Background: The introduction of natural language processing (NLP) technologies has significantly enhanced the potential of self-administered interventions for treating anxiety and depression by improving human-computer interactions. Although these advances, particularly in complex models such as generative artificial intelligence (AI), are highly promising, robust evidence validating the effectiveness of the interventions remains sparse.

Objective: The aim of this study was to determine whether self-administered interventions based on NLP models can reduce depressive and anxiety symptoms.

Methods: We conducted a systematic review and meta-analysis. We searched Web of Science, Scopus, MEDLINE, PsycINFO, IEEE Xplore, Embase, and Cochrane Library from inception to November 3, 2023. We included studies with participants of any age diagnosed with depression or anxiety through professional consultation or validated psychometric instruments. Interventions had to be self-administered and based on NLP models, with passive or active comparators. Outcomes measured included depressive and anxiety symptom scores. We included randomized controlled trials and quasi-experimental studies but excluded narrative, systematic, and scoping reviews. Data extraction was performed independently by pairs of authors using a predefined form. Meta-analysis was conducted using standardized mean differences (SMDs) and random effects models to account for heterogeneity.

Results: In all, 21 articles were selected for review, of which 76% (16/21) were included in the meta-analysis for each outcome. Most of the studies (16/21, 76%) were recent (2020-2023), with interventions being mostly AI-based NLP models (11/21, 52%); most (19/21, 90%) delivered some form of therapy (primarily cognitive behavioral therapy: 16/19, 84%). The overall meta-analysis showed that self-administered interventions based on NLP models were significantly more effective in reducing both depressive (SMD 0.819, 95% CI 0.389-1.250; $P<.001$) and anxiety (SMD 0.272, 95% CI 0.116-0.428; $P=.001$) symptoms compared to various control conditions. Subgroup analysis indicated that AI-based NLP models were effective in reducing depressive symptoms (SMD 0.821, 95% CI 0.207-1.436; $P<.001$) compared to pooled control conditions. Rule-based NLP models showed effectiveness in reducing both depressive (SMD 0.854, 95% CI 0.172-1.537; $P=.01$) and anxiety (SMD 0.347, 95% CI 0.116-0.578; $P=.003$) symptoms. The meta-regression showed no significant association between participants' mean age and treatment outcomes (all

$P > .05$). Although the findings were positive, the overall certainty of evidence was very low, mainly due to a high risk of bias, heterogeneity, and potential publication bias.

Conclusions: Our findings support the effectiveness of self-administered NLP-based interventions in alleviating depressive and anxiety symptoms, highlighting their potential to increase accessibility to, and reduce costs in, mental health care. Although the results were encouraging, the certainty of evidence was low, underscoring the need for further high-quality randomized controlled trials and studies examining implementation and usability. These interventions could become valuable components of public health strategies to address mental health issues.

Introduction

Background

Depression and anxiety pose a substantial worldwide burden. In 2020, depression and anxiety affected approximately 246 million and 374 million people, respectively [1]. Moreover, these conditions reduce individuals' quality of life and have significant economic repercussions [2]. The World Health Organization estimates that depression and anxiety result in a loss of US \$1 trillion annually due to loss of productivity [3]. In addition, their increasing incidence and a lack of health resources challenge the health care systems and workforce to meet the growing demand for mental health care services adequately [4].

In response, self-administered technology-based interventions have emerged as promising solutions for managing these conditions. These self-guided interventions enable users to progress through treatments independently, without external support [4], and they have demonstrated the potential to reduce costs; save health providers' time; and improve satisfaction and access to care, especially during crises and quarantine periods, for patients with mental health conditions living in remote areas, those with disabilities, or those unable to afford traditional care [5]. However, despite the potential of self-directed interventions to manage mental health problems, many of these interventions face important challenges in user engagement and adherence [6].

Self-administered interventions that are effective vary by delivery format, including web-based platforms, mobile apps, and virtual or augmented reality [7,8]. These interventions can be integrated within a professional intervention package or be completely independent of any external support [9,10]. Furthermore, they can be based solely on the presentation of relevant therapeutic information, typically based on a behavioral cognitive approach [10-12], or rely on machine learning (ML) models to process the natural language of clients' responses [13].

Natural language processing (NLP) offers a promising avenue for enhancing the efficacy of self-administered interventions. Defined as a cross-disciplinary field focused on enabling computers to comprehend, process, and interact with human language [14], NLP has the potential to make self-directed

interventions more cost-effective and accessible and facilitate fidelity and engagement of patients through better interaction [15].

Moreover, NLP can be categorized into 2 main approaches: rule based and artificial intelligence (AI) based. Rule-based NLP uses predefined linguistic rules to guide text interpretation, offering high explainability but limited flexibility in handling complex language nuances [16]. Conversely, AI-based NLP, encompassing ML and deep learning techniques, learns from extensive data to process language. It has shown remarkable success in various NLP tasks due to its scalability and ability to manage linguistic ambiguities [17].

The advent of large language models and multimodal large language models has further enhanced the capabilities of NLP-based health interventions. These advances are not limited to enhanced user interaction but extend to personalizing therapeutic modalities to the patient's unique requirements, as demonstrated in specific psychotherapeutic settings [18].

Previously, other systematic reviews, such as those conducted by Le Glaz et al [19] and Zhang et al [20], analyzed the impact of NLP on mental health. However, these reviews primarily focused on the general applications of NLP in mental health. In addition, another systematic review demonstrated promising results for NLP-based interventions in mental health, but the findings encompassed a broad range of mental health disorders and did not specifically address self-administered interventions [15].

Objectives

Although these advances are highly promising, analysis of their effectiveness and safety in managing mental health concerns such as depression and anxiety remains fragmented [21]. This study aims to systematically review available literature to determine the effect of self-administered NLP-based interventions on symptoms of depression and anxiety.

Methods

Design and Protocol Registration

This study systematically searched available literature in the principal health databases and synthesized the main quantitative results in a meta-analysis. Our study adheres to the PRISMA

(Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines (refer to [Multimedia Appendix 1](#) for the PRISMA 2020 checklist) and the Cochrane Collaboration recommendations for meta-analyses [22]. The protocol for this systematic review was registered in the PROSPERO repository (CRD42023472120).

Eligibility Criteria

Our study follows the PICOS (Population, Intervention, Comparison, Outcomes, and Study Design) framework to evaluate whether interventions based on NLP models can

effectively reduce depressive and anxiety symptoms. We define these symptoms as follows: (1) depressive symptoms are defined as a mood disorder characterized by the persistent presence of a profound sense of sadness, loss of interest or pleasure in daily activities, and a general lack of energy; and (2) anxiety symptoms are characterized by the anticipation of imagined events that are perceived as potential threats, causing emotional distress and physiological tension.

The eligibility criteria for our review are presented in [Textbox 1](#).

Textbox 1. Eligibility criteria for the review determined using the PICOS (Population, Intervention, Comparison, Outcomes, and Study Design) framework.

Review eligibility criteria

- **Population:** we included studies with participants of any age group (child, adolescent, adult, and older adult) with or without previous comorbidities. Eligible studies must report participants who have been diagnosed with depression or anxiety through an interview or consultation with a mental health professional (eg, physician, psychologist, or psychiatrist) or assessed using validated psychometric instruments.
- **Intervention:** the intervention must be based on natural language processing (NLP) models such as large language models, multimodal large language models, artificial intelligence–led systems (ie, digital conversational agent, chatbot, or interactive voice response), and other NLP models. We included interventions regardless of their primary design purpose, provided they were self-administered.
- **Comparison:** we considered both passive (ie, waiting lists, nonintervention control groups, or placebos) and active (ie, web-based or face-to-face psychological interventions, virtual reality, serious games, biofeedback for mental health problems, pharmacological therapies to treat symptoms of depression and anxiety, or animal-assisted therapies) comparators.
- **Outcomes:** we included studies measuring depressive and anxiety symptom scores using validated psychometric questionnaires (eg, Patient Health Questionnaire-9, Beck Depression Inventory, Hamilton Depression Rating Scale, Generalized Anxiety Disorder-7, Beck Anxiety Inventory, Hamilton Anxiety Rating Scale, or similar instruments).
- **Study Design:** we included randomized controlled trials and quasi-experimental studies (without a control arm or randomization groups) that assessed the effect of NLP-based interventions on depressive and anxiety symptoms. We excluded narrative reviews, systematic reviews, scoping reviews, and other nonoriginal research designs. Only peer-reviewed publications (original articles or briefs) were included; proceedings, posters, and other similar items were excluded. There were no exclusion criteria based on language, publication date, or setting (ie, clinical or community settings).

Information Sources and Search Strategy

The databases we used for the systematic review were Web of Science, Scopus, MEDLINE (by PubMed), PsycINFO (by EBSCO), IEEE Xplore, Embase, and Cochrane Library. The search strategy included terms related to NLP as well as depression and anxiety, along with health science descriptors (refer to [Multimedia Appendix 2](#) for the search strategy). Our search included any document available from inception to November 3, 2023.

Selection Process

We downloaded all records identified by the search strategy in RIS format and compiled them into an EndNote (Clarivate) file, which served as a repository for all retrieved records. Next, we used automated and manual methods to remove duplicate records. We exported the list of unique records from EndNote to Rayyan (Rayyan Systems Inc) for the selection process. First, 2 pairs of authors (JG-S with RG-A and GQ-C with GL-C) independently assessed the abstracts and titles of the studies to ensure that they met the inclusion criteria. Two pairs of authors reviewed the resulting retrieved text independently (JG-S with RG-A and GQ-C with GL-C). Any excluded studies were recorded along with the reasons for their exclusion (refer to [Multimedia Appendix 3](#) for a list of the excluded studies). If disagreements arose between the reviewers at either stage, they

were resolved by discussion. A third reviewer (DV-Z) was consulted if disagreement persisted to decide whether the study met the inclusion criteria. Records were included or excluded depending on whether they met the inclusion criteria. At the title and abstract stage, if it was unclear whether a record met all the inclusion criteria, it could proceed to the full-text stage, where a more detailed review was carried out (a sensitive approach). However, at the full-text stage, all inclusion criteria had to be met for final acceptance.

The title and abstract review were performed in English because this is the language in which the databases save the metadata. The full-text review and results extraction were mainly performed in English and Spanish (the languages the reviewers speak). When studies in other languages were found, the reviewers used DeepL Translator (DeepL SE) to translate the documents into English before proceeding with the review and extraction. Therefore, our review had no language limitations. It is important to note that all papers evaluated in the full-text review and extraction were in English.

Data Collection

Two pairs of authors (JGS with RGA and GQC with GLC) independently collected the information from the included studies using a predefined collection form in a Microsoft Excel sheet. Initially, a pilot data extraction process was conducted

on 5 data sets reviewed by all raters with 85% agreement. Subsequently, minor changes were made to the final version of the extraction form to improve the clarity of the extracted data, which included the following: (1) general information (ie, authors, year of publication, title, country, and language); (2) participant characteristics (ie, age range, sex, number of participants, and diagnosis); (3) intervention characteristics (ie, type of NLP model, duration, frequency, and brief description of the intervention); (4) comparator (passive or active); and (5) main outcomes (ie, means, SDs, preintervention and postintervention measures, and the effect size for control and intervention groups).

Risk-of-Bias Assessment and Certainty of Evidence

We used the JBI critical appraisal tools to identify potential biases that may have occurred during the design, conduct, and analysis of the studies. For quasi-experimental studies, we used the JBI critical appraisal checklist for quasi-experimental studies [23], which is a checklist with 9 questions for assessing potential bias. For randomized controlled trials (RCTs), we used the JBI critical appraisal tool for the assessment of risk of bias in RCTs [24], which is a 13-question checklist evaluating the internal and statistical validity of the conclusions of RCTs. On the basis of the answers from both assessment tools, reviewers decide whether to include the reviewed study. Two reviewers used these tools independently to assess the risk of bias in the studies included in the meta-analysis. Any disagreement between the reviewers about whether to include or exclude a study was resolved by discussion. If the disagreement persisted, a third reviewer was asked to arbitrate.

We used the Grading of Recommendations Assessment, Development, and Evaluation (GRADE) methodology to assess the certainty of evidence regarding the intervention's effects. This methodology evaluates the certainty of evidence based on several criteria, including risk of bias, inconsistency, indirectness, and imprecision [25]. Given that the GRADE approach is primarily focused on RCTs, and the GRADE working group has not yet reached a consensus on the combination of results from randomized and nonrandomized trials, we applied this evaluation exclusively to the RCTs included in our review.

Synthesis Methods

Narrative Synthesis

To address the multifaceted nature of the factors involved in self-administered NLP-based interventions for symptoms of depression and anxiety, we adopted a comprehensive framework for data synthesis based on an adaptation of the categories from the framework for NLP applications for mental health interventions proposed by Malgaroli et al [15] in the context of self-administered NLP interventions. This systematic approach thoroughly integrates all relevant factors, providing a coherent structure for our analysis. We categorized data from eligible studies into four primary domains: (1) demographic and sample descriptions, (2) NLP technical aspects, (3) clinical categories, and (4) intervention results. Due to the nature of our study, the last category is presented through the findings of the meta-analysis and analysis of subgroups.

Meta-Analysis

We performed analyses using Stata (version 18.0; StataCorp LLC). Meta-analysis was only performed if at least 3 studies of the same design type (ie, randomized or quasi-experimental controlled trials) assessing the same outcome were available. The analysis was differentiated by outcome and by study type. Standardized mean differences (SMDs) with 95% CIs were used for meta-analyses and summary statistics of the studies because the results of the included studies were measured using different scales. SMD is the mean difference between the intervention and control groups divided by the pooled SD.

The standard measure of effect size to be considered for the Hedges g analyses includes small (SMD 0.2), moderate (SMD 0.5), and large (SMD >0.8) effect sizes. These thresholds were used to evaluate the combined effect of the analyzed interventions using Hedges g . Hedges g , unlike Cohen d , corrects for possible risk of bias associated with small sample sizes, making it a more appropriate measure for our analyses [26].

Heterogeneity Analysis

The assessment of statistical heterogeneity involved the following tests: the Cochran Q test statistic to detect the presence of heterogeneity between studies, the I^2 Higgins and H^2 index statistics to measure the extent of variability between studies due to heterogeneity, and the between-study variance (τ^2) to assess the variance between the effects observed across the studies. If the overall assessment indicated high heterogeneity, random effects models were used to estimate the effect of the interventions in general.

Publication Bias Analysis

If there were >10 studies in the meta-analysis, we conducted both visual and quantitative tests to detect biases. Our visual examination used a funnel plot; the quantitative test used was the Egger regression test, which can capture the effects of small studies and other potential information biases [27]. We identified selection bias if we observed an asymmetric funnel plot distribution and a significant Egger regression test result ($P < .05$). In cases of asymmetry, the trim-and-fill method proposed by Duval and Tweedie [28] was implemented as a bias correction technique to estimate the number of missing studies for the meta-analysis.

Analysis of Subgroups

If the meta-analysis data allowed, we assessed intervention effects using the NLP-based models from the selected studies. Such models could include rule-based NLP, AI-based NLP, or other NLP. In addition, we assessed the impact of interventions on subgroups, including gender, disease severity, prior therapies, concurrent depression and anxiety disorders, and age ranges.

We performed a random effects meta-regression using aggregate-level data. Our analysis specified the variables containing the SE within each study using the *metareg* command and the *wsse* option in Stata. The meta-regression was a function of the mean age of the participants and was only applied to the overall meta-analysis. Our analysis yielded a meta-regression coefficient with 95% CI.

