not be stressed about getting appointments without taking off work. (25-34-year-old African American female) With PTSD, I don't sleep well. To not have to get up and drive. Closest facility is 45 min-1 hour away... To not have to drive is great. I live in the country on purpose. I wouldn't go to therapy without webSTAIR. (35-44-year-old mixed-race female) I liked that it was online and for whatever reason felt like a safer environment than sitting face to face with someone. (25-34-year-old White female) It's easy to get complacent too, catch 22 at your home. Easy to get distracted, too comfortable at home so easily distracted. (25-34-year-old White male)
Theme 4: technical issues are common but not insurmountable	<ul style="list-style-type: none"> If you're working on something and push the back button you delete everything you did. You have to start over. (35-44-year-old African American female) I didn't like the fact the info I wrote down in the modules, therapist couldn't see, so when we were reviewing, I would have to go back in and start from the beginning. It would be helpful if she could see what I wrote. (35-44-year-old African American female) Sometimes couldn't hear each other or it would freeze. Normal facetime issues. More issues with computer, iPad or iPhone crystal clear, perfect. (35-44-year-old American Indian or Alaskan Native female)

Theme 1: Coaching Provides Accountability and Support

The presence of regular check-ins with a coach kept participants accountable and motivated them to do the work and stay on track by providing guidance as to when they should complete the next module. Only 1 participant noted that the regular check-ins with their coach and expectations about content completion each week felt like too much pressure, but this was uncommonly reported. Most respondents indicated they appreciated check-ins.

I knew that we were going to have our sessions. So it helped with accountability – like actually doing the work because we're going to talk about it. And she keeps me on track because she tells me this is when you're going to do the next module. [35-44-year-old Black or African-American female]

Coaches provided emotional support and helped participants understand and apply the webSTAIR content to their own lives. Participants often noted a good rapport with their coach, and many would have liked to talk to them more simply because they enjoyed talking with them. As a mixed-race male in his early 30s commented, "She was awesome. She always remembered what was going on with me. She helped with materials."

The majority of participants were satisfied with the number of sessions with their coach, regardless of the number of coaching sessions they received. Those that did express a preference for more sessions cited a variety of reasons, most commonly the desire for more emotional support and clarification about the content. Participants perceived coaching sessions as a time to process their feelings and better understand how content applied to their individual situation. The coaching sessions were considered an essential component of webSTAIR and were highly valued.

Theme 2: Self-Pacing Offers Value That Meets Individual Needs

Participants generally liked the format of webSTAIR, which allowed them to take their time and interact with and respond to the web-based content. Having time between reviewing the material and meeting with their coach helped participants feel less pressure and less rushed than standard face-to-face psychotherapy using evidence-based psychotherapy protocols, as in "No pressure to feel like you get an answer right or wrong or in a hurry to get it done" (35-44-year-old White male). They were able to reflect on and practice the skills webSTAIR aimed to teach them. In many cases, this led to more thoughtful reactions to the content, which informed meetings with their coach and made them more productive. A White male in his mid-forties commented:

It made you use your mind and think about stuff. You can go to counseling all day long and you don't get as much accomplished in an hour... [I] think on your own time, allows you to think outside the box.
[35-44-year-old White male]

In contrast to those who liked the self-paced format, a small number of participants reported they would have liked the pace to be more personalized or more self-paced. For example, a few participants would have liked to speed through some of the content that they felt they did not need or take more time (eg, more time in between video coaching sessions) to go deeper into the content they thought they needed most without feeling rushed. However, the desire for the pace to be more personalized did not impact their satisfaction with the program.

A minority of participants noted difficulty understanding or remembering the content between sessions.

By the time I got to the second module, I would forget about the first one. I would forget notes I had for my coach and was often unable to write down my questions. I would forget before next time.
[45-54-year-old White female]

Some participants successfully prepared for coaching sessions by taking detailed notes about the content and their questions, or by reviewing the webSTAIR content immediately before meeting with their coach. This strategy was acceptable for some webSTAIR participants, but others found it tedious or “annoying” to have to refresh between sessions to avoid forgetting the content, though this was uncommonly reported.

Theme 3: Comfort and Convenience of the Web-Based Format Made it Easier to Access Care

Participants liked the convenience of the coach-guided, web-based format, which allowed flexible scheduling and reduced travel time. The ability to meet on the web allowed veterans to engage in care they may not have otherwise engaged in due to distance or other logistical factors, such as difficulty scheduling around work or childcare obligations. A Hispanic male in his late 30s explained how and why the web-based format was more convenient:

Able to do it from home. I cannot take advantage of many mental health services at the VA; VA is 30-40 minutes from my home. I was glad I was able to take advantage of this.

In addition to the logistical benefits, participants liked that they did not have to confront crowded waiting rooms at their facility. Instead, they could participate in the program from home, where they felt most comfortable and, in some cases, where they felt most safe. A minority of participants found it more difficult to find privacy in their own homes, away from the people they lived with, and others found themselves more prone to distractions at home. According to 1 participant, a White female in her mid-forties, “...the same thing that made it nice also made it not so nice.” However, privacy issues or distractions at home were not commonly reported.

Theme 4: Technical Issues Are Common but not Insurmountable

The majority of participants experienced some technical challenges with the video coaching sessions, and almost half experienced difficulty with the website. Participants spontaneously reported that about a third of all the technical challenges they experienced occurred only 1 or 2 times throughout the entire program. For issues that did not resolve on their own, participants were able to troubleshoot, either independently or with their coach, to complete their sessions and web-based content. In cases where coaches were able to help solve problems or troubleshoot, their guidance seemed to ameliorate the negative impact on patient satisfaction.

[Had] difficulties quite a few times, but she always made it work. [35-44-year-old Hispanic female]

Technical issues included being unable to hear the other person, issues with the link to the video session, and difficulty with the video freezing or closing unexpectedly. Sometimes the issue resolved quickly on its own and occurred infrequently. Other times, the issue could be attributed to a recent update or a setting that needed to be changed on their device. Strategies that were frequently used by coaches to help troubleshoot included pivoting to the phone for audio, sending different pieces of equipment to use, and offering emotional support that someone would help them resolve the issue. A White female in her mid-forties said:

One time we [experienced video issues]; [we] just turned off the audio, [and] video was still there and [we] used phone for audio. Work around; it worked just fine.

Only 1 participant spontaneously reported having had to reschedule a session with their coach due to connection issues. More often, participants shared that they were still able to meet on the web with their coach despite issues with the video connection, in part because of their coach's persistence.

It didn't connect twice but she worked hard to get it connected, so we still had our sessions.
[35-44-year-old African American female]

Participants reported a wide range of issues with the website, including trouble accessing the tools or videos, glitches such as issues with the “back” or “next” button, difficulty with the website kicking them out or freezing up, and issues with the equipment that made accessing all the content from the modules difficult. Several participants spontaneously reported that they resolved the issue with the website through independent troubleshooting, usually by closing and reopening the browser: “Sometimes the role play [exercise] wasn't working right. Closed out the browser and then it would work fine” (35-44-year-old Hispanic female). In at least 1 case, an issue with the website was resolved when the coach sent the participant a VA iPad (Apple Inc). Issues that were most easily resolved included the website or web content freezing up and issues with the “back” button not working.

More persistent issues with the website included typed responses not saving, being unable to access program materials, such as worksheets or role plays, and difficulty printing. There was only

1 case in which a participant spontaneously shared that they had to reschedule a session due to technical issues with the website and an inability to access program materials. More often, participants found workarounds, like taking screenshots instead of printing and writing down their responses.

Typing info into forms/worksheets. Happened 2 times, then I quit. I started writing it down. [45–54-year-old White female]

Discussion

Principal Results

This study contributes to the literature on satisfaction with web-based mental health treatments by qualitatively exploring mechanisms that lead to better or worse patient experiences with technology-based mental health tools, in addition to satisfaction with the patient-provider relationship. Results from this study may help clinicians and researchers tailor interventions in a way that increases satisfaction with web-based mental health treatments. Our chief findings were as follows: (1) the presence of a coach or therapist to help guide a web-based intervention was vital for accountability and support; (2) a flexible, self-paced format enabled participants to fit the treatment into their schedule more easily and give them time to reflect on the content in between sessions; (3) participants liked the comfort and convenience of the web-based format, as it decreased travel time and opened up access to mental health services that may otherwise have been too difficult to obtain; and, (4) despite most participants experiencing technical difficulties, a common issue with web-based treatments, participants in our sample were able to troubleshoot those issues and complete the program and it did not appear to impact their overall satisfaction. Although participants generally reported positive responses to the intervention, some reported a desire to have more control over the pacing of modules based on their individual mastery of the module's content.

Comparison With Previous Work

Consistent with the literature, the coach-guided support contributed to the high level of satisfaction observed in this study. Participants noted the importance of the coach for their support and accountability. Coaches helped keep participants on track, knowing that they are going to discuss the module in their next session. Coaching helped participants apply the content to their own lives and made it relatable, enhancing the program's value for patients. Consistent with previous work by this team, participants in this study often noted a high level of satisfaction with their coach, and many commented on the likeability or effectiveness of their coach [40]. Previous work suggests that engagement and efficacy in technology-based mental health interventions are often low without therapist support [41], which may be why the value of coaching was such a prevalent theme in our exploration of satisfaction in this study. Like participants in other coach-guided, internet-based studies, webSTAIR participants experienced excellent relationships with their coaches, and they were able to achieve this over video [30,42–44].

Previous studies of technology-based mental health interventions suggest that the most frequently reported reason for dissatisfaction is related to intervention pacing that moves too quickly [45]. Participants in this study often noted the benefit of the self-paced format of webSTAIR, as it allows more time and space to reflect on, practice, and absorb the content compared to standard, synchronous, evidence-based psychotherapy sessions in which participants may feel pressure to respond and process material in the moment. Additional time to review the material between professionally guided sessions contributed to the considerable satisfaction that we have observed in this study.

Participants in this study generally appreciated the comfort and convenience of the web-based format. Approximately 62% (46/74) of our participants were rural, so decreasing drive time to their provider, in some cases, may have enabled participants to receive care they would not have otherwise been able to access. About 57% (42/74) of our participants were women, and all had a history of trauma. This may have contributed to why participants felt more comfortable receiving their care in their own homes and why they appreciated avoiding crowded VHA waiting rooms. These findings echo previous studies that found similar benefits of telehealth for patients with obsessive-compulsive disorder and veterans receiving mental health care over video telehealth [29,46].

When using video telehealth, about a third of participants noted they only encountered 1–2 technical issues, which they were able to resolve with minimal interruption. Others with more significant interruptions were able to troubleshoot on their own or with their coach to eventually get connected or access the web-based material. Since this study describes the experiences of participants who completed webSTAIR, we can presume that they were able to navigate technical issues and complete the program. Given these findings, we can infer that if a technical issue is eventually resolved, the presence of the technical issue may not impact overall satisfaction. For this reason, resilience, supportive troubleshooting, and having a backup plan (eg, using the phone for sound when audio does not work) may contribute to greater satisfaction and the successful completion of internet-based interventions.

Limitations

The primary limitation of our study is selection bias. Our interview sample consisted of participants who completed the webSTAIR program and were prescreened to have adequate access to video telehealth. These factors may result in more positive experiences with the program, as reflected in the data. The 37% (74/202) response rate may have further exacerbated selection bias and resulted in more positive feedback. These patients were more likely to have the time and motivation to participate in an interview. The experiences of those who may not have felt the program's impact or did not feel inclined to participate in an interview were not captured. Additionally, the study was not randomized, and we do not have a control group to compare satisfaction among those who dropped out of the study. However, as a qualitative study, our aim was to provide a detailed description of participant experiences and explore how common themes across experiences may be relevant to

clinicians and researchers interested in web-based mental health treatments.

Conclusions

Our findings suggest that a combination of self-paced, web-based content and a coach-guided intervention may integrate the best of both worlds, that is, the convenience and flexibility of a web-based modality and the structure, guidance,

and accountability of a traditional psychotherapy approach. Our results indicate that providers and researchers should design tech-based interventions that are sensitive to individual differences and that integrate coaching support, as participants highly value coaching support for their digital interventions. Future research should focus on the impact of satisfaction on engagement, retention, and the therapeutic benefits of web-based mental health interventions.

Abstract

Background: Heart rate variability (HRV) biofeedback is often performed with structured education, laboratory-based assessments, and practice sessions. It has been shown to improve psychological and physiological function across populations. However, a means to remotely use and monitor this approach would allow for wider use of this technique. Advancements in wearable and digital technology present an opportunity for the widespread application of this approach.

Objective: The primary aim of the study was to determine the feasibility of fully remote, self-administered short sessions of HRV-directed biofeedback in a diverse population of health care workers (HCWs). The secondary aim was to determine whether a fully remote, HRV-directed biofeedback intervention significantly alters longitudinal HRV over the intervention period, as monitored by wearable devices. The tertiary aim was to estimate the impact of this intervention on metrics of psychological well-being.

Methods: To determine whether remotely implemented short sessions of HRV biofeedback can improve autonomic metrics and psychological well-being, we enrolled HCWs across 7 hospitals in New York City in the United States. They downloaded our study app, watched brief educational videos about HRV biofeedback, and used a well-studied HRV biofeedback program remotely through their smartphone. HRV biofeedback sessions were used for 5 minutes per day for 5 weeks. HCWs were then followed for 12 weeks after the intervention period. Psychological measures were obtained over the study period, and they wore an Apple Watch for at least 7 weeks to monitor the circadian features of HRV.

Results: In total, 127 HCWs were enrolled in the study. Overall, only 21 (16.5%) were at least 50% compliant with the HRV biofeedback intervention, representing a small portion of the total sample. This demonstrates that this study design does not feasibly result in adequate rates of compliance with the intervention. Numerical improvement in psychological metrics was observed over the 17-week study period, although it did not reach statistical significance (all $P > .05$). Using a mixed effect cosinor model, the mean midline-estimating statistic of rhythm (MESOR) of the circadian pattern of the SD of the interbeat interval of

normal sinus beats (SDNN), an HRV metric, was observed to increase over the first 4 weeks of the biofeedback intervention in HCWs who were at least 50% compliant.

Conclusions: In conclusion, we found that using brief remote HRV biofeedback sessions and monitoring its physiological effect using wearable devices, in the manner that the study was conducted, was not feasible. This is considering the low compliance rates with the study intervention. We found that remote short sessions of HRV biofeedback demonstrate potential promise in improving autonomic nervous function and warrant further study. Wearable devices can monitor the physiological effects of psychological interventions.

Introduction

Overview

Mental health conditions are common, with approximately 25% of the population in the United States experiencing a mental health disorder in a given year [1]. Since the COVID-19 pandemic, there have been increasing rates of anxiety, depression, and other psychological conditions [2]. This has disproportionately impacted health care workers (HCWs) who are at a higher risk of depression, anxiety, insomnia, and distress compared to the general population [3-6]. Over half of the physicians and approximately 40% of the nurses in the United States experience burnout, almost twice that of other professions [7]. Additionally, during the COVID-19 pandemic, approximately 1 in 5 HCWs were experiencing some degree of posttraumatic stress disorder [8]. Thus, HCWs represent a vulnerable population in which further study of mental health interventions is needed.

Unfortunately, access to mental health services can be limited [9]. Digital technologies, including smartphone apps and wearable devices, provide an opportunity to improve health care access and aid mental health professionals in the management of psychological conditions. Collectively, they can assess subjective and objective metrics of psychological and physiological well-being. Apps can remotely collect validated psychological assessments while wearable devices are able to monitor physiological metrics such as heart rate variability (HRV), a hypothesized indirect measure of the autonomic nervous system (ANS) [10-13]. HRV is a measure of the physiological variation in the time intervals between adjacent heartbeats [14]. It is hypothesized to be generated by heart-brain interactions and ANS processes, reflecting the activity of the sympathetic and parasympathetic nervous system tone on heart rate [10,15].

Higher HRV has been associated with reduced frustration, higher performance, and positive psychological adjustments [16]. Reduced HRV has been associated with reduced self-regulation, variable degrees of psychological tension, and anxiety [17,18]. Oscillations in heart rate occur due to the influence of respiration on the sinoatrial node of the heart and central nervous system respiratory pacemaker fluctuations. Interestingly, at 1 resting respiratory rate, the relationship between breathing and heart rate is asynchronous, with the heart rate increasing following

inhalation [19,20]. This respiratory sinus arrhythmia is controlled by the vagus nerve, with increased vagal output producing greater heart rate variation, thereby reflecting the parasympathetic influence on the heart [21]. It has been shown that the amplitude of HRV is related to breathing frequency with maximum effect at a breathing rate of 0.1 Hz or 6 breaths per minute [19].

Mind-body interventions, such as deep breathing exercises, can improve resilience, psychological well-being, physiological functions, autonomic imbalance, mood, cardiopulmonary output, and immune function [22-25]. Adaptive changes in the central nervous system, characterized as reduced sympathetic tone, have been described with these exercises [26-28]. Achieving deep breathing rates of 4.5-6.5 breaths per minute results in higher HRV indices compared to baseline, with higher parasympathetic and baroreflex function [29]. This has been shown to positively impact physical function; athletic performance; quality of life; and psychological features such as anxiety, depression, and resilience [30-32]. The individual breath per minute rate producing the optimal HRV effect (resonance frequency) can be determined from measures of the heart and respiratory rate in real-time biofeedback sessions [33]. Changes in HRV secondary to respiratory rate modification can create a positive feedback loop further increasing HRV respiratory changes, elicited through biofeedback [19].

Biofeedback is a self-regulatory behavioral method that trains individuals to control physiological function through real-time information about these physical parameters [34]. HRV biofeedback involves the real-time visualization of HRV metrics and breathing's effect on this metric. It has been shown to increase HRV in adults [31,35-37]. There is significant empirical support for the use of office- or laboratory-based HRV biofeedback programs for the improvement of psychological conditions. In a recent meta-analysis of 14 studies, HRV biofeedback was shown to improve depressive symptoms in several psychophysiological conditions, as well as increase psychological well-being [38]. Large reductions in self-reported stress and anxiety have been demonstrated with HRV-directed biofeedback [31], as well as positive impacts on anger, athletic performance, sleep, and quality of life [39]. A systematic review of HRV biofeedback further demonstrated significantly improved symptoms of anxiety, depression, panic disorders, and posttraumatic stress disorder in 70% of the included studies [40].

However, despite the effectiveness of HRV-directed biofeedback, there are limitations to the implementation of such a technique. These interventions often rely on structured training and computer- or laboratory-based practice sessions that are often performed in the laboratory setting. This makes it challenging to broadly implement such techniques, limiting access to populations that may be most likely to benefit. This has prompted several studies using HRV biofeedback remotely and outside the laboratory setting with computer-based programs that demonstrated effect [36,41,42]. An additional significant obstacle to HRV biofeedback is the length of time required for each session, which can last up to 40 minutes [43]. Most also incorporate at least 1 laboratory session per week in addition to the daily home sessions [44]. These long and structured sessions, however, limit the ability of individuals to institute an HRV biofeedback program into their daily lives. Short sessions of HRV biofeedback might therefore provide a greater impact if they are able to elicit an autonomic response. Interestingly, short sessions of HRV biofeedback can successfully modify HRV and improve the regulation of emotional reactivity and therefore warrant further evaluation [45,46]. Gross et al [47] used 5 short 3- to 5-minute HRV biofeedback sessions. However, these were led by in-person practitioners. They demonstrated that HRV was successfully moderated and increased during these sessions; however, it was not changed overall from before training to after training. Deschodt-Arsac et al [45] furthered the evaluation of short-session HRV biofeedback by evaluating a twice-daily 5-minute biofeedback session in athletes, demonstrating an increase in autonomic function and a decrease in anxiety levels.

HRV measurements during and after biofeedback sessions evaluating physiological effects are often over brief periods and are in the clinic or laboratory setting. This limits the evaluation of its effectiveness on an individual's physiological status and further restricts biofeedback sessions to the office setting. Wearable devices provide a potential means to assess HRV remotely, passively, and outside the laboratory setting and, thus, a possible means to monitor HRV biofeedback in a real-world setting. Wearable-based HRV assessment can be performed through either electrocardiography (ECG) or photoplethysmography (PPG). ECG is the gold standard for HRV assessment as the graphical representation of cardiac activity enables the calculation of beat-to-beat intervals with reliability to the millisecond level [48]. Most commercially available wearables and all wrist- or hand-worn devices that measure HRV rely on PPG technology. PPG tracks heartbeats by measuring the alterations of light from an LED that reaches a photodiode created by pressure changes in veins with each heartbeat [49]. Several studies have used wearable devices to assess response to HRV-directed biofeedback sessions. However, these have primarily used wearables that both monitor and implement biofeedback at the same time. Chung et al [50] demonstrated in a small pilot study that the Lief Smart Patch can assess and deliver HRV-directed biofeedback to effectively modify HRV. However, HRV assessments, generated from an ECG tracing, were over very brief periods around the biofeedback sessions. Similarly, Lin et al [51] demonstrated that using an HRV biofeedback wearable device for a least 4 weeks was needed to demonstrate an effect on HRV. However,

studies that have evaluated sensor-type preference in biofeedback have found that participants prefer wrist- or arm-worn sensors for monitoring [52]. Given the ubiquitous use of commercial smartwatches, many of which measure HRV, there is an opportunity to expand HRV-directed biofeedback monitoring with such devices. Commercial devices such as the Apple Watch [12,53,54], fPolar V800 [13,55], Empatica E4 wristband [56], and Fitbit Charge HR [57] have been shown to generate valid and reliable assessments of heart rate and HRV, with high agreement with ECGs. Furthermore, the use of HRV calculated through PPG signatures has been shown to be a reliable and valid method for the assessment of HRV in the setting of HRV-directed biofeedback [58].

Thus, the potential benefits of short sessions of HRV biofeedback coupled with the growth of digital technologies and wearable devices present an opportunity to expand the application and monitoring of HRV-directed biofeedback. To evaluate this approach, we launched a feasibility study to evaluate smartphone-based short sessions of HRV biofeedback in HCWs and monitored its impact using common commercially available wearable devices.

Objectives

The primary aim of the study was to determine the feasibility of fully remote, self-administered short sessions of HRV-directed biofeedback in a diverse population of HCWs. We hypothesized that fully remote HRV-directed biofeedback would have high compliance rates by HCWs. The secondary aim was to determine whether a fully remote, HRV-directed biofeedback intervention significantly alters longitudinal HRV over the intervention period. We hypothesized that HRV-directed biofeedback would significantly alter longitudinal HRV measurements. The tertiary aim was to estimate the impact of this intervention on metrics of psychological well-being. It was hypothesized that psychological well-being would improve with HRV-directed biofeedback. Study feasibility will be assessed by the percentage of HCWs who are at least 50% compliant with the intervention over the study period.

Methods

Ethical Considerations

This study has been approved by the institutional review board at the Icahn School of Medicine at Mount Sinai (STUDY-21-00596). The study was retrospectively registered on ClinicalTrials.gov (NCT05958329). All participants signed informed consent. All study procedures were performed in accordance with the ethical standards outlined in the Helsinki Declaration of 1975, as revised in 2000. The study data was deidentified, with each participants data linked to a unique study identification number. Additionally, all data was stored on Mount Sinai's HIPAA compliant servers.

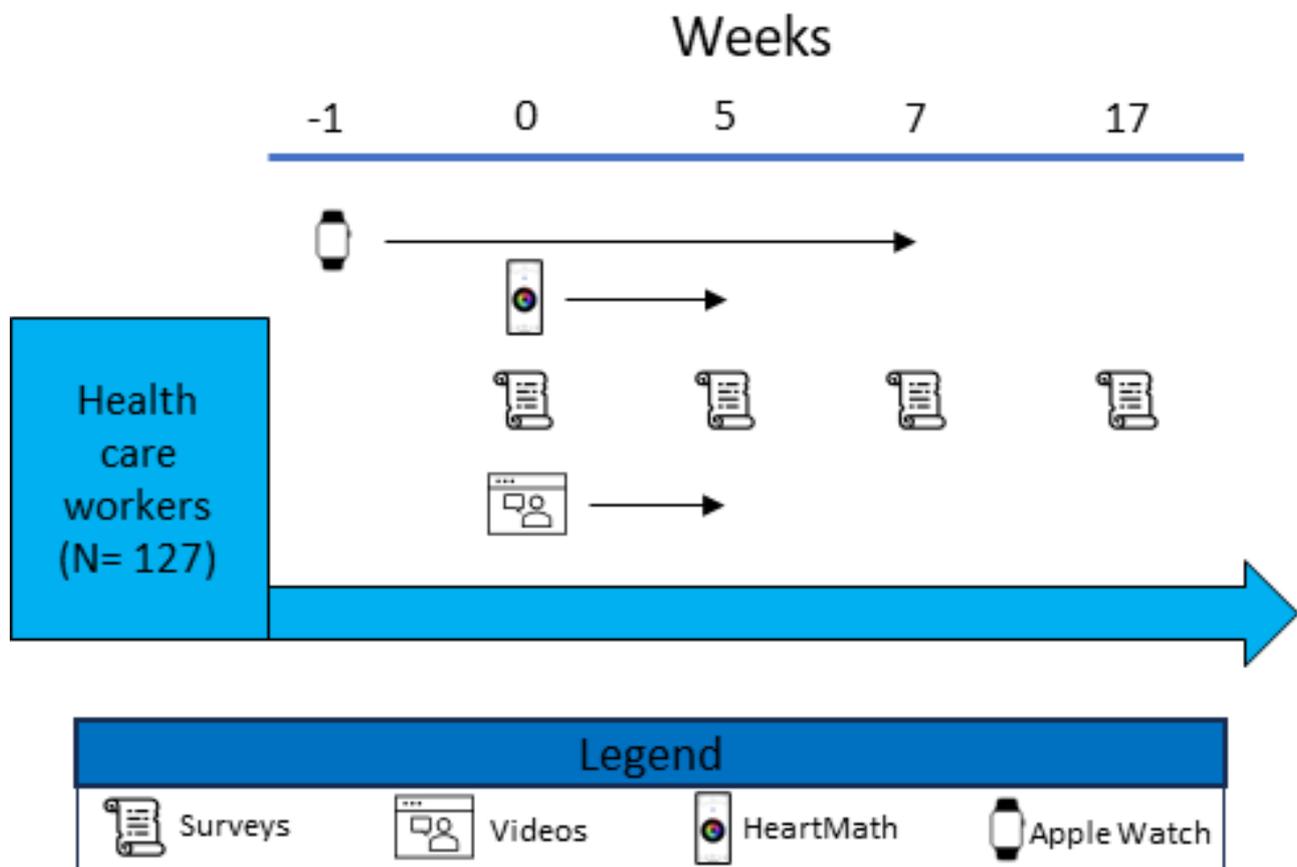

Study Design

The Warrior Shield study was an open-label prospective pilot clinical trial that enrolled HCWs across 7 hospitals in New York City (Figure 1). Participants were recruited from The Mount Sinai Hospital, Morningside Hospital, Mount Sinai West, Mount Sinai Beth Israel, Mount Sinai Queens, New York Eye and Ear

Infirmery, and Mount Sinai Brooklyn. Eligible participants were aged 18 years or older, employees at 1 of the participating sites, had an iPhone series 6 or higher, and had or were willing to

wear an Apple Watch 5 or greater. Potential participants were excluded if they had an underlying chronic disease or used a medication that is known to impact ANS function.