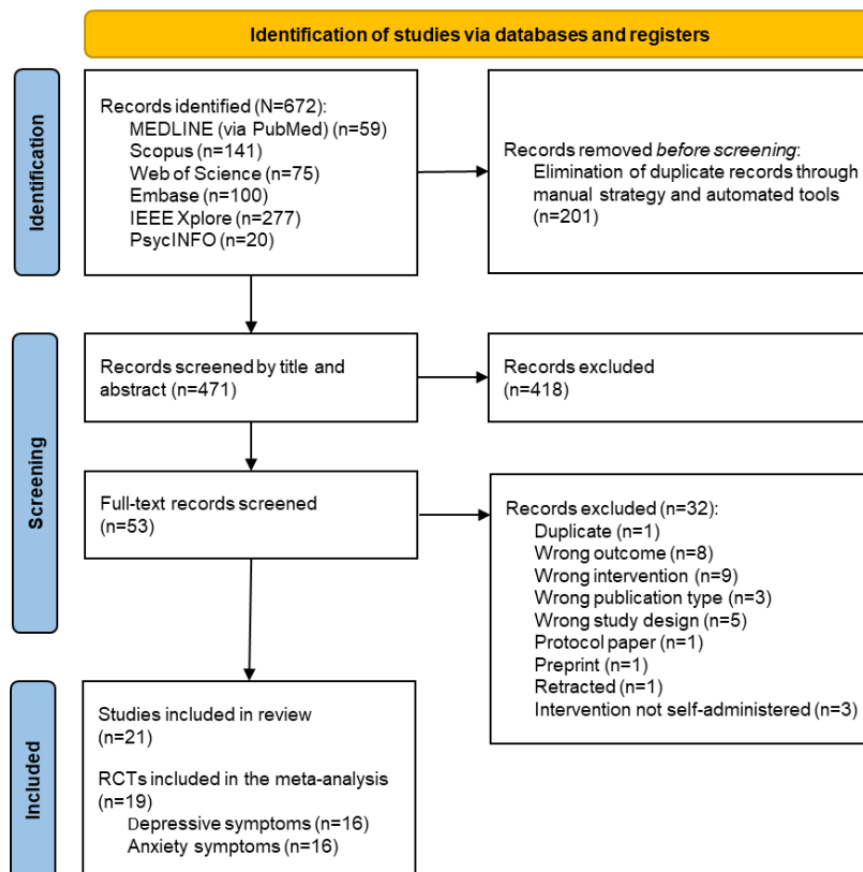

Results

Study Selection

Initially, 672 records were identified in the different databases; after eliminating 201 (29.9%) duplicates, 471 (70.1%) records advanced to title and abstract review. Of these 471 records, 418 (88.7%) were discarded, leaving 53 (11.3%) records for full-text review. Subsequently, 32 (60%) of the 53 records were

excluded, resulting in 21 (40%) articles selected for review. Of these 21 articles, 19 (90%) were included in the meta-analysis on depressive and anxiety symptoms. Of the 19 studies included in the meta-analysis, 16 (84%) reported sufficient data for the meta-analysis of depressive symptoms, and another 16 (84%) reported sufficient data for the meta-analysis of anxiety symptoms. [Figure 1](#) shows the complete review process, and [Multimedia Appendices 3 and 4 \[29-49\]](#) list the articles excluded and included, respectively.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of the selection process. RCT: randomized clinical trial.

Characteristics of the Included Studies

Of the 21 studies identified, 19 (90%) were RCTs [29-47], and 2 (10%) were quasi-experimental studies without a control group [48,49]. Most of the studies (16/21, 76%) were published between 2020 and 2023, and 81% (17/21) were conducted in high-income countries. The United States was the country with the most publications among the selected studies (10/21, 48%). Regarding the characteristics of the populations studied, the majority (16/21, 76%) focused on adults. With regard to the outcomes assessed, depressive symptoms were analyzed in 95% (20/21) of the studies and anxiety symptoms in 90% (19/21).

We found 29 potential comparisons between interventions and controls because 5 (24%) of the 21 studies reported ≥ 3 arms. AI-based NLP applications were the most common intervention (11/21, 52%), while the most common control conditions were waiting list or no intervention (8/21, 38%) and information, psychoeducation, or bibliotherapy (8/21, 38%). The most commonly used scales to measure depressive and anxiety symptoms were the Patient Health Questionnaire (PHQ; PHQ-9 and PHQ-8; 13/21, 62%) and the Generalized Anxiety Disorder-7 (GAD-7; 10/21, 48%), respectively. [Table 1](#) shows the characteristics of the studies, divided into RCTs and uncontrolled quasi-experimental studies.

NLP Technical Aspects

Of the 21 included studies, 10 (48) used rule-based approaches, while 11 (52%) used AI-based techniques. Within the AI-based category, of the 11 studies, 4 (36%) implemented deep learning methods, 6 (55%) did not specify the AI technique used, and 1 (9%) used ML algorithms. Regarding the specific NLP techniques used, sentiment analysis was used in 18% (2/11) of the studies, and natural language understanding was used in 18% (2/11). Notably, 7 (64%) of the 11 studies did not specify the NLP techniques used in their interventions. This distribution highlights a diverse application of NLP methods in addressing symptoms of depression and anxiety, with more than half of the studies (11/21, 52%) leveraging advanced AI techniques, albeit often without detailed specification (7/11, 64%).

The input modality for the NLP interventions was primarily text based in 19 (90%) of the 21 studies, while 1 (5%) study used either text or voice, and 1 (5%) study used voice alone. Regarding output modalities, text was predominantly used in 20 (95%) of the 21 studies, while only 1 (5%) study used voice. The language of the NLP input and output varied among the studies. Of the 21 studies, 7 (33%) used English, and 3 (14%) used Chinese, while Japanese, Spanish, and Italian were used in 1 (5%) study each. However, 38% (8/21) of the studies did not specify the language used for the NLP input and output.

Demographics and Sample Descriptions

Overview

The study participants' demographic characteristics were analyzed for rule-based NLP studies and AI-based NLP studies. All 21 studies provided demographic information regarding the sample or testing data set used for the intervention. Demographic data for rule-based NLP studies are reported only for the intervention samples. By contrast, AI-based NLP studies were expected to provide demographic information for the training data used to develop the AI-based models and the participants involved in the intervention or experiment.

Training Sample Description

None of the AI-based NLP studies provided detailed demographic information regarding the training data. While 3 (27%) of the 11 AI-based NLP studies mentioned the source of their training data (Stanford Sentiment Treebank data set, ad hoc user utterances from an unspecified source, and Emotion Support Conversation data set), they did not describe the demographic characteristics of these data sets.

Testing Data or Intervention Sample Description

Across all studies, gender distribution varied significantly. Of the 21 studies, in 3 (14%), only women participated; in 16 (76%), >50% of the participants were women; and in 2 (10%), >50% of the participants were men. Regarding the age of the participants, 20 (95%) of the 21 studies reported the mean age of their samples. Of these 20 studies, 9 (45%) involved participants aged >30 years, 10 (50%) included participants aged between 18 and 29 years, and 1 (5%) included participants aged <18 years. Participants' special conditions were also considered in the analysis. Of the 21 studies, 4 (19%) included participants with chronic diseases, 7 (33%) focused on

individuals with mental disorders, and 7 (33%) included university students, while 4 (19%) involved participants with other conditions. Specifically, among the 7 studies that focused on mental disorders, 2 (29%) included participants with a positive screening for depression, and 2 (29%) focused on participants with a positive screening for substance use disorder. Among the 4 studies that included participants with chronic diseases, there were diverse conditions, such as diabetes mellitus (n=1, 25%), cancer (n=1, 25%), inflammatory bowel disease (n=1, 25%), and dementia (n=1, 25%).

Focusing on the 11 AI-based NLP studies, the gender distribution of the intervention samples was as follows: in 9 (82%) studies, the majority of the participants were women; and in 2 (18%) studies, the majority of the participants were men. Regarding age distribution, of the 10 studies that reported mean ages, 5 (50%) involved participants aged >30 years, and 5 (50%) included participants aged between 18 and 29 years. With regard to special conditions in the intervention samples, of the 11 studies, 2 (18%) included participants with chronic diseases, 2 (18%) focused on individuals with mental disorders, 6 (55%) included university students, and 2 (18%) involved participants with other conditions (participants with panic disorder: n=1, 50%; and participants with a positive screening for depression: n=1, 50%). For chronic conditions, of the 2 studies, 1 (50%) involved patients with dementia, and 1 (50%) included patients with diabetes mellitus.

Clinical Categories

The included studies were evaluated for their focus on clinical presentation and the delivery of therapeutic interventions. Only 1 (5%) of the 21 studies reported having a component of diagnosis and screening for mental health problems, although it did not specify the disease or the methods used for diagnosis.

Most of the studies (19/21, 90%) declared that they delivered some form of therapy through their NLP interventions. By contrast, 2 (10%) of the 21 studies did not include any therapeutic component. Among the 19 studies that delivered therapy, 16 (84%) implemented cognitive behavioral therapy, 1 (5%) combined cognitive behavioral therapy with dialectical behavioral therapy, and 2 (11%) reported delivering therapy but did not specify the therapeutic approach used.

Meta-Analysis Findings

Main Meta-Analysis

Only 16 (76%) of the 21 studies were included in the meta-analysis, excluding the uncontrolled quasi-experimental studies (n=2, 10%) and the RCTs with insufficient data for meta-analysis (n=3, 14%). The rationale for excluding the 2 quasi-experimental studies was that a meta-analysis specific to this study design required at least 3 studies of the same design type assessing the same outcome. For the depressive symptoms (Figure 2 [29-37,39-45]), the overall meta-analysis showed that self-administered interventions based on NLP models were significantly more effective in reducing depressive symptoms compared to various control conditions (waiting list or no intervention, treatment as usual, psychoeducation, and other computer-based conversational interventions; SMD 0.819, 95% CI 0.389-1.250; $P<.001$). In addition, high heterogeneity was

observed in the overall meta-analysis ($I^2=92.7\%$, 95% CI 78.3%-96.4%; $H^2=3.71$, 95% CI 2.15-5.27; $\tau^2=0.97$; $P<.001$). Regarding publication bias, the funnel plot analysis showed evidence of bias (Egger test coefficient=3.61, 95% CI 0.45-6.78; $P=.03$; [Multimedia Appendix 5](#)).

For the outcome of anxiety symptoms ([Figure 3 \[30-34,36-46\]](#)), the global meta-analysis showed that self-administered NLP model-based interventions were significantly more effective in reducing depressive symptoms compared to various control

conditions (waitlist or no intervention, treatment as usual, psychoeducation, and other conversational computer-based interventions; SMD 0.272; 95% CI 0.116-0.428; $P=.001$). In addition, high heterogeneity was observed in the overall meta-analysis ($I^2=64\%$, 95% CI 0.5%-81.6%; $H^2=1.67$, 95% CI 1.00-2.33; $\tau^2=0.07$; $P<.001$). Regarding publication bias, the funnel plot analysis showed no evidence of bias (Egger test coefficient=-0.22, 95% CI -1.55 to 1.11; $P=.73$; [Multimedia Appendix 5](#)).

Figure 2. Forest plot for control conditions versus self-administered interventions based on natural language processing models to reduce depressive symptoms.

Figure 3. Forest plot for control conditions versus self-administered interventions based on natural language processing models to reduce anxiety symptoms.

Subgroup Analyses

We also conducted a detailed analysis according to the type of comparator, intervention, and the scale used, evaluating the results for depressive symptoms and anxiety symptoms separately. For depressive symptoms, self-administered interventions based on NLP models were found to be more effective than information, psychoeducation, or bibliotherapy (SMD 1.481, 95% CI 0.368-2.594; $P=.009$). Similarly, AI-based NLP models were more effective than the set of control conditions (SMD 1.059, 95% CI 0.520-1.597; $P<.001$) for reducing depressive symptoms. Regarding the scale used, studies using the PHQ-9 or PHQ-8 showed that self-administered interventions based on NLP outperformed the set of control conditions (SMD 0.914, 95% CI 0.417-1.410; $P<.001$).

For the outcome of anxiety symptoms, self-administered interventions based on NLP models were more effective than waitlist or no intervention (SMD 0.196, 95% CI 0.042-0.351; $P=.01$) and information, psychoeducation, or bibliotherapy

(SMD 0.561, 95% CI 0.195-0.927; $P=.003$). In addition, the use of AI-based NLP models had a higher effect than the average of the control conditions (SMD 0.302, 95% CI 0.073-0.532; $P=.01$) in reducing anxiety symptoms. Regarding the scale used, studies using the GAD-7 showed that self-administered interventions based on NLP had a higher effect than the average of the control conditions in reducing anxiety symptoms (SMD 0.333, 95% CI 0.074-0.592; $P=.01$). Full details of this subgroup analysis are presented in [Table 2](#).

Given that factors such as age may influence the outcomes of depressive and anxiety symptoms, we performed a meta-regression to assess whether the mean age of participants affected the overall meta-analysis results. Our analysis revealed that the mean age was not significantly associated with the point estimates for either depressive symptoms (coefficient=-0.037, 95% CI -0.092 to 0.019; $P=.18$) or anxiety symptoms (coefficient=-0.010, 95% CI -0.030 to 0.010; $P=.29$). Detailed results of the meta-regression are presented in [Table 3](#).

Risk of Bias and Certainty of Evidence

In the overall analysis of the risk of bias for the outcome of depressive symptoms, the majority of the studies (9/16, 56%) had an overall low risk of bias, while only 19% (3/16) had an overall high risk of bias (Figure 4A). Regarding the dimensions assessed, the lowest risk of bias was observed in reporting and analysis strategies (15/16, 94%), followed by participant loss or missing data (14/16, 88%). However, intervention delivery showed an unclear risk of bias due to limited reporting in the reviewed manuscripts. By contrast, for the outcome of anxiety symptoms, half of the studies (8/16, 50%) had an overall low risk of bias, while only 12% (2/16) had an overall high risk of bias (Figure 4B). At the level of each dimension assessed, all studies had a low risk of bias in reporting and analysis strategies, and 81% (13/16) had a low risk of bias in outcome measurement and retention throughout the study. Detailed risk-of-bias analyses for each study are available in Multimedia Appendix

6 for depressive symptoms and Multimedia Appendix 7 for anxiety symptoms.

We found that, for the outcomes studied (depressive symptoms and anxiety symptoms), the evidence was of very low certainty (Table 4). This was mainly due to several factors. First, there was a high risk of bias, with 3 (19%) of the 16 studies presenting an overall high risk of bias for depressive symptoms and 2 (12%) of the 16 studies presenting an overall high risk of bias for anxiety symptoms. Second, there was significant inconsistency, as indicated by an overall I² value of >60%. In addition, indirectness was a major concern due to the high variability in the interventions, controls, and sample characteristics across the studies. Finally, publication bias was strongly suspected due to the marked right-side asymmetry revealed by the funnel plot. Notwithstanding these limitations, the findings provide a preliminary understanding of the potential effects of self-administered NLP-based interventions on depressive and anxiety symptoms.

Figure 4. Risk of bias grouped for the outcomes of (A) depressive symptoms and (B) anxiety symptoms.

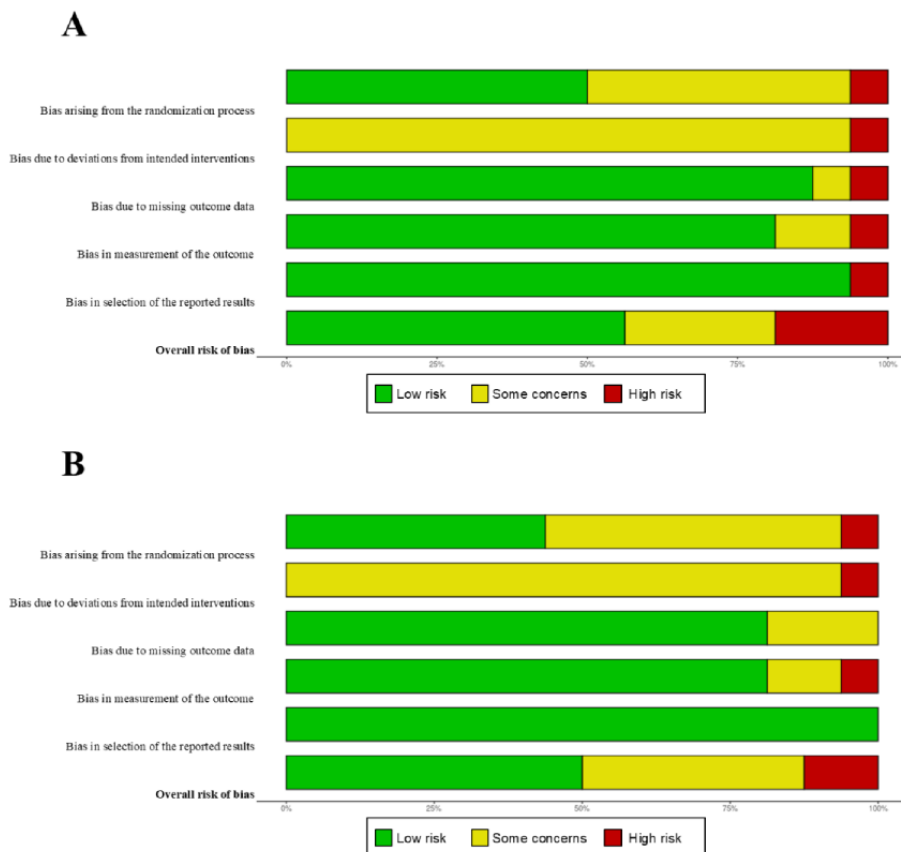

Table 4. Summary of findings and certainty of evidence using the Grading of Recommendations Assessment, Development, and Evaluation methodology.