Figure 1. Participants were prospectively enrolled and followed for 17 weeks. Participants wore their Apple Watch for at least 7 days before starting the intervention period (week 0) and used it through week 7 of the study. The HeartMath device was used throughout the 5-week intervention period. Participants answered surveys at baseline, week 5, week 7, and week 17. In total, 5 weekly educational videos describing HeartMath and the basis behind the intervention were available for viewing through the 5-week intervention period.

HCWs were recruited from the participating hospitals through emails sent to hospital employees and through study flyers (Figure S1 in [Multimedia Appendix 1](#)) placed in hospital common areas, including cafeterias and lobbies. Furthermore, participants who completed other digital studies run by our group were messaged with information about this study. Participants were provided with a US \$50 gift card after completing 6 weeks of study activities. If a participant did not have an Apple Watch, he or she was able to borrow 1 for the duration of the study. This was returned to the research staff on completion of the study. Additionally, the participants had to return the HeartMath Inner Balance biofeedback device (HeartMath, LLC) at the end of the study.

Study Procedures

Overview

Participants downloaded our ehive study app to their smartphones and self-verified inclusion and exclusion criteria before signing the electronic consent. Participants then electronically requested their HeartMath Inner Balance biofeedback device and an Apple Watch if they did not have 1 of their own wearable devices. Participants were recommended

to wear the Apple Watch for a minimum of 8 hours per day. On receiving the Inner Balance device and after at least 7 days of wearing the Apple Watch, participants started the HRV biofeedback intervention, as described below. This continued for 5 weeks. Validated surveys to assess psychological well-being were completed at baseline in the ehive app. Surveys were repeated at week 5, week 7, and week 17. Participants were asked to wear the Apple Watch for at least 7 weeks after starting the intervention to enable HRV monitoring. They were reminded to participate in the study through regularly scheduled push notifications to their smartphones and automated email reminders sent by the study team.

ehive App

The ehive app is the centralized digital research platform of The Hasso Plattner Institute for Digital Health at Mount Sinai Hospital, New York, New York. The patient-facing portion of the platform is a smartphone app that enables electronic consenting of participants. Customizable patient-reported outcomes measures and other tasks such as the study surveys and weekly study videos are embedded in the app and can be tracked for compliance. This app can track participant compliance and engage participants through light touch

measures such as customized push notifications and customized emails to participants to maintain engagement. It has been downloaded by over 1484 participants and has been used to collect over 51 million wearable-based data points and over 132,241 surveys [11].

Survey Instruments

Several validated surveys were evaluated throughout the intervention period. The 10-item Connor-Davidson Resilience Scale (CD-RISC 10) is a 10-question survey that measures resilience. Higher scores reflect higher resilience, with each question graded on a 5-point Likert scale [59]. The following question is an example of what is included in the survey: “I am able to adapt when changes occur.” The emotional support 2-item Patient-Reported Outcomes Measurement Information System (PROMIS) questionnaire is graded from 2 to 10 points, with higher scores reflecting higher perceived emotional support. It measures whether an individual has someone who will listen to them and with whom they can discuss their feelings [60]. An example of a question included in this survey is “I have someone who will listen to me when I need to talk.” The Perceived Stress Scale 10 (PSS-10) is a validated survey assessing perceived stress. It is 10 questions scored from 0 to 40, with higher scores correlating with elevated perceived stress [61]. An example item in this survey includes “In the last month, how often have you been upset because of something that happened unexpectedly?” The 2-Item Global Health and Quality of Life Scale asks participants to grade how their quality of life and health are in general. Higher scores correlate with lower health and quality of life [60]. The following is an example question included in this survey: “In general, would you say your health is excellent, very good, good, fair, or poor?” The Patient Health Questionnaire-4 (PHQ-4) is a 4-question survey that screens for anxiety and depression and is graded from 0 to 12 points. Higher scores reflect more severe impairment [62]. An example question from this survey is “Over the last week, how often have you been bothered by the following problem? Feeling nervous, anxious, or on edge.” The National Institutes of Health (NIH) PROMIS positive affect and well-being scale is a 23-question survey graded on a 5-point Likert scale. Higher scores reflect higher degrees of positive affect and well-being [63]. The following question is an example from this survey: “Lately I had a sense of well-being never, rarely, sometimes, often, or always?”

HeartMath Intervention

The HeartMath biofeedback system is developed by the HeartMath Institute, which is a nonprofit research and educational organization that develops and provides easy-to-use self-regulation tools focused on HRV biofeedback [64]. Its tools and techniques have been tested in a range of settings with good efficacy and uptake in conditions ranging from blood pressure, heart failure, stress, and trauma syndromes [65-68]. It is used in a range of settings and has been widely implemented in the health care industry, being offered to HCWs and patients at institutions such as Kaiser Permanente and the Veteran Administration Hospitals and Clinics [69,70]. The Inner Balance app combines a smartphone app (Figure S2 in [Multimedia Appendix 1](#)) with an optical ear sensor enabling real-time HRV

visualization, assessment, and optimization during biofeedback sessions. Participants downloaded the Inner Balance app to their smartphones and set up an account using the login information provided by the study team. HeartMath’s Inner Balance pulse sensor clips on the participant’s ear and links through Bluetooth directly to an individual’s smartphone. The sensor contains an optical photodetector that samples up to 125 Hz providing real-time HRV assessment. Clip-on ear sensors have been shown to provide an accurate assessment of HRV compared to ECG [71]. Through HRV calculations, it produces an index of coherence, as a percentage of time in high, medium, or low coherence, through breathing and self-generated positive emotions [72]. A flower-shaped central visual pacer is present in the app, which paces a participant’s breathing. Through integration with sensed HRV, the app is able to reinforce the correct technique for HRV optimization [65,73,74].

Participants used the Inner Balance app for one 5-minute session per day for 5 weeks. Compliance was tracked remotely through the HeartMath system. HRV biofeedback sessions are usually supplemented with in-person or structured education sessions. To enable learning remotely, weekly educational videos were provided to participants in the custom ehive app. Five weekly videos provided information on (1) how to use the technology; (2) an introduction to HRV, biofeedback, and coherence; (3) a description of what coherence is and how it works; (4) how to incorporate biofeedback techniques into everyday life; and (5) reinforcement of what is learned in prior videos. Each video was less than 20 minutes in length and could be watched over the week.

Wearable Device

HRV was measured by the Apple Watch Series 5 or 6 that was worn by participants throughout the intervention and postintervention period. The Apple Watch contains a PPG optical sensor with both a green light diode and a light-sensitive photodiode [75]. This creates time series peaks that are filtered for ectopic beats and used to generate interbeat intervals. HRV was automatically calculated by the Apple Watch using the SD of the interbeat interval of normal sinus beats (SDNN) [76]. SDNN is a time-domain HRV metric that reflects both sympathetic and parasympathetic nervous system activity [10]. The only HRV metric available from the Apple Watch is SDNN. Multiple HRV measurements were generated by the Apple Watch throughout each 24-hour period in which individuals were wearing the device. These data were retrieved through our ehive app. The Apple watch calculates each of these SDNN measurements over 60-second windows, with a bias toward nighttime measurements, to minimize artifacts in the readings. The algorithms used by the Apple Watch for artifact rejection and ectopic beat handling are proprietary and not publicly available. However, they likely use well-described algorithms in this space [64]. While this is a limitation, the PPG-based HRV calculations from Apple Watches have been validated against ECG [12,77].

Statistical Analysis

Data are presented descriptively as the mean and SD or frequency and percentages, as appropriate. Mean values for each psychological assessment were obtained at baseline; just

before initiation of HRV biofeedback; and at week 5, week 7, and week 17. Changes over time in the psychological assessment were analyzed using mixed effects models with participants as random effects. Week-5, week-7, and week-17 survey results were each compared for statistical differences to the baseline values.

HRV is captured by the Apple Watch in a relatively sparse and nonuniform sampling and follows a circadian pattern [78,79]. To account for frequent daily measures of HRV that are collected from wearable devices over a several-week period, statistical methods that take into account these changes are needed. Daily circadian rhythms have been previously modeled by nonlinear cosinor methods [80]. This approach models the circadian HRV rhythm each day over 24 hours and enables the data to be described using circadian parameters (Figure S3 in [Multimedia Appendix 1](#)): (1) midline-estimating statistic of rhythm (MESOR): the midline of the rhythm, or a rhythm-adjusted mean, over the 24 hours; (2) acrophase: a measure of the time of the highest values that reoccur each day; and (3) amplitude: characterizes half the extent of the variation in every 24 hours. To fully use the cyclical nature of the physiological metrics, as well as the longitudinal measurements, mixed-effect cosinor models were used to model HRV over time based on the *cosinormixedeffects* R package (R Core Team) [81]. This expands the nonlinear cosinor methods to account for correlations of repeated measurements within a participant over time. As has been previously described, a cosinor model uses the nonlinear function $Y(t)=M + A\cos(2\pi t/\tau + \phi) + e_i(t)$, where τ is the period ($\tau=24$ h), M is the MESOR, A is the amplitude, and ϕ is the acrophase. This can be converted into the linear model with $x=\sin(2\pi t/\tau)$, $z=\cos(2\pi t/\tau)$. HRV can

be written as $Y(t)=M + \beta x_t + \gamma z_t + e_i(t)$ [82]. The mixed-effect cosinor model extends the linear framework in a longitudinal setting through the inclusion of random effects θ_i that models the within-patient correlation and expressed as $Y_{it} = (M + \beta x_{it} + \gamma z_{it}) + W_{it}\theta_i + e_i(t)$, where $\theta_i \sim \text{MVN}(0, \Sigma)$ [81]. Bootstrapping procedures were used to calculate the confidence intervals of the model estimates. Age, sex, and BMI were included as covariates in the HRV analyses with participants as random effects.

HRV was evaluated using the above approach for each 7 days of the study. The baseline measurement reflects the 7 days preceding the initiation of the HRV-directed biofeedback. Each subsequent 7-day period, over the 7-week HRV observation period, was compared to this baseline value. All analyses were carried out at the 2-sided .05 significance level using SAS (version 9.4; SAS Institute Inc) and R (version 4.2.2; Foundation for Statistical Computing). Since this was a proof-of-concept study, there was no adjustment for the multiplicity of hypothesis testing.

Results

Quantitative Findings

In total, 127 participants consented to the study between July 2021 and April 2022. The mean age of these participants was 37.3 (SD 10.6) years, with 93 (73.8%) being female. In total, 72 (56.7%) of these participants started the intervention and used the Inner Balance device at least 1 time (>0% compliance), while 49 (38.6%) participants were at least 20% compliant, and 21 (16.5%) participants were at least 50% adherent over the 5-week intervention period ([Table 1](#)).

Table 1. Demographic information for participants signing consent, those who used the intervention at least 1 time, those with at least 20% compliance, and those with at least 50% compliance.

Characteristics	Signed consent (N=127)	Compliance >0% (n=72)	Compliance ≥20% (n=49)	Compliance ≥50% (n=21)
Age (years), mean (SD)	37.3 (10.6)	38.4 (11.0)	38.0 (11.0)	37.7 (12.1)
Male, n (%)	33 (26.2)	22 (31)	13 (26.5)	5 (23.8)
BMI (kg/m ²), mean (SD)	25.3 (5.5)	25.3 (5.5)	25.3 (5.6)	27.3 (6.5)
Race, n (%)				
Asian	32 (25.6)	15 (21.4)	11 (22.9)	2 (10)
Black	15 (12)	9 (12.9)	6 (12.5)	3 (15)
White	69 (55.2)	43 (61.4)	29 (60.4)	14 (70)

Unknown	4 (3.2)	2 (2.9)	1 (2.1)	1 (5)
Hispanic or Latino, n (%)	29 (23.8)	16 (23.5)	11 (23.4)	6 (30)
Smoking: never or rarely, n (%)	103 (81.1)	57 (79.2)	40 (81.6)	17 (81)
Anxiety, n (%)	29 (24.4)	16 (23.5)	10 (20.4)	6 (28.6)
Depression, n (%)	25 (19.8)	15 (20.8)	10 (20.4)	6 (28.6)

The percentage of participants who watched the entire weekly video decreased throughout the study. A video introducing the study at enrollment was watched in its entirety by 100% of

participants. The video in week 2 was watched in its entirety by 54% (68/127) of participants, the week 3 video was watched by 47% (60/127) of participants, the week 4 video was watched

by 42% (53/127) of participants, and the week 5 video was watched by 39% (49/127) of participants. There was a technology tutorial video that provided information about the Inner Balance system. This was watched in its entirety by 65% (83/127) of participants.

Overall, the acceptability of the study was good. Participants were asked how satisfied they were with the HeartMath Intervention on a scale of 1 (not satisfied) to 7 (very satisfied). In total, 79 participants answered the question with a median score of 5. Out of the 81 participants who answered the question as to whether they pursued additional learning about HeartMath outside of the study, 17.3% (n=14) reported in the affirmative. Participants who pursued additional learning about HeartMath were more satisfied with the HeartMath intervention, scoring their degree of satisfaction with a mean of 6.07 (SD 0.86) compared to those who did not pursue outside learning (mean 4.45, SD 1.52).

Psychological Assessment

In participants who were at least 50% compliant (n=21) with the Inner Balance device, resilience scores were noted to numerically increase between the baseline assessment, week 5, week 7, and week 17. However, none of these values differed significantly from the baseline assessment. Social support scores (emotional support 2-item PROMIS questionnaire) similarly demonstrated a numerical increase from baseline (mean 8.13, SD 1.46) to week 5 (mean 8.60, SD 0.89), week 7 (mean 9.80,

SD 0.45), and week 17 (mean 8.67, SD 2.31). None of these increases were statistically significant compared to the baseline assessment. Stress scores (PSS-10) numerically decreased in the $\geq 50\%$ compliant cohort, dropping from mean 20.63 (SD 5.95) at baseline to mean 10.67 (SD 7.77) at week 17. The change in stress scores at week 5 ($P=.24$), week 7 ($P=.45$), and week 17 ($P=.26$) were not significantly different compared to the baseline assessment. PHQ-4 scores, which increase when there is greater psychological impairment, decreased from baseline through week 17. In the $\geq 50\%$ compliant cohort there was not a statistically significant change in these values, compared to the baseline assessment, at week 5 ($P=.83$), week 7 ($P=.55$), or week 17 ($P=.38$). NIH PROMIS positive affect and well-being scores rose as well over the 17 weeks in the $\geq 50\%$ compliant cohort, reflecting increasing positive affect and well-being. Due to the small number of individuals in this cohort, we were not able to calculate P values for this comparison. The 2-Item Global Health and Quality of Life Scale increased over the observation period, demonstrating higher quality of life. This change, compared to baseline, did not reach the level of statistical significance at week 5 ($P=.50$), week 7 ($P=.62$), or week 17 ($P=.36$). Overall, psychological assessments additionally demonstrated numerical improvement over the 5-week intervention period and through the 17-week follow-up period in those who used the Inner Balance device at least once and in those who were $\geq 20\%$ compliant, though they did not differ significantly from the baseline assessments (Table 2).

Table 2. The mean psychological assessments are presented at baseline, week 5, week 7, and week 17 in each compliance group. The mean scores for each survey at week 5, week 7, and week 17 are compared against the baseline scores. *P* values reflect the significance of this comparison. Compliance groups are defined as those performing the intervention at least 1 time, those with at least 20% compliance, and those with at least 50% compliance.

Physiological Metrics

There was an average of 4.7 (SD 3.5) HRV measurements obtained per participant per day. The average length of time of each sample was 59 seconds. The median SDNN value obtained in the full cohort was 38 milliseconds with a minimum and maximum value of 10 milliseconds and 200 milliseconds, respectively. We fit a cosinor model evaluating differences in HRV (SDNN) each week over the 5-week intervention period and over the 2 weeks following the intervention period. There were no significant changes from baseline in the amplitude or acrophase of the circadian pattern of SDNN in all 3 compliance groups (Table 3). Significant changes were noted in the MESOR of the circadian pattern of SDNN in participants who are $\geq 50\%$ compliant with the intervention. In this group, the mean MESOR was 50.20 (95% CI 41.16-58.78) during the baseline 7-day period. A numerical but not significant rise ($P=.12$) in the MESOR was observed during week 1 of the intervention (mean 52.59; 95% CI 43.65-61.08). There were significant changes in

the mean MESOR of the circadian pattern of SDNN found during week 2 (mean 55.00; 95% CI 46.11-63.37; difference 4.80; 95% CI 1.63-7.91; $P<.001$), week 3 (mean 54.25; 95% CI 45.27-62.76; difference 4.04; 95% CI 0.64-7.00; $P=.01$), and week 4 (mean 55.70; 95% CI 46.77-63.94; difference 5.50; 95% CI 2.31-8.60; $P<.001$) compared to baseline (Figure 2). The MESOR during week 5 of the intervention and the 2 weeks after the end of the intervention did not demonstrate significant changes compared to baseline.

In the participants who used the Inner Balance device at least once and in those who were $\geq 20\%$ compliant with the intervention, there was only 1 significant change in the MESOR observed over the 7-week follow-up period. There was a significant change in the MESOR of the circadian HRV pattern in participants with $>0\%$ compliance with the intervention during week 1 (mean 45.46; 95% CI 39.30-51.58; difference 1.48; 95% CI 0.10-2.88; $P=.04$), compared to the baseline 7-day period.

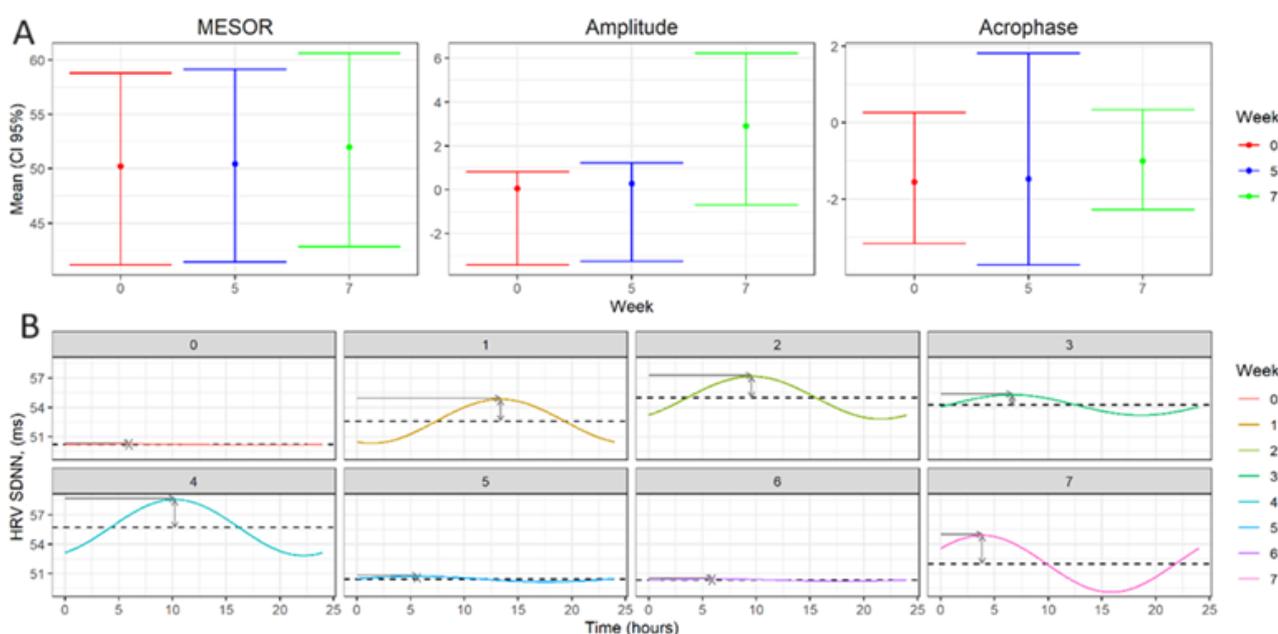

Table 3. The mean midline-estimating statistic of rhythm (MESOR), amplitude, and acrophase are presented for each week of the observation period. heart rate variability (HRV) circadian parameters were calculated for each 7 days of the study, with the baseline readings representing the 7-day preintervention period. Comparisons between each HRV metric 7-day period and the baseline 7-day period were performed. P-values reflect the significance of each comparison. Compliance groups are defined as those performing the intervention at least 1 time, those with at least 20% compliance, and those with at least 50% compliance.

Figure 2. (A) Plots show the mean (95% CIs) heart rate variability (HRV) midline-estimating statistic of rhythm, amplitude, and acrophase for participants at baseline, week 5, and week 7. (B) Plots show the average weekly circadian HRV rhythm for participants at baseline and over the first 7 weeks of the study period for participants with at least 50% compliance (n=21). midline-estimating statistic of rhythm; SDNN: SD of the interbeat interval of normal sinus beats.

Discussion

Overview

Overall, we found that using brief remote HRV biofeedback sessions and monitoring its physiological effect using wearable devices, in the manner that the study was conducted, was not feasible. This is considering the low compliance rates with the study intervention. However, there was a numerical improvement in all psychological metrics over the intervention period, and compliant participants had a measurable physiological change in wearable assessed HRV. In addition, participants were in general satisfied with the HeartMath system that was used. This supports the potential for at-home, HRV-directed biofeedback and wearable-based monitoring to be effective, but only when participants are engaged. The findings highlight the challenges with maintaining engagement in large remote intervention studies.

This study built on the existing literature supporting the use of short sessions of HRV biofeedback by using a short 5-minute HRV biofeedback session that could be performed on an individual's smartphone. Furthermore, it took the structured

education that often accompanies biofeedback and divided it into easily digestible short videos, which individuals could absorb at their own pace. This framework pilots an approach that enables the intervention to be used by individuals who might not have the time to engage in a more structured program. Furthermore, while the physiological effects of biofeedback are often evaluated through brief HRV assessments, we used a commonly used commercial wearable device to monitor its impact. While HRV data were available from the HeartMath device during the short biofeedback sessions, this represented only a very brief assessment of the physiological effect in a relatively small number of compliant participants (n=21). These measurements do not assess the intervention's sustained effect on an individual's physiological parameters, which is of primary interest in this study. Therefore, our focus was on analyzing and leveraging the longitudinal HRV data provided by the Apple Watch. The benefit of this approach is 2-fold in that it can unobtrusively monitor the intervention's effect and evaluate the intervention's impact over longer periods through its assessment of circadian features of autonomic function. Importantly, we demonstrated that the MESOR of the circadian pattern, which reflects the mean HRV reading over the observation period,

increased in participants compliant with the intervention, reflecting increased parasympathetic tone. Previous studies have demonstrated that commercially available wearable devices may be able to monitor and identify psychological states through HRV monitoring [82,83]. The results of this study extend these observations by demonstrating that commonly used wearable devices can potentially be used to monitor the physiological effects of psychological interventions and warrant further evaluation.

We used the HeartMath system, which uses a well-studied HRV biofeedback tool, as described above. We found that psychological metrics were numerically improved with the intervention. However, these changes did not meet statistical significance. A primary driver of this observation is likely the low rate of adherence, as the number of people who were at least 50% compliant with the intervention was only 21 individuals. While the trend in improvement was evident in all 3 adherence groups, statistical significance may have been met if the number of participants $\geq 50\%$ compliant was larger or if rates of adherence were well over 50%. Given the limited number of participants, we were not able to perform a sensitivity analysis to determine the minimum adherence or engagement rate needed to elicit an effect. However, the trends we observed in psychological metrics warrant further study of this approach. Another potential hypothesis as to why we did not see statistical improvement in the psychological metrics may be that the cohort is relatively healthy compared to other groups undergoing psychological interventions. However, when we look at psychological metrics such as resilience, we see that the mean CD-RISC 10 score for the entire cohort was 27.05, compared to the general population's mean of 31.8 (SD 5.4) [84]. Therefore, the cohort is less resilient at baseline and presumably would benefit from such an intervention. Interestingly, we did demonstrate that short sessions of HRV biofeedback are able to significantly modify HRV. The performance of just half or more of the 5-minute biofeedback sessions in 1 week significantly impacted the circadian features of HRV and increased parasympathetic tone. While we did not observe this significant difference during the fifth week of the intervention in this cohort, the sample size was small, and engagement varied week by week, likely explaining the drop in effectiveness in the final week. During the 2 weeks after the intervention period, HRV was not significantly different from baseline. This observation demonstrates that sustained employment of short sessions of biofeedback is required for ongoing physiological effects. This is an important finding, as there are scarce studies evaluating the long-term impact of HRV biofeedback on HRV metrics, with few studies demonstrating sustained short-term effects [85,86]. Further studies evaluating the duration of physiological effects are needed.

While 127 participants initially joined the study, only 21 (16.5%) participants used the intervention at least half of the time. While low rates of persistent engagement can be seen across remote digital psychological intervention studies, future work using this remote biofeedback intervention should focus on direct means to maintain engagement. This could include coaching models or community-based engagement such as "leaderboards." [87] Additionally, dedicated study coordinators checking in

with each participant could potentially improve adherence and participant engagement. Adherence may be increased by focusing recruitment efforts on individuals most interested in biofeedback programs. Our recruitment methods opened the study up to any HCW across multiple hospitals. However, focusing recruitment efforts on individuals interacting with hospital psychological support systems would engage individuals more likely to be interested in performing psychological interventions. Furthermore, we could hypothesize that the most engaged participants may have some degree of knowledge or interest in digital technologies, given the employment of apps and wearable devices. Therefore, such programs may be most effectively deployed in tech-savvy populations. While 79 participants rated the acceptability of the Heart Math system and were overall satisfied with it, we, unfortunately, did not have qualitative data regarding its acceptability or feasibility.

There are several additional limitations to this study. One important limitation is the limited external evaluation of Apple Watch-generated HRV measurements. There have been several studies evaluating and validating the Apple Watch's accuracy in measuring HRV. These studies have compared calculations derived from metrics collected from the Apple Watch with ECG measures. Turki et al [54] demonstrated that in 6 healthy participants, HRV acquired from R-R interval estimates derived from Apple Watch measures of heart rate are reasonable estimates of HRV derived from an ECG. Similarly, Hernando et al [12] validated the R-R intervals derived from the Apple Watch and the HRV metrics calculated from these series against readings derived from a single lead ECG acquired from the Polar band in 20 participants. Khushhal et al [53] performed a similar study on 21 individuals during exercise, demonstrating agreement in HRV metrics calculated from Apple Watch outputs compared to the Polar HR monitor. These studies demonstrate that Apple Watch metrics, used in the calculation of HRV by the device, are valid. However, the algorithms describing how the Apple Watch cleans the PPG data for ectopic beats and artifacts are not publicly available, and therefore limited data demonstrating how Apple calculated HRV metrics compared to ECG-derived measures. While this is a limitation of the study, we still incorporated the Apple Watch as it also serves the important purpose of demonstrating the potential for commonly used commercial devices to monitor the effect of HRV-directed biofeedback. HRV was only assessed in 1-time domain metric (SDNN) in this study, limiting the evaluation of other HRV metrics with the study outcomes. However, SDNN is 1 of the most common HRV features evaluated when studying resilience or the impact of HRV on psychological or physiological features [19]. Further study evaluating other HRV metrics is needed in the future to determine how other HRV parameters are impacted by short sessions of remote HRV-biofeedback. Another limitation is that we did not have exit surveys to understand why certain individuals were not compliant with study components, such as watching weekly videos or using the HeartMath device consistently. A final limitation is that HRV is not specific and can be impacted by many environmental factors beyond the covariates we controlled in the analysis. This is an important limitation to recognize as there is the potential

for unmeasured covariates to impact the results, including such things as ongoing tobacco use and menstrual cycles.

Conclusion

We demonstrated that fully remote, short HRV biofeedback sessions, using light touch engagement measures, have low compliance rates. However, we did find numerical improvement

in psychological assessments over the intervention and follow-up period and alterations of wearable assessed HRV measures in compliant individuals. This supports the need for further evaluation of remotely used short sessions of HRV biofeedback and of the use of wearable devices to monitor response if higher rates of engagement can be achieved.

Abstract

Background: The care environment significantly influences the experiences of patients with severe mental illness and the quality of their care. While a welcoming and stimulating environment enhances patient satisfaction and health outcomes, psychiatric facilities often prioritize staff workflow over patient needs. Addressing these challenges is crucial to improving patient experiences and outcomes in mental health care.

Objective: This study is part of the Patient-Reported Experience Measure for Improving Quality of Care in Mental Health (PREMIUM) project and aims to establish an item bank (PREMIUM-CE) and to develop computerized adaptive tests (CATs) to measure the experience of the care environment of adult patients with schizophrenia, bipolar disorder, or major depressive disorder.

Methods: We performed psychometric analyses including assessments of item response theory (IRT) model assumptions, IRT model fit, differential item functioning (DIF), item bank validity, and CAT simulations.

Results: In this multicenter cross-sectional study, 498 patients were recruited from outpatient and inpatient settings. The final PREMIUM-CE 13-item bank was sufficiently unidimensional (root mean square error of approximation=0.082, 95% CI 0.067-0.097; comparative fit index=0.974; Tucker-Lewis index=0.968) and showed an adequate fit to the IRT model (infit mean square statistic ranging between 0.7 and 1.0). DIF analysis revealed no item biases according to gender, health care settings, diagnosis, or mode of study participation. PREMIUM-CE scores correlated strongly with satisfaction measures ($r=0.69-0.78$; $P<.001$) and weakly with quality-of-life measures ($r=0.11-0.21$; $P<.001$). CAT simulations showed a strong correlation ($r=0.98$) between CAT scores and those of the full item bank, and around 79.5% (396/498) of the participants obtained a reliable score with the administration of an average of 7 items.

Conclusions: The PREMIUM-CE item bank and its CAT version have shown excellent psychometric properties, making them reliable measures for evaluating the patient experience of the care environment among adults with severe mental illness in both outpatient and inpatient settings. These measures are a valuable addition to the existing landscape of patient experience assessment, capturing what truly matters to patients and enhancing the understanding of their care experiences.

Introduction

The health care environment, which encompasses design features (ie, cleanliness, food, privacy, waiting time, basic amenities) and the overall atmosphere (or climate) [1], has been recognized as a significant factor influencing the experiences of patients with severe mental illness (SMI) [2-5]. It is an important factor in the quality of patient care [2,6-8], contributing to improved patient satisfaction [9] and improved health outcomes [10,11]. In a recent study, patients identified a welcoming environment as one of the most important aspects of their care [12]. Indeed, a calm and welcoming environment helps to improve patients' sense of control and empowerment and, consequently, reinforces their willingness to follow recommended treatments. In addition, the care environment is the patients' first impression and can lead to a positive image of the therapeutic process [13]. A supportive environment promotes communication between patients and staff, can help reduce stressful stimuli, and thus prevents relapses and risky behavior. The priority for psychiatric facilities is therefore to provide patients with a warm and safe atmosphere that allows for positive social interactions, with opportunities for stimulating activities, enabling patients to facilitate their recovery and transition to the community. Different theoretical models can shed light on the additional nonpharmacological and biopsychosocial effects of a patient's care experience, including the placebo response effects and the set and setting theory [14,15].

Recommended features to promote patient recovery [16-19] include smaller, home-like units with well-decorated common spaces, open designs, access to nature and daylight, and an

environment that is clean, well laid out, and ensures privacy and security for personal effects. However, psychiatric facilities are often criticized for prioritizing staff workflow over patient needs [2], leading in some cases to a perceived "prison-like atmosphere" [16,20,21] characterized by conflicting routines and rules and a lack of stimulation [22,23]. Some patients have reported feelings of boredom, loneliness, and stigmatization in these environments [21-26]. The lack of stimulating activities and positive social interactions is a barrier to patients' successful recovery [24-30]. These negative experiences can contribute to decreased patient satisfaction, increased levels of anxiety and stress among patients, ineffective care, and signs of burnout among staff [27,31,32]. Emphasis should be placed on the design of psychiatric facilities, as a difficult environment is a barrier to care, and patients often perceive such an environment as a lack of attention from staff [30]. In psychiatry, patients cope with an unfamiliar and potentially stressful environment [33], and a better understanding of their experiences is essential to identify and improve current barriers.

Given this growing interest, it is necessary to provide a valid and reliable instrument for measuring patients' experience of the care environment, applicable to both inpatient and outpatient settings, as care pathways for patients with SMI often combine several care modalities. Previous research has demonstrated that patients with SMI can provide reliable and valid responses to self-administered questionnaires; the impact of psychiatric symptoms and cognitive deficits seems to be negligible [34,35]. The French group PREMIUM (Patient-Reported Experience Measure for Improving Quality of Care in Mental Health) is developing item banks and computerized adaptive tests (CATs) to improve the systematic use of patient-reported experience measures in mental health care [36]. The use of CATs

significantly reduces measurement burden by administering a limited number of items targeted to the respondent's experience level, aiming to improve measurement accuracy.

The objective of this study was to calibrate an item bank and develop a CAT to assess the care environment experienced by adult patients with SMI. These measures will contribute to the current landscape of patient experience measures by providing a valuable complement to PREMIUM measures and capturing what really matters to patients.

Methods

Study Population and Procedure

This is a national, multicenter, cross-sectional study conducted between January 2016 and December 2021. Patients were recruited through in- and outpatient psychiatric settings of a French teaching hospital (Assistance Publique-Hôpitaux de Marseille), the FondaMental Foundation's expert centers [37], and through an online survey. In mental health settings, stable patients who met the inclusion criteria were identified and approached by a member of their usual care team to invite them to participate in the study. The link to the web survey was distributed through patient associations.

Inclusion criteria were as follows: age older than 18 years and younger than 65 years with a diagnosis of schizophrenia, bipolar disorder, or major depressive disorder (MDD), receiving inpatient or outpatient psychiatric care, and speaking or reading French. Vulnerable persons (ie, pregnant or nursing women, persons under legal protection) or those unable to complete a self-administered questionnaire were not included in the study.

Current recommendations suggest a sample size of 300-500 observations for multiparameter item response theory (IRT) models [38-40]. Consequently, we estimated that a sample of around 500 patients would be sufficient to obtain reasonably stable estimates.

Data Collection

Data were collected through paper questionnaires in health care settings and online through a web survey. Patients reported the following sociodemographic and clinical characteristics: gender, age, educational level, marital status, occupational status, main diagnosis (schizophrenia, bipolar disorders, or MDD), duration of illness, and quality of life (QoL) as measured using the medical outcome study 12-item Short Form (SF-12) [41], which describes 8 QoL dimensions: physical functioning, social functioning, role physical, role emotional, mental health, vitality, bodily pain, general health, and 2 composite scores for physical and mental QoL (ranging from 0 to 100, with higher scores indicating better QoL). Adequate psychometric properties of the SF-12 have been demonstrated among individuals with SMI [42], and the SF-12 has proven to be a good alternative to the SF-36 for minimizing response burden.

The PREMIUM for Care Environment (PREMIUM-CE) item bank consists of 16 items designed for patients with SMI and measures their experience regarding the care environment over the past 4 weeks. Participants respond to the items on a 5-point Likert scale ranging from "strongly disagree" to "strongly agree"

with a "not applicable" response option. Additionally, an overall satisfaction item ("Overall, are you satisfied with the health care facilities in which you receive care?") and a visual analog scale (VAS; minimum 0 to maximum 10) were collected. PREMIUM-CE items were identified through face-to-face interviews with patients with SMI and a systematic review of existing patient-reported experience measure; then the item pool was refined based on an expert review and cognitive interviews with patients with SMI [4,5,36].

Statistical Analysis

Basic Descriptive Analysis

Descriptive statistics were calculated to describe participants' characteristics, including frequencies and percentages for categorical variables and means and SDs for continuous variables. Response rates, means and SDs, and ceiling and floor effects were also calculated for each item.

IRT Assumptions

Unidimensionality, local independence, and monotonicity are the 3 fundamental assumptions of IRT [43]. Data were randomly divided into 2 data sets (n=249 each), one for exploratory factor analysis and one for confirmatory factor analysis (CFA) with the weighted least squares mean and variance estimator to ensure that the PREMIUM-CE was sufficiently unidimensional [44]. Local independence was examined using residual correlations from the final CFA model. Monotonicity was examined using visual inspection of characteristic item curves.

Calibration and Fitting an IRT Model

Item parameters were estimated using the generalized partial credit model (GPCM) [45] and compared to the partial credit model [46]. IRT handles missing values by using full information maximum likelihood estimation, which uses all available information, and GPCM is recommended when the amount of missing data is high (20% or more) [38]. Item fit was assessed by examining the mean square infit statistics, which reflect the information-weighted mean squared residuals between the observed and expected response patterns. PREMIUM-CE scores (θ) were estimated by the Bayesian Expected a Posteriori estimation method [47], and a linear transformation was performed to obtain PREMIUM-CE scores ranging from 0 to 100 (higher scores indicate better experience with the care environment). The information curve of the final item bank was calculated, and high measurement precision was defined as an information score >10, corresponding to a reliability of >0.90 [39].

Differential Item Functioning Analysis

DIF was examined using ordinal logistic regression models [48,49] by gender (man vs woman), age (median distribution), care setting (outpatient vs inpatient), psychiatric diagnosis (schizophrenia vs bipolar disorder vs MDD), and mode of study participation (online survey vs health care settings).

External Validity

Construct validity was examined through convergent and discriminative validity assessments. For convergent validity, Spearman's rank correlations were computed between

PREMIUM-CE scores and both satisfaction (global satisfaction item and VAS) and QoL (SF-12 subscales and composite scores) scores. Our hypothesis was that PREMIUM-CE scores would have strong correlations with satisfaction scores ($r > 0.60$), which are 2 related measures, and weak correlations with QoL scores ($r < 0.30$). For discriminant validity, relationships between PREMIUM-CE scores and sociodemographic and clinical characteristics of the respondents were examined by using 2-tailed t tests, ANOVA, and Pearson correlations. The Q-Q plot was used to determine that the data are approximately normally distributed. Based on previous studies of the determinants of patient satisfaction with psychiatric services [3,50,51], our hypotheses were that higher levels of patient experience of the care environment were associated with older age, being female, being nonsingle, or being in an outpatient setting.

CAT Simulations

These simulations using participants' actual responses were run from the calibrated item bank and compared to identify the best performing CAT version. The stopping rules were based on standard error of measurement (SEM) values of 0.33, 0.44, and 0.55 (corresponding to a reliability between 0.90 and 0.70 [52]). The item administered at baseline was the one that offered the most information to the population mean ($\theta=0$), and then items were administered according to the maximum Fisher information criterion [53].

The indicators used at each stage of the psychometric analyses are presented in Table S1 in [Multimedia Appendix 1](#) [44,54-70]. All of the statistical analyses were performed using the following software: SPSS (version 20.0; IBM Corp), MPlus (version 7.0; Muthen & Muthen), and R (version 4.2.0; R Core Team), using packages *mirt* [71], *lordif* [72], *BifactorIndicesCalculator* [73], and *mirtCAT* [74]. A 2-tailed $P < .05$ was considered statistically significant.

Ethical Considerations

This study was conducted in accordance with the Declaration of Helsinki and approved by the relevant ethics committee (2014-A01152-45). The study was registered in ClinicalTrials.gov (NCT02491866). All participants provided nonopposition, as required by French law. Additionally, all data were anonymized.

Results

Sample Characteristics

Of the 498 participants, 50.2% (250/498) were men, 72.3% (345/477) were unemployed, 73.5% (350/476) were single, and 70.5% (337/478) had an education level of a bachelor's degree or higher. The average age was 40.9 (SD 11.9) years, and the mean duration of illness was 12.9 (SD 9.3) years. In total, 51.8% (253/488) of the participants had a diagnosis of schizophrenia, 24.4% (119/488) had bipolar disorder, or 23.8% (116/488) had MDD, and 77.7% (387/497) of them were outpatients. The characteristics of the sample are presented in [Table 1](#).

Table 1. Sample characteristics.

^aSF-12: 12-item Short Form.

Basic Descriptive Statistics

The mean item scores ranged from 2.07 (SD 1.32) to 3.24 (SD 0.89), and most items had a missing data rate <10% (except items CE10, CE12, and CE15). The floor and ceiling effects ranged from 1.8% to 10.6% and from 10% to 45.2%, respectively. The interitem correlation values ranged from 0.01 to 0.79, and 3 pairs of items showed too high interitem

correlations (>0.70): items CE3-CE4 ($r=0.73$), items CE3-CE5 ($r=0.78$), and items CE4-CE5 ($r=0.79$). Items CE3 and CE5 were excluded because their content was considered less relevant than the remaining items. The lowest scores were for item CE15 ("food was of good quality"), item CE12 ("you had access to media (telephone, computer, internet or Wi-Fi connection, etc)," and item CE10 ("the health care facilities were well equipped"). [Table 2](#) summarizes the distribution of responses for each item.

Table 2. Descriptive statistics of PREMIUM-CE item bank.

Item number	Content item	Score, mean (SD)	Floor effect (%)	Ceiling effect (%)	Missing values (%)	Skewness coefficient	Interitem correlations (Range)
CE1	The health care facilities were easily accessible (distance from home, parking, etc)	3.13 (1.09)	4.6	45.2	2	-1.42	0.01-0.66
CE2	The health care facilities were easy to find (eg, signage present and adapted)	3.13 (1.04)	3.4	43.4	1.8	-1.34	0.10-0.51
CE3	The health care facilities were welcoming	2.86 (1.17)	6.2	35.1	0.2	-0.96	0.27-0.78
CE4	The health care facilities were well-laid-out	2.91 (1.09)	4.8	33.5	0.4	-1.04	0.26-0.79
CE5	The health care facilities were pleasant	2.68 (1.19)	6.8	28.7	0	-0.72	0.27-0.79
CE6	The health care facilities were quiet enough	2.83 (1.15)	7.0	30.9	0.4	-1.06	0.21-0.50
CE7	The health care facilities were comfortable (chairs, armchairs, beds, etc)	2.89 (1.07)	4.8	30.1	0.4	-1.09	0.31-0.64
CE8	The health care facilities were clean	3.24 (0.89)	1.8	44.8	0.2	-1.46	0.21-0.63
CE9	The health care facilities were adapted to your needs	3.01 (1.03)	3.4	36.3	1.2	-1.13	0.23-0.68
CE10	The health care facilities were well equipped (materials for activities, group rooms, etc)	2.63 (1.22)	5.8	21.3	20.5	-0.68	0.25-0.66
CE11	The waiting time was acceptable	2.76 (1.21)	7.2	30.7	1.8	-0.90	0.30-0.49
CE12	You had access to media (telephone, computer, internet or Wi-Fi connection, etc)	2.24 (1.39)	10.0	17.5	26.7	-0.21	0.18-0.52
CE13	The sanitary facilities (toilets, bathroom, etc) were clean	3.08 (1.05)	3.2	39.2	7.4	-1.24	0.19-0.63
CE14	The health care facilities guarantee the respect for your privacy	3.12 (1.06)	4.4	41.8	4.6	-1.41	0.25-0.59
CE15	The food was of good quality, if you had to eat	2.07 (1.32)	10.6	10.0	39.4	-0.15	0.01-0.31
CE16	The smoking ban was respected	3.16 (1.02)	3.2	42.6	6.8	-1.37	0.21-0.50

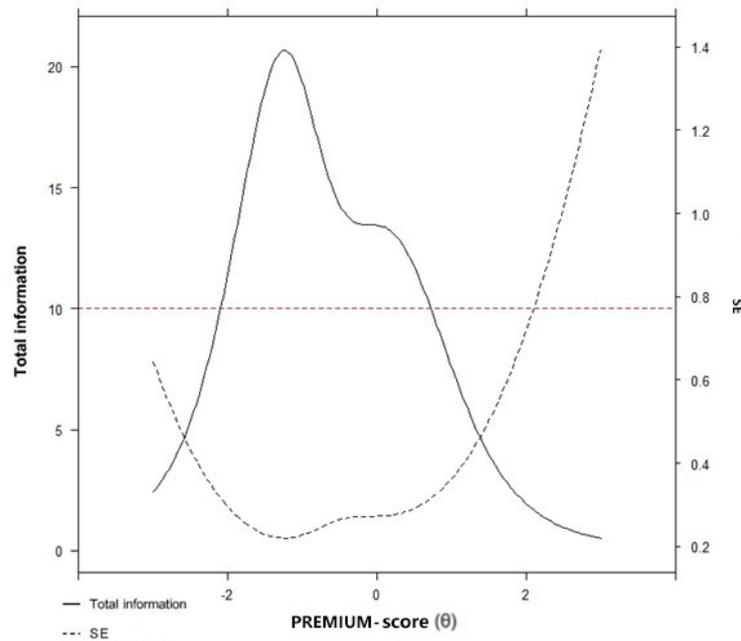

IRT Assumptions

In EFA, 2 factors had eigenvalue greater than 1, and the scree plot and parallel analysis indicated 2 factors. The eigenvalue of the first factor was 6.46 and explained 46.11% of the total variance; the second factor was 1.33, and the ratio was 4.86. Evaluations indicated that the 2 spatial accessibility items (CE1 and CE2) may form a separate factor, and after a content review, only item CE1 was kept as it was deemed the most relevant. The 1-factor CFA model provided evidence to support the unidimensionality of the remaining 13 items (root mean square error of approximation [RMSEA]=0.082; 95% CI 0.067-0.097; comparative fit index=0.974; Tucker-Lewis index=0.968) and no items showed local dependence (all residual correlations were above |0.20|). Of the 13 items in the bank, 10 were recoded to meet the monotonicity assumption (Table S2 in [Multimedia Appendix 1](#)), which improved the model fit (Akaike information criterion=-3343.78 and Bayes information criterion=-3428). Cronbach α was .91.

Calibration and Fitting an IRT Model

The GPCM was used to calibrate the item bank and showed superior fit compared to the partial credit model (10,192.60 and 10,367.43 for Akaike information criterion and 10,382.07 and 10,506.38 for Bayes information criterion; and $\chi^2=198.84$; $P<.001$); item fit was good (infit values ranging between 0.74 and 1.00). IRT parameter estimates for the 13 items showed slopes ranging from 0.55 to 2.85 and thresholds ranging from -2.07 to 2.29. Item parameters and item fit are provided in Table S2 in [Multimedia Appendix 1](#). As shown in [Figure 1](#), PREMIUM-CE provided the most information in the scale range between -2.6 and 1.4 and had a high measurement accuracy (reliability >0.90) in a shorter range between -2.1 and 0.7 (which corresponds to 88.6% of total information). Item CE7 was the most informative of the bank—"the health care facilities were comfortable," whereas item CE15 was the least informative—"the food was of good quality."

Figure 1. The test information for the Patient-Reported Experience Measure for Improving Quality of Care in Mental Health for Care Environment (PREMIUM-CE) item bank.

Differential Item Functioning Analysis

Responses to items CE6 (quiet) and CE13 (sanitary) were flagged for overall DIF but with negligible magnitude according to health care settings. Likewise, the DIF magnitude was negligible for item CE16 (smoking ban) according to mode of study participation and for item CE15 (food) according to gender, mode of study participation, and diagnostic after pooling bipolar disorder and MDD (mood disorders vs schizophrenia; $P=.02$; $\Delta R^2=.013$). None of the items showed significant DIF for age. DIF results are provided in Table S3 in [Multimedia Appendix 1](#).

External Validity

As expected, there were strong correlations between the PREMIUM-CE item bank and overall satisfaction and VAS, supporting convergent validity. Similarly, all SF-12 dimensions were weakly correlated with the PREMIUM-CE item bank, except for bodily pain and vitality. Associations were found between better experience of the care environment (ie, higher PREMIUM-CE scores) and older age, being a woman, being voluntarily admitted to a hospital, and being recruited through health care facilities. There was no significant effect of educational level, marital status, employment status, diagnosis, or duration of illness. These results are presented in [Table 3](#).

CAT Simulations

As reported in Table 4, the results of the CAT simulations based on SEM <.33 and <.44 were both acceptable in terms of accuracy and precision, but the scenario based on SEM <.33

(corresponding to a reliability of 0.90) was the most efficient. Of the 498 participants included in the simulation, 79.5% (396) achieved a reliable score with an average of 7 items administered.

Discussion

Principal Findings

In this study, we report the calibration and initial evaluation of a new PREMIUM-CE item bank measuring patients' experience of the care environment that can be used for CATs. The PREMIUM-CE questionnaire is the first available questionnaire thus far to assess the quality of the care environment, applicable in outpatient and inpatient settings, for adults with SMI. This new measure covers different facets of the care environment, including ease of access in time and space, facility layout and basic amenities, food quality, comfort and cleanliness, respect for privacy, and smoking ban. PREMIUM-CE items address both concerns common to all patients (eg, cleanliness or food) and those more specific to psychiatric patients (eg, therapeutic workshops). Existing instruments measure more objective aspects (eg, checklists fulfilled by direct observation), and patients with SMI were not involved in the development and validation process [75].