Outcome	Assessment of certainty of evidence						Effect: Hedges <i>g</i> , SMD ^a (95% CI)	Certainty of evidence
	Studies (RCTs ^b), n (participants, n)	Risk of bias	Inconsistency	Indirectness	Imprecision	Publication bias		
Depressive symptoms	16 (1516; control: 760, intervention: 756)	Very serious ^c	Very serious ^d	Very serious ^e	Not serious	Strongly suspected ^f	0.82, lower (0.39-1.25)	⊕○○○ ^g
Anxiety symptoms	16 (2642; control: 1312, intervention: 1330)	Very serious ^h	Very serious ^d	Very serious ^e	Not serious	Strongly suspected ^f	0.27, lower (0.12-0.43)	⊕○○○

^aSMD: standardized mean difference.

^bRCT: randomized controlled trial.

^cOf the 16 studies, 3 (19%) present an overall high risk of bias.

^dOverall I^2 value >60%.

^eThere is a high variability in the interventions, controls, and sample characteristics.

^fThe funnel plot reveals a marked right-side asymmetry.

^gVery low (each filled circle [⊕] signifies a higher level of certainty, while each empty circle [○] indicates a lower level of certainty).

^hOf the 16 studies, 2 (12%) present an overall high risk of bias.

Discussion

Principal Findings

Our results indicate that self-administered interventions based on NLP models have a significant overall effect on reducing depressive and anxiety symptoms compared to various control conditions. Our study used random effects models to estimate this overall effect, thus accounting for heterogeneity among the interventions analyzed. Therefore, we consider the results to be robust. At the level of each intervention group and control group, we observed variability in their effectiveness in reducing symptoms of depression and anxiety, which could be due to the limited number of studies available for meta-analysis. In particular, conversational computer-based interventions were shown to be effective in reducing depressive and anxiety symptoms compared to pooled control conditions. In addition, NLP-based interventions overall outperformed psychoeducation and bibliotherapy in reducing both depressive and anxiety symptoms. Furthermore, these interventions were more effective than waitlist or no intervention in reducing anxiety symptoms.

These findings support the usefulness of self-administered NLP-based interventions in alleviating such common mental health problems as depressive and anxiety symptoms. Thus, they have the potential to be implemented in primary care settings, where they could represent a valuable public health strategy to improve the mental health of the population.

Comparison With Other Studies

Our findings are consistent with previous research that has examined the application of NLP-based models at various stages of mental health care in both clinical and community settings [50-52], indicating that NLP-based interventions may effectively alleviate symptoms of emotional disorders. The robustness of our research is strengthened by the fact that most of the studies included in the meta-analysis of depressive (9/16, 56%) and

anxiety symptoms (8/16, 50%) have a low risk of bias, indicating that our findings are derived from rigorous and reliable research.

A previous scoping review highlighted the heterogeneity of the tools used to assess the effects of dialogue interventions on mental health [53]. However, our review found that in the case of RCTs focusing on depressive and anxiety symptoms, validated instruments such as the PHQ-9 and GAD-7 were used, reducing the risk of bias and making the results more robust. Nevertheless, we highlight the lack of studies using experiential sampling or real-time measures to assess depressive and anxiety symptoms, which could provide a more accurate assessment of the impact of these self-administered NLP-based interventions.

The subgroup analysis showed variability in the effectiveness of the interventions in reducing depressive and anxiety symptoms, which may be due to the limited number of studies analyzed. Another possible explanation lies in the variety of NLP-based models used and their level of sophistication. Interventions using conversational agents based on advanced deep ML models showed significant results compared to other strategies, such as rule-based chatbots [54]. Unlike simpler NLP-based models, conversational agents offer better performance on various tasks [54]. However, more complex models also require high computational costs and large amounts of data for optimization [55,56], which may limit their adaptability to the different linguistic and cultural needs of different regions [57]. It is important to note that high-income countries have led research in this field and have advanced technological resources for developing these AI-based models compared to low- and middle-income countries [58,59]. This situation represents a challenge and a potential source of inequity in access to, and the implementation of, NLP-based interventions within public health systems.

Implications for Clinical Practice and Public Health

A previous systematic review on the general use of NLP and ML in mental health also identified the potential of NLP-based interventions to improve population mental health [19]. However, our study differs in that it focuses only on self-applied interventions to reduce depressive and anxiety symptoms, thus contributing to a specific aspect of NLP-based interventions. Our study provides a valuable starting point for future research to confirm the effectiveness of NLP-based interventions in the real world and their ability to be implemented within the public health system. There is a need to evaluate the implementation and promotion of these interventions as part of mental health strategies because this could be an effective strategy to reduce depressive and anxiety symptoms in health service users [60,61]. Given their accessibility through digital platforms, these interventions have the potential to reduce the burden of depressive and anxiety disorders at the population level [62,63] while also being cost-effective and a way to optimize mental health resources [64]. To ensure successful implementation within the public health system, using the Artificial Intelligence–Quality Implementation Framework could be beneficial [65]. However, it is crucial to develop protocols that ensure confidentiality and respect for the ethics and privacy of patient data at all stages of implementation and use [66]. In addition, it is important to consider the digital determinants of health [67], such as access to appropriate devices, the internet, and stable connectivity, because these factors pose challenges for implementation in low- and middle-income countries.

Strengths and Limitations

The main strength of our study is that we conducted an exhaustive review of available literature on the subject and that the main meta-analysis was based on RCTs, which is the most robust design for determining the effect of an intervention. However, our study has several limitations. First, the methodological variability of the included studies led to high heterogeneity in both outcomes, which could affect the interpretation of our findings despite using random effects models for their management. Second, the various measurement tools used in the studies could introduce measurement bias. However, we believe that our study minimized this risk by including only studies that used validated instruments and an effect size that controls for heterogeneity among measures such as the SMD. Third, the lack of clarity in the description of the studied groups may have introduced a risk of bias in assessing their effectiveness because there is no clear taxonomy for grouping NLP-based interventions. Fourth, the global meta-analysis for depressive symptoms identified the potential existence of publication bias, which could overestimate results in favor of trials with positive effects. Therefore, we encourage researchers to report their studies, even if they have negative results, to understand the effect of these interventions better. Fifth, variability in the standards for diagnosing and treating depression and anxiety, as well as in the criteria for determining

recovery among the included studies, may have affected the interpretation of the efficacy of the interventions and the generalizability of the findings to different populations. This heterogeneity highlights the importance of considering the context in which NLP-based interventions are applied and the need to adapt them to the characteristics of different populations [11]. Finally, the GRADE assessment shows that the evidence for self-administered NLP-based interventions on depressive and anxiety symptoms is of very low certainty. This suggests caution in interpreting these potential benefits. High risk of bias, significant inconsistency (high I^2 values), and high indirectness complicate the findings. Suspected publication bias further skews the results because studies with nonsignificant or negative outcomes may be underreported. To overcome these limitations in future reviews, we recommend focusing on specific interventions and encouraging researchers to share their primary data to strengthen the quality and reliability of meta-analytic analyses.

Conclusions

Our systematic review and meta-analysis support the use of self-administered interventions based on NLP models to reduce depressive and anxiety symptoms. These findings enhance the theoretical understanding of how advanced NLP tools can effectively deliver psychological therapy, improving cognitive and emotional self-regulation in individuals. By demonstrating the efficacy of various NLP-based interventions, our study advances the theoretical framework by elucidating the mechanisms through which these technologies can replicate and potentially enhance traditional therapeutic processes.

The integration of NLP with different therapeutic modalities offers a novel approach to mental health treatment, expanding the accessibility and scalability of evidence-based interventions. However, the certainty of evidence for the effectiveness of these interventions remains very low, primarily due to a high risk of bias, significant inconsistency, and indirectness in the included studies. Therefore, there is a crucial need for RCTs with larger sample sizes and rigorous methodologies to strengthen the inferential power of future meta-analyses.

Moreover, while our findings are encouraging, there is a need for systematic reviews that examine the implementation processes of these interventions in depth, as well as qualitative studies that evaluate their usability and feasibility. Such research will be essential for effectively recommending the adoption of NLP-based self-administered interventions in public health systems.

Our study provides a valuable starting point for future research to validate the efficacy and practical implementation of these interventions as components of standard mental health care. Ensuring their integration into public health strategies could enhance the mental health outcomes of diverse populations, particularly those who may have limited access to traditional therapeutic resources.

Acknowledgments

This project was in part funded by the National Institutes of Health (R33HL143317). The authors thank Piero Segobia and Carlos García-Navarrete for their collaboration in the initial stages of drafting the manuscript. We used DeepL [68] to translate specific sections of the manuscript and Grammarly [69] to improve the wording of certain sections.

Authors' Contributions

Abbreviations

AI: artificial intelligence

GAD-7: Generalized Anxiety Disorder-7

GRADE: Grading of Recommendations Assessment, Development, and Evaluation

ML: machine learning

NLP: natural language processing

PHQ: Patient Health Questionnaire

PICOS: Population, Intervention, Comparison, Outcomes, and Study Design

PRISMA: Preferred Reporting Items for Systematic Reviews and Meta-Analyses

RCT: randomized controlled trial

SMD: standardized mean difference

Abstract

Background: Mental stress and its consequent mental health disorders (MDs) constitute a significant public health issue. With the advent of machine learning (ML), there is potential to harness computational techniques for better understanding and addressing mental stress and MDs. This comprehensive review seeks to elucidate the current ML methodologies used in this domain to pave the way for enhanced detection, prediction, and analysis of mental stress and its subsequent MDs.

Objective: This review aims to investigate the scope of ML methodologies used in the detection, prediction, and analysis of mental stress and its consequent MDs.

Methods: Using a rigorous scoping review process with PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines, this investigation delves into the latest ML algorithms, preprocessing techniques, and data types used in the context of stress and stress-related MDs.

Results: A total of 98 peer-reviewed publications were examined for this review. The findings highlight that support vector machine, neural network, and random forest models consistently exhibited superior accuracy and robustness among all ML algorithms examined. Physiological parameters such as heart rate measurements and skin response are prevalently used as stress predictors due to their rich explanatory information concerning stress and stress-related MDs, as well as the relative ease of data acquisition. The application of dimensionality reduction techniques, including mappings, feature selection, filtering, and noise reduction, is frequently observed as a crucial step preceding the training of ML algorithms.

Conclusions: The synthesis of this review identified significant research gaps and outlines future directions for the field. These encompass areas such as model interpretability, model personalization, the incorporation of naturalistic settings, and real-time processing capabilities for the detection and prediction of stress and stress-related MDs.

machine learning; deep learning; data preprocessing; stress detection; stress prediction; stress monitoring; mental disorders

Introduction

Background

Mental health has become a public health concern. According to the Institute of Health Metrics and Evaluation, in 2019, about 53 million people in the United States and about 1 in 8 individuals worldwide (about 1 billion people) have at least 1 mental health disorder (MD) [1]. An MD is defined as an impairment in a person's cognition, emotional control, or behavior patterns that has clinical significance and is often linked to distress or functional impairment [2]. MDs severely limit people's daily functioning and can be fatal [3,4]. In 2019, mental health (MH) problems accounted for 6.6% of all disability-adjusted life years in the United States, making it the fifth most significant cause of disability overall [1,5].

Some of the more prevalent MDs are anxiety disorders, depression or mood disorders, bipolar disorders, psychotic disorders (including schizophrenia), eating disorders, social disorders, disruptive behavior, and addictive behaviors [2]. In 2019, anxiety and depression have been the most prevalent forms of MDs (301 and 280 million people affected worldwide, respectively). Anxiety disorder encompasses emotions of concern, anxiety, excessive fear, or associated behavioral problems that are severe enough to affect everyday activities [2]. Symptoms include an unproportionate level of stress compared to the significance of the triggering event, difficulty in putting worries out of one's mind, and nervousness [6,7]. Generalized anxiety disorder, panic attacks, social anxiety disorder, and posttraumatic stress disorder (PTSD) are all examples of different types of anxiety disorders [2,8]. Depression is characterized by a long-lasting sadness and a lack of desire to be active. One of the main symptoms of depression is the inability to enjoy or find pleasure in most of one's daily activities as well as feeling sadness, anger, or emptiness [2,9]. A depressive episode typically lasts for at least 2 weeks. In addition, a loss of self-worth, feelings of hopelessness for the future, and suicidal thoughts are indicators and symptoms of depression. People who are depressed are more prone to commit suicide [2,9,10].

Stress is categorized into distress, which typically has chronic negative effects on health, and eustress, which is short-term and positively influences motivation and development [11]. Throughout this paper, the term stress is specifically used to denote distress rather than eustress. Mental stress has been shown to significantly contribute to developing and worsening anxiety and depression disorders [12-14]. Mental stress is the body's natural response to various events in which a person feels that the demands of their external environment exceed their psychological and physiological resources for dealing with those demands [15]. Mental stress leads to an asynchrony between the sympathetic and parasympathetic nervous systems (SNS and PNS), which are the main divisions of the autonomic nervous system [16] and serve an important role in regulating vital biological activities [17,18]. The SNS is an integrative system that responds to potentially dangerous circumstances. Activation of the SNS is part of the system responsible for

controlling "fight-or-flight" responses. The PNS is responsible for the body's "rest-and-digest" processes.

Given the important role and impact of stress in MDs, previous research has investigated various qualitative and quantitative methods to measure and monitor stress to inform effective stress mitigation approaches. While majority of stress literature relies on self-reported measures, recent literature has used physiological variables such as heart rate (HR); HR variability (HRV) [19-23]; and behavioral data (eg, speech, movement, and facial expressions) [24] to understand changes to SNS and PNS associated with stress. The recent advances in sensor and mobile health technologies have resulted in the emergence of big data related to MH, as well as advanced bioinformatics methods, tools, or techniques to use such data for modeling or inference. One such tool that has recently emerged as a robust, rapid, objective, reliable, and cost-efficient technique for studying chronic illnesses and MDs is machine learning (ML). ML uses advanced statistical and probabilistic techniques to construct systems that can automatically learn from data. Several characteristics of ML make it suitable for applications in MH monitoring including significant pattern recognition and forecasting capabilities [25], the capacity to extract crucial information from various data resources and the opportunity to create personalized experiences [25], and the ability to analyze large amounts of data in a short time [26]. As such, ML has gained popularity and has been applied to MH data to enable detection, monitoring, and treatment [27]. The objective of this research is to review the literature to summarize and synthesize the application of ML in the detection, monitoring, or prediction of stress and stress-related MDs, in particular, anxiety and depression. This paper documents method-specific findings such as data types, preprocessing methods, and different algorithms used, as well as the type and characteristics of studies that used ML.

Traditional statistical methods, such as linear regression, logistic regression (LR), 1- or 2-tailed *t* tests, and ANOVA [28], have been widely used in the past to detect and analyze stress and stress-related MDs. These methods have proven useful in specific contexts, such as comparing means of different groups or modeling linear relationships between variables. As demonstrated by Machado et al [21], Adjei et al [22], Yoo et al [23], Chen et al [24], and Jordan and Mitchell [25], these methods have provided valuable insights in situations wherein the data are relatively simple and adhere to the underlying assumptions of the statistical techniques. However, when faced with complex, high-dimensional MH data, which have become increasingly available, thanks to advancements in technology and data collection techniques, these traditional statistical methods might not be sufficient. The limitations of these methods stem from their inherent simplicity and the assumptions they rely on, which might not hold true in the context of MH data. For example, linear regression and LR analyses assume linear relationships between variables, while *t* tests and ANOVA require specific assumptions about the data distribution. These assumptions may not be applicable in the case of intricate and heterogeneous MH data, potentially leading to inaccurate or incomplete conclusions.

Advanced data analytics methods, such as ML, offer a more powerful and flexible alternative to traditional statistical methods. ML algorithms, with their significant pattern recognition and forecasting capabilities [25], are capable of capturing complex, nonlinear relationships between variables and can adapt to various data distributions. These capabilities enable ML techniques to provide more accurate and insightful predictions, classifications, and associations in the context of MH data [29]. In addition, ML algorithms can handle large-scale, high-dimensional data more efficiently than traditional methods, allowing researchers to analyze vast amounts of information from diverse sources, such as eHealth records, wearable devices, and web-based platforms [26]. This capacity for handling big data is crucial for understanding the multifaceted nature of MDs and developing tailored interventions. ML techniques also offer the advantage of automation and adaptability, allowing them to continuously learn and improve as new data become available [25]. This iterative learning process enables the development of more sophisticated and accurate models for detecting, monitoring, and predicting stress and stress-related MDs over time.

While traditional statistical methods have contributed significantly to our understanding of stress and stress-related MDs in specific contexts, the growing complexity and volume of MH data necessitate the adoption of advanced data analytics methods such as ML. By leveraging the power of ML, researchers can gain deeper insights into the underlying patterns and relationships between stress and MDs [29], ultimately leading to the development of more effective stress mitigation approaches and improved care for individuals who have anxiety, depression, and other MDs.

Acknowledging the substantial contributions of traditional statistical methods, it becomes evident that the escalating complexity and scale of MH data demand the adoption of more sophisticated approaches such as ML. This advancement stands not as a replacement but as an essential evolution in the analytical toolbox available to researchers. As this paper delves into the myriad ways that ML has been applied to MH, particularly in the realms of stress, anxiety, and depression, it seeks to consolidate the current knowledge on the subject.

Textbox 1. Keywords and search strategy for articles since 2017 (last 5 years).

Search strategy

First keyword: predict OR detect

AND

Second keyword: mental health OR mental disorder OR depression OR anxiety OR stress

AND

Third keyword: machine learning OR deep learning OR data mining OR pattern classification OR artificial intelligence OR neural networks

Study Selection, Inclusion, and Exclusion Criteria

Articles that did not fully use ML for stress or stress-related MDs evaluations were excluded from the research. Studies published in languages other than English were also excluded.

Objectives

By examining the types of data, preprocessing methods, and the algorithms used in existing studies, this review aspires to offer a detailed synthesis of the field. It aims to provide a clearer understanding of ML's effectiveness in the detection, monitoring, and prediction of MDs, setting a foundation for future research and the enhancement of therapeutic strategies for those impacted by these conditions.

Methods

Protocol and Registration

This scoping review adhered to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines [30]. No formal review protocol was registered due to the exploratory nature of this study, which aimed to map out existing research rather than address a prespecified hypothesis. This approach aligns with the methodological flexibility often required in emergent areas of research.

Eligibility Criteria

We included studies published in English from 2017 to 2022 that used ML techniques to evaluate MDs, specifically focusing on stress and stress-related conditions. Studies were excluded if they did not use ML as the primary analysis method or if they were published in languages other than English.

Information Sources

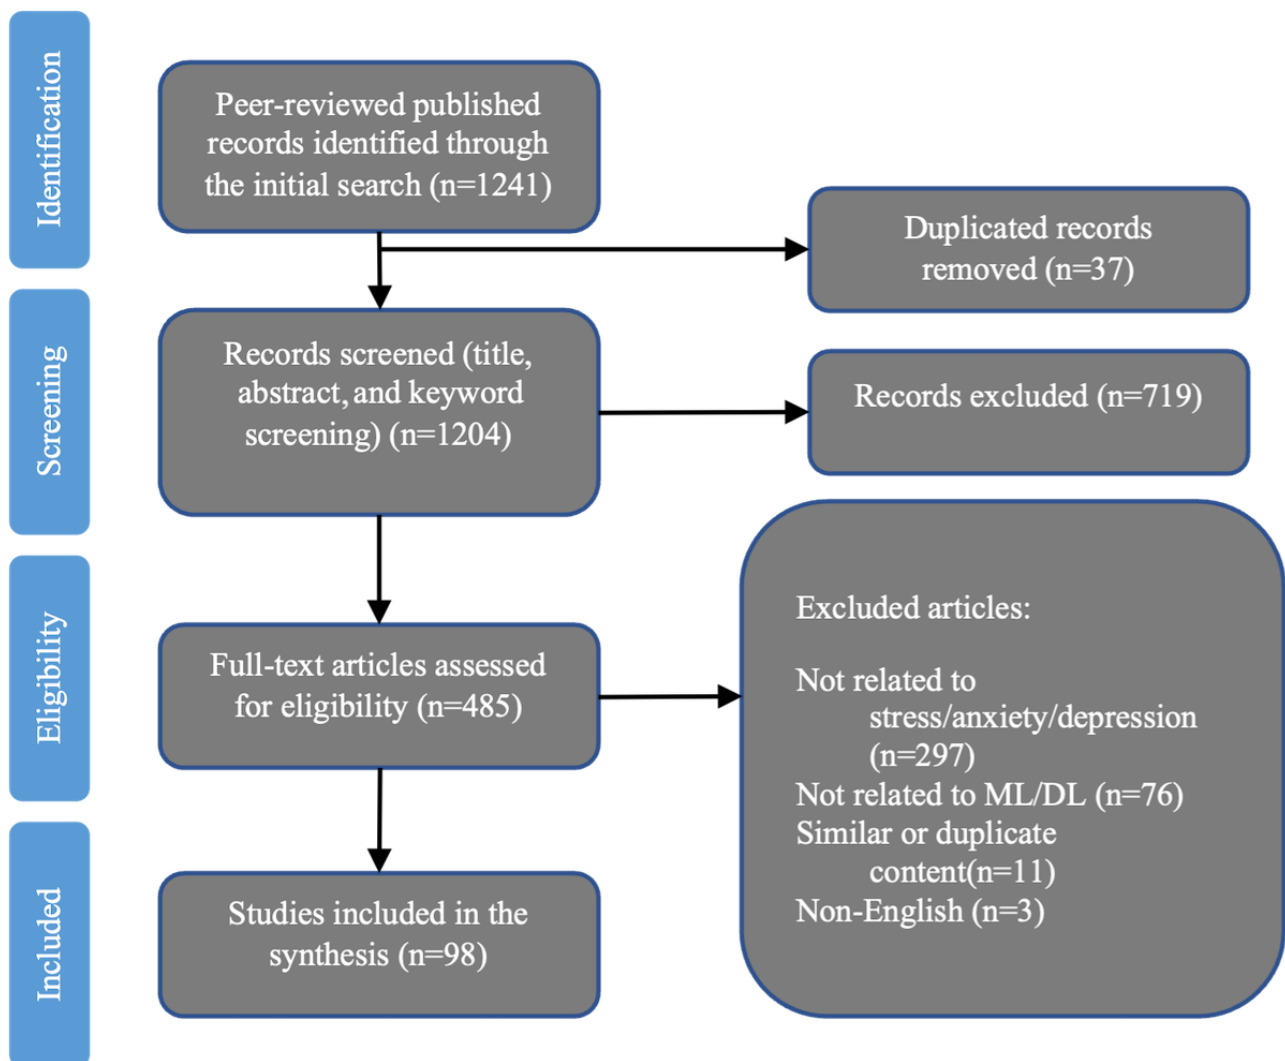

The literature search involved databases such as EI Engineering Village, Web of Science, ACM Digital Library, and IEEE Xplore. Additional sources were identified through contact with experts and review of references in relevant articles.

Search Strategy

A comprehensive search was conducted using a combination of keywords related to ML and MDs (Textbox 1). The search strategy was designed to capture a broad spectrum of ML applications within this field. The full search list from all databases is available in Multimedia Appendix 1 [31-50].

The initial search yielded 1241 results. After duplicate articles were deleted and eligibility was confirmed using Rayyan (Qatar Computing Research Institute) [51], 1204 (97.02%) articles remained. After applying the exclusion criteria, 98 (8.14%) papers were selected for full review (Figure 1).

Figure 1. Preferred items for scoping literature review and meta-analysis flowchart (modified from Tricco et al [30]). DL: deep learning. ML: machine learning.

Data Charting Process

Data charting was conducted by 2 reviewers independently using a standardized form, which had been pretested on a subset of included studies. Discrepancies were resolved through discussion or consultation with a third reviewer. Study authors were contacted for clarification or additional data where necessary.

Data Items

Data extracted included publication year, study design, population characteristics, ML techniques used, outcomes measured, and key findings. Other variables sought included data preprocessing methods and performance metrics of the ML models. Simplifying assumptions, such as considering different ML algorithms within the same family as a single technique, were made to facilitate synthesis.

Synthesis of Results

Data were synthesized descriptively, and the findings were grouped by ML techniques, data type, and preprocessing techniques. Where possible, quantitative performance metrics were extracted or derived. Results were analyzed in the context of the overall study designs and populations to highlight trends and identify gaps in the current research landscape. No formal critical appraisal or quantitative meta-analysis was conducted due to the diversity of the included studies and the scoping nature of this review.

Results

In this section, types of data, preprocessing techniques, and ML techniques used on the data in the literature have been reviewed and compared with the existing literature.

Types of Data

Overview

Various data types were used in the studies (n=98) that used ML algorithms for stress and stress-related MDs. Studies used questionnaires (n=31, 32%); HRV (n=25, 26%); skin response (eg, skin temperature, skin conductance, etc; n=24, 24%); photoplethysmogram (PPG; n=21, 21%); electrocardiogram

(ECG; n=19, 19%); HR (n=17, 17%); electroencephalogram (EEG; n=9, 9%); acceleration or body movement (n=8, 8%); text data (n=7, 7%); respiratory signals (n=7, 7%); electromyogram (EMG; n=3, 3%); eye tracking (n=3, 3%); speech signals (n=3, 3%); and others (n=4, 4%) including audio signals (n=2, 2%), blood pressure (BP; n=1, 1%), and hormones (n=1, 1%). [Table 1](#) shows the distribution of the type of data used for stress detection using ML techniques.

Table 1. Number of articles by type of data (n=98).

Type of data	Articles, n (%)
Questionnaire	31 (32)
HRV ^a	25 (25)
Skin response	24 (24)
HR ^b	17 (17)
EEG ^c	9 (9)
Body movement	8 (8)
Respiratory	7 (7)
Text	7 (7)
EMG ^d	3 (3)
Eye-tracking	3 (3)
Speech signals	3 (3)

^aHRV: heart rate variability.

^bHR: heart rate.

^cEEG: electroencephalogram.

^dEMG: electromyogram.

Heart Measures

Heart metrics are primarily used for stress detection and are typically gathered through 2 main methods: ECG and PPG. ECG is a noninvasive diagnostic test that records the heart's electrical activity, while PPG is a noninvasive optical technique that detects changes in blood volume within the tissue's microvascular bed. By using these methods, it is possible to measure various heart-related parameters, including HR, as well as time and frequency domain features of HRV and BP.

HRV Measures

HRV (n=25, 26%) has been used to assess MH issues, such as stress, anxiety, and depression, due to its rich time and frequency

domain features [53]. The blood volume pulse signal is another effective method for capturing HRV features, as it represents the heart's beat-to-beat volume changes. From the blood volume pulse signal, time-domain measures such as the root mean square of successive RR interval differences (RMSSD), SD of neural network (NN) intervals, and SD of RR intervals can be derived. In addition, the frequency domain aspects of HRV, including total power (frequencies <0.4 Hz), low frequencies (LFs; ranging from 0.04 to 0.15 Hz), and high frequencies (HFs; between 0.15 and 0.4 Hz), reflect the autonomic nervous system's dynamics during beat-to-beat measurements of the HR ([Figure 2](#)) [54,55]. These HRV measures, both in the time and frequency domains, provide a nuanced view of the physiological underpinnings associated with various MH conditions.

Figure 2. Depiction of heart’s beat-to-beat measurements using blood volume pulse (BVP) signal (A) and power spectral density (PSD) of RR intervals (the signal is bandpass filtered with cutoff frequencies of 0.04 Hz and 0.4 Hz) (B). HF: high frequency; LF: low frequency.

(A)

(B)

HR Measures

One of the most important indicators of stress is an abrupt increase in HR (n=17, 17%). Among the physiological signals, HR is among the top measures that explain stress in ML models, and it has been used in different studies with almost all ML algorithms [56-58].

BP Measures

BP (n=1, 1%) can be obtained by pulse transit time or by pressure cuffs [59]. Stressful conditions create an influx of hormones that increase HR and constrict blood vessels, leading to a temporary BP elevation [60]. In most cases, BP recovers to its prestress level after the stress response diminishes [61]. Schultebrucks et al [62] used systolic BP as one of the measures in predicting one’s level of susceptibility to PTSD.

EEG Data

EEG (n=9, 9%) detects brain electrical activity. Compared with other brain mapping techniques for stress detection, it is more practical due to several factors including affordability, noninvasiveness, nonintrusiveness, and, most importantly, its high temporal resolution [63]. The high temporal resolution of EEG makes it appropriate for real-time stress detection, as well as deep learning (DL) approaches, which require large data sets for training [63-67].

The most commonly used EEG features for the detection of stress are the power of different frequency bands (α , 8-13 Hz; β , 12.5-30.0 Hz; θ , 4.5-7.5 Hz; γ , 30-40 Hz), average and SD of a specific time window of EEG signal, and time-frequency features obtained by discrete wavelet transform algorithm [67-69]. It has also been shown that statistical features of EEG signals, such as kurtosis and entropy, are useful features in stress prediction using ML algorithms [66]. Moreover, power spectral density (PSD), correlation, divisional asymmetry, rational asymmetry, and power spectrum are other EEG features that have been used in different studies for stress detection [70].

Since EEG signals are collected from the scalp, they include excessive noise and have high uncertainty. Therefore, signal processing and feature selection or extraction are important steps while dealing with EEG data. Several well-developed methods are available for treating the EEG data. Among them, latent space derived from auto-encoders and signal reconstruction techniques such as artifact subspace reconstruction (ASR) are well-known methods that can be applied on EEG data to significantly reduce the artifacts [65]. These methods are also fast enough to make real-time detection feasible.

The amygdala and hippocampus are the parts of the brain that have the major responsibility for human reactions to stress [71]. Brain activity caused by stress in those regions would affect the prefrontal cortex. Studies collecting data from the prefrontal cortex have also verified that EEG data from this brain region can be used for stress detection [72]. EEG can be collected from the prefrontal cortex using off-the-shelf EEG recording products such as Muse and Neurosky Mindwave [66,69,70,72].

Eye Tracking

Eye-tracking features (n=3, 3%) can be indicators of stress. For example, to diagnose the level of stress, the changes in the striations of muscle material in the iris as a response to stress can be used as features for ML algorithms. In other words, pupil diameter, which is controlled by iris sphincter muscles, can be used as a feature [73]. Other eye-tracking features that have been used for stress detection are visual fixations, saccade movements, pupil size, microsaccades, and the number of eye blinks in a specific time window during a certain task [74-76].

Skin Response

A skin response (n=24, 24%) can be defined as a stimulus-regulated electrodermal response and is typically measured using electrodes placed on the fingertips or hands. Skin response is usually associated with an increase in sympathetic activity on inducing stress events [77]. The skin

becomes a better conductor of electricity when it is stimulated either externally or internally by physiologically stimulating factors, including stressful conditions [78].

Respiratory Signals

Mental stress can affect different respiratory cycle phases and breathing patterns (n=7, 7%) [79,80]. For example, it has been discovered that stress had no impact on overall breath duration (respiration rate) but that exhalation periods were longer and pause periods were shorter in the stress experiment than in the neutral condition [81].

On the basis of the findings of several studies, it can be concluded that respiratory signal is one of the top contributing factors in the explanation of stress in ML models. The most common time-domain respiratory signal features that are extracted for stress detection are root mean square, IQR, and mean square differences between adjacent elements of breathing rate and blood oxygenation levels. The most commonly used frequency domain features of the respiratory signal are the power of LFs (<2 Hz), the power of HF (>2 Hz), and the ratio of the power of LFs over the power of HF (LF and HF) [58,62,63,82-84].

EMG Data

EMG (n=3, 3%) detects the electrical activity of muscles at rest, during a modest contraction, and during a strong contraction [85]. Similar to acceleration data, several studies have shown that using EMG data can help increase the performance of ML models trained on ECG data. The action potential intrigued in the EMG during stress can reduce the variance for decision-making of classification models that use ECG [58,86,87].

Hormones

It has been shown that stress can alter the levels of glucocorticoids, catecholamines, growth hormones, and prolactin in the bloodstream. Therefore, in ML models, levels of hormones such as cortisol, dehydroepiandrosterone sulfate, thyroid-stimulating hormone, free triiodothyronine, and free thyroxine can be used as predictors for the detection of stress-related disorders (n=1, 1%) [62].

Acceleration and Body Movement

Mental stress may cause a wide variety of behavioral and body movement symptoms such as shaking hands and feet, which can be measured by the acceleration data (n=8, 8%) [88]. Moreover, research has shown that people with a greater stress score had less variance in their activity level and body movements [89-91]. For example, in older adults, stressful life events can be related to a reduced rate of regular physical exercise [92]. Time and frequency features such as mean absolute deviation from the mean, the total power of acceleration, SD, the mean norm of acceleration, absolute integral, and peak frequency of each axis are the features of hand and body acceleration used for stress detection [31,57,93]. One practical characteristic of motion and acceleration data is that they can be used to identify sources of noise in other signals. For example, motion data can help distinguish stress from

physical activity (eg, exercise) when other physiological measures, such as ECG, have uncertainty in prediction [94,95].

Audio and Speech Signals

Speech Signals

Using speech signals (n=3, 3%), it is feasible to diagnose and assess neurological disorders and MDs [96]. Moreover, studies have shown that like body acceleration and EMG, features of speech signals can make stress predictions of heart measurements more robust. The best explanatory parameters of speech signals are frequency domain parameters (eg, PSD, strongest frequency from fast Fourier transform) and time-frequency features such as Mel-frequency cepstral coefficient [56,97,98]. Since time-frequency measures are 2-dimensional measurements with a high number of samples, they make this signal suitable for use in convolutional NN (CNN) models of stress and depression detection [99].