PREMIUM-CE has undergone rigorous psychometric evaluation, consistent with previous studies conducted as part of the French PREMIUM initiative [36]. Although the RMSEA was slightly above the criterion of <.08, our results provide evidence of sufficient unidimensionality, and the item pool meets the assumptions for IRT modeling. Research has shown that the RMSEA statistic is problematic for assessing the unidimensionality of item banks measuring health concepts [76], as RMSEA is sensitive to model complexity (number of estimated parameters) and skewed data distributions [77]. These results are comparable to other calibration studies of item banks of patient-reported measures [78-83]. Overall, our results demonstrate that PREMIUM-CE has strong psychometric properties for patients with SMI, with negligible measurement bias by gender, health care settings, and mode of study participation. Items CE10, CE12, and CE15 had a higher rate of missing data than the other items, but this rate was below 40%, which remains acceptable by psychometrics standards [84]. In addition, these items had lower scores compared to others, meaning that efforts should be targeted on these aspects

to improve the experience of patients with SMI. Future studies should examine whether changes to these items are required. The absence of a large DIF magnitude according to health care settings will make it possible to study changes in the experience of psychiatric patients over time, for whom care pathways often combine inpatient and outpatient care modalities. The 13 items in the final version of the PREMIUM-CE are listed in [Multimedia Appendix 1](#), Table S4. In addition, the CAT version showed comparable measurement accuracy to the full item bank with high correlations between scores with an average of only 7 items administered.

External validity, explored using validated questionnaires and sociodemographic and clinical data, generally supported our initial hypotheses. Previous research has demonstrated that some factors, such as age, gender, marital status, and physical and mental health status, can influence individuals' experiences within a specific environment [2,3]. It is important to note, however, that the literature has not consistently established clear associations for age, gender, and marital status [3]. According to our results, older age, being female, being voluntarily admitted, and reporting a good physical and mental quality of life are associated with higher levels of patient experience of the care environment. As previously described [85], women reported higher levels of experience than men. Likewise, older people tend to be more accommodating, perhaps because they have fewer expectations than younger people [86]. Also, contrary to what might be expected, voluntarily admitted patients reported higher levels of experience than outpatients, although some patients reported a preference for community mental health treatment, which they considered less stigmatizing [87] and compatible with professional and social functioning. Furthermore, the literature has shown that hospitalization, particularly in the context of involuntary admission, can have a negative impact on patient experience [3], because it can be experienced as traumatic or particularly stressful for patients [88].

However, our results suggest that patients voluntarily admitted to the hospital may have a more holistic and structured experience compared to outpatients, conducive to positive therapeutic relationships with staff, whereas constraint has a negative effect on therapeutic relationships in the case of involuntarily admitted patients [88-90]. Finally, a positive but weak association was found between higher levels of patient experience and better QoL, as previously reported in other studies [51]. A calm and welcoming care environment contributes to patients feeling more comfortable and safer [50], which can reduce stress and anxiety and enhance relationships with staff, thereby promoting patients' recovery. Participants completing the online survey reported a poorer experience of the care environment than participants in health care settings because the latter may be more favorable due to fear of a negative effect on their relationships with staff, or this difference may be due to a possible recall bias.

The most poorly rated items by patients were related to accessing equipment (CE10), media (CE12), and food (CE15). Difficulties with access to equipment (eg, for art therapy) and media (eg, televisions or computers) are related to boredom, isolation, frustration, and higher levels of distress in patients

[25]. A variety of individual or group activities could be offered to patients, such as therapeutic workshops in self-expression (ie, writing), art (ie, photography or painting), psychosocial rehabilitation (ie, cooking, which may also improve diet habits), or body awareness (ie, sophrology), to help patients develop social skills and promote social reintegration, improve confidence and self-esteem, build emotional resilience, and enjoy themselves. Facilities should have basic amenities such as affordable Wi-Fi and a working television in a common room accessible to all patients. Likewise, rooms should be equipped with a minimum package of free channels; however, not all facilities are equally equipped, and the cost of access to Wi-Fi and pay television channels can vary by as much as 2-fold. The content of what is broadcast on television should also be a therapeutic consideration. For example, it seems logical to avoid broadcasting distressing news or uninspiring programs and to favor the broadcasting of cultural works that could be the object of an exchange after viewing, such as a film club. The use of cell phones in health care settings presents challenges in terms of the potential risk of theft or breakage, as well as concerns about maintaining confidentiality. Additionally, it can be a source of tension with staff (eg, if the telephone credit is exceeded). There is no law that prohibiting the use of cell phones because communicating is a fundamental individual freedom, but the internal rules of the facilities can regulate their use by specifying the times and places of use and prohibit taking pictures of patients and staff. Furthermore, psychiatrists may occasionally prohibit a patient from keeping a cell phone, computer, or tablet as part of a medical decision, particularly in the case of placement in a seclusion room or for medical conditions. Previous studies have shown that a healthy diet is essential for good mental health and can prevent the worsening of symptoms [91,92], and that patients' satisfaction with hospital food services strongly influences their overall satisfaction with hospital care [93]. Diets such as the Mediterranean diet have been shown to improve patient outcomes [91]. Providing a menu tailored to patient preferences while focusing on food quality (taste, presentation, flavor, preparation, and variety), as well as the hospital environment, will help improve inpatient appetite and satisfaction [93]. In summary, the current challenges of hospital food service are to transition to a diet that is lower in meat, closer to the Mediterranean diet, without plastic packaging, and low in processed products while increasing the attractiveness of local and seasonal products, all while maintaining costs [91]. By contrast, the most highly rated items by patients were related to spatial accessibility (CE1), cleanliness (CE8), and smoking ban (CE16). Although health care facilities are under a total smoking ban throughout their whole facilities (including in specifically dedicated "smoking areas" or outside), the reality is often more flexible to accommodate patients who cannot leave the health care facilities, even temporarily (eg, patients under constraint). Proposals for smoking cessation assistance should be systematically offered to patients.

Limitations

Some limitations of this study are worth noting. Our sample size, while relatively modest, was sufficient to obtain accurate estimates. Current recommendations suggest that at least 300

observations are sufficient when using multiparameter models like the GPCM [38-40]. However, our results showed that the assumptions required for IRT calibration were met and that the model fit was adequate. In addition, some DIF analyses comparing subgroups with sample sizes smaller than those recommended for DIF analyses (at least 200 observations per group [94]) may have lacked the statistical power to detect a statistically significant DIF. These DIF findings should be regarded as preliminary, and future work with a larger sample will allow us to confirm these results. Although participants from the online survey and those from health care settings may have reported different levels of experience, this mixed survey design was chosen to ensure inclusivity across various subgroups, as supported by previous research on the equivalence of administration methods [95]. DIF analysis revealed that none of the items was flagged with a large DIF magnitude according to the patient's mode of study participation, suggesting that the data can be pooled without substantial bias. It was not possible to calculate a participation rate or to compare the characteristics of respondents and nonrespondents. This study was widely disseminated nationally, and our sample included inpatients and outpatients with diverse characteristics from different geographic regions of the country. Patients self-reported their diagnosis, and some data (488/498, 2.5%) were missing. However, the risk of misdiagnosis is considered minimal because all participants were fully informed about the study scope and

diagnostic criteria. Additionally, this approach closely mirrors the real-world conditions of PREMIUM use. The title of the study mentioned general experience of care to limit the self-selection bias of patients with extreme care environment experiences. Future work will confirm the generalizability of our results. PREMIUM-CE has greater measurement accuracy for patients with scores between -2.1 and $+0.7$ (ie, reporting low to moderate levels of experience), and thus more items are needed to estimate scores for patients at both ends of the latent continuum. Future work should also reevaluate the precision and accuracy of the CAT in an independent sample and under real-world conditions. Finally, criterion validity could not be assessed because, to our knowledge, no gold standard was available and evidence for construct validity was limited. Future validation studies should examine the relationship between this new measure and objective assessments of the care environment (eg, evaluation by architects or other professionals).

Conclusion

The PREMIUM-CE item bank and its CAT version have demonstrated strong psychometric properties, making them robust measures for assessing patient experience of the care environment, applicable in both outpatient and inpatient settings, for adults with SMI. These measures contribute to the current landscape of patient experience measures by providing a valuable complement to PREMIUM measures of what really matters to patients.

Acknowledgments

The authors wish to thank Baumstarck Karine, Boucekine Mohamed, Loundou Anderson, and Michel Pierre for their statistical and methodological support. This research received funding through institutional grants from the French Programme de recherche sur la performance du système des soins and the Agence Technique de l'Information sur l'Hospitalisation. The sponsors had no role in study design, collection, analysis, and interpretation of data, report writing, or the decision to submit the study for publication.

Authors' Contributions

LB was responsible for the conceptualization, supervision, project administration, and funding acquisition. SF was responsible for the methodology, formal analysis, and writing the original draft. LB, SF, and GF are responsible for review and editing. All the authors read and agreed to the published version of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Emotional clarity has often been assessed with self-report measures, but efforts have also been made to measure it passively, which has advantages such as avoiding potential inaccuracy in responses stemming from social desirability bias or poor insight into emotional clarity. Response times (RTs) to emotion items administered in ecological momentary assessments (EMAs) may be an indirect indicator of emotional clarity. Another proposed indicator is the *drift rate* parameter, which assumes that, aside from how fast a person responds to emotion items, the measurement of emotional clarity also requires the consideration of how careful participants were in providing responses.

Objective: This paper aims to examine the reliability and validity of RTs and drift rate parameters from EMA emotion items as indicators of individual differences in emotional clarity.

Methods: Secondary data analysis was conducted on data from 196 adults with type 1 diabetes who completed a 2-week EMA study involving the completion of 5 to 6 surveys daily. If lower RTs and higher drift rates (from EMA emotion items) were indicators of emotional clarity, we hypothesized that greater levels (ie, higher clarity) should be associated with greater life satisfaction; lower levels of neuroticism, depression, anxiety, and diabetes distress; and fewer difficulties with emotion regulation. Because prior literature suggested emotional clarity could be valence specific, EMA items for negative affect (NA) and positive affect were examined separately.

Results: Reliability of the proposed indicators of emotional clarity was acceptable with a small number of EMA prompts (ie, 4 to 7 prompts in total or 1 to 2 days of EMA surveys). Consistent with expectations, the average drift rate of NA items across multiple EMAs had expected associations with other measures, such as correlations of $r=-0.27$ ($P<.001$) with depression symptoms, $r=-0.27$ ($P=.001$) with anxiety symptoms, $r=-0.15$ ($P=.03$) with emotion regulation difficulties, and $r=0.63$ ($P<.001$) with RTs to NA items. People with a higher NA drift rate responded faster to NA emotion items, had greater subjective well-being (eg, fewer depression symptoms), and had fewer difficulties with overall emotion regulation, which are all aligned with the expectation for an emotional clarity measure. Contrary to expectations, the validities of average RTs to NA items, the drift rate of positive affect items, and RTs to positive affect items were not strongly supported by our results.

Conclusions: Study findings provided initial support for the validity of NA drift rate as an indicator of emotional clarity but not for that of other RT-based clarity measures. Evidence was preliminary because the sample size was not sufficient to detect

small but potentially meaningful correlations, as the sample size of the diabetes EMA study was chosen for other more primary research questions. Further research on passive emotional clarity measures is needed.

Introduction

Background

Emotion regulation is highly relevant to subjective well-being from both hedonic and eudaimonic perspectives. According to the hedonic perspective, well-being is the experience of happiness or the occurrence of positive affect (PA) and absence of negative affect (NA) [1]. In the eudaimonic perspective, well-being arises when individuals live with a sense of growth, meaningfulness, and purpose [2]. People often engage in emotion regulation to obtain hedonic benefits (eg, feel more PA and reduce NA) [3], but eudaimonic motivations have been found to be important as well [4] (eg, downregulation of negative emotions to achieve a sense of growth in one's ability to handle daily stressors).

An important aspect of emotion regulation is emotional clarity, a person's ability to lucidly identify the type of emotion they are experiencing [5]. Emotional clarity is highly relevant to the James Gross Model of Emotion Regulation [6]. The model consists of emotion regulation strategies that are either "antecedent-focused" or "response-focused," which refers to whether the strategy is used before or after an emotional response fully develops. In the updated emotion regulation model of Gross, understanding and identifying one's emotions accurately (ie, emotional clarity) are precursors to both these types of emotion regulation strategies [7]. Therefore, individuals with low emotional clarity are less likely to use emotion regulation strategies (as they are failing to identify the need for them), which can negatively impact well-being. Lower emotional clarity has often been associated with reduced mental health [8-10], although there are exceptions. For instance, prior research has suggested that higher emotional clarity may be adaptive primarily for individuals who do not have very frequent and strong experiences of negative emotions but maladaptive for those who frequently have strong feelings of NA [11].

Both direct and indirect measures of emotional clarity have been developed [12,13]. Direct assessments involve the metacognitive task of reflecting on one's emotional clarity level, while indirect assessments measure the performance of a task relevant to emotional clarity (ie, answering emotion items) and do not require self-insight [12]. Emotional clarity is commonly directly assessed with cross-sectional self-report measures such as the clarity subscales of the Trait Meta-Mood Scale [14] and the Difficulties in Emotion Regulation Scale (DERS) [15], but indirect measures have been argued to have potential advantages over self-report assessments [12,13]. For instance, they could help avoid possible issues with subjective reports, including poor insight into emotional clarity and the possibility of social desirability bias (ie, participants not wanting to report

uncertainty about their feelings) [12,16]. However, for the potential utility to be realized, further investigations of the validity of indirect measures of emotional clarity are needed.

Assessing Emotional Clarity With Item Response Times

Response times (RTs) to emotion questions in ecological momentary assessments (EMAs) have been argued to be indirect measures of emotional clarity at the momentary (within-person) level [12]. Theoretically, the greater an individual's momentary affective clarity, the less time should be needed to provide a rating of momentary affect [12], whereas longer RTs to affect items should be indicative of lower emotional clarity. Evidence supporting this theory has been found, such as shorter RTs to affect items being associated with better momentary emotion regulation and mood [12]. However, emotional clarity may be confounded with emotional intensity [9], and evidence suggests the validity of RTs as a measure of affective clarity is enhanced by controlling for emotional intensity at the within-person (and not between-person) level [17].

There was no strong evidence that the study-long aggregates of emotion item RTs (between-person level) could act as indicators of trait emotional clarity [12,17]. These aggregates were found to not have significant relationships with global measures of emotional clarity and have inconsistent relationships with global emotion regulation measures [12,17]. Suggested reasons for the lack of a relationship between global measures of emotional clarity and the aggregate of emotion item RTs include a modality difference (ie, self-report vs indirect behavior-based assessment), low conceptual correspondence (ie, different forms of emotional clarity are being assessed), and difference in assessment timing (ie, 1 time vs repeated EMA measurements) [12,17]. The relationships between the study-long aggregate of emotion item RTs and subjective well-being variables of relevance to emotional clarity (eg, depression and anxiety) [8,18] were not examined, which could have served as useful additional convergent validity tests. Finally, the possibility that processing speed had a confounding effect on correlations between study-long aggregates of emotion item RTs and other variables was not investigated. In prior research, RTs to emotion EMA items have been found to have moderate correlations with processing speed measures [19], suggesting that individual differences in emotion item RTs may at least in part be attributable to processing speed.

Assessing Emotional Clarity With the Drift Rate Parameter

Another indirect measure of emotional clarity was recently proposed, drift rate, which is computed using the drift-diffusion model [20]. This model, which is often used in cognitive

psychology, was explicitly developed to disentangle different components of RTs [21]. The drift-diffusion model proposes that decisions (eg, choosing responses on EMA items) are made through the accumulation of information until a threshold of sufficient information (as determined by the individual) is reached [21]. Decisions can be fast if the speed of information accumulation (ie, drift rate) is fast, if the threshold for a decision (ie, boundary separation or response caution) is low, or both. The D-diffusion item response theory (IRT) model is an IRT version of the drift-diffusion model that was specifically designed for the analysis of self-report ratings, such as emotion ratings [22]. In the context of answering mood questions, the D-diffusion IRT model additionally considers that RTs may also be fast if extremes of the emotion are experienced (ie, very high or low levels), making the provision of ratings more straightforward [20]. When the D-diffusion model is applied to EMA responses and their RTs, it can take into account all the aforementioned influences on RTs and output drift rate. In the EMA context, drift rate can be interpreted as the speed of access to information relevant to the question being asked [20,21], which here is information regarding emotions. A more detailed description of how the drift rate parameter was computed can be found in the *Emotional Clarity Measure 2: Drift Rate From the Drift-Diffusion Model* subsection in the *Methods* section.

A person would be considered to have high emotional clarity when responding both fast and carefully to emotion items, which differs from how emotional clarity assessed via RTs considers only speed. As the absolute difference between a person's NA level and the level of NA captured by an item increases, the D-diffusion model assumes that an individual would be expected to have faster RTs as a result of the so-called "distance-difficulty" principle, a well-established phenomenon in the RT literature [23], whereby the more items contrast with a person's state, the easier they are. For instance, an individual with a very low NA would be expected to quickly respond to an item asking about being scared (an item often associated with a high NA) [24], whereas the same individual would be expected to require a longer RT for an item asking about irritability (which has been associated with a low NA) [24]. According to the D-diffusion model, response caution is low when a person responds similarly quickly (or slowly) to all items regardless of their content (an indication that the person did not answer carefully). Assuming a particular observed item RT, when response caution is lower (ie, less information is gathered), drift rate (ie, the rate of information accumulation or information divided by time) would also be lower. Conversely, for a person with a higher response caution, the estimated drift rate (and emotional clarity) would be greater for the same RT.

Our initial evidence suggested that the drift rate parameter derived from EMA NA items may be an indicator of emotional clarity of low versus high NA, including expected relationships (ie, negative associations) at the between-person level with neuroticism and depression [20], but we did not account for factors aside from emotional clarity that could impact drift rate. For instance, drift rate could be impacted by individual differences in the general speed of responding to questionnaires (eg, due to reading speed, motor behavior, and familiarity with computer use). Studies on emotional clarity measured by survey

item RTs had accounted for individual differences in this baseline speed of responding by adjusting for it [12], but this was not done in our prior study [20]. Cognitive processing speed was hypothesized to also potentially impact drift rate but was also not adjusted for, as the measure was not available in the prior study [20].

Objectives

Trait Emotional Clarity

There has been substantial prior research and interest in examining emotional clarity as a trait [12,14,15], but further research on the indirect (instead of direct) measurement of individual differences in emotional clarity via EMA data is needed. Compared to traditional cross-sectional self-report measures, indirect measurement of individual differences in emotional clarity potentially has the advantage of less susceptibility to self-report biases stemming from causes such as social desirability and poor insight [12,16]. Furthermore, if an emotion is being assessed via EMA, *indirect assessment of emotional clarity via emotion items affords the possibility of capturing individual differences in emotional clarity without burdening participants with additional items*. The use of EMA methodology is ubiquitous in a broad range of fields [25-27], and the use of EMA emotion items is commonplace [28]. Indirect assessment of trait emotional clarity would, therefore, make the investigation of emotional clarity possible for a large number of EMA data sets without additional emotional clarity items.

The focus of this paper was to examine the reliability and validity of 2 RT-based indirect indicators of individual differences in emotional clarity among adults with type 1 diabetes (T1D). One indicator was the average of repeated measures of RTs to emotion items, and the other was the average of repeated measures of drift rate (ie, the speed of accessing information about one's current affect) derived from emotion items. In validity testing, in contrast to prior work [20], *individual differences in the baseline speed of responding and processing speed were controlled for*. We examined data from an EMA study of adults with T1D [29]. EMA surveys (which included emotion items) were completed 5 to 6 times a day (depending on the participants' sleep schedule) for 2 weeks, and the RTs for each item were recorded. Notably, RT-based metrics can vary within people, and their study-long averages can vary across people. Multilevel modeling was used to account for both these potential sources of variance.

Emotional clarity may be of particular relevance for adults with T1D. Compared to the general population, adults with T1D may be exposed to stressors more frequently, specifically emotional distress related to the daily care of diabetes. A prior study estimated that performing all recommended diabetes self-management activities would require >2 hours daily [30]. Given such burden and associated diabetes distress (emotional distress specific to the daily care of diabetes), individuals with diabetes are more likely to experience lower subjective well-being, such as more symptoms of depression, compared to healthy populations [31]. Diabetes distress has been found to be negatively associated with emotion regulation ability [32]. Therefore, emotional clarity, a possible precursor to emotion

regulation [10], may be integral for adults with T1D to cope with the burden of the condition. Poor coping with diabetes can lead to the neglect of diabetes self-management behaviors, which can amplify the health consequences of diabetes. Greater diabetes distress has been associated with lower adherence to insulin regimens [33,34], while greater depressive symptoms have been associated with lower adherence to diet, exercise, and glucose testing recommendations [35].

Reliability

The reliability of the proposed measures for emotional clarity was investigated by examining the test-retest stability of the measures across EMA measurement occasions.

Table 1. Hypothesized associations of the negative affect (NA) and positive affect (PA) clarity indicators with subjective well-being and emotion regulation.

	Emotional clarity indicator			
	NA drift rate	PA drift rate	RT ^a for NA items ^b	RT for PA items
Subjective well-being				
Satisfaction with life	Positive	Null	Positive	Null
Neuroticism	Negative	Null	Negative	Null
Depression	Negative	Null	Negative	Null
Anxiety	Negative	Null	Negative	Null
Diabetes distress	Negative	Null	Negative	Null
Emotion regulation and its 6 components				
Emotion regulation difficulties (overall)	Negative	Null	Negative	Null
Limited strategies	Negative	Null	Negative	Null
Nonacceptance	Negative	Null	Negative	Null
Impulse control difficulties	Negative	Null	Negative	Null
Difficulties with goal directedness	Negative	Null	Negative	Null
Lack of awareness	Negative	Negative	Negative	Negative
Lack of emotional clarity	Negative	Negative	Negative	Negative

^aRT: response time.

^bMultiplied by -1 so that higher values indicate greater emotional clarity.

Hypothesized Associations With Subjective Well-Being

Past literature has found that increased emotional clarity and emotion regulation ability, as assessed by questionnaires or RTs to emotion items, were associated with greater subjective well-being, including greater life satisfaction [36], lower neuroticism [9], lower depression [18], fewer anxiety symptoms [8], and less diabetes distress [32]. However, following the results of the study by Thompson et al [9], we hypothesized that these relationships should hold only for indicators of NA clarity, not PA clarity.

Hypothesized Associations With Emotion Regulation

We considered the valence of emotions in the generation of our hypotheses regarding associations between passively collected indicators of emotional clarity and emotion regulation, given previous work showing that the clarity of positive emotions had different associations with other measures (eg, neuroticism and depression) compared to the clarity of negative emotions [9].

Validity

The validity of the RT-based indicators of emotional clarity was tested by examining their associations with well-validated measures of relevance to emotional clarity. In forming our hypotheses (summarized in Table 1), we made a distinction between the clarity of PA and the clarity of NA because of prior research suggesting that the latter had associations with mental health while the former did not [9]. Therefore, we speculated that the awareness of NA is a more direct precursor to the application of coping strategies and successful coping than the awareness of PA.

The DERS [15] has 6 subscales representative of emotion regulation components (listed in Table 1), as well as an overall score. Of the 6 DERS subscales, 4 (67%) specifically assess problems with regulating NA (ie, limited access to emotion regulation strategies when upset, nonacceptance of negative emotional responses, impulse control difficulties when upset, and difficulties with goal-directed behaviors when upset); we hypothesized that greater difficulties indicated on each of these component scales would be associated with lower NA clarity on the proposed RT-based measures [10], whereas we did not expect them to be associated with PA clarity on the RT-based measures (Table 1). That is, we expected NA clarity to precede and hence be more relevant to NA regulation than PA clarity, consistent with prior findings of associations between neuroticism and NA clarity, but not PA clarity [9]. The remaining 2 (33%) components of emotion regulation (ie, a lack of emotional awareness and lack of emotional clarity) are not specific to the regulation of NA [15]; therefore, we hypothesized that they would be associated with the clarity of both NA and

PA using the RT-based measures. Notably, 1 of these 2 components assesses self-reported emotional clarity; we expected that this component would have associations of a greater magnitude with RT-based measures of NA and PA clarity compared to other emotion regulation subscales. Finally, we hypothesized an association between the DERS total score and indicators of NA clarity but not indicators of PA clarity because 4 (67%) of the 6 DERS subscales were relevant to emotion regulation when experiencing NA.

Adjustment by Individual Differences in RT and Processing Speed

We examined whether adjusting the RT-based emotional clarity indicators by individual differences in RT and participant processing speed would affect the results of the convergent or divergent validity tests. Both RTs to survey items and drift rate were expected to not be purely indicators of emotional clarity but likely also be impacted by processing speed [19,20,37] and differences in the baseline speed of responding [12]. Therefore, we examined the robustness of the results of validity testing when statistically adjusting for both these variables.

Methods

Overview

The analyzed data were from an EMA study focused on investigating the relationships among momentary blood glucose level, emotional state, and functioning in adults with T1D [29]. Participants were recruited from 3 clinical sites through health care provider referrals, mailings, flyers, and emails. Inclusion criteria were having a diagnosis of T1D, being able to speak and read English or Spanish, and the ability and willingness to carry out study procedures (eg, completion of EMAs and cognitive tests on smartphones). Study procedures included the completion of baseline surveys, training in the use of study devices, 2 weeks of 5 to 6 EMAs and ambulatory cognitive tests daily, and follow-up surveys. EMA surveys began at participants' selected wake-up time each day and were administered at 3-hour intervals after that until sleep time. If a participant reported that they would likely be sleeping by the time of the sixth survey (ie, 15 hours after the first survey), then they were given the option to complete 5 surveys daily instead of 6. To encourage EMA compliance, 3 brief check-in emails or calls were scheduled with study staff. In addition, if EMA survey completion was low, then study staff would contact the participant to query if any support was required. The study procedures are described in greater depth in a protocol paper [29].