Audio Signals

For laboratory-based studies, audio signals (eg, beeping sounds; n=2, 2%) can be used to stimulate stress events in participants [100,101].

Text Data

Social media content (n=7, 7%) is frequently subjected to reviews, opinions, and influence, as well as sentiment analysis. Natural language processing methods may be used to evaluate social networking posts and comments for mood and emotion to detect whether a user is stressed [102-108].

Questionnaire

Different questionnaires (n=31, 32%) are used for the diagnosis of stress and MDs including anxiety and depression. The scores from different items on these questionnaires can be used as dependent and independent variables in ML studies. The questionnaires mentioned here were selected based on their prevalence in the literature as well as their relevance to the ML outcomes being predicted. For instance, some studies have successfully leveraged scores from multiple questionnaires, such as the Diagnostic and Statistical Manual of Mental

Disorders, Depression Anxiety and Stress Scale, Edinburgh Perinatal/Postnatal Depression Scale, Center for Epidemiological Studies-Depression survey, Mean Opinion Score, Hamilton Depression Rating Scale, State-Trait Anxiety Inventory, Posttraumatic Stress Disorder Checklist for Diagnostic and Statistical Manual of Mental Disorders, Beck Depression Inventory, Beck Anxiety Inventory, Hospital Anxiety and Depression Scale, Goldberg's Depression Scale, self-reports, and clinician reports [109-126].

Preprocessing Techniques

In this section, important preprocessing techniques that have yielded significant findings and how they are used to help the detection of stress and its related MDs have been reviewed.

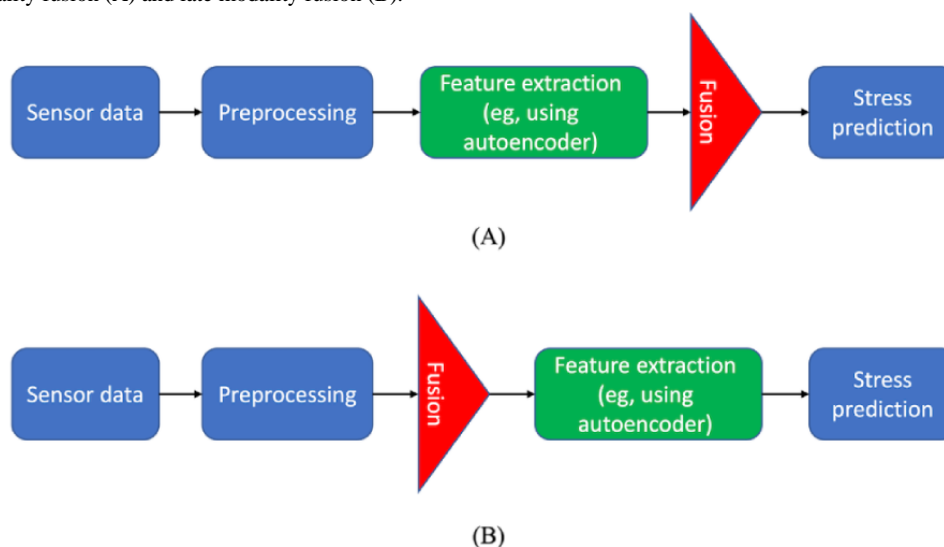

Synthetic Minority Oversampling Technique

In the detection of stress and its related MDs, the number of samples for the stress or MD class is usually significantly lower than the nonstress or non-MD class. This imbalance in the number of samples for each class leads to a bias in prediction (toward the majority class). To correct for data bias, it is possible to oversample the underrepresented group. In stress detection studies using ML models, the synthetic minority oversampling technique is one of the most common approaches to boost the minority class, which creates new samples by synthesizing those already available in the data (by combining their features; n=3, 3%) [31,110,127].

Early Modality Fusion

In ML models used for the prediction of stress with a multimodal approach, it has been shown that early fusion of multimodal data before feature extraction is more effective and achieves a better performance (n=1, 1%). This is because early modality fusion better catches the important characteristics that are coherent with each other. For example, a study showed that combining different measures including skin response, skin temperature, and body acceleration before feature extraction outperforms the approach that extracts the features for each measure separately and combines them afterward (Figure 3) [128].

Figure 3. Early modality fusion (A) and late modality fusion (B).

PSD Method

In physiological signals for stress detection, usually the power of the signal changes during the moments of stress. PSD ($n=13$, 13%) explains the frequency-based power distribution of a time series and reveals the locations of strong and weak frequency variation. Welch's method is one of the most common approaches for calculating PSD [65]. PSD is often used in studies that include frequency domain HRV features for stress detection such as total HF or LF power [82-84,101,129-136].

ILIOU Method

In the detection of MDs, such as depression and anxiety, using ML techniques, having the least error rate is significantly important so that the person can take further actions appropriately. In this matter, the data preprocessing step has an important role in minimizing the noise and bias toward the false prediction. Iliou et al [114] proposed ILIOU ($n=1$, 1%), a data mapping and transformation method that identifies useful information for the detection of MDs, especially for depression. This method outperforms common data preprocessing techniques such as principal component analysis (PCA), evolutionary search algorithm, and isomap for the detection of depression.

PCA Method

PCA ($n=3$, 3%) is a method for lowering the dimensionality of such data sets while maximizing interpretability and minimizing loss of information. It does this by generating new variables that are uncorrelated and progressively optimize variance [58,90,123].

Independent Component Analysis

Independent component analysis (ICA; $n=4$, 4%) is a computational and statistical method for uncovering hidden elements underlying random variables, observations, or signals. This method is mostly used for removing artifacts from stationary signal noises of the multichannel data. ICA optimizes higher-order statistics such as kurtosis, while PCA optimizes the covariance matrix of the data, which reflects second-order

statistics. In stress detection using physiological signals that contain stationary noises (eg, eyeblink noise in EEG) it is recommended to remove noises using ICA [63-65,67].

ASR Approach

ASR ($n=1$, 1%) is an adaptive approach for removing artifacts from signal recordings on the web or offline, mostly nonstationary signal noises. To identify artifacts based on their statistical qualities in the component subspace, a PCA on covariance matrices is repeatedly computed [137]. Since there are usually substantial nonstationary noises in the EEG data, in order to classify stress at multiple levels using EEG data, using ASR before classification is highly recommended [65].

Latent Growth Mixture Modeling

Growth mixture modeling ($n=1$, 1%) is to discover numerous hidden subpopulations, describe longitudinal development within each hidden subpopulation, and investigate variation in hidden subpopulations' rates of change. Latent growth mixture models are gaining popularity as a statistical tool for estimating individual development over time and for probing the presence of latent trajectories, in which people belong to the trajectories that are not directly observable [62,138,139].

Dynamic Time Warping

It is common practice to transform data from 2 time series into vectors and then compute the Euclidean distance between the resulting points in vector space to determine the degree of similarity or dissimilarity between the series, regardless of whether they vary in time or velocity. Dynamic time warping (DTW) method ($n=1$, 1%) can be applied to find such similarities that may exist between people in terms of their mood series. As an example, one may compare time series to find whether they match for stress, depression, or anxiety. Moreover, it can be used to forecast the mental condition of persons with substantially comparable series patterns [130,140]. The difference between DTW and Euclidian matching is that unlike Euclidean matching, DTW considers the distance of each point in one sequence to every point in the other sequence to determine the similarity between them (Figure 4).

Figure 4. Dynamic time warping (left) versus Euclidian matching (right; modified from Portilla and Heintz [142]).

Kalman Filter

The Kalman filter ($n=2$, 2%) is a technique for making predictions about unknown variables (eg, missing data) based on observable data. Kalman filters include 2 iterative steps,

predict and update, that are used to estimate states using linear dynamical systems in state-space format. Iterative cycles of predict and update are performed until convergence is achieved [143]. Kalman filter has been used to handle the missing data for stress detection in some studies [144,145].

Autoencoders

Autoencoders (n=3, 3%) are a type of NNs that learn a representation of the data in lower dimensions than the original data (encoding) by regenerating the input from the encodings (decoding). For data with very high dimensionality, usually clustering is not optimized because of the noise present in the original data. Hence, it is an appropriate practice to use the encoded representation of the data, obtained by autoencoders,

to have lower and more optimized dimensions for clustering [65,108,146].

Self-Organizing Map

In ML, a self-organizing map (n=3, 3%) produces a low-dimensional, typically 2-dimensional, representation of a high-dimensional data set while preserving its topology by creating clusters. Therefore, it is possible to visualize and analyze high-dimensional data more easily (Figure 5) [107,133,147].

Figure 5. Representation of self-organizing map (SOM) before (left) and after mapping (right; modified from Cho et al [133]).

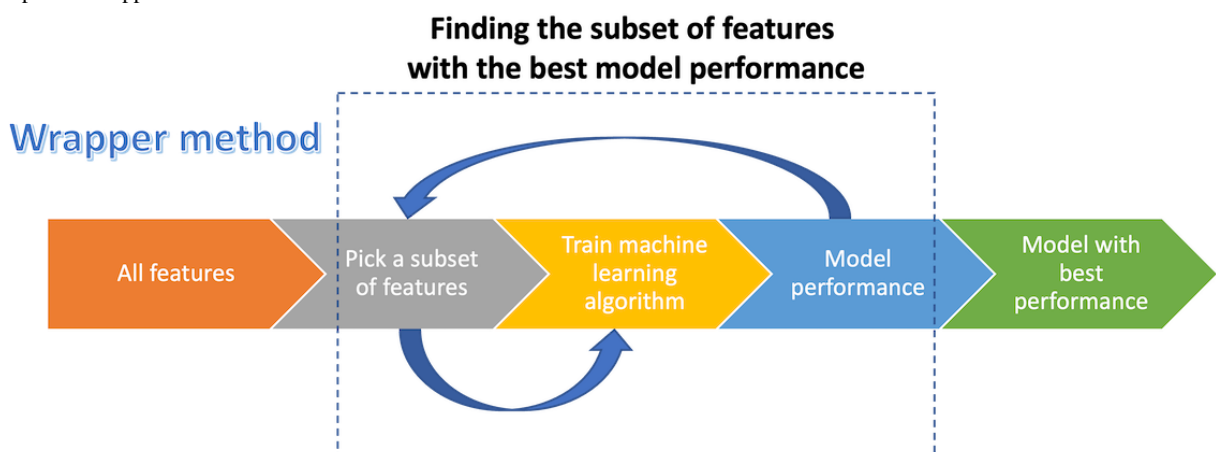

Wrapper Feature Selection Methods

Wrapper methods try to use a subset of features while training a model. Changes will be made to the feature subset on the basis of the performance of the prior model (Figure 6). Therefore, finding the best features using the wrapper method is a search

problem. These methods often have high computing costs [148]. Some of the most common wrapper methods are naive search, sequential forward feature selection, sequential backward feature selection, and generalized sequential search [149]. Some studies used this approach as their feature selection technique [72,75].

Figure 6. Steps of a wrapper feature selection method.

Filter Feature Selection Methods

In general, filter methods are used as a preprocessing step without regard to any ML algorithms. Statistic tests are used

instead to select features based on their correlation with dependent variables (Figure 7). The filter feature selection methods used in the literature are mentioned in subsequent sections.

Figure 7. Steps of a filter feature selection method.

Filter method

Chi-Square Test

This test checks for independence between categorical features and the target variable. Features with high chi-square scores are selected, implying a strong association with the target variable, which may be valuable for the model (n=3, 3%) [56,135,150].

Pearson Correlation

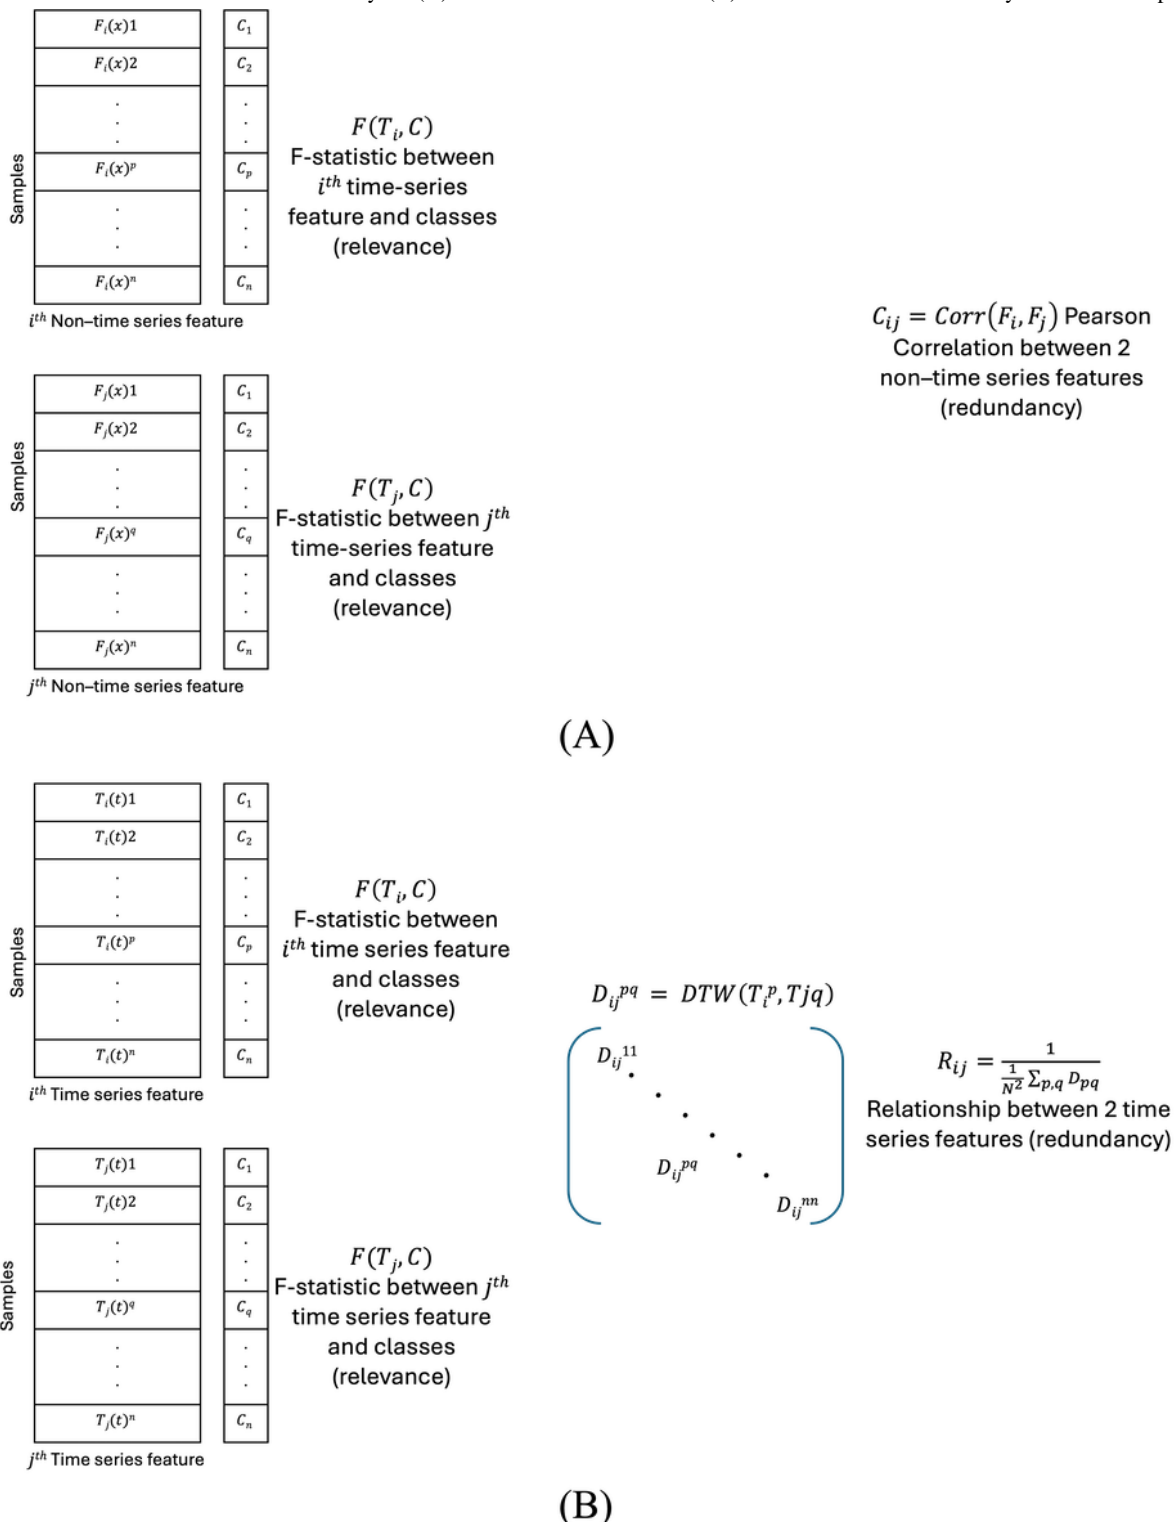

Pearson linear correlation coefficient (n=2, 2%) is a way to quantify how closely 2 sets of data are correlated linearly. It indicates how different measures are related to each other by a number between -1 and 1. Therefore, among highly correlated variables, some of them can be removed, as they do not add useful information to ML models [113,151].

Minimum Redundancy Maximum Relevance

The maximum relevance minimum redundancy technique (n=2, 2%) chooses characteristics having a high correlation to output

(relevance) and a low correlation to one another (redundancy). The F statistic is used to determine the correlation between features and the output, while the Pearson correlation coefficient (for non-time series features) and DTW (for time-series features) may be used to calculate the correlation between features (Figure 8). The objective function, which is a function of relevance and redundancy, is then maximized by selecting features one at a time using a greedy search. Mutual information difference and mutual information quotient criteria are both frequently used objective functions that depict the difference or quotient between relevance and redundancy [152,153]. Using this feature selection method, Giannakakis et al [130] have ranked ECG measurements in the order of importance as mean HR, LF, NN50, SD of HR, pNN50, LF or HF, RMSSD, HF, and total power.

Figure 8. Calculation of relevance and redundancy for (A) nontime series features and (B) time-series features. DTW: dynamic time warping.

ML Techniques

The ML algorithms used for stress and MD detection have been reviewed in this section. The papers (n=98) used the DL approach or NN (n=38, 39%), LR (n=26, 27%), naive Bayes (NB; n=22, 22%), decision tree (DT; n=23, 23%), boosting (eg, adaptive boosting, extreme gradient boosting [XGBoost], etc; n=22, 22%), random forest (RF; n=37, 38%), discriminant analysis (DA; eg, linear DA and quadratic DA) (n=6, 6%), fuzzy

C-means (FCM; n=2, 2%), k-nearest neighbors (KNNs; n=22, 22%), and support vector machines (SVMs; n=48, 49%). Table 2 shows the distribution of articles by ML model (refer to Table S1 in Multimedia Appendix 2 [29-31,33,36,39-43,56-63, 65, 66, 68, 69, 73, 75-77, 79, 80, 84, 88, 90, 91, 94,99,100,105,107-112,114-117,119,122-129,137, 139,141,142,146,147,154-160] to find which papers have used each ML technique).

Table 2. Number of articles for each machine learning (ML) model (n=98).

ML model	Articles, n (%)
NN ^a	38 (39)
LR ^b	26 (26)
NB ^c	22 (22)
DT ^d	23 (23)
Boosting	22 (22)
AdaBoost ^e	8 (8)
XGBoost ^f	15 (15)
RF ^g	37 (38)
LDA ^h and QDA ⁱ	6 (6)
Fuzzy	2 (2)
K-means	4 (4)
KNN ^j	22 (22)
SVM ^k	48 (49)
Other	19 (19)

^aNN: neural network.

^bLR: logistic regression.

^cNB: naive Bayes.

^dDT: decision tree.

^eAdaBoost: adaptive boosting.

^fXGBoost: extreme gradient boosting.

^gRF: random forest.

^hLDA: linear discriminant analysis.

ⁱQDA: quadratic discriminant analysis.

^jKNN: k-nearest neighbors.

^kSVM: support vector machine.

LR Technique

LR (n=26, 27%) is a supervised parametric ML technique in which multiple independent variables will be used to detect the occurrence of stress or normal conditions [72,117]. Some studies used the numerical independent variables (eg, HRV time-domain features: RMSSD, HR, and pNN50) [94,155] or categorical data (eg, answers to multiple choice questions) obtained from questionnaires [107,114,115].

NB Algorithm

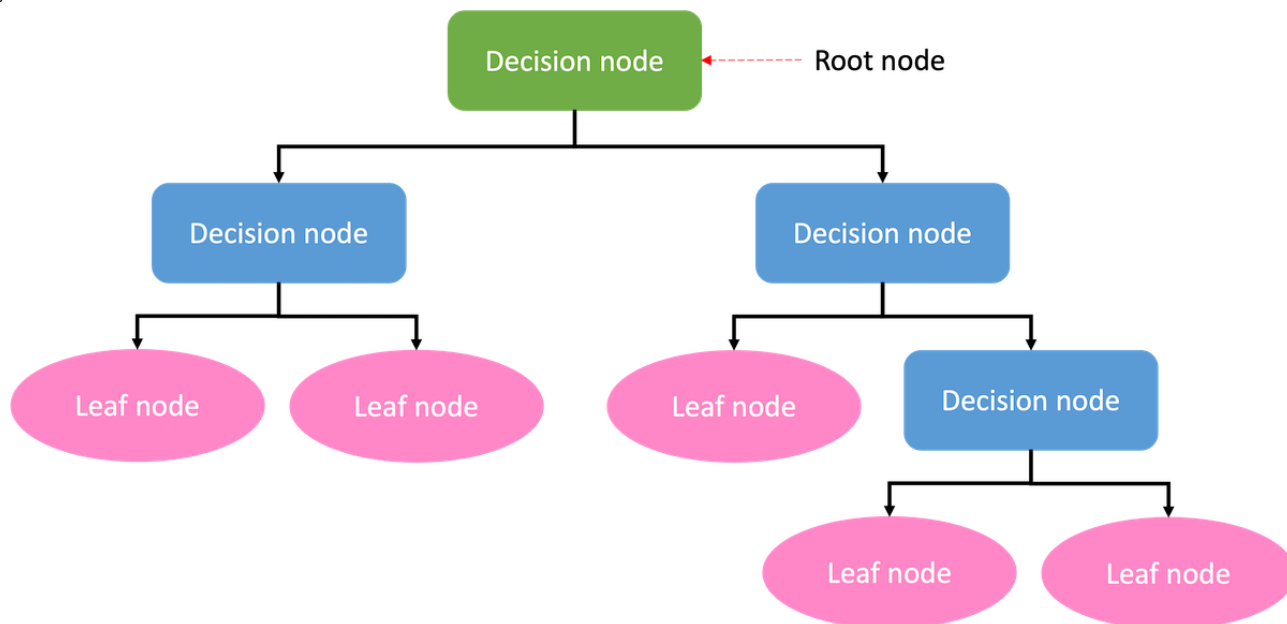

NB algorithm (n=22, 22%) is a supervised, generally parametric, classification method that uses the Bayes Theorem as its

foundation and has the naive assumption of predictor independence. In other words, the NB classifier assumes that the existence of a given independent variable to predict the dependent variable is independent of the presence of any other independent variable that predicts the dependent variable.

DT Algorithm

The DT (n=23, 23%) is a supervised nonparametric ML algorithm used in classification and regression applications. It comprises a root node, branches, internal nodes, and leaf nodes in a hierarchical, tree-like structure (Figure 9).

Figure 9. Structure of a decision tree.

Boosting Algorithm

Boosting (n=22, 22%) is an ensemble learning for reducing training errors by combining a group of weak learners. When using the Boosting algorithm, models are fitted on random samples of data, and then models are trained repeatedly in a sequence. When each model starts being trained in that sequence, it attempts to make up for the flaws of the one that came before it. The most commonly used Boosting algorithms are adaptive boosting, gradient boosting, and XGBoost.

RF Algorithm

RF (n=37, 38%) is a supervised nonparametric ensemble learning algorithm that uses many DTs built during the training process. The RF algorithm is used for both classification and regression problems. When it comes to classification, the RF’s output is the class that most of the DTs choose. For regression purposes, an individual tree’s predicted mean or average is returned as the output. Using RFs, we can overcome the tendency of DTs to overfit their training data.

DA Algorithm

DA (n=6, 6%) is a supervised parametric classification algorithm that works with data including a dependent variable and independent variables and is mostly used to classify the observation into a certain group based on the independent variables in the data. Linear DA and quadratic DA are the 2 forms of DA.

KNN Algorithm

KNN (n=22, 22%) is a nonparametric supervised ML algorithm that is used for both classification and regression purposes. In classification, the algorithm determines the label of a new sample not available in the training data by assigning the label of the majority of k-nearest training data points to that new sample (Figure 10). In regression, the output for each sample is the average of the values of KNNs to that sample (not including the sample itself). In this literature, KNN has only been used for classification.

Figure 10. Example of k-nearest neighbor classification with K=7. In this example, the label of “Class C” is assigned to the new (black) datapoint since the majority of the 7-nearest datapoints to the new datapoint are from “Class C.”.

SVM Algorithm

SVM (n=48, 49%) is a parametric supervised ML algorithm used for both classification and regression problems. It can solve both linear and nonlinear problems using nonlinear kernels. For classification, the SVM algorithm finds a line (or a hyperplane for nonlinear kernels) between each pair of classes of the training data in a way that the margin distance of that line or

hyperplane to the closest point of each of those 2 classes is maximized (Figure 11). This is repeated for all pairs of classes in the data set. Then, the obtained lines are used as boundaries for the classes. In regression, the SVM tries to find the line or hyperplane that within a very small margin of has the maximum number of data points. That line or hyperplane was used for regression.

Figure 11. Visual representation of support vector machine algorithm.

K-Means Clustering

K-means clustering (n=4, 4%) is an unsupervised ML algorithm that aims to arrange objects into groups based on their similarity. To find those similarities, it calculates the distance of data points into K random cluster centroids and assigns each data point to its closest centroid. The location of each centroid is then updated by the average value of all data points associated with that centroid. This process is repeated until there is no change in the location of the centroids. In ML models for stress detection, K-means clustering has been used in the literature for the personalization of the ML models [58,67], and for labeling the data set [146,156].

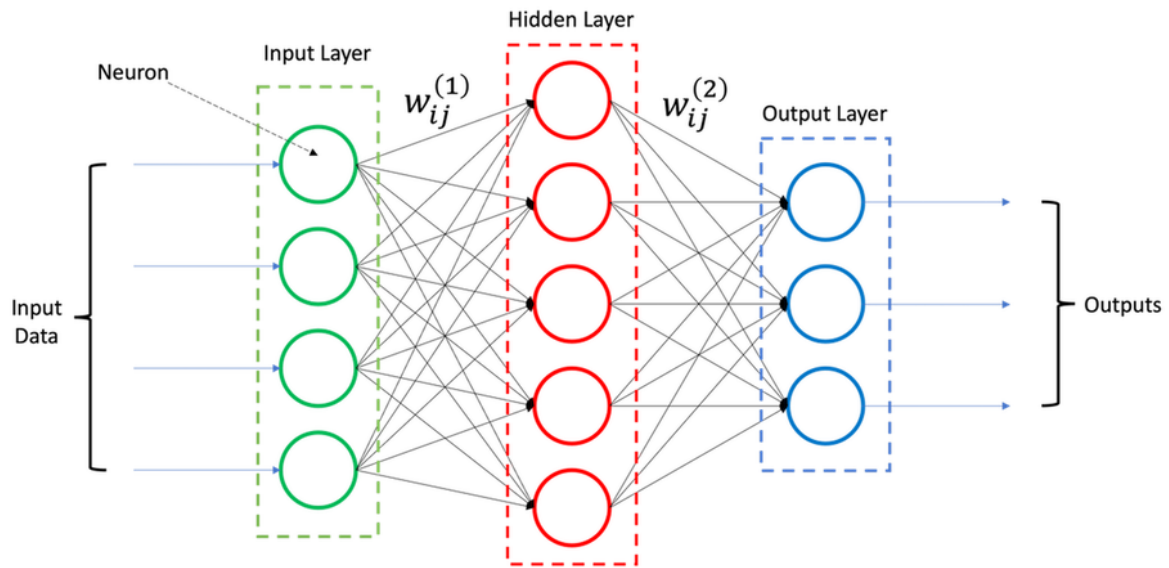

NN Method

DL methods are a subset of ML methods, and NNs are at the heart of the DL algorithms. The NN (n=38, 39%) is a method for implementing ML that uses interconnected nodes or neurons arranged in a layered structure resembling the human brain. The different types of NNs have been explained in subsequent sections.

Artificial Neural Network

It is possible to think of a single perceptron (or neuron) as an abstract LR. In each layer of artificial neural networks (ANNs), a group of multiple perceptron or artificial neurons is used. Figure 12 shows an ANN with 1 layer and its working mechanism.

Figure 12. (A) Representation of an artificial neural network with 1 hidden layer. $W_{ij}^{(1)}$ and $W_{ij}^{(2)}$ denote the weights of the links connecting the first layer (input layer) to the hidden layer and the weights of the links connecting the second layer to the next layer (output layer), respectively. (B) Representation of how a single neuron works. First, all the outputs of the previous layer are multiplied by the weights associated with the links connecting them to the j th neuron of the next layer and summed by a bias (summation and bias step). The result is then passed through an activation function (activation step).

(A)

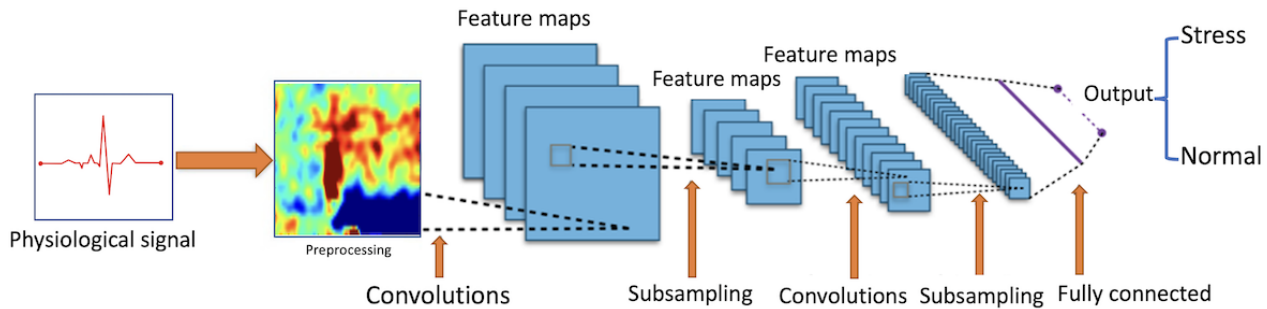

(B)

CNN Approach

CNNs are a form of NN that is especially adept at handling data structures with a grid-like layout, such as images or objects.

Classification and computer vision applications are common uses for CNNs (Figure 13).

Figure 13. Representation of convolutional neural network for a physiological signal.

Recurrent Neural Network Approach

A recurrent neural network (RNN) is a subset of ANNs designed specifically for use with time-series data and other sequence-based data. Long short-term memory (LSTM) networks are the most common type of RNNs. In RNNs, the attention mechanism is a method that simulates cognitive attention in NNs. The purpose of the impact is to encourage the network to give greater attention to the small but significant portions of the input data by enhancing some and reducing others. Since stress may alter a small portion of physiological data (eg, ECG), attention mechanisms can be used to detect stress using RNNs when large data sets are available [141].

Cong et al [102] introduced X-A-BiLSTM, which is a DL model that includes XGBoost (to filter data and handle imbalanced data) and attention Bi-LSTM (LSTM with forward and backward memory and attention mechanism) NN used for stress classification using text data.

Other ML Techniques

The total number of studies in this category include (n=19, 19%) of studies.

Voting Ensemble Classifier

The classification is decided based on weighted voting, which is determined by using a voting ensemble approach. The voting classifier allows for voting in which the final class labels are determined either by the class chosen most frequently by the classification models or by the average of the output probabilities from each classification model. In the literature, this method has been used for PTSD detection [127], stress, and stress-related MDs [84,95,118,156,157].

FCM Clustering

FCM is a clustering approach that assigns every data point to all the clusters with a certain probability instead of assigning each point to only 1 cluster. For instance, a data point that is near the cluster's center will have a high degree of membership, while a data point that is distant from the cluster's center will

have a low degree of membership [158]. Since depression and anxiety are not discrete measures, some studies have used FCM as an alternative to other clustering techniques for the detection of these MDs [114,116].

Discussion

Principal Findings

In this review, the recent ML algorithms; preprocessing techniques; and data (eg, physiological data, questionnaire data, etc) used in the detection, prediction, and monitoring of stress and the most common MDs (ie, depression, anxiety, other stress-related MDs) have been reviewed.