Ethical Considerations

All study procedures were approved by the University of Southern California's Institutional Review Board (proposal #HS-18-01014). Informed consent was provided before study participation. Participants were compensated US \$200 via a reloadable debit card for completion of all study procedures. Study data were deidentified before analysis.

Measures

RT-Based Measures of Emotional Clarity

The clarity of PA was assessed with RTs to EMA items about how happy, content, enthusiastic, or excited participants felt "right now," while the clarity of NA was assessed with RTs to EMA items asking how tense, upset, sad, or disappointed participants felt in the moment. These emotion adjectives were taken from the "Stress and Working Memory" study [38] and were chosen because they mapped neatly onto the circumplex model of affect [39]. That is, there were 2 items in each of the 4 circumplex dimensions (ie, unpleasant and activated, unpleasant and deactivated, pleasant and activated, and pleasant and deactivated), thereby ensuring that a range of emotion types was represented. The responses were all given on slider scales from 0 (not at all) to 100 (extremely). These emotion items were administered at every EMA prompt using the mobile EMA app (ilumivu [40]). Items were presented one at a time on study-provided smartphones. For each item, RTs were recorded in milliseconds. RTs that were deemed too fast (ie, <0.2 seconds) or too slow (ie, >30 seconds) were set to missing for analyses (5979/461,896, 1.29% of the observations) because such outliers could be indicative of careless responding or distractions during survey completion [20,41].

Emotional Clarity Measure 1: Median RTs

NA and PA clarity were computed as the median RT of the 4 NA items and the 4 PA items at each EMA prompt [12,17] (RTs were multiplied by -1 such that higher values indicate greater clarity). In this paper, median RT for NA items will be referred to as NA RT and median RT for PA items as PA RT.

Following prior research, the median RTs were adjusted for the baseline speed of responding to partial out individual differences in RT stemming from factors such as reading and screen tapping speed [12,17]. We assessed participants' baseline speed by taking the median RT across all EMA occasions on a multiple-choice question asking what they were doing immediately before the survey.

Emotional Clarity Measure 2: Drift Rate From the Drift-Diffusion Model

Drift rates for both NA and PA items were calculated for each EMA following procedures described in detail in a prior study [20] with software code available [42]. In brief, we estimated the drift rates for each person and EMA measurement occasion using the IRT based-variant of the drift-diffusion model that was specifically developed for use with self-report (eg, EMA) items. Because the IRT model requires binary variables, responses to PA and NA items were converted into dichotomous variables such that responses below the midpoint of the scale were coded as 0, while responses at or above the midpoint of the scale were coded as 1. Previous analyses have shown that drift rate measures derived from continuous items that were dichotomized demonstrate convergent validity with items that were already presented to respondents in a binary response format [20]. Next, we examined whether the dichotomized PA and NA item sets were unidimensional, a condition necessary for the calculation of drift rate; we conducted a confirmatory factor analysis in Mplus (version 8.8; Muthén & Muthén) [43]

using the weighted least square mean and variance adjusted estimator, using cluster-robust SEs to account for the nesting of multiple EMA measurement occasions within individuals. We examined whether fit indices were within the traditional ranges for acceptable model fit, including a root mean square error of approximation (RMSEA) of at least <0.08 , comparative fit index (CFI) and Tucker-Lewis Index (TLI) of at least >0.90 , and standardized root mean square residual (SRMR) of <0.08 [44]. Within and between-person reliability (McDonald omega) coefficients were also computed for the dichotomized and nondichotomized NA and PA items [45].

A drift-diffusion model was then applied to the RTs and dichotomized response values for PA and NA items using the *diffIRT* package in R (R Foundation for Statistical Computing) [22], where drift rate and RTs were modeled as latent factors. Factor score estimates for the drift rate parameter were then calculated for each EMA occasion, separately for NA and PA. To examine the fit of the drift-diffusion model on the PA and NA item sets, we examined the level of consistency between the observed and diffusion model-predicted RT distributions with histograms and density plots.

The drift rate parameters used in our primary analyses are a processed version of the drift rate parameters from the diffusion IRT models referred to as the *absolute drift rate*, computed as the mean absolute difference between the drift rate parameter factor scores and the item difficulty levels. The drift rate parameter is an estimation of a person's tendency to report high NA (or PA) in a moment after taking into account both a person's responses and item RTs. However, emotional clarity should be indicated by the speed in carefully accessing one's mood regardless of its valence (eg, high or low NA). Therefore, following the distance-difficulty hypothesis-informed formula for the speed of information accumulation in the D-diffusion model [22], we found the absolute value of the difference between the drift rate parameter and average item difficulty and operationalized this absolute drift rate as emotional clarity. These absolute drift rates were then log transformed to normalize their distributions. When used in analyses, drift rates were also adjusted by baseline speed.

Other Measures

The measures used for convergent or divergent validity testing were completed before ("baseline") or after ("follow-up") the EMA study period. Life satisfaction was assessed with the Satisfaction with Life Scale [46], neuroticism with the Ten-Item Personality Inventory [47], depression with the Patient Health Questionnaire [48], anxiety with the Generalized Anxiety Disorder Scale [49], diabetes distress with the Problem Areas in Diabetes Scale short form [50], and emotion regulation with the DERS short form (DERS-SF) [15]. The Ten-Item Personality Inventory, Patient Health Questionnaire, Generalized Anxiety Disorder Scale, and DERS-SF were administered at baseline, while the Satisfaction with Life Scale and Problem Areas in Diabetes Scale short form were completed at follow-up [29].

Processing speed was assessed with the Symbol Search task [51], an ambulatory cognitive test administered as part of every EMA prompt [29]. The Symbol Search task captured perceptual speed, which is a component of processing speed [51,52].

Participants were presented with 2 cards at the top and 2 cards at the bottom of the phone screen, each with 2 symbols. As quickly as they could, they were asked to choose the card at the bottom of the screen that matched with one of the cards on top. The task consisted of 20 trials, and processing speed was measured as the median RT in accurate trials, only for sessions with at least 70% (14/20) matching accuracy [51]. Symbol Search RTs were calculated such that higher values indicate faster processing speed.

Statistical Analyses

Reliability

Reliability was assessed for each of the emotional clarity indicators: NA drift rate, PA drift rate, NA RT, and PA RT. It was calculated using the following formula: $\text{between-person reliability} = \frac{\text{variance (between-person)}}{\text{variance [between-person] + variance [within-person]/n}}$ [53], where between-person variance is the variance in the average of scores across measurement occasions (ie, EMA prompts), within-person variance is the variance of scores across measurement occasions within a person, and n is the number of measurement occasions. Between and within-person variance were calculated with multilevel models, with EMA prompts nested in individuals, where the measure of interest (eg, the NA drift rate) was specified at both levels 1 and 2. To examine how many measurement occasions would be needed to obtain acceptable reliability (≥ 0.7) for each emotional clarity indicator, we estimated how reliability changed as a function of the number of measurement occasions, moving from 2 EMA prompts to a maximum of 70 prompts. Mplus (version 8.10) [43] was used for reliability analyses via the package *MplusAutomation* [54] in the statistical software R (The R Foundation) [55].

Validity

Validity testing was performed for average NA drift rate, PA drift rate, NA RT, and PA RT. To account for the nested data structure, with multiple EMA prompts nested in individuals, we estimated correlation coefficients between the emotional clarity indicators and other measures using multilevel structural equation models (MSEMs). Multilevel variables with both within- and between-person variance (NA drift rate, PA drift rate, NA RT, PA RT, and processing speed) were specified at both level 1 (within-person) and level 2 (between-person), with latent means estimated at level 2 of the MSEM. As all cross-sectional measures only contained between-person variance, they were entered into the MSEM at level 2 and allowed to correlate with the NA drift rate, PA drift rate, NA RT, and PA RT variables. To adjust for individual differences in baseline speed, NA drift rate, PA drift rate, NA RT, and PA RT were regressed on baseline speed at level 2 of the MSEM. In addition, covariances were specified between baseline speed and all other level-2 variables. Prior research indicated that RTs to tasks were affected by the time of day [19,56]. Therefore, at level 1, all the RT-based metrics were adjusted for (ie, regressed on) the time of day, coded as a categorical variable, where a participant's first survey per day was categorized as taking place in the morning, their final scheduled survey of the day as taking place in the evening, and all their surveys in between as taking

place midday. The reference group was “midday,” meaning that at level 2, the latent means for the RT-based metrics were for midday surveys.

Various sensitivity tests were also conducted. Separate multilevel regression models explored whether adjustment for emotional intensity impacted the relationships between RT and each cross-sectional measure, such that NA RT and PA RT were additionally regressed on linear and quadratic terms of overall NA and PA ratings (ie, average rating across NA or PA items within an EMA survey), respectively. In supplemental analyses in which all the proposed emotional clarity indicators were controlled for processing speed, they were all regressed on processing speed at level 2. Finally, we tested whether the association between NA and PA drift rate and other measures would differ if the drift metrics were computed from mood items that were dichotomized at each person’s mean NA and PA response rather than the scale midpoint. For all analyses, data from all participants were included regardless of completion rates because MSEM estimate latent averages of variables at level 1 that account for potential unreliability stemming from sparse participant data [57]. All validity analyses were conducted in *Mplus* (version 8.10) [43] using maximum likelihood with robust SEs. Code for both the reliability and validity analyses is provided [58].

Results

Descriptive Statistics

Characteristics of the study sample, 196 adults with T1D, are shown in [Table 2](#). The median EMA completion rate over the 2-week study period was 92% (IQR 11%).

Descriptive statistics for the EMA variables are presented in [Table 3](#). Distributions for RTs to individual NA and PA items are shown in [Figures S1 and S2 in Multimedia Appendix 1](#), respectively. [Tables S1 and S2 in Multimedia Appendix 1](#) show the between-person correlations between (unadjusted) study measures.

A unidimensional model was found to fit both the (dichotomized) 4 NA and 4 PA items acceptably, justifying the calculation of drift rates for both types of items. For NA, $\chi^2=10.6$, $P=.005$; CFI=0.998; TLI=0.994; RMSEA=0.018; and SRMR=0.018, while for PA, $\chi^2=53.3$, $P<.001$; CFI=0.989; TLI=0.966; RMSEA=0.044; and SRMR=0.031. All these values were within commonly suggested ranges for acceptable model fit [44]. The within-person omega estimate for the 4 dichotomized NA items was 0.710, while the between-person omega estimate was 0.938. For the 4 dichotomized PA items, the within-person omega estimate was 0.674, and the between-person omega estimate was 0.939. The within-person omega estimate for the 4 nondichotomized NA items was 0.793, while the between-person omega estimate was 0.955. For the 4 nondichotomized PA items, the within-person omega estimate was 0.773, and the between-person omega estimate was 0.937. For all PA and NA items, the observed RT distributions (histograms) were consistent with the drift-diffusion model–predicted RT distributions as per density plots of these RTs ([Figures S1 and S2 in Multimedia Appendix 1](#)), indicating a good fit overall for the D-diffusion IRT model [22].

^dRT: response time.

Reliability

Figure S3 in [Multimedia Appendix 1](#) shows the between-person reliabilities as a function of the number of EMA prompts completed for each proposed emotional clarity indicator. For all indicators, reliability increased with more prompts, but each of the proposed emotional clarity indicators demonstrated acceptable reliability (ie, ≥ 0.70) with a relatively small number of EMA occasions. NA RT required 5 EMA prompts for acceptable reliability, and PA RT required 4 prompts. Both average NA and PA drift rates showed 0.70 reliability when 7 EMA prompts were completed.

Validity

Relationships between NA RT and other measures were not consistent with our hypotheses. No significant associations were found with subjective well-being or emotion regulation measures ([Table 4](#); P values ranging from .08 to .98). PA RT was not significantly associated with any well-being or emotion regulation variable ([Table 4](#); P values ranging from .25 to .93), except, unexpectedly, for diabetes distress ($r=0.17$; $P=.009$). After adjustment for processing speed, the associations between both NA RT and PA RT and diabetes distress were unexpectedly significant in a positive direction ($r=0.14$; $P=.03$ and $r=0.20$;

$P=.002$, respectively). Adjustment for emotional intensity changed effects very minimally at the between-person level, consistent with the findings of a prior study [17], so the results from that model were not reported here. Both NA RT and PA RT had significant associations with processing speed ($r=0.25$; $P<.001$ and $r=0.21$; $P=.001$, respectively).

The associations between NA drift rate and other measures were consistent with our hypotheses overall. Unexpectedly, NA drift rate was not related to the lack of emotional clarity ($P=.13$) or 3 of the other DEERS subscales ([Table 4](#); P values from .18 to .76). It was also not associated with life satisfaction ($P=.17$). However, a greater NA drift rate was significantly associated with lower neuroticism ($r=-0.18$; $P=.01$), depression ($r=-0.27$; $P<.001$), anxiety ($r=-0.27$; $P<.001$), and diabetes distress ($r=-0.17$; $P=.005$); lower overall difficulties with emotion regulation (total DEERS score; $r=-0.15$; $P=.03$); less limited emotion regulation strategies ($r=-0.15$; $P=.048$); and lower lack of emotion awareness ($r=-0.18$; $P=.009$). Adjustment by processing speed resulted in minimal changes. When NA and PA drift rates were computed from mood items that were dichotomized at each person's mean NA and PA ratings (rather than at the scale midpoint), the results showed mostly nonsignificant correlations with other measures (refer to [Table S3](#) in [Multimedia Appendix 1](#)).

Table 4. Between-person correlations between emotional clarity indices and other measures. All correlations were adjusted for the baseline speed of responding and time of day, but only columns with adjusted values additionally had processing speed as a control variable.

Consistent with expectations, PA drift rate was not significantly associated with most subjective well-being or NA-specific emotion regulation measures (Table 4; *P* values from .09 to .76). Unexpectedly, PA drift rate was not significantly associated with emotional clarity ($P = .59$) or emotional awareness ($P = .20$) before or after adjustment for processing speed. Furthermore, contrary to expectations, a greater PA drift rate was associated

with greater diabetes distress ($r = 0.17$; $P = .009$). Neither NA drift rate nor PA drift rate had significant associations with processing speed ($P = .18$ and $P = .78$, respectively). Without adjustment for baseline speed, a few of the associations differed, such as the relationship between NA drift rate and life satisfaction ($r = 0.16$; $P = .02$; Table 5).

Discussion

Principal Findings

The most notable finding from this study was that the average NA drift rate, a proposed indicator of typical emotional clarity, had expected associations overall with validated measures of subjective well-being and emotion regulation, both before and after adjustment for processing speed and emotional intensity. By contrast, NA RT, another proposed indicator of typical emotional clarity, did not have the anticipated associations with the validated measures. Relative to NA drift rate, NA RT may be confounded by a greater number of factors aside from emotional clarity.

Nevertheless, there is no sufficient evidence to conclude that the average NA drift rate is a valid indicator of NA clarity, while the average NA RT is not a valid indicator of NA clarity due to sample size constraints. In post hoc power analyses, with our sample size of 196 participants, there was 80% power to detect a between-person correlation of 0.20. Therefore, the study may have been underpowered to detect small correlations that might still be meaningful. Furthermore, the sample size was not chosen a priori to be sufficiently powered to detect between-person relationships after adjustment for multiplicity of testing [59] because the sample size was conditioned on research questions that were more primary for the diabetes EMA study.

While we cannot conclude that NA drift rate is a valid indicator of NA clarity, our results suggest that researchers in future studies should continue to investigate NA drift rate as an implicit measure of emotional clarity. We applied stringent validity tests by adjusting for both individual differences in the baseline speed of responding and processing speed and found significant associations between NA drift rate and 4 (80%) of the 5 subjective well-being ratings. Correlations with 4 (67%) of the 6 emotion regulation subscales were in the expected directions. Finally, it is notable that NA drift rate had a correlation of 0.63 (*P* < .001) with NA RT. People with a higher NA drift rate responded faster to the NA emotion items, had greater subjective well-being (eg, fewer depression symptoms), and had fewer difficulties with overall emotion regulation, which are all aligned with the expectation for an emotional clarity measure. Collectively, study results suggest that NA drift rate deserves further attention in future research.

Some of the magnitudes of correlations between NA drift rate and other study measures were comparable to sizes of correlations between formal (self-report) assessments of emotional clarity and other measures found in prior studies. One study found that in a group with generalized anxiety disorder, a self-report assessment of emotional clarity had correlations of –0.29 and –0.33 with depression and anxiety, respectively [60], which are similar to the correlations found in this study. In the same study, the association between emotional clarity and depression or anxiety was not significant in the healthy control group [60], suggesting that the mental health status of the sample may affect the magnitude of the observed relationships. Other correlations found between emotional clarity and depression were –0.24 in a clinical sample [61] and –0.29 in elementary school-aged children [62]. Correlations between self-reported emotional clarity and neuroticism ranged between –0.31 in a sample of adolescents [63] and –0.37 in a sample of college students [64], and correlations between emotional clarity and life satisfaction ranged between 0.31 in adolescents [65] and 0.35 in undergraduate students [36], which are larger than the correlations observed in this study.

When NA drift rate was computed from mood items that were dichotomized at each person's mean response rather than the scale midpoint, no significant associations were observed with other study measures. The distance-difficulty hypothesis underlying the D-diffusion model that was used to generate the NA drift parameter assumes that people respond faster to items that contrast more with their current state [23]. According to this hypothesis, an individual with very low NA (regardless of their average level of NA) was expected to quickly report not being scared (an item often associated with high NA). Dichotomizing mood at each person's own midpoint created a variable representing whether their mood was higher or lower relative to their personal average and not higher or lower in absolute terms (which could be approximated by dichotomizing at the scale midpoint). Perhaps, the former was less relevant to the distance-difficulty hypothesis compared to the latter because it captured relative mood and not actual mood, leading to the creation of NA drift parameters with no associations with other study measures.

The reliabilities for the average NA drift rate, PA drift rate, NA RT, and PA RT were all acceptable with a small number of EMA prompts (ie, 4 to 7 EMA prompts or 1 to 2 days of EMA

surveys). Therefore, reliable measurement of these proposed emotional clarity indicators would likely be feasible in most EMA studies where affect items are administered and RTs are recorded.

Secondary Findings

We found preliminary evidence supporting the argument that emotional clarity deficits are valence specific [9]. NA drift rate and PA drift rate had differential associations with self-report measures. Furthermore, they were moderately correlated with each other ($r=0.38$; refer to Table S1 in [Multimedia Appendix 1](#)). Had NA and PA drift rates been redundant with one another, a high correlation would have been expected.

Greater PA drift rate and PA RT were unexpectedly found to be associated with higher diabetes distress and not associated with the awareness or clarity subscales of the DERS. It is unclear why people with greater diabetes distress would have greater clarity of positive emotions. Perhaps, when overwhelmed with burden from diabetes, people had a greater appreciation of positive emotional states and hence greater clarity of PA. One possible reason why PA drift rate and PA RT had far from significant associations with self-reported emotional clarity may have been because, given that other items in the DERS-SF asked questions relevant to the NA context, participants were primed to answer the emotional clarity questions with reference to feeling NA. More assessments of the validity of PA drift rate and PA RT are needed.

Future Directions

More conclusive evidence of the validity of RT-based measures of emotional clarity may come from studies where NA clarity can be manipulated, and the proposed emotional clarity indicators can be compared for sensitivity to these changes. For instance, people who undergo a mindfulness intervention may be expected to have higher NA clarity in the period following the intervention, and this effect should be reflected in changes in drift rates or RTs to NA EMA items.

EMA mood item RT-based measures of emotional clarity have a great potential utility. They can serve as indices of emotional clarity that do not require burdening participants with additional emotional clarity items. Furthermore, they can help avoid possible issues with subjective reports, including poor insight into emotional clarity and the possibility of social desirability bias [12]. Although the validity of the RT-based emotional clarity measures at the within-person level was not investigated in this study, such validity would allow for the investigation of changes in emotional clarity within and across days and the situational factors that contribute to them. For the potential utility of EMA mood item RT-based measures of emotional clarity to be realized, further investigations of the validity of EMA RT-based measures of emotional clarity (ie, at both the between-person and within-person levels) are needed.

Limitations

We had decided not to adjust for multiple comparisons, but to also acknowledge that any results would require replication by future studies. It has been argued that the need for adjustment for multiple comparisons should be evaluated on a case-by-case

basis and P value adjustment should not be used for all analyses [66]. For instance, adjustment for multiple comparisons comes with not only the benefit of lowering type 1 error but also the disadvantage of increasing the chance of type 2 error. Therefore, one factor to consider when deciding whether to adjust for multiple comparisons is the relative cost of type 1 and type 2 errors for a particular research question [67]. In confirmatory studies with results that have implications for changes in clinical practice or the use of a treatment, the cost of a type 1 error may be higher than that of a type 2 error; hence, P value adjustment for multiple comparisons would be sensible [66]. When performing post hoc analyses on existing data as part of theory building and testing (and without direct treatment implications), the relative cost of a type 2 error may be higher; hence, there may be a stronger argument for not using multiple comparisons adjustment [66]. That is, a type 2 error could cause researchers to not detect potentially important findings [68]. If adjustment is not used, there would need to be an acknowledgment that, to account for the possibility of a type 1 error, further research is needed to examine whether results can be replicated [66].

Nevertheless, we still tested the effect of false discovery rate adjustment on the P values of correlations for the different groups of hypotheses that were tested (eg, association between NA drift rate and subjective well-being measures). Adjustments for multiple comparisons are often applied separately for distinct families of hypotheses [69]. Tables S4 and S5 in [Multimedia Appendix 1](#) show the false discovery rate-adjusted P values associated with [Tables 4](#) and [5](#), respectively. The biggest differences to note were that several of the associations between NA drift rate and emotional regulation measures were no longer significant.

Using the drift-diffusion model had the advantage of reducing the impact of individual differences in response caution (and potential careless responding) from emotion item RTs but had the disadvantage of assuming a 2-choice task (eg, a high vs low NA) underlying people's emotion ratings. Because the drift-diffusion model required making the continuous PA and NA items dichotomous for data analysis, granular differences in emotional clarity may have been missed with the drift rate parameter.

We were unable to examine the within-person validity of RT-based clarity measures because EMA measures key to such testing (eg, self-reported emotional clarity and mood regulation success) [12] were not administered in this study. Future studies are needed to examine the within-person validity of the drift rate parameter as a within-person indicator of emotional clarity.

The context in which RTs for emotion items were calculated was similar but not identical to that in prior work. For instance, in this study, median RTs for EMA were calculated based on RTs to 4 items. In prior studies, the median RTs for 5 to 8 items were computed [12,17]. In the original paper examining the validity of RTs to emotion items as indicators of emotional clarity, bipolar mood items were used (eg, items with options from "very unhappy" to "very happy") [12], whereas our study analyzed unipolar mood items. The results of this study may have been impacted to an extent by differences in EMA

administration, such as variations in the type of emotion items used.

Additional evidence is needed that study results generalize beyond adults with T1D. Other populations with an increased likelihood of experiencing lower subjective well-being (eg, individuals with various chronic conditions) [70] may be appropriate targets for future emotional clarity studies.

Conclusions

A measure of NA drift rate derived from RTs to momentary NA items had expected associations with validated measures of relevance to emotional clarity, providing initial evidence

supporting its validity as an indicator of individual differences in the clarity of negative emotions. The validities of NA RT, PA RT, and PA drift rate were not strongly supported by our results. More studies are needed to investigate the validities of NA and PA drift rate and NA and PA RT with larger sample sizes. The development of passive measures of emotional clarity would help create minimally burdensome measures of emotional clarity that are less vulnerable to possible issues from subjective self-reports, such as poor clarity insight and social desirability bias. Such measures may be useful in investigations relevant to the role of emotional clarity in people's experience of well-being.

Abstract

Background: Paranoia is a spectrum of fear-related experiences that spans diagnostic categories and is influenced by social and cognitive factors. The extent to which social media and other types of media use are associated with paranoia remains unclear.

Objective: We aimed to examine associations between media use and paranoia at the within- and between-person levels.

Methods: Participants were 409 individuals diagnosed with schizophrenia spectrum or bipolar disorder. Measures included sociodemographic and clinical characteristics at baseline, followed by ecological momentary assessments (EMAs) collected 3 times daily over 30 days. EMA evaluated paranoia and 5 types of media use: social media, television, music, reading or writing, and other internet or computer use. Generalized linear mixed models were used to examine paranoia as a function of each type of media use and vice versa at the within- and between-person levels.

Results: Of the 409 participants, the following subgroups reported at least 1 instance of media use: 261 (63.8%) for using social media, 385 (94.1%) for watching TV, 292 (71.4%) for listening to music, 191 (46.7%) for reading or writing, and 280 (68.5%) for other internet or computer use. Gender, ethnoracial groups, educational attainment, and diagnosis of schizophrenia versus bipolar disorder were differentially associated with the likelihood of media use. There was a within-person association between social media use and paranoia: using social media was associated with a subsequent decrease of 5.5% (fold-change 0.945, 95% CI 0.904-0.987) in paranoia. The reverse association, from paranoia to subsequent changes in social media use, was not statistically significant. Other types of media use were not significantly associated with paranoia.

Conclusions: This study shows that social media use was associated with a modest decrease in paranoia, perhaps reflecting the clinical benefits of social connection. However, structural disadvantage and individual factors may hamper the accessibility of media activities, and the mental health correlates of media use may further vary as a function of contents and contexts of use.