On the basis of this review, it is concluded that among classic ML algorithms (excluding DL approaches), supervised models of SVMs and RF have been used more often and achieved better performance in terms of model accuracy and robustness (measured by parameters such as area under the receiver operating characteristic curve). The accuracy of ML models is a critical indicator of their utility in real-world applications. The review demonstrates that SVM consistently achieves high accuracy across various data types, including HR, HRV, and skin response. For instance, SVM achieved 93% accuracy with HR, PPG, and skin response data in the study by Nath et al [29] and 96% with skin response data in the study by Srividya et al [156]. These results underscore SVM's robustness in handling complex, nonlinear data. RF also shows commendable performance, with an accuracy of 99.88% in the study by Trevisan [159], reflecting its strength in ensemble learning to mitigate overfitting and noise.

Moreover, among the predicting measures for stress and stress-related MDs, HR, HRV, and skin response have been used most often (Figure 14). These measures were the major explaining factors in the ML algorithms to predict stress and stress-related MDs. It is noticeable that DL approaches are becoming more popular as these techniques provide unique specifications that classic ML algorithms cannot provide.

Figure 14. Distribution of machine learning (ML) models used for each type of data. In this figure, skin response and heart measures (including heart rate, heart rate variability, and blood pressure) have been shown separately because of their high use and importance in the literature. Other psychophysiological measures include electroencephalogram, electromyogram, eye tracking, and respiratory signals. Activity includes body movement. Sentiment data include speech and text data. Finally, perceived measures include questionnaires and self-report data. DT: decision tree; KNN: k-nearest neighbors; LDA: linear discriminant analysis; LR: logistic regression; NB: naive Bayes; NN: neural network; QDA: quadratic discriminant analysis; RF: random forest; SVM: support vector machines.

Since stress is a time-dependent event, the relationship between different lags of time can be important for detection of stress. RNNs and CNNs will take into account the relationship between data points in different time series for their decision-making, and they have the potential to enhance the detections. DL models, specifically CNNs and LSTMs, show promising results, with CNNs achieving 92.8% accuracy in HRV and ECG data in the study by Quintero et al [155], indicating their potential in feature-rich physiological data. However, it is worth noting that DL models require substantial data for training, which may limit their applicability in studies with smaller data sets. Attention mechanism in RNNs is a new technique that is becoming popular for finding anomalies in physiological signals. However, based on the review of literature, this mechanism has only been used on text data (not on physiological signals) to detect stress. Therefore, the attention mechanism is the technology that can be further used for physiological signals to detect stress.

Unsupervised ML (and DL algorithms) such as clustering techniques have been used mostly for the preprocessing step to label the data (if labels are not available) and also for finding a representation of the data that achieves the best performance in detection algorithms.

For data preprocessing, feature selection (ie, filter and wrapper methods) and extraction techniques are commonly used. In feature extraction approaches, latent representations of data by transformations such as the output of encoder in autoencoders have been useful to remove data noises and to make the data more compact, making further computations more efficient. PCA and ICA are other most common feature extraction approaches used in the literature.

Among the selected features, statistical indicators of heart measurements such as the mean and SD of HR, along with time

and frequency representations of HRV such as RMSSD and total LF and HF power, were most widely used. Heart measurements have also been used more often than other measurements, as they are unobtrusive, noninvasive, affordable, and easier to measure and describe a big portion of stress events. After those measurements, skin response measures have been found to be one of the most important factors in the detection of stress and its related disorders. The time-frequency approaches to analyzing time-series data are becoming more popular in this area as they are proper representations of data for DL approaches that can be more accurate and robust. As an example, for DL algorithms, RNNs with attention mechanisms can help to find portions of data related to stress and its related disorders with higher confidence.

Most of the study models do not interpret the ML models and look at them as black boxes. This limits the contribution to the body of science. Shapley additive explanations is a technique used by some studies to interpret the models such as the evaluation of features to find the most important ones and how in what direction each feature affects the predictions. Shapley additive explanations correlation plot provides insight into the distribution of the features themselves, as well as the relationship between their influence on the model. In other words, it provides the importance of each feature in the prediction of the dependent variable by considering both the main effect and the interaction effect of that feature with other features in the data [31,62,120,159,161,162].

Despite progress in stress detection methodologies, the exploration of personalized models has been limited. Most studies have not gone beyond basic normalization techniques, overlooking the fact that physiological measures are as distinct to individuals as biometric identifiers. A notable exception can be found in a select few studies [67,128,160], which have used

more sophisticated personalization techniques, integrating complex data transformations to account for individual variability.

Strengths of the Review

In undertaking this scoping review, we have embarked on a rich exploration of the applications of ML in the field of stress detection, articulating a narrative that is both comprehensive and detailed. The review lays out a landscape in which diverse data types are not merely cataloged but deeply analyzed for their roles and interconnections within the broader context of methodological approaches. This provides a robust understanding of the field's current state and its complexities.

This review has documented a comprehensive assessment of various physiological measurement techniques, including HRV, EEG, ECG, and so on. This assessment is not just a recounting of the types of data used in the literature but a thoughtful consideration of how each contributes to a multifaceted understanding of stress indicators. It is an acknowledgment that the signals of stress are as complex as the condition itself, necessitating a rich palette of investigative tools.

The review also examines a range of advanced preprocessing techniques such as maximum relevance minimum redundancy, self-organizing map, synthetic minority oversampling technique, and PCA. This examination sheds light on how different studies leverage these methods to refine the quality of the data fed into ML models, thereby potentially enhancing the models' accuracy and reliability in detecting stress. It is an illustration of how sophisticated data treatment can lead to more nuanced insights, even if our methodology did not directly use these techniques.

Limitations

Our scoping review acknowledges its inherent constraints, including a possible selection bias due to potential omissions of pertinent studies. It serves as a contemporary cross-section of the rapidly evolving domains of ML and MH, underscoring the imperative for periodic scholarly review to sustain its relevance and precision. While we survey a broad spectrum of ML techniques applied to stress detection, we do not extensively assess their efficacy, suggesting a fertile ground for future empirical investigations to assess these methods across diverse data cohorts and settings. In addition, while we address the preprocessing techniques and their impact on model performance, our discussion does not delve into detailed technical analysis. Finally, the crucial issue of model interpretability is touched upon but not explored in depth, presenting an opportunity for further scholarly explorations.

Conclusions and Future Directions

Overview

The pivotal insights from this review underscore the potential of ML to redefine the approach to MH care, particularly in the diagnosis and management of stress-related conditions and

MDs. As we have discerned, there is an expansive field ripe for further exploration, with research gaps suggesting a number of promising directions. Guided by these insights, we can now chart a course for future research that not only expands the boundaries of our scientific understanding but also translates into tangible improvements in clinical practice.

Real-Time and Naturalistic ML Applications

The scarcity of real-time studies in naturalistic settings has highlighted the importance of developing ML models that accurately reflect and respond to the complexities of real life. Future research must prioritize the creation of algorithms capable of operating amidst the unpredictability of daily life, providing immediate insights and adaptable interventions. These models hold the potential to transform practice by offering tools that can preemptively identify stress and MD symptoms, enabling clinicians to intervene before conditions worsen.

Temporal Data and DL

Our review illuminates the untapped potential of time-series data in capturing the evolution of stress and MDs. DL techniques, specifically designed to interpret complex, sequential data, could lead to breakthroughs in how we understand and predict MH trajectories. For practice, this means more sophisticated diagnostic tools that can provide a nuanced picture of a patient's MH over time, enabling personalized treatment plans that are responsive to the patient's changing condition.

Personalization in ML Models

The need for individualized care for MH cannot be overstated. The heterogeneity of stress responses and MD symptoms calls for personalized ML models tailored to individual physiological and behavioral patterns. Future research should focus on leveraging multitask learning to refine algorithms that adapt to individual baselines, enhancing the personalization of care. For clinicians, this means access to tools that can more accurately reflect and respond to the unique needs of each patient, reducing the risk of misdiagnosis and improving treatment efficacy.

Predictive analytics can be instrumental in identifying key factors that contribute to misdiagnosis and delayed help seeking. Future studies should look to build on this knowledge to inform the creation of interventions that encourage timely and accurate diagnosis. In practice, this could lead to the development of targeted screening tools that assist clinicians in recognizing at-risk individuals more effectively. The integration of clinical expertise with ML innovation is crucial for the development of tools that are both advanced and clinically relevant. Collaboration between health care professionals, patients, and artificial intelligence developers will be essential in creating user-centered tools that address real-world needs. This collaborative approach will likely result in the development of artificial intelligence applications that are more intuitive and effective in clinical settings.

Abstract

Background: Insomnia is a prevalent condition with significant health, societal, and economic impacts. Cognitive behavioral therapy for insomnia (CBTI) is recommended as the first-line treatment. With limited accessibility to in-person-delivered CBTI (ipCBTI), electronically delivered eHealth CBTI (eCBTI), ranging from telephone- and videoconference-delivered interventions to fully automated web-based programs and mobile apps, has emerged as an alternative. However, the relative efficacy of eCBTI compared to ipCBTI has not been conclusively determined.

Objective: This study aims to test the comparability of eCBTI and ipCBTI through a systematic review and meta-analysis of equivalence based on randomized controlled trials directly comparing the 2 delivery formats.

Methods: A comprehensive search across multiple databases was conducted, leading to the identification and analysis of 15 unique randomized head-to-head comparisons of ipCBTI and eCBTI. Data on sleep and nonsleep outcomes were extracted and subjected to both conventional meta-analytical methods and equivalence testing based on predetermined equivalence margins derived from previously suggested minimal important differences. Supplementary Bayesian analyses were conducted to determine the strength of the available evidence.

Results: The meta-analysis included 15 studies with a total of 1083 participants. Conventional comparisons generally favored ipCBTI. However, the effect sizes were small, and the 2 delivery formats were statistically significantly equivalent ($P < .05$) for most sleep and nonsleep outcomes. Additional within-group analyses showed that both formats led to statistically significant improvements ($P < .05$) in insomnia severity; sleep quality; and secondary outcomes such as fatigue, anxiety, and depression. Heterogeneity analyses highlighted the role of treatment duration and dropout rates as potential moderators of the differences in treatment efficacy.

Conclusions: eCBTI and ipCBTI were found to be statistically significantly equivalent for treating insomnia for most examined outcomes, indicating eCBTI as a clinically relevant alternative to ipCBTI. This supports the expansion of eCBTI as a viable option to increase accessibility to effective insomnia treatment. Nonetheless, further research is needed to address the limitations noted, including the high risk of bias in some studies and the potential impact of treatment duration and dropout rates on efficacy.

Introduction

Background

Insomnia, characterized by difficulties initiating or maintaining sleep, which are perceived as distressing and result in significant impairment of daytime functioning, is a common concern in the general population [1]. It is estimated that approximately 20% of the population experience episodic symptoms of insomnia, resulting in negative consequences for daytime functioning, for example, fatigue, with approximately 10% fulfilling the diagnostic criteria for an insomnia disorder [1]. The association between insomnia and adverse physical and mental health outcomes has been thoroughly documented, with numerous prospective studies showing increased risk of developing cardiovascular disease [2,3], infectious diseases such as the common cold or pneumonia [4,5], all-cause dementia [6,7], mental disorders such as depression and anxiety [8], and social withdrawal and loneliness [9,10]. In addition, not only short but also long sleep duration, both possible indicators of sleep disturbances, have been associated with increased mortality [11,12]. Beyond the personal health implications, insomnia is associated with societal costs through increased health care use, higher levels of work absenteeism, diminished work-related productivity, reduced learning capacity, and poorer academic performance [13-15]. This underlines the extensive societal and economic burdens posed by untreated sleep disturbances.

While hypnotic medications are commonly used to treat insomnia, they are not recommended for long-term use due to the risk of developing tolerance and dependence [16] as well as a wide range of adverse consequences, including daytime drowsiness, impaired cognitive function, increased risk of accidents or falls, and rebound insomnia upon discontinuation [17,18]. Instead, the major sleep medicine and research organizations recommend cognitive behavioral therapy for insomnia (CBTI) as the first-line treatment for insomnia [19-21]. CBTI usually involves a combination of two or more of the following five components [17]: (1) *sleep restriction therapy*, which aims at promoting more efficient and consolidated sleep patterns by first reducing the time spent awake in bed and then gradually allowing the person to increase time in bed [22]; (2) *stimulus-control therapy*, which aims to strengthen the connection between the bed and sleep by associating the bed and bedroom with sleep rather than wakefulness [23]; (3) *relaxation techniques*, which aim to reduce stress, anxiety, and tension that may interfere with falling asleep or staying asleep [24]; (4) *cognitive therapy*, which targets negative thought patterns and maladaptive beliefs about sleep [25]; and (5) *sleep hygiene education*, which focuses on establishing healthy habits and optimizing the sleep environment to promote better sleep [26]. Several meta-analyses have supported the efficacy of CBTI, demonstrating both short-term [16,27] and long-term effects [28] on insomnia, not only as the primary problem but also as a comorbid condition, for example, in patients with

chronic pain [29] and survivors of cancer [30]. Compared with pharmacotherapy, CBTI has been found to be at least as effective in reducing insomnia symptoms and generally demonstrates more durable effects [31].

Nonetheless, substantial challenges remain in extending assistance to those affected. Individuals with insomnia rarely receive guideline-compliant treatment, hindered by various obstacles. These include insufficient numbers of trained CBTI providers, low rates of referral by primary care physicians, and geographical and physical barriers that deter patients from receiving help [32-34]. To address these challenges, several alternative eHealth delivery formats of CBTI have been developed and evaluated [32]. These alternatives include telephone- and videoconference-delivered CBTI and fully automated web-based programs and mobile apps.

Recently published meta-analyses have revealed statistically significant and clinically meaningful effects of eHealth CBTI (eCBTI) on various measures, including insomnia severity; self-reported sleep quality; and sleep diary-based outcomes such as sleep onset latency (SOL), wake after sleep onset (WASO), total sleep time (TST), and sleep efficiency [35,36]. This efficacy extends not only to individuals with insomnia as their primary concern [37,38] but also to those with comorbid insomnia, for example, survivors of cancer [39]. However, the results of recent systematic reviews and network meta-analyses comparing various delivery formats of CBTI suggest that in-person-delivered CBTI (ipCBTI) is generally superior to eCBTI, more so for insomnia severity than for sleep diary outcomes [40,41]. In contrast, a network meta-analysis investigating a Food and Drug Administration-authorized prescription eCBTI compared to traditional ipCBTI found that eCBTI was the most efficacious regarding insomnia severity [42].

The inconclusive results of the existing meta-analyses could be due to their reliance on both direct and indirect comparisons and variations in treatment length, dosage, content, and control group types across studies of both formats, which may compromise comparability [41]. To date, no meta-analysis has focused exclusively on randomized controlled trials, conducting direct head-to-head comparisons of eCBTI and ipCBTI, and it thus remains unclear how well the 2 delivery formats compare in terms of efficacy.

In addition, when examining the equivalence or nonequivalence of 2 interventions with meta-analysis, the conventional nonsuperiority null hypothesis test procedure is insufficient. Here, a nonsignificant result merely indicates a failure to reject the null hypothesis of no difference, which cannot conclusively determine nonequivalence or equivalence [43]. To truly test whether treatments are equivalent, we must reject the null hypothesis of nonequivalence, which means that differences in effect sizes (ESs) are as large as or larger than a predetermined equivalence margin [44]. One will usually choose equivalence margins based on previously determined minimal important

differences (MIDs), referring to the minimal difference in an outcome of interest that can be viewed as clinically meaningful [45].

Objectives

Given the prevalence of insomnia and the need for diverse treatment approaches, establishing the equivalence or nonequivalence of digital and traditional CBTI delivery formats is crucial. The possible equivalence or nonequivalence of eCBTI and ipCBTI has not yet been subjected to meta-analysis. The aim of this study was, therefore, to test the comparability of eCBTI and ipCBTI with a systematic review and meta-analysis of equivalence based on randomized controlled trials directly comparing the 2 delivery formats.

Methods

This study was registered with PROSPERO (registration CRD42023390811) and conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analysis) statement (Multimedia Appendix 1) [46].

Search Strategy

The electronic databases of CINAHL, Cochrane, Embase, PsycINFO, and PubMed were searched for publications from

the earliest time available until January 5, 2024. Keywords related to insomnia (eg, sleep disturbance OR sleep disorder) were combined with keywords related to CBTI (eg, cognitive behavioral OR CBT) and keywords pertaining to eHealth (eg, telehealth OR digital). The search strings were constructed in collaboration with a skilled librarian. Table S1 in Multimedia Appendix 2 comprises detailed search strings for each database. The electronic database searches were supplemented with backward searches of reference lists of included studies. No separate protocol in addition to the one registered with PROSPERO was prepared. The main methodological changes to the original registered protocol were as follows: (1) the search date was changed from 1991 to the earliest time available due to the inclusion of additional electronic delivery formats, for example, telephone-based interventions, and (2) we also extracted data on secondary nonsleep outcomes of fatigue, anxiety, and depression.