Introduction

Background

Paranoia, defined as the “unfounded fear that others intend to cause you harm” [1], is the most commonly identified delusion in schizophrenia spectrum conditions [2] and is also experienced in bipolar disorder, unipolar depression, borderline personality disorder, and other conditions [3-5]. Paranoia is a spectrum of beliefs and experiences spanning mild (eg, people talk about

you behind your back) to severe ideas of threat (eg, people are trying to harm you) [6]. Paranoid experiences along this hierarchy are associated with social functioning problems including poorer interpersonal relationships, reduced marital satisfaction, and difficulties with peers [7-12]. Paranoia can fluctuate over the course of days as a function of cognitive and interpersonal factors [13-15]. Factors that have been associated with increased paranoia include rumination, loneliness, and social exclusion, whereas distraction and being in the company of familiar individuals have been associated with decreases in

paranoia [13,14,16,17]. Many of these social and cognitive experiences may be influenced by day-to-day engagement with media [18], but it is unclear whether media use influences paranoia in schizophrenia and bipolar disorder.

Possible Effects of Media on Paranoia

Media are vehicles for accessing or sharing information, including for leisure, social, and occupational purposes [19]. This definition encompasses both digital (eg, social media) and traditional (eg, books) forms of media. Similar to other environmental exposures, media may potentially influence a person's paranoia by informing the degree of perceived environmental threat. Better situating the naturalistic effects of media on paranoia may help guide lifestyle counseling and the development of media-based interventions for this symptom dimension.

Multiple mechanisms might contribute to the effects of media on paranoia. First, media activities can provide a distraction that helps a person move away from persecutory thoughts. Social media may help decrease paranoia by facilitating access to social support and reducing loneliness. However, both traditional and digital media activities may also promote paranoia if they perpetuate harmful avoidance behaviors (eg, if a socially withdrawn person watches TV instead of going out and seeing friends) or directly amplify the perception of environmental threat (eg, through consumption of catastrophic news or conspiracist discourses). Additionally, social media has several features that distinguish it from in-person communication; some of these features, such as asynchronicity and lower availability of nonverbal cues, may hypothetically increase uncertainty about social relationships [20], which might build on a person's paranoia.

There is currently limited evidence regarding the relationship between media use and paranoia. Recent studies with the general population (in Canada and the United Kingdom) have found cross-sectional associations between greater use of digital media and higher levels of psychotic-like experiences [21,22], including paranoia [23], but 2 studies with prospective data did not find robust associations between media use and the subsequent risk of psychotic-like experiences [22,24]. Rather than reflecting causal effects of media on paranoia, the concurrent association between media use and paranoia in the general population may be due to confounders, such as preexisting mental health problems and social adversity [24]. However, these findings may not apply to individuals with psychotic or mood disorders, in whom there is generally a greater propensity for paranoia, and thus potentially a greater sensitivity to media effects that are otherwise not apparent in non-clinical populations. As such, surveys indicate that 25% - 35% of individuals with psychotic or mood disorders believe that digital devices can increase their paranoia [25,26].

To our knowledge, only 1 previous study has examined the associations of media use and paranoia in a clinical sample [27]. This study by Berry et al [27] included 44 participants: 19 individuals with schizophrenia spectrum or bipolar disorder and 25 nonclinical individuals. Participants completed ecological momentary assessments (EMAs) of social media use and paranoia 6 times daily over 6 days. Posting about feelings,

venting on social media, viewing profiles of people who were not "friends," and lower perceived social rank were associated with higher paranoia at the next time point. The results therefore supported a possible contribution of specific social media experiences to paranoia. However, the results may have been affected by unmeasured confounders, such as individual differences in social adversity or mental health that predisposed individuals to certain patterns of social media behaviors. In addition, because the usage of other types of media was not assessed, it remains unclear to what extent the risk is specific to social media. Another potential gap is whether day-to-day fluctuations in paranoia reciprocally make people more or less drawn to media use [28]—a reverse association that has yet to be examined.

Population Differences in Media Use and Paranoia

An important consideration in investigating the relationship of media activities with paranoia is that media-related behaviors vary between populations. Some studies have found, for example, that people with schizophrenia are less likely than those with bipolar disorder to use digital media [29,30], perhaps reflecting the impact of socioeconomic disadvantage on media access and digital literacy. Similarly, in the general population, there is evidence of unequal access to media technologies as a result of socioeconomic disadvantage [31,32]. Gender is another factor linked to differences in media use, with meta-analytic evidence of higher prevalence of problematic social media use in women versus men [33].

The risk of paranoia may also vary between populations. Although there is limited comparative data, paranoia appears to be common in both schizophrenia and mood disorders and to have similar psychosocial and neurobiological correlates across diagnostic groups [2,4,34,35]. One study found no difference in patterns of attributional bias between schizophrenia and bipolar disorder, suggesting shared cognitive mechanisms [34]. However, paranoia appears to be relatively less common in unipolar depression with psychotic features than in schizophrenia and bipolar disorder, indicating different levels of risk between diagnoses [36]. Likewise, in the general population, levels of paranoia may be higher among men than among women [8]. Whether these epidemiological features might translate into diagnosis- or gender-specific effects of media on paranoia remains unknown.

This Study

To advance knowledge about the relationship between media use and paranoia, this study draws from an EMA sample comprising adults with schizophrenia and those with bipolar disorder. EMA provides dense, repeated measures that are well suited for analyzing bidirectional relationships between media use and paranoia. With EMA data, confounders from individual traits can be removed using within-person analyses, where each person is their own comparator over time [37]. We thus aimed to examine media use and its bidirectional associations with paranoia in people with schizophrenia and those with bipolar disorder, both at the between- and within-person levels. To identify whether specific types of media activities are uniquely associated with paranoia, we considered social media and 4 other types of media use: watching TV, listening to music,

reading or writing, and internet or computer use. We first evaluated associations of sociodemographic and clinical characteristics with any versus no use of each type of media across the study period. Then, we examined the associations between media use and paranoia at the between- and within-person levels. We explored moderating effects of gender and clinical group on within-person associations. We hypothesized that social media use would be associated with subsequent increases in paranoia, and that this association would be greater in women than in men. We did not formulate hypotheses for other types of media.

Methods

Participants

Data were obtained from a study designed to assess the introspective accuracy of self-reported cognition and functioning in the context of mental illness [38]. Participants were adults aged 18 - 65 years meeting diagnostic criteria for schizophrenia (or schizoaffective disorder) and bipolar disorder (type 1 or 2). Recruitment sites included The University of Texas at Dallas, Miller School of Medicine–University of Miami, and University of California San Diego. Participants were recruited via medical centers, public mental health and local community clinics, nonprofit organizations, direct contact by service providers, follow-up with research participants from previous projects, study flyers, and internet-based advertisements.

Diagnostic information was collected by trained interviewers using the Mini International Neuropsychiatric Interview [39] and the psychosis module of the Structured Clinical Interview for *DSM-5 (Diagnostic and Statistical Manual of Mental Disorders [Fifth Edition])* [40]. Final diagnoses were generated through a local consensus procedure. Inclusion criteria were clinical stability (ie, no hospitalization or extended emergency department visit) for a minimum of 6 weeks and no significant (>20%) medication dose changes in the past 2 weeks. Participants with bipolar disorder had to have at least 1 mood episode recurrence or incomplete remission from a first episode, indicating stage 3 severity or higher according to the classification of Frank et al [41]. Exclusion criteria were nonproficiency in English; a current or past medical or neurological disorder that may affect brain functioning (eg, brain tumors and seizures); intellectual disability or pervasive developmental disorder; active substance use of moderate severity or higher; and any visual or hearing impairment limiting assessments.

Baseline Assessments

During the initial interview, participants reported their age, gender (male, female, or other), race (Asian, Black or African American, White, or other), ethnicity (Hispanic or non-Hispanic), educational attainment, and relationship status. Trained raters assessed symptom severity the day before the first EMA survey using the Positive and Negative Syndrome Scale (PANSS) [42] for schizophrenia-related symptoms, the Montgomery-Åsberg Depression Rating Scale for depressive symptoms [43], and the Young Mania Rating Scale [44] for mania-related symptoms.

The PANSS consists of 30 items, each scored on a scale from 1="Absent" to 7="Extreme." Its positive symptom subscale (7 items, total score range 7 - 49) includes 1 item that measures the severity of suspiciousness and paranoia (P6). Negative symptoms were assessed with the PANSS using the 2-factor model by developed Khan et al [45], which identifies dimensions of expressive and experiential deficits. The items for reduced emotional experience include emotional withdrawal (N2), passive or apathetic social withdrawal (N4), and active social avoidance (G16). The items for reduced emotional expression include blunted affect (N1), poor rapport (N3), lack of spontaneity and flow of conversation (N6), and motor retardation (G7).

EMAs

Participants completed EMA surveys via the NeuroUX platform (Playpower Labs Inc) with either their own smartphone or a smartphone provided by the study investigators. The initial protocol planned that all participants would be provided smartphones, but participants were allowed to use their own smartphones following the onset of the COVID-19 pandemic to facilitate more flexible participation. In the context of this rapid modification of the protocol, data on smartphone ownership were not collected systematically and thus could not be analyzed.

Participants received SMS text messages prompting them to complete internet-based surveys 3 times daily for 30 days. Data were instantly uploaded to cloud-based servers. Text messages were sent at stratified random intervals within, on average, 2-hour windows and between 9 AM and 9 PM. The first and last daily assessment times were adapted to each participant's typical sleep and wake schedules. Survey responses were only allowed within 1-hour periods following deployment of the SMS text messages. Participants had the option of silencing the alarms for 30-minute intervals (eg, if driving).

Media use was measured using checkbox questions about activities performed since the previous survey. Response options included six items: (1) using "social media (eg, Facebook, Twitter)"; (2) "watching TV"; (3) "listening to music"; (4) "reading, writing, or journaling"; (5) "shopping online"; and (6) "other internet, computer, or tablet use." Due to low endorsement rates for shopping on the web, this activity was merged with other internet, computer, or tablet uses. Other types of activities, such as working, exercising, eating, etc, were also measured as part of this questionnaire [46] but were not analyzed in this study. Participants could report multiple activities per assessment. For each type of media, these checkbox questions produced dichotomous indices of use at each survey (0=did not use and 1=used).

Paranoia was measured using the following item: "Since the past alarm, how much have you had thoughts that others might want to harm you or that people are untrustworthy?" Response choices ranged from 1 to 7, with higher values indicating greater severity or frequency. In support of the convergent validity of this item, we found that individual mean scores for paranoia across the 30 days were significantly correlated with scores on the PANSS suspiciousness item (Spearman $\rho=0.41$, $P<.001$). Both media use and paranoia were measured 3 times daily.

Statistical Analysis

Analyses were conducted in R (version 4.1.2; The R Foundation). Codes are available on the web [47]. To minimize the impact of potentially invalid entries, we excluded participants who completed less than one-third of EMA surveys, following a common rule of thumb in EMA research [48]. Characteristics of included and excluded participants were compared to consider attrition effects; in line with recommendations for descriptive statistics [49], we used effect sizes instead of P values for these comparisons. Descriptive analyses such as the root-mean-square of successive differences (RMSSD) and the intraclass correlation coefficient were used to evaluate the variability of paranoia EMAs [50].

To examine sociodemographic and clinical correlates of media use, we dichotomized each type of media use as any versus no use over the follow-up period. We regressed these dichotomous variables on the predictors using logistic regressions adjusted for age and gender. To account for pairwise evaluations of 16 predictors with each media type, we report nominal statistical significance after adjustment for the false discovery rate (using the Benjamini and Hochberg [51] method) in addition to uncorrected 95% CIs.

Next, to examine associations between ecological momentary reports of media use and paranoia (between and within persons), we used generalized mixed models with observations nested in individuals [52]. Models were estimated using maximum likelihood with Laplace approximation. We considered 2 directions of association: media use as a function of paranoia, and paranoia as a function of media use. For models of media use as a function of paranoia, we applied the binomial distribution (logistic regression) given that media use assessments were dichotomous. For models of paranoia as a function of media use, we applied a gamma distribution with log-link function given the skewed distribution of paranoia. All models included random intercepts, mean levels of the predictor, and lagged mean-centered values of the predictor. Random slopes of the lagged mean-centered predictor were also added

if they improved model fit ($P < .05$) on the likelihood ratio test [53]. Values of 95% CI not overlapping the null were considered significant.

For each model of media use and paranoia, we subsequently explored potential moderating effects of gender (0=male, 1=female) and clinical group (0=schizophrenia, 1=bipolar) on within-person associations. Interactions were considered statistically significant at $P < .05$. Recognizing, however, that interaction analyses are frequently underpowered due to weaker effects [54], we also probed interactions if the P value ranged between .05 and .10 and reported them as “tentative.” To probe interactions, we estimated marginal slopes of lagged mean-centered predictors as a function of the moderator [55].

In sensitivity analyses, we considered whether including all participants (ie, not removing participants who completed less than one-third of EMA surveys) impacted the primary results. We also considered the impact of auto-correlation by controlling for the lagged dependent variables.

Ethical Considerations

All participants provided written informed consent, and the institutional review board of each university approved the study (The University of Texas at Dallas, #18 - 93; Miller School of Medicine–University of Miami, #20180352; and University of California San Diego, #180716).

Results

Of 446 participants, 409 completed at least one-third of the EMA surveys (Table 1). Completion of at least one-third of assessments was associated with the site of recruitment, higher educational attainment, and non-Hispanic ethnicity (effect sizes ≥ 0.100 ; see Table S1 in Multimedia Appendix 1). Table 2 provides descriptive statistics on paranoia EMAs, indicating higher mean ratings and greater intraindividual variability (higher SD and RMSSD) of paranoia in the schizophrenia versus bipolar disorder group.

Table . Characteristics of participants in the schizophrenia and bipolar disorder groups. Positive symptoms were measured with the positive symptom subscale of the Positive and Negative Syndrome Scale (PANSS; score range 7-49). Reduced emotional experience (range 3-21) and reduced emotional expression (range 4-28) were measured with negative symptom and general psychopathology items of the PANSS. Depressive symptoms were measured with the Montgomery-Åsberg Depression Rating Scale (range 0-60). Mania-related symptoms were measured with the Young Mania Rating Scale (range 0-60).

^bRMSSD: root-mean-square of successive differences.

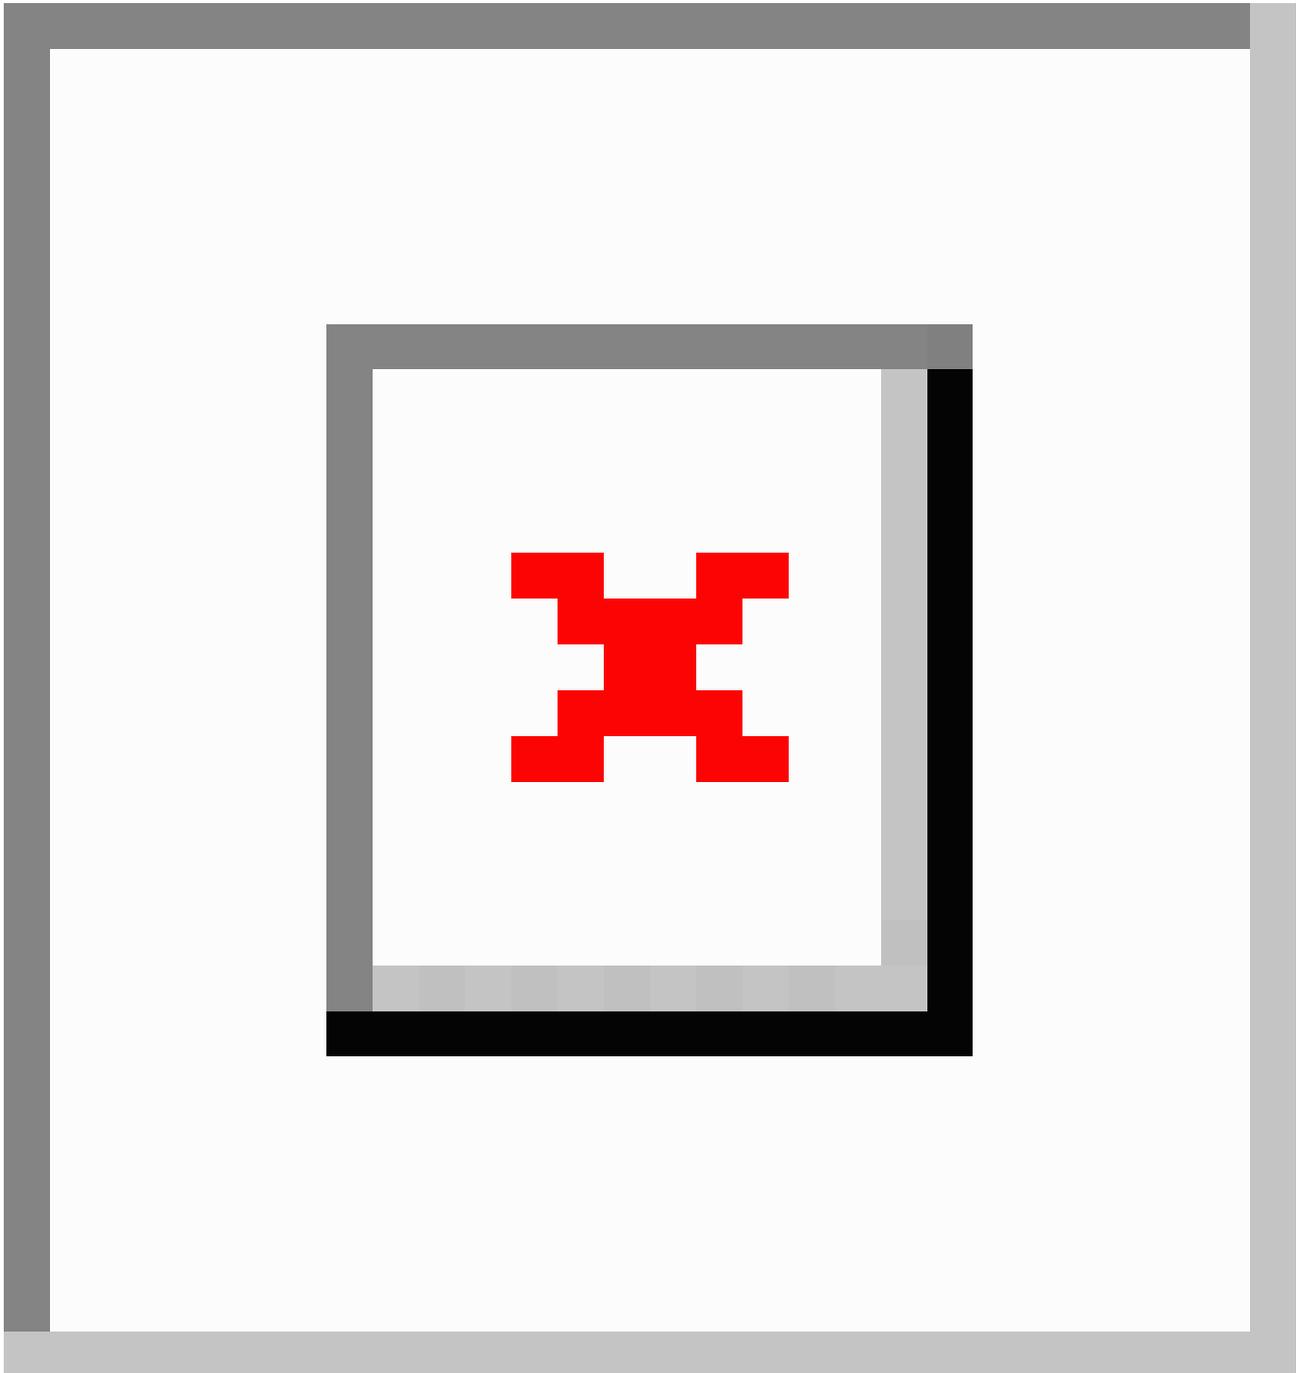

^cICC: intraclass correlation coefficient.

Of the 409 participants, the following subgroups reported at least 1 instance of media use: 261 (63.8%) for using social media, 385 (94.1%) for watching TV, 292 (71.4%) for listening to music, 191 (46.7%) for reading or writing, and 280 (68.5%) for other internet or computer use. Within each of these subgroups, there was a total of 1982 reports of social media over 18,478 available surveys (10.7%), 6779 reports of watching TV over 26,911 available surveys (25.2%), 1997 reports of listening to music over 20,778 available surveys (9.6%), 864 reports of reading or writing over 13,478 available surveys (6.4%), and 2500 reports of other internet or computer use over 19,649 available surveys (12.7%).

Factors Associated With Any Versus No Media Use

Figure 1 presents factors associated with any versus no use of each type of media. After adjustment for the false discovery rate, female versus male gender was associated with higher odds of social media use. Black or African American individuals (versus White individuals) had lower odds of other internet or computer use. Hispanic versus non-Hispanic ethnicity was associated with lower odds of listening to music. Higher educational attainment was associated with higher odds of social media use, reading or writing, and other internet or computer use. Diagnosis of bipolar disorder versus schizophrenia was associated with higher odds of social media and other internet or computer use. Higher levels of positive symptoms (but not paranoia) were associated with lower odds of other internet or computer use.

Figure 1. Odds ratios (95% CIs) of any versus no use of each type of media as a function of participant characteristics. Logistic regression models were adjusted for age and gender (n=409). Statistical significance after adjustment for the false discovery rate across columns (adjusted $P < .05$) is indicated in boldface. Comparator category for female gender: male gender; for Black or African American (“Black”), Asian, and other racialized groups: White; for Hispanic ethnicity: non-Hispanic ethnicity; for some college education and college degree or higher: high school or lower; and for the bipolar group: the schizophrenia group. Paranoia is the mean rating for paranoia across ecological momentary assessments (range 1 - 7).

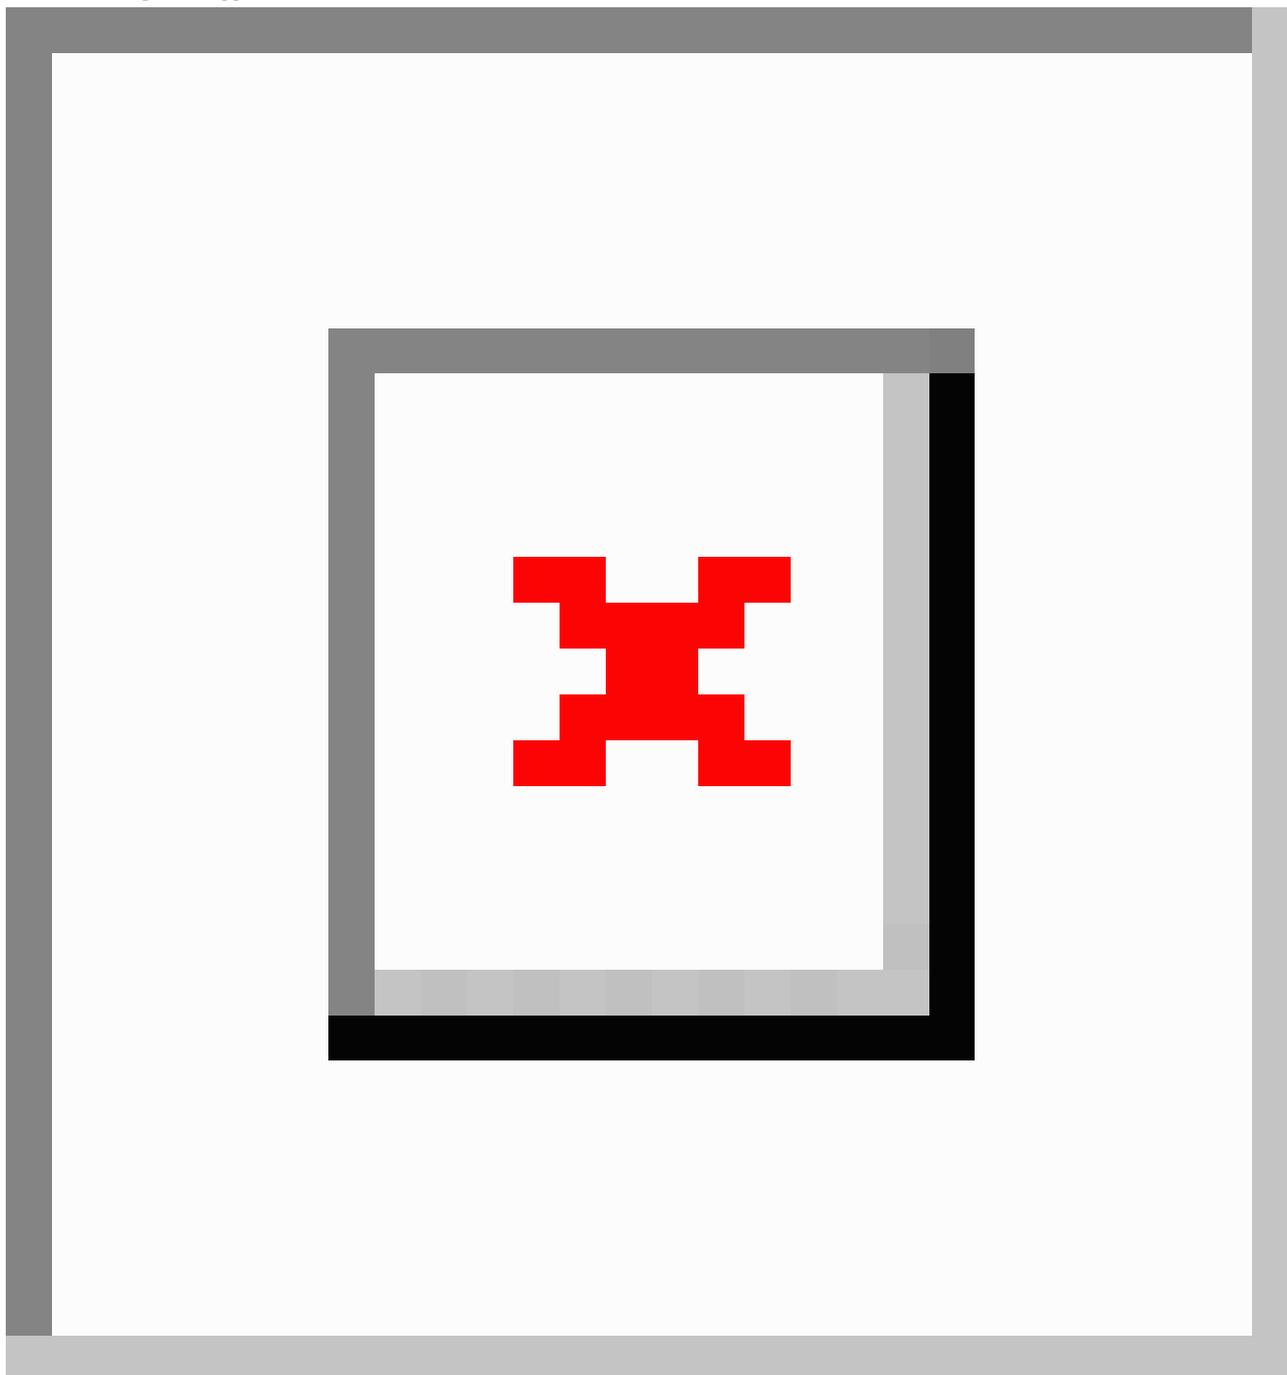

Paranoia as a Function of Media Use

Figure 2 presents the mean ratio (between persons) and fold-change (within persons) in paranoia as a function of media use. Analyses are in the subsets of participants reporting that type of media (ie, subgroups ranging from n=191 for reading or writing to n=385 for watching TV). Across types of media,

associations were not significant at the between-person level: participants' average levels of media use were not associated with their average levels of paranoia. At the within-person level, social media use above a person's average was associated with a ~5.5% reduction in their level of paranoia on the subsequent survey (fold-change 0.945; 95% CI 0.904-0.987). Other within-person associations were not significant.

Figure 2. Paranoia as a function of preceding (lagged) media use in gamma mixed models with observations nested within individuals. Predictors included mean levels of media use (for between-person associations) and lagged mean-centered media use (for within-person associations). All models include random slopes of lagged mean-centered media use.

There was a tentative moderating effect of the clinical group on the within-person association of social media use with paranoia (coefficient, lagged social media use×bipolar disorder versus schizophrenia=1.084; $P=.07$). According to this interaction, there was a within-person association between social media use and subsequently reduced paranoia in the schizophrenia group (fold-change 0.900, 95% CI 0.840-0.965). In the bipolar disorder group, however, the same association was not statistically significant (fold-change 0.975, 95% CI 0.923-1.031). There was also a tentative moderating effect of the clinical group on the association between listening to music and paranoia (coefficient, lagged music×bipolar disorder versus schizophrenia=0.939; $P=.08$). According to this interaction,

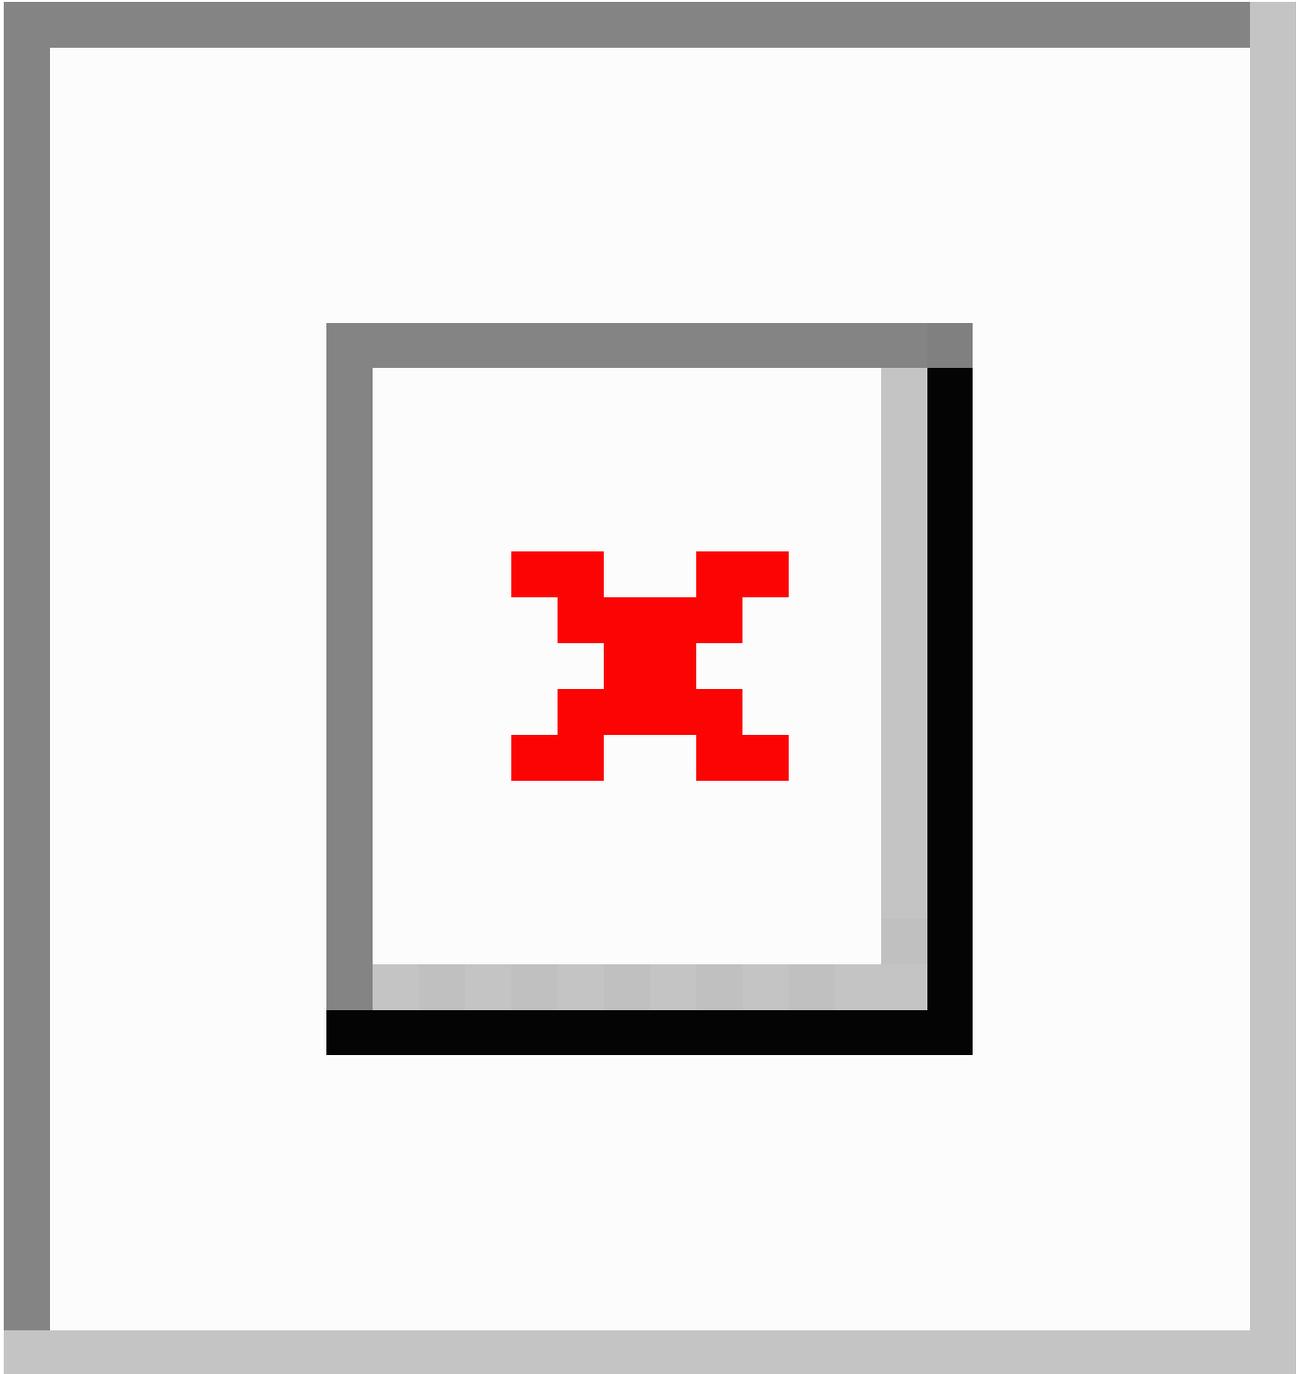

there was a within-person association between listening to music and subsequently decreased paranoia in the bipolar disorder group (fold-change 0.949, 95% CI 0.906-0.995). This association was not significant in the schizophrenia group (fold-change 1.011, 95% CI 0.961-1.063). Other moderating effects of gender or clinical group did not pass the $P<.10$ threshold and were not probed further.

Media Use as a Function of Paranoia

Figure 3 presents odds ratios of each type of media use as a function of paranoia. Associations were not significant at the between-person level: participants' average levels of paranoia were not associated with the odds of media use. There were also

no significant associations at the within-person level: participants' variations in paranoia relative to their personal average did not predict variations in their odds of media use over time. The moderating effects of gender or clinical group over within-person associations did not pass the threshold of $P < .10$ and were not probed further.

Figure 3. Media use as a function of preceding (lagged) paranoia in generalized logistic mixed models with observations nested in individuals. Predictors include mean levels of paranoia (for between-person associations) and lagged mean-centered paranoia (for within-person associations). Models of social media use and TV include random slopes of lagged mean-centered paranoia. Other models include random intercepts only. Lagged mean-centered paranoia was removed from models of reading or writing due to lack of convergence (indicated by "NA" in the bottom panel).

Additional Analyses

Within- and between-person associations of media use and paranoia were consistent in the full sample, that is, after lifting the exclusion rule for participants with less than one-third of EMA surveys (see Figures S1 and S2 in [Multimedia Appendix 1](#)). Results were also consistent in models adjusted for lagged values of the dependent variables, suggesting no impact of

auto-correlated effects on the association between lagged social media use and lower paranoia (see Figures S3 and S4 in [Multimedia Appendix 1](#)). Post hoc, we explored associations between media use and paranoia on concurrent surveys, instead of across lagged surveys. None of the concurrent associations were significant (see Figures S5 and S6 in [Multimedia Appendix 1](#)).

Discussion

Principal Findings

In a large cohort of individuals with schizophrenia or bipolar disorder, we examined the usage of social media and 4 other types of media, and their associations with paranoia over 30 days of EMA surveys. Sociodemographic and clinical characteristics were associated with the likelihood of any versus no use of media types. In individuals who did use those media over the follow-up period, media use was either associated with no significant change in paranoia, or some decrease, depending on the type of media and diagnostic group.

We did not find evidence that media use predicted increased paranoia overall, or that paranoia predicted subsequent media use. Contrary to our hypothesis, there was instead an association between social media use and a subsequent decrease in paranoia. The reduction was approximately 5.5% in the total sample and up to 10% in the schizophrenia group. Although there are no established benchmarks for interpreting the clinical significance of paranoia reductions on the present scale, it should be noted that these reductions are smaller than 1-point changes relative to the 7-point range of the scale, leading us to interpret them as modest. The reverse associations (between paranoia and subsequent social media use) and concurrent associations (between paranoia and concurrent social media use) were not significant, supporting a temporal sequence between social media use and subsequent decreases in paranoia.

Although social media may have negative effects on mental health through negative social comparisons, increased uncertainty in social communication, and other mechanisms [20,27,56], there is evidence that people with psychosis [57] and other mental health conditions [58] primarily use social media to connect with friends or family. Other studies have found that (physical) exposure to familiar social company and lower levels of loneliness are associated with decreased paranoia [14,16]. Building on this literature, this finding may reflect the effect of web-based social company through social media on reducing paranoia. The fact that this association was stronger in the schizophrenia versus bipolar disorder group is of unclear significance. In the literature, loneliness has been reported as a risk factor for paranoia regardless of whether people have a psychotic disorder [16], suggesting that increased social company through social media could hypothetically be protective across diagnostic groups. We believe that the lack of an association between social media and paranoia in the bipolar disorder group may be a consequence of the group's lower intraindividual variation in paranoia, which constrained the ability to detect effects of social media.

To our knowledge, the only previous investigation of longitudinal associations between social media use and paranoia is the one conducted by Berry et al [27]. While they did not directly assess the perception of web-based social company, they found that viewing social media newsfeeds predicted lower paranoia, whereas a perceived low social rank when using social media predicted higher paranoia. Their results, in line with community-based research on other aspects of well-being [59,60], indicate that social media can have both positive and

negative associations with mental health depending on the contents of use. Our study measured social media use as a whole and did not distinguish among browsing, posting, or private messaging on social media. Hence, the results may be best understood as average correlates of media behaviors, spanning reductions in paranoia to increases therein, with differences in the direction of association that may arise from unmeasured individual, environmental, and media-related factors [61].

After probing a tentative (not statistically significant) interaction, we also found an association between listening to music and a subsequent decrease in paranoia in people with bipolar disorder. Potentially beneficial effects of music have been described in an internet-based sample of 457 adults with schizophrenia in the United States, where 42% of them reported that listening to music or audio files helped with managing auditory hallucinations [25]. The association in this study was modest in size, but it could be argued that in some individuals, listening to music promotes distraction from paranoid thoughts [17].

Differences in the likelihood of media use as a function of participant characteristics indicate the potential impacts of socioenvironmental adversity. Consistent with prior research [29,30], participants diagnosed with schizophrenia rather than bipolar disorder were less likely to report any versus no social media use and any versus no other forms of internet and computer use, a gap that may stem from lower socioeconomic status and functional impairments associated with schizophrenia. Black versus White participants and those who did not go to college were also less likely to report any versus no internet or computer use. Prior research from clinical samples in the United States and other western countries similarly show that lower educational attainment was associated with a lower likelihood of using digital media [26,32,62], and in a US sample of 322 people receiving psychiatric care, participants of racialized minority groups were less likely than White participants to use social media [29]. These associations may reflect the impact of systemic inequities on material deprivation and lower media-related literacy, which are some of the most common barriers to digital media use in clinical and nonclinical populations [31,32].

Strengths and Limitations

This study is novel in its examination of media use in a large sample of participants with psychiatric diagnoses, who altogether contributed thousands of EMA surveys. By modeling associations between media use and paranoia at the within-person level, we were able to remove potential influences from time-invariant confounders such as sociodemographic features [63], thereby lending greater credence to possible causal effects of media use on paranoia. However, this method is not exempt from other sources of bias, including those from time-varying confounders: for example, a person's use of social media could be triggered by a momentary increase in the availability of social support, which could be driving subsequent improvements in paranoia, thus acting as a time-varying confounder of the association between social media use and decreased paranoia. The validity of the media use questionnaire could not be assessed, but previous research has found moderate correlations between self-reported digital media use and app-

or device-based activity logs [64]. The types of media evaluated here were not exhaustive and they aggregated heterogeneous media contents that may be differentially associated with paranoia. Each type of media was assessed with a single item, which was open to the respondent's interpretation: for example, social media may have been understood by some participants and not others as including private messaging. Dichotomous assessments of media use did not provide information on the duration and contents of use (eg, browsing newsfeeds or messaging individuals). Paranoia EMA was evaluated with a single item, which had a significant, moderate correlation with clinician-rated trait paranoia but has not been validated in external samples. Our findings were also bound by a specific time frame of 3 assessments per day that produced intervals of hours between measures, potentially underestimating the frequency of media use. Effects of media use on paranoia may unfold over longer intervals than those assessed here (eg, after weeks of intense exposure). Lastly, while lower incidence of paranoia in the bipolar group might have constrained statistical power, the results raise the possibility of diagnosis-specific associations with media use, which may help better tailor media-based interventions.

Future research that provides more detailed assessments of media use over various time frames will be needed to examine these questions. Inclusion of putative mechanisms (eg, decreased loneliness) and concurrent symptoms (eg, negative symptoms) will also help elucidate the pathways between media use and paranoia. Another direction for future research is to consider associations of media use with paranoia in additional populations, notably adolescents and individuals with other mental health conditions such as borderline personality disorder and depression.

Conclusions

This study found that social media use was associated with modest decreases in paranoia in a sample of individuals with schizophrenia or bipolar disorder. A better understanding of the social and cognitive possibilities of media technologies may help guide lifestyle counseling and media-based interventions for this population. However, systemic inequities and individual factors may hamper the accessibility of media, and the mental health correlates of media use may further vary as a function of specific contents and contexts of use.

Acknowledgments

This research was supported by a National Institute of Mental Health (NIMH) grant (RO1MH112620) awarded to AEP. VP is supported by an award from the Fonds de recherche du Québec – Santé and the Ministère de la santé et des services sociaux (FRQS-MSSS). The funders had no role in the preparation of this paper.

Data Availability

The data in this study are being deposited in the NIMH's Research Domain Criteria (RDoC) repository. They will be available for public access 6 months after data lock. In the interim, the data that support the findings of this study are available from AEP upon reasonable request.

Authors' Contributions

VP designed the research questions, reviewed the literature, conducted the analyses, and drafted the manuscript. AEP contributed to writing the manuscript and was the lead for funding acquisition and data collection. CAD, RCM, and PDH contributed to funding acquisition and data collection. RAA contributed to formulating the analytic plan. All authors contributed to manuscript editing and data interpretation and approved the final manuscript.

Conflicts of Interest

RCM is a cofounder of KeyWise AI, Inc, and NeuroUX, Inc. The terms of these arrangements have been reviewed and approved by the University of California San Diego in accordance with its conflict of interests policies. PDH has received consulting fees or travel reimbursements from Alkermes, Bio Excel, Boehringer Ingelheim, Intra-Cellular Therapies, Minerva Pharma, Otsuka America, Regeneron, Roche Pharma, and Sunovion Pharma. He receives royalties from the Brief Assessment of Cognition in Schizophrenia and the MATRICS Consensus Battery. He is chief scientific officer of i-Function, Inc. Abstract

Background: In West Africa, healers greatly outnumber trained mental health professionals. People with serious mental illness (SMI) are often seen by healers in “prayer camps” where they may also experience human rights abuses. We developed “M&M,” an 8-week-long dual-pronged intervention involving (1) a smartphone-delivered toolkit designed to expose healers to brief psychosocial interventions and encourage them to preserve human rights (M-Healer app), and (2) a visiting nurse who provides medications to their patients (Mobile Nurse).

Objective: We examined the feasibility, acceptability, safety, and preliminary effectiveness of the M&M intervention in real-world prayer camp settings.

Methods: We conducted a single-arm field trial of M&M with people with SMI and healers at a prayer camp in Ghana. Healers were provided smartphones with M-Healer installed and were trained by practice facilitators to use the digital toolkit. In parallel, a study nurse visited their prayer camp to administer medications to their patients. Clinical assessors administered study measures to participants with SMI at pretreatment (baseline), midtreatment (4 weeks) and post treatment (8 weeks).

Results: Seventeen participants were enrolled and most (n=15, 88.3%) were retained. Participants had an average age of 44.3 (SD 13.9) years and 59% (n=10) of them were male. Fourteen (82%) participants had a diagnosis of schizophrenia and 2 (18%) were diagnosed with bipolar disorder. Four healers were trained to use M-Healer. On average, they self-initiated app use 31.9 (SD 28.9) times per week. Healers watched an average of 19.1 (SD 21.2) videos, responded to 1.5 (SD 2.4) prompts, and used the app for 5.3 (SD 2.7) days weekly. Pre-post analyses revealed a significant and clinically meaningful reduction in psychiatric symptom severity (Brief Psychiatric Rating Scale score range 52.3 to 30.9; Brief Symptom Inventory score range 76.4 to 27.9), psychological distress (Talbieh Brief Distress Inventory score range 37.7 to 16.9), shame (Other as Shamer Scale score range 41.9 to 28.5), and stigma (Brief Internalized Stigma of Mental Illness Scale score range 11.8 to 10.3). We recorded a significant reduction in days chained (1.6 to 0.5) and a promising trend for reduction in the days of forced fasting (2.6 to 0.0, $P=.06$). We did not identify significant pre-post changes in patient-reported working alliance with healers (Working Alliance Inventory), depressive symptom severity (Patient Health Questionnaire-9), quality of life (Lehman Quality of Life Interview for the Mentally Ill), beliefs about medication (Beliefs about Medications Questionnaire-General Harm subscale), or other human rights abuses. No major side effects, health and safety violations, or serious adverse events occurred over the course of the trial.

Conclusions: The M&M intervention proved to be feasible, acceptable, safe, and clinically promising. Preliminary findings suggest that the M-Healer toolkit may have shifted healers’ behaviors at the prayer camp so that they commit fewer human rights abuses.

Introduction

Mental health systems in West Africa are constrained in their resources, infrastructure, and access to trained mental health personnel, limiting their capacity to deliver care [1,2]. In part due to these limitations, and in part due to local belief systems that frame mental health problems as spiritual rather than medical or psychological in nature [3,4], people with serious mental illness (SMI) in the region are often treated by traditional or faith healers, who are in abundance [5,6].

Healers often provide services at spiritual centers or “prayer camps”—rustic facilities where family members bring their relatives with mental illness, developmental disabilities, or substance use problems to be “healed” [7]. Pragmatically, prayer camps serve as West Africa’s de facto inpatient units and psychiatric residential homes. Once there, individuals seeking care may be retained at prayer camps for weeks, months, or even years at a time. Prayer camps are unregulated by any authorities, for the most part. Healers rarely have training in the etiology, assessment, or treatment of psychopathology, and their clients will seldom receive psychotropic medications or evidence-based psychosocial interventions. Healers provide spiritual consultation, prescribe prayer, and administer various ceremonial or herbal remedies [8,9]. In the absence of both training and resources to manage mental illness, healers may also engage in practices that have dangerous effects and constitute human rights abuses. These may include forced fasting, flogging, confinement in overcrowded or unsanitary conditions, and chaining patients to trees or concrete slabs so that they do not escape the camp’s grounds [9,10]. Chaining or similar forced mechanical restraining of people with SMIs, particularly those exhibiting signs of psychosis, are common practices in many low- and middle-income countries and are psychologically and physically damaging [11-13]. Despite the well-documented harsh practices used by some healers, and the negative attention their practices receive from Western media and human rights groups, these paraprofessionals continue to receive referrals and fill a societal need.

Our multinational team works closely with traditional and faith healers and people with SMI in West Africa. Through consultation, bilateral information sharing, articulation of mutual respect, and transparency in our activities, we have fostered partnerships with healers and their prayer camp communities [14-16]. These ties have served as the building blocks for cross-sector collaborations that are designed to improve the safety and quality of care that people with mental illness receive at prayer camps.

Findings from these collaborations have led us to develop M&M, a dual-pronged intervention involving (1) a smartphone-delivered mobile health treatment support toolkit (M-Healer app) designed to expose healers to brief psychosocial

interventions, encourage them to preserve human rights in their practice, and prompt them to monitor the status of the people they serve, and (2) a visiting community nurse who provides pharmacological care directly to their patients at the prayer camp (Mobile Nurse). The combination of healer-facing support technology, which can be installed on mobile devices that are widely accessible to healers throughout the region, and patient-facing pharmacotherapy delivered by medically trained personnel, which are more widely available than specialty mental health providers, may be a scalable strategy for addressing unmet mental health and quality-of-care needs in the region. Here we report on the first field trial of the integrated M&M intervention in a prayer camp in Ghana.

Methods

Study Design

The study involved a field trial of the integrated M&M intervention at a large prayer camp in Ghana. The objectives of the study were to (1) examine the safety and acceptability of the intervention among people with mental illness who are treated at the camp (hereinafter referred to as “patients”) and the prayer camp staff who provide them with services (hereinafter referred to as “healers”) and (2) evaluate the preliminary effectiveness of the intervention package.

Ethical Considerations

The study was approved by the institutional review boards of the University of Washington (00015549) and the University of Ghana (00001276). All study participants provided informed consent. Both healer and patient participants were compensated 75 Ghanaian Cedi (US \$5.83) for their engagement in each assessment interview with study personnel.

Study Procedures

Initially, members of the investigative team met with the leader of the prayer camp (hereinafter referred to as “the Prophet”) to describe the project (ie, objectives, procedures, and timeline), introduce members of the team, and demonstrate the M-Healer technology on a smartphone. During this meeting, the team was introduced to the 4 healers who would participate in the study. In a second meeting, the team met with the healers separately to discuss their routine practices at the camp, describe the “enhanced” services they would be trained to deliver in the context of the study, solicit feedback, cocreate the study’s operational timeline, and address any questions or concerns.

Candidate patients for intervention were suggested by prayer camp staff and screened on-site by study team personnel. The initial screening was conducted by study doctors (psychiatry residents). Participants were evaluated for general medical and psychiatric fitness for participation. Medical assessment included measurement of temperature, pulse, BMI, blood pressure, random blood sugar, blood hemoglobin level, and malaria. The

study inclusion criteria were as follows: (1) being aged 18 years or older; (2) speaking English or Twi; (3) being a current inpatient staying at a study prayer camp; (4) having a diagnosis of schizophrenia spectrum disorder (ie, schizophrenia, schizoaffective disorder, delusional disorder, or schizophreniform disorder), bipolar disorder, or major depressive disorder, as determined by study staff administering the relevant sections of the Structured Clinical Interview for the *Diagnostic and Statistical Manual of Mental Disorders* (Fifth Edition) during screening. Candidates were excluded if they had a serious physical illness or needed urgent medical attention (eg, they had a high fever, serious infection, visible injury, or hemorrhage). Individuals who met the criteria and who were interested in participating were enrolled in the study. Participants were provided with a snack and meal by the study staff during assessment visits.

Intervention Description

M&M is an 8-week-long dual-pronged intervention package comprising psychoeducation, skills training, and treatment support scaffolding tools delivered to healers via the M-Healer toolkit app, and pharmacotherapy that is administered directly to patients at prayer camps by a visiting mobile nurse.

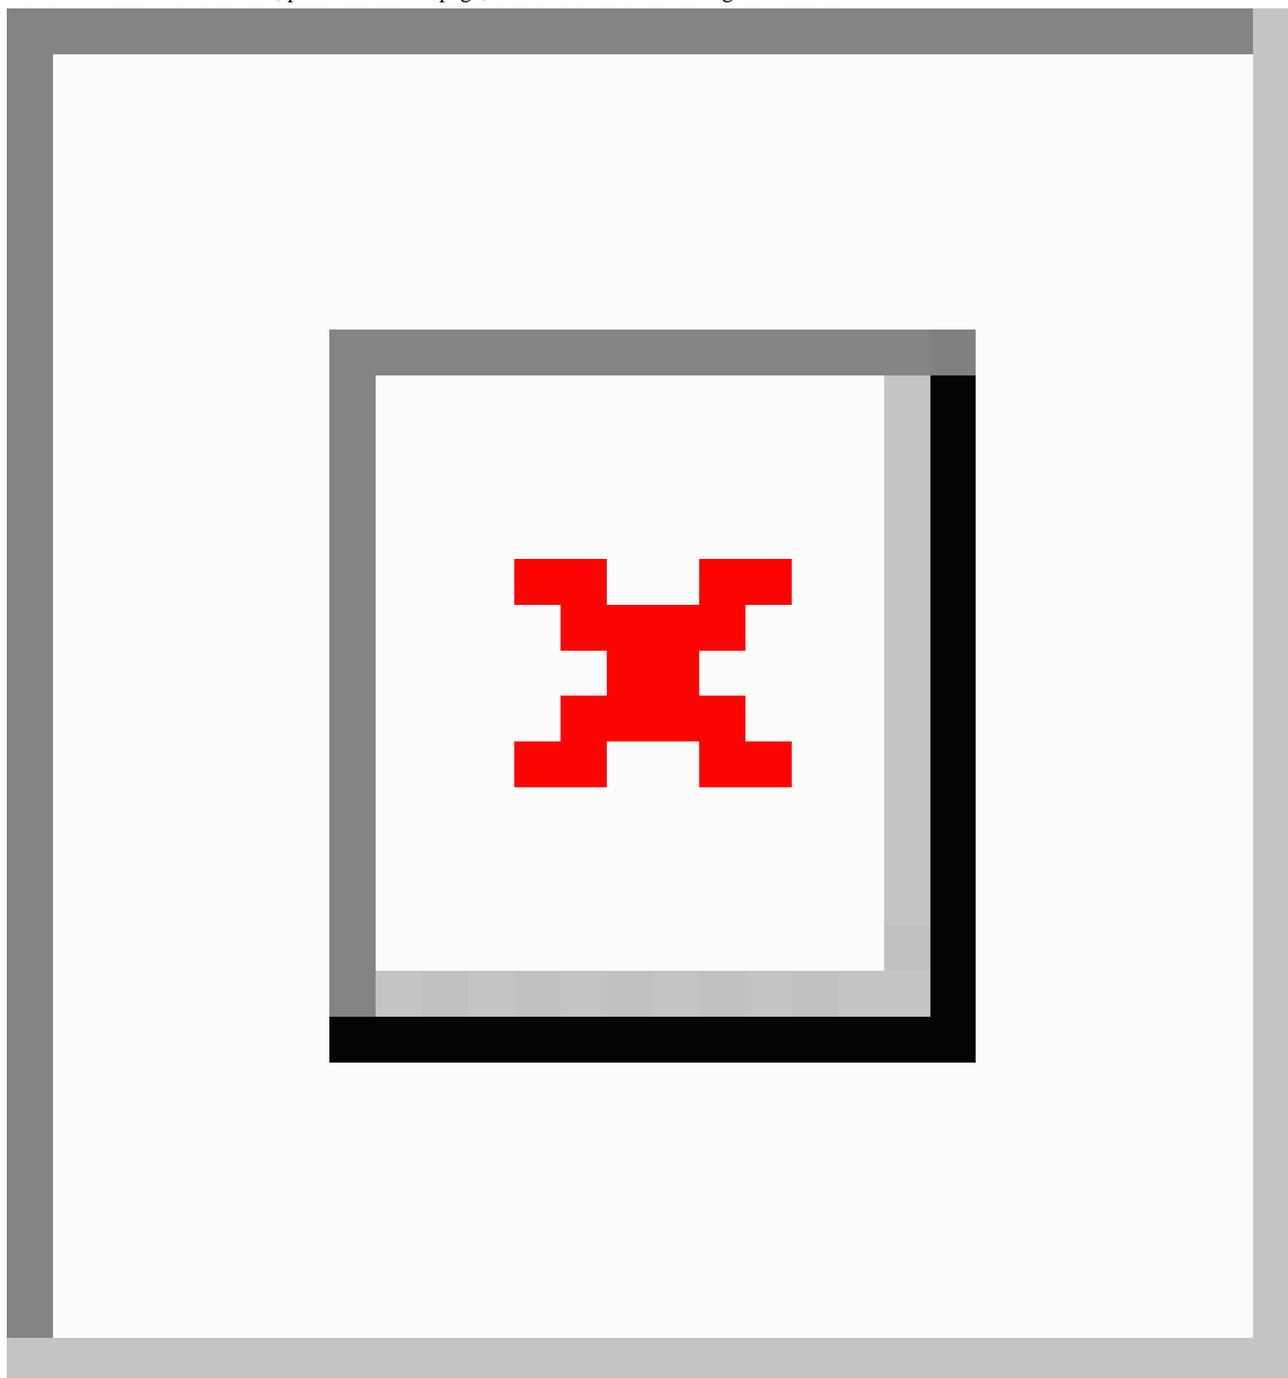

Intervention Component 1: M-Healer Toolkit

M-Healer is an Android Smartphone app that was specifically designed to serve as a digital toolkit for healers providing care to people with mental illness in West Africa [16]. The goal of the toolkit is to provide exposure to psychoeducational materials and to support basic monitoring of patient progress. Once installed on an Android device, the app does not require an active data plan or internet connectivity to operate, mitigating possible disruptions in functionality in resource-constrained environments. M-healer is available in English and Twi, the 2 most common languages spoken in Ghana. The app has 4 core functionalities. First, M-Healer provides psychoeducation on the administration of psychosocial interventions such as guided relaxation techniques, rapport building, verbal de-escalation, challenging dysfunctional beliefs about psychiatric symptoms, and preservation of human rights and dignity in practice. All content is accessible “on demand” from the home screen and delivered as brief digital animations or audio recordings (Figure 1). Second, M-Healer allows healer users to create a list of active patients currently at the camp to support basic tracking and

monitoring of individual progress. New patients are assigned a number, and healers have the option to also record an audio identifier for each individual. Every day, M-Healer prompts the healer to check in with each patient and provide a rating on whether they are doing better, worse, or the same as the day before. Ratings are assigned in the form of emojis with happy, sad, or neutral facial expressions. Once entered, a daily rating is added to a series of small icons showing patient progress over several days, which enables the healer to track patient progress over time (Figure 1). Third, M-Healer has push notifications, prompting users to watch the “video of the day” drawn from the bank of psychosocial digital animation training videos. Fourth, alongside these user-facing functionalities, M-Healer also tracks the frequency and duration of use in a given time frame, allowing the study staff and the nurse to monitor healers’ interactions with the M-Healer toolkit.

Healer participants were provided Android smartphones with M-Healer installed and activated, which they were allowed to retain at the conclusion of the study. Healers were trained by 2 practice facilitators (study coinvestigators) and the study nurse on how to use M-Healer. Practice facilitation was conducted over 2 sessions in a designated space within the prayer camp, which was removed from the areas where patients resided. In the first session, the practice facilitators established rapport and trust, introduced the M-Healer toolkit, and taught some technical and clinical skills to the healer. This session was interactive and involved demonstrations of how to use the system and its features. Each healer had an opportunity to practice these features with the assistance of the facilitators and the nurse. To help the healers understand how they could use M-Healer skills in caring for their patients, facilitators led role-plays, which involved the use of preselected videos and providing real-time instruction as the healers navigated through their devices. Role-playing skills in the videos involved the participation of both cofacilitators or a cofacilitator and a volunteer who modeled as a healer and patient. Role-playing sessions on how to add patients and track their progress involved all healers. As the lead facilitator led the training, the other study team members walked around to assist healers who were experiencing navigational or technical difficulties. To conclude the session, healers were tasked to watch a video, listen to an audio module, and check in and track the progress of their patients on a daily basis.

Figure 1. M-Healer home screen, patient check-in page, and on-demand human rights module.

The second facilitation session was designed to strengthen rapport and trust, refine technical skills, and strengthen clinical skill acquisition. The facilitators and study nurse reviewed the healers' experiences of using M-Healer and their use data. Healers' efforts in using the app were also acknowledged and praised. Healers were then asked to demonstrate how to watch a video or listen to an audio module, add a new patient for daily monitoring, and record their patients' progress. The facilitators addressed any questions and concerns. At the end of the session, the healers were reminded to watch a video, listen to an audio module, and check in with their patients daily moving forward. After these 2 training sessions, the healers continued to receive ongoing M-Healer support from the study nurse during weekly site visits. During these visits, the nurse had opportunities to

interact with the healers, inquire about and address their difficulties, check and record their user data, and encourage their use of the app.

Intervention Component 2: Mobile Nurse

A registered mental health nurse trained to use the World Health Organization's Mental Health Gap Action Programme–Intervention Guide (mhGAP-IG; version 2.0) served as the intervention's mobile nurse. Participants were prescribed medications by the screening study doctors. When possible, the prescribers opted to recommend long-acting injectable medications for participants with symptoms of psychosis to mitigate the risk of poor adherence to oral medication regimens. The use of long-acting injectable

medications was facilitated by the fact that most of the participants had received treatment with antipsychotics prior to their entry into the camp. Participants ultimately decided whether they would take medication and specified their preferred medication modality. The nurse monitored participants' BMI, blood pressure, pulse, and temperature weekly and monitored their random blood sugar monthly. The nurse conducted weekly assessments of response to treatment and medication side effects using mhGAP-IG guidance. The nurse was supervised clinically by 2 study psychiatrists and instructed to call them if they encountered any urgent treatment-related problems that were not clearly described by the mhGAP-IG or the study protocol. The clinical team maintained active, real-time telecommunication to facilitate timely consultation and a weekly clinical team meeting to review nonurgent inquiries.

Data Collection

Study assessors (masters'-level clinical psychologists) administered a battery of measures to patient participants at baseline, midintervention (week 4), and post intervention (week 8). Assessments were administered in English or Twi using a tablet-based data collection software REDCap (Research Electronic Data Capture) to facilitate secure, password-protected, on-site digital data collection. We collected information on demographics, psychological symptoms, psychological distress, quality of life, and prayer camp experiences.

Patient participants' psychiatric symptoms were measured at baseline, midtreatment, and post treatment using three measures: (1) the Brief Psychiatric Rating Scale (BPRS) [17], an 18-item clinical assessor-rated measure of current indicators of psychiatric illness including somatic concern, anxiety, emotional withdrawal, conceptual disorganization, feelings of guilt, tension, mannerism and posturing, grandiosity, depressive mood, hostility, suspiciousness, hallucinatory behavior, motor retardation, uncooperativeness, unusual thought content, blunted affect, excitement, and disorientation; the study assessors rated each indicator from 1 ("not present") to 7 ("extremely severe"), with higher scores indicating more severe symptoms (range 18-126); (2) the Brief Symptom Inventory (BSI) [18], a 53-item self-report assessment measuring 9 symptom dimensions; patients rated how much each symptom has bothered them in the past 8 days from 0 ("not at all") to 4 ("extremely"), with higher scores indicating more severe distress over the past 7 days (range 0-212); and (3) the Patient Health Questionnaire-9 [19], a 9-item depressive symptom scale in which respondents self-report how often (1="not at all" to 4="nearly every day") they experience symptoms including feeling depressed and hopeless over the prior 2 weeks.

The following measures were also administered at baseline, midtreatment, and post treatment. Psychological distress was measured using the Talbieh Brief Distress Inventory [20], a 24-item self-report measure using a Likert scale for prior-month frequency rating (0="not at all" to 4="extremely"). Higher scores represent more severe distress. Quality of life was measured using the global quality-of-life items from the Lehman Quality of Life Interview for the Mentally Ill [21], whereby participants rate how they feel about various aspects of their

life from 1 ("terrible") to 7 ("delighted"), and higher scores indicate higher quality of life. Shame was measured using the Other as Shamer Scale [22], an 18-item self-report (range 8-32; higher scores correspond to higher experiences of guilt and shame). Patient beliefs about medication were assessed using the Beliefs about Medications Questionnaire-General Harm subscale [23], internalized stigma was measured with the Brief Internalized Stigma of Mental Illness scale [24], and patient working alliance with the healers at the camp was assessed with an adapted version of the Working Alliance Inventory [25].

Human rights abuses were measured at baseline, midtreatment, and post treatment. At each assessment, study assessors interviewed patient participants and asked them to self-report on their experiences during the preceding week, up until and including the day of the assessment. Specially, they were asked to report the number of days they were chained or shackled (ie, "days chained"), the number of days they were forced to take herbal remedies, the number of hours they were held in isolation, and the total number of times they were touched on their genitals in an uncomfortable manner in the previous week.

To characterize the sample before treatment, we collected data on individuals' history of sexual abuse (Sexual Abuse Severity Scale) [26] substance use (Tobacco, Alcohol, Prescription Medications, and Other Substances scale) [27], and social support (Oslo Social Support Scale) [28] at baseline.

To measure the feasibility of the M-Healer intervention, we collected data post treatment on healers' use of the M-Healer technology, as well as knowledge and skills related to engagement with M-Healer. At each visit, study staff viewed the password-protected M-Healer data analytics screen on the healers' phones and recorded data including the number of days on which the app was used, the number of videos watched, the number of user-initiated app interactions, and the number of prompts to which the healers responded. To assess fidelity, healers participated in a 12-item verbally administered knowledge checklist whereby healers agreed or disagreed with statements regarding M-Healer knowledge domains. Healers performed 3 behavioral tests to demonstrate skills learned in M-Healer modules by interacting with the study staff acting as a standardized patients in role-played scenarios common to prayer camp settings. Study staff rated healer-demonstrated skills in a checklist.

Statistical Analysis

Descriptive statistics were used to characterize patient participants and their psychiatric and psychosocial factors at all study visits. We used paired samples *t* tests to compare baseline to midtreatment and baseline to posttreatment mean scores. For participants missing <50% of scale items for a psychosocial scale, item-level scores were imputed as the median score across the participant's existing scale items (person-median imputation) [29]. Psychosocial scores were not analyzed for participants missing ≥50% of scale items. Quantitative analyses were conducted using Stata (version 17; StataCorp).

Results

In total, 29 patients were screened for study eligibility among whom 19 (65.5%) were eligible to participate and 17 (89.5%) were enrolled (Figure 2). The majority of participants (n=15, 88.3%) were retained for midtreatment (4 weeks) and posttreatment (8 weeks) follow-up visits. Participants had an average age of 44.3 (SD 13.9) years; 59% (n=10) of them were male, and 82% (n=14) of them identified as Christian (Table 1). Fourteen (82%) participants had a diagnosis of schizophrenia, 1 had a comorbid diagnosis of major depressive disorder, and 2 were diagnosed with bipolar disorder. The average number

of weeks spent residing in the camp was 72.6 (SD 111.9), and this was the first experience in a prayer camp for 41% (n=7) of participants.

We found a significant and clinically meaningful reduction in psychiatric symptom severity from pretreatment to posttreatment as measured by the BPRS and the BSI (Table 2). Subjective ratings of psychological distress and shame were significantly lower post treatment than before treatment. Participants had significantly reduced internalized stigma about their mental health conditions from pretreatment to posttreatment. We recorded a significant reduction in days chained from pretreatment to posttreatment.

Figure 2. Flowchart for prayer camp participant enrollment. *Reasons for ineligibility were not mutually exclusive. **Malaria Rapid Diagnostic Test positive: n=1; hemoglobin level < 8% and symptoms: n=1; pulse > 120 bpm and symptoms: n=2. ***Participants returned for the 8-week visit.

^jA 6-item scale with an absolute range of 6-42; higher scores indicate better quality of life.

^kA 4-item scale with an absolute range of 4-20; higher scores indicate better working alliance.

^lFrequency over the past week.

Psychiatric symptoms measured with the BPRS and BSI were reduced midtreatment compared to those at baseline. Unfavorable beliefs about medications had decreased by the midtreatment visit compared to those at baseline. We observed a trend toward statistical significance for reduction in forced

fasting by the posttreatment follow-up visit ($P = .06$). Over the intervention period, we did not identify changes in patient-reported working alliance with healers, depressive symptom severity, quality of life, days forced to take herbal

remedies, hours retained in isolation, or number of times a participant reported being touched in an uncomfortable manner.

Results with imputed variables were not meaningfully different from those obtained from raw data. Notably, a significant decrease in unfavorable beliefs about medications from pretreatment to posttreatment was identified in the nonimputed data set; yet, this change was not detected in the imputed data set. Participants' scales with imputed values were predominantly only missing 1-2 items, which were imputed using person-median values per scale to retain the available data.

In the initial visit to the prayer camp, 15 participants consented to receiving pharmacotherapy. For schizophrenia treatment, fluphenazine decanoate (25 mg/mL) was the most commonly prescribed pharmacotherapy (n=12, 80.0%), followed by trihexyphenidyl (5 mg tablet; n=6, 40.0%) and risperidone (2 mg; n=3, 20.0%); some participants were prescribed multiple medications. Among participants with bipolar disorder, fluphenazine decanoate (25 mg), risperidone (25 mg), and trihexyphenidyl (5 mg) were each prescribed to 6.7% (n=1) of participants. Overall, 110 medication follow-up visits were conducted by the mobile nurse.

Four healers were trained to use M-Healer and their usage of the app was monitored weekly. M-Healer feasibility measures indicated that healers had an average of 31.9 (SD 28.9) user-initiated app uses per weekly visit, watched 19.1 (SD 21.2) videos, responded to 1.5 (SD 2.4) prompts, and used the app for 5.3 (SD 2.7) days a week. Healers had posttreatment average knowledge assessment checklist scores of 11.75 (absolute range 9-14, total possible score=16). Two healers successfully demonstrated all 3 behavioral skills, 1 healer demonstrated 2 skills, and 1 healer demonstrated 1 skill.

Discussion

Principal Results

The combination treatment package deployed in this study was designed to inform and shape West African healers' practices and to provide symptomatic relief to individuals with psychiatric illnesses receiving services at their prayer camps. The intervention proved to be feasible and acceptable to healers and their patients. Healers were able to navigate the M-Healer system successfully on the study smartphone devices that were provided to them. Healers expressed a clear understanding of M-Healer functionalities, watched psychoeducational videos, and listened to the audio lessons over the study period. Healers in the study self-initiated M-Healer use throughout the intervention period above and beyond system-prompted interactions and chose to view M-Healer videos and listen to audio lessons at a rate that far exceeded our expectations. Healers' use of the app was very frequent—almost daily. When evaluated, healers were able to describe the content accurately and to demonstrate skills that they had learned from the app.

Healers agreed to grant the mobile nurse access to the individuals they treated at the prayer camp, the majority of whom were placed in locked dormitories, with some shackles. The nurse was able to assess, provide pharmacotherapy to, and monitor these patients weekly without difficulty or obstruction,

despite these austere conditions. All patients approached by our study team expressed openness to meeting with the nurse, and all but 1 expressed interest in receiving pharmacotherapy to manage their psychiatric symptoms and improve their health.

The combined intervention proved to be clinically promising. Patient participants experienced significant reductions in the severity of their psychiatric symptoms, psychological distress, subjective feelings of shame, and internalized stigma over the course of the intervention. Moreover, patient participants reported a significant reduction in the days during which they were chained or shackled by the healers and a nonsignificant trend of reduction in the days during which they were forced to fast. These findings suggest that exposure to the training content delivered by the M-Healer toolkit may have shifted healer behaviors after the intervention was implemented at the prayer camp's study site. One participant was discharged from the prayer camp and allowed to return to their family over the course of the intervention by prayer camp staff.

The intervention proved to be safe. The study helped promote better care in the prayer camp's study site. Over the course of the intervention, 3 participants were identified by our study staff as requiring immediate medical attention and were referred to the district hospital where they received care. The nurse monitored medication side effects weekly. No major side effects, health and safety violations, serious adverse events, or other major complications occurred over the course of the field trial.

Poststudy debriefing interviews with healers indicated that they felt some ambivalence about M-Healer content. On one hand, they enjoyed the opportunity to learn about novel psychosocial illness management strategies and indicated that the digital toolkit informed the way they engaged with their patients. On the other, some expressed frustration that the toolkit's human rights module seemed too critical of their practices (eg, M-Healer's guidance to refrain from chaining patients). Given that current prayer camp practices do not prioritize preservation of human rights, this tension may have been inevitable. A more complete report on the findings from these interviews will be provided in a separate qualitative study.

Limitations

The study has several limitations. First, the study involved patient participants and healers at a single prayer camp, limiting study generalizability. Prayer camps vary dramatically in terms of their size, practices, and openness to research and outsider involvement in their day-to-day activities. Future multisite research in several prayer camps can help determine the generalizability of our findings to other settings. Second, we relied on study participants' self-reports to determine whether they experienced human rights abuses at the camp. Participants may have underreported these events due to shame, fear of retaliation, or to protect camp staff. Third, the study sample was small, allowing only for preliminary examination of treatment effects. Despite the exploratory nature of our evaluation of outcomes, promising evidence of clinical effectiveness was recorded. Future research involving larger samples will facilitate more robust evaluation of the effects of the intervention on participants' health and well-being. Finally, prayer camp staff had previous experience being involved in research with our

team. It will be important to examine the intervention in research-naïve prayer camps to evaluate whether such relationships are necessary for successful intervention uptake and outcomes.

Conclusions

In West Africa, traditional and faith healers greatly outnumber trained mental health professionals. Healers hold political capital and are respected by the local population. These key stakeholders can serve as facilitators, conduits, obstructionists, or blockades to the delivery of evidence-based mental health services in their communities. Engaging healers and training them to provide compassionate psychosocial interventions themselves and opening the doors of their prayer camps to medical professionals who can also deliver pharmacological interventions have the potential to enhance the regional capacity to address unmet mental health needs.

Previous research has demonstrated that pharmacotherapy can be conducted successfully at prayer camps. While psychotropics may help effectively manage the psychiatric symptoms of patients staying at prayer camps, those improvements did not translate to reductions in the days during which patients were shackled [14]. This study demonstrated that adding a key component—a healer-facing digital health training toolkit—can impact how healers interact with their patients, including a

reduction in the use of mechanical restraints. These findings are encouraging and suggest that the M&M intervention holds promise as a dual-pronged model for both improving mental health outcomes and reducing human rights abuses in West African prayer camps. If future research finds similarly robust treatment effects on a larger scale, this will provide important information for Ghanaian policy makers. Such findings would demonstrate that a combination of accessible technologies coupled with individuals trained to deliver interventions in the field may help reconfigure how prayer camps serve people with SMI. Ghanaian government mandates, monitoring, and enforcement over the last few years are beginning to produce positive effects on the reduction of human rights abuses in prayer camps. In addition to barring harmful practices, the government can also play a key role in supporting the adoption of new models of care. Through targeted trainings and appropriate oversight, individuals who are already working in the field (eg, government-employed district nurses or members of the Psych Corps—psychology graduates who are posted to health facilities across the country as part of their national service) could be leveraged to train healers and other paraprofessionals in the use of evidence-based digital mental health technologies. Government investment in such force-multiplying activities and technologies can prove to be a pragmatic and scalable approach for addressing significant professional workforce shortages in the region.

Acknowledgments

The study was supported by a grant award from the US National Institute of Mental Health (R01MH127531-01A1; DBZ and AOA). The authors thank the camp leader for permitting the study to be conducted at his faith healing camp and for the collaboration he fostered between camp staff and the study team. The authors acknowledge and thank the head of the district health management team for sending a district nurse to the study site to engage with the study nurse to facilitate continuation of pharmacological care, the district health management team that facilitated the acquisition of national health insurance cards for the study, and the study participants.

Conflicts of Interest

DBZ has financial interests in Merlin LLC and FOCUS technology. He has had an intervention content licensing agreement with Pear Therapeutics and has provided consultation services to Trusst Health, K Health, Boehringer Ingelheim, eQuility, Deep Valley Labs, and Otsuka Pharmaceuticals. KO and SO have provided consultation services to Janssen pharmaceuticals.