Inclusion and Exclusion Criteria

On the basis of the Population, Intervention, Comparison, and Outcome (PICO) approach [47], the inclusion criteria in Textbox 1 were used.

Textbox 1. Inclusion criteria.

Population

- Adults and adolescents (aged ≥ 12 years) with (1) self-reported poor sleep quality or symptoms of insomnia assessed with relevant instruments, for example, the Insomnia Severity Index (ISI) [48] or the Pittsburgh Sleep Quality Index (PSQI) [49], or (2) an insomnia diagnosis established by a structured clinical interview. Studies of children aged < 12 years and studies focusing on other medical sleep disorders (eg, sleep apnea and narcolepsy) were excluded. No exclusions were made based on comorbid disorders.

Intervention

- Electronically delivered eHealth cognitive behavioral therapy for insomnia (eCBTI), defined as cognitive behavioral therapy for insomnia (CBTI) delivered remotely or using digital means without in-person contact, for example, CBTI delivered via telephone or video, web-based CBTI, or smartphone-based CBTI. CBTI was defined as any combination of ≥ 2 of the standard CBTI components, that is, sleep restriction therapy, stimulus-control therapy, relaxation, cognitive therapy, and sleep hygiene education. Other eHealth interventions aimed at treating insomnia, for example, mindfulness-based interventions, were excluded, as were stand-alone CBTI components.

Comparison

- eCBTI had to be directly compared with in-person-delivered CBTI (ipCBTI), defined as any combination of ≥ 2 standard CBTI components delivered in person, either individually or in a group format. Other in-person-delivered interventions aimed at treating insomnia, including stand-alone CBTI components, were excluded.

Outcomes

- Studies should report means with SDs or SEs; change scores; effect sizes (eg, Cohen d) or data that could be converted into an effect size for at least 1 relevant sleep outcome, that is, insomnia severity or clinically significant sleep disturbance assessed with relevant scales such as the ISI [48] and the PSQI [49]; structured clinical interviews; or a relevant sleep parameter assessed with a sleep diary, actigraphy, or polysomnography. Only randomized controlled trials published in English in peer-reviewed journals were included. Case studies, open trials, and other nonrandomized controlled trials were excluded, together with studies with sample sizes < 10 .

Study Selection and Data Extraction

Identified references were imported into the web-based software program Covidence (Veritas Health Innovation) [50]. After duplicate removal, title and abstract screening was performed, followed by full-text screening. One author (SMK) conducted the final search, with 3 authors (SMK, DSC, and PC) conducting the screening process independently. Discrepancies were

resolved through discussions and, in case of disagreement, by including a fourth author (RZ). The primary outcome was total sleep disturbance calculated as the combined, that is, averaged, results for insomnia severity and sleep quality assessed with validated scales, for example, the Insomnia Severity Index (ISI), the Pittsburgh Sleep Quality Index (PSQI), or similar scales. Secondary sleep outcomes were insomnia severity measured with the ISI; sleep quality measured with the PSQI; and the

sleep diary or actigraphy-based outcomes of SOL, WASO, TST, and sleep efficiency calculated as TST relative to time in bed. In addition, we extracted data on the secondary nonsleep outcomes of fatigue, anxiety, and depression, as well as for study characteristics that could potentially explain (moderate) any variations in the differences between ipCBTI and eCBTI, including mean sample age, the proportion of women in the sample, study dropout rates, the type and degree of therapist contact, the number of treatment sessions, treatment length, and the type and number of CBTI components in each condition. A total of 3 authors (SMK, DSC, and PC) extracted data from the included studies independently, and discrepancies were resolved through discussion and by including a fourth author (RZ).

Risk of Bias Assessment

The revised Cochrane Risk of Bias tool [51] was used to evaluate the risk of bias in the included studies. Five sources of bias were assessed: (1) bias arising from the randomization process, (2) bias due to deviations from intended interventions, (3) bias due to missing outcome data, (4) bias in the measurement of the outcome, and (5) bias in the selection of the reported result. All studies were evaluated for each of the 5 potential sources of bias and rated as either low risk, high risk, or some concerns on the primary outcome of sleep disturbance. In addition, an overall assessment of the risk of bias was conducted for each study. As the number of dropouts in studies investigating eCBTI is generally high, with mean attrition rates ranging from 22% to 25% [36,52], it was decided to use a less conservative criterion in domain 3. We thus considered the availability of data from $\geq 90\%$ of the participants at the postintervention assessment time-point sufficient. The assessments were conducted independently by 3 authors (SMK, DSC, and PC). Disagreements were solved by negotiation.

Data Analysis

Hedges' g , a variation of Cohen d correcting for a possible bias due to a small sample size [53], was used as the standardized ES. All ES calculations were based on differences between the ipCBTI and eCBTI intervention groups in changes (means and SDs) from preintervention to postintervention time points and from preintervention to follow-up time points, standardized by change score SDs. If the relevant data were not reported, we contacted the authors, requesting them to provide this information. We also analyzed the mean differences across the different sleep-related outcomes, that is, mean differences in ISI and PSQI scores; percentages for sleep efficiency; and minutes for SOL, WASO, and TST. ESs were pooled using the inverse variance method, taking the precision of each study into account. A random-effects model was used in all analyses, with positive ESs indicating ipCBTI being more efficacious than eCBTI. If studies reported results for >1 measure per outcome, for example, insomnia severity or sleep quality, we chose the most commonly used outcome measure, that is, the ISI for insomnia severity and the PSQI for sleep quality, so that only 1 result per study was used in each data synthesis, ensuring the independence of results.

Differences between ipCBTI and eCBTI were first analyzed using a conventional random-effects test of superiority for results at both postintervention and follow-up. The pooled ESs

were then subjected to analyses of equivalence [44], testing whether the CI fell within an equivalence interval based on the clinical significance thresholds (or MIDs) previously suggested for the various sleep outcome measures. Thus, the MIDs were 0.5 SD for the standardized mean differences of sleep disturbance, insomnia severity, sleep quality, sleep efficiency, SOL, WASO, and TST, as suggested in a previous study [54]. The MIDs for the mean differences were 4.4 points on the PSQI [55], 5% for sleep efficiency, 10 minutes for SOL, and 15 minutes for WASO and TST [54]. The 6-point MID previously suggested for the ISI [56] was based on an analysis of within-subject improvement, that is, minimal important change. We therefore used $0.5 \times$ the average SD of 4.2 (2.6 points) for ISI at baseline in patients with insomnia reported in the original validation paper [48]. This SD corresponds well with the average SD of 4.1 found for ISI scores across studies at baseline in this review. The equivalence interval of SD 0.25 for depression was chosen based on the MID previously suggested [57]. As no specific MIDs were available for the measures of fatigue and anxiety, 0.5 SD was chosen as the equivalence interval for these measures [58]. The equivalence test is based on two 1-sided tests, with the 2 interventions considered to be statistically significantly equivalent if the largest of the 2 P values is $<.05$ [44].

Heterogeneity was explored by calculating the I^2 statistic [59,60]. In addition, we calculated the 95% prediction interval, that is, the interval in which 95% of future observations from the same family of studies are expected to fall [61]. Possible reasons for heterogeneity of the differences between ipCBTI and eCBTI were explored with moderator analyses comparing the ESs of studies according to the following study characteristics: mean sample age, the proportion of women in the sample (%), overall study dropout (%), the difference in dropout between eCBTI and ipCBTI (%), therapist contact in the eCBTI condition (reference: fully automated, ie, no direct or indirect therapist contact), the number of treatment sessions, and treatment duration (weeks). In addition, we explored the possible role of the number of CBTI components used in ipCBTI and eCBTI, respectively. Both categorical and continuous moderators were analyzed with meta-regression when K (the number of studies in the analysis) was ≥ 10 .

When K was ≥ 10 , the possibility of publication bias was evaluated with funnel plots and the method developed by Egger et al [62]. If the results were suggestive of publication bias, we planned to calculate an adjusted ES using the Duval and Tweedie trim and fill method [63]. The calculations were conducted with Comprehensive Meta-Analysis (version 4; Biostat, Inc) [64] and various formulas in Microsoft Excel.

Finally, to assess the potential efficacy of each condition, we calculated the pooled within-group differences for each condition at postintervention and follow-up for all outcomes.

Supplementary Bayesian Analyses

To aid the interpretation of the results, we conducted a supplementary Bayesian model-averaged meta-analysis [65] of the overall comparisons of ipCBTI and eCBTI at postintervention and follow-up. The procedure examined the

results of four models: (1) the fixed-effect null hypothesis, that is, the difference between ipCBTI and eCBTI is nonzero (fH_0), (2) the fixed-effect alternative hypothesis, that is, the difference is zero (fH_1), (3) the random-effects null hypothesis (rH_0), and (4) the random-effects alternative hypothesis (rH_1). The Bayesian model-averaged analysis thus avoids selecting either a fixed- or random-effects model and addresses 2 questions in light of the observed data: What is the plausibility that the overall effect is 0, that is, equivalent? and Is there a between-study variability in the ESs? Bayesian methods enable direct probability statements about the hypotheses themselves and avoid other issues associated with null hypothesis significance testing, such as the overreliance on relatively arbitrary P value thresholds and the dichotomization of results into “significant” and “nonsignificant” [66]. We chose an uninformed prior probability, that is, 25%, of the 4 models and 2000 iterations. Concerning parameter distributions, we chose previously recommended defaults [65], using a 0-centered Cauchy prior with a scale of 0.707 for the ES and an empirically informed prior distribution of nonzero between-study deviation

estimates from 705 meta-analyses [67]. This distribution has been approximated by an inverse-gamma (1, 0.15) prior on the SD (Tau) [65]. The Bayesian analyses were conducted with the computer software JASP (version 16; University of Amsterdam) [68]. All data included in this review are available in tables and figures in the manuscript or [Multimedia Appendix 2](#).

Results

Study Selection

A total of 5180 records were identified via databases, and 2 additional records were identified via reference lists. After 2039 (39.36%) duplicates were removed, 3141 (60.64%) references were screened by title and abstract. Full-text screening was carried out for 1.66% (52/3141) records, and after assessing eligibility, we identified 32% (17/52) full-text reports of 15 unique randomized head-to-head comparisons of ipCBTI and eCBTI. The results of the study selection process are shown in [Figure 1](#). A list of studies excluded after full text screening with reasons for exclusion is provided in Table S2 in [Multimedia Appendix 2](#).

Figure 1. Study selection flowchart. CBTI: cognitive behavioral therapy for insomnia; eCBTI: eHealth cognitive behavioral therapy for insomnia; ipCBTI: in-person-delivered cognitive behavioral therapy for insomnia.

Study Characteristics

The characteristics of the included studies are summarized in [Table 1](#). Of the 15 studies, most studies were conducted in the

United States ($K=5$, 33%), followed by Canada ($K=3$, 20%) and the Netherlands ($K=2$, 13%). The rest of the studies ($K=5$, 33%) were all conducted in different countries. A total of 1083 participants were included in the 15 studies and randomized to

eCBTI and ipCBTI treatment conditions. A little more than half, 666/1083 (61.5%), were women. The mean age of the total sample was 40.6 (SD 11.3) years, with mean sample ages ranging from 15.5 to 55.1 years. Of the 15 studies, most focused on insomnia as the primary problem (K=11, 73%), and 4 studies (27%) focused on patients with comorbid insomnia, that is, people maintaining sobriety from alcohol (K=1, 25%), survivors

of breast cancer (K=1, 25%), and patients with posttraumatic stress disorder (K=2, 50%). All studies had insomnia as an inclusion criterion, based on diagnostic criteria; validated questionnaires; or quantitative criteria such as SOL, WASO, or early morning awakenings of ≥ 30 minutes occurring at least 3 nights a week, or sleep efficiency $< 85\%$.

^aeCBTI: eHealth cognitive behavioral therapy for insomnia.

^bipCBTI: in-person-delivered cognitive behavioral therapy for insomnia.

^cStudy dropout: proportion of participants lost to follow-up at the most distant time point after baseline.

^dTreatment dropout: proportion of participants who dropped out of treatment (defined as completing <50% of treatment cores or sessions).

^eROB 2: Cochrane Risk of Bias.

^fSQ: sleep quality.

^gSOL: sleep onset latency.

^hWASO: wake after sleep onset.

ⁱTST: total sleep time.

^jNR: not reported.

^kTIB: time in bed.

^lNo data.

^mN/A: not applicable.

ⁿPTSD: posttraumatic stress disorder.

Sleep outcomes reported in the 15 included studies were insomnia severity (K=13, 87%), with the ISI being the most frequently used instrument (K=11, 85%), and sleep quality (K=5, 33%), with the PSQI being used by all studies reporting this outcome. Sleep diaries and actigraphy were used in 11 (73%) and 3 (20%) studies, respectively, assessing sleep parameters such as SOL, WASO, TST, time in bed, and sleep efficiency. A total of 11 (73%) studies assessed depression, with the Hospital Anxiety and Depression Scale (HADS) [86] (K=3, 27%) being the most frequently used, followed by the Beck Depression Inventory (BDI) [87] (K=2, 18%), the Patient Health Questionnaire (PHQ) [88] (K=2, 18%), and the Center for Epidemiologic Studies Depression Scale (CES-D) [89] (K=2, 18%). Of the 15 studies, 9 (60%) studies assessed anxiety, with most (K=4, 44%) using the HADS, followed by the General Anxiety Disorder-7 (GAD-7) [90] (K=2, 22%), and 7 (47%) studies assessed fatigue, with most frequently using the Multidimensional Fatigue Inventory (MFI) [91] (K=4, 57%). A total of 14 studies reported follow-up data, with time to follow-up ranging from 9 to 52 weeks.

In all but 1 (7%) of the 15 studies, eCBTI was delivered individually. In most studies (K=10, 67%), eCBTI involved some degree of interaction with a treatment provider, with

real-time, synchronous therapist contact being available in 8 (53%) studies and asynchronous support, for example, via email, being offered in 2 (13%) studies. One (7%) study provided both synchronous and asynchronous therapist contact. In 4 (27%) studies, eCBTI was provided completely without interaction with a treatment provider, for example, in a fully automated format. ipCBTI was primarily delivered individually (K=10, 67%), with 5 (33%) studies using a group format.

Risk of Bias

The risk of bias in the individual studies is summarized in Figure S1 in [Multimedia Appendix 2](#). Of the 15 studies, 10 (67%) were characterized as having some concerns regarding the overall risk of bias, and the remaining 5 (33%) were classified as having a high risk of bias overall. No studies were characterized as having a low risk of bias. The reasons for a study being categorized as having a high risk of bias stemmed primarily from “bias due to missing outcome data” due to the combination of high rates of missing outcome data and failure to include analyses correcting for this, for example, sensitivity analyses. Bias raising “some concerns” primarily stemmed from “bias in the measurement of the outcome” due to the combination of using a self-reported outcome and nonblinding. Only few studies had attempted some element of blinding. Of the 15 studies, 3

(20%) [79,81,84] reported that participants were kept blind to study hypotheses, 1 (7%) reported that treatment providers were kept blind to study hypotheses [79], and 2 (13%) reported that the data analyst was blinded to the allocation status of the participants [83,84]. In addition, bias raising “some concerns” stemmed from “bias in the selection of the reported result” due to inadequate preregistration of the analytical strategy.

Comparing Intervention Characteristics of ipCBTI and eCBTI

More participants had dropped out of eCBTI than out of ipCBTI at both postintervention (104/528, 19.7% vs 72/526, 13.7%) and follow-up (176/509, 34.6% vs 145/509, 28.5%). However, the differences did not reach statistical significance ($P=.17$ and $.46$). No between-condition differences were found in the mean number of sessions (6.0 vs 6.1; $P=.91$), the duration of the intervention (6.7 weeks vs 6.6 weeks; $P=.83$), or the number of CBTI components (4.5 vs 4.6; $P=.83$).

Within-Group Effects

As presented in Table S3 in Multimedia Appendix 2, statistically significant ($P<.05$) improvements from preintervention to postintervention time points and from preintervention to follow-up time points were observed for both ipCBTI and eCBTI for all self-reported sleep outcomes. At postintervention time points, the ESs (Hedges' g) ranged from 0.27 (TST) to 1.97 (ISI) for ipCBTI and from 0.23 (TST) to 1.36 (ISI) for eCBTI. Similarly, at follow-up, the ESs ranged from 0.43 (TST) to 1.88 (ISI) for ipCBTI and from 0.39 (TST) to 1.41 (total sleep disturbance) for eCBTI. For the few actigraphy-based sleep

outcomes at postintervention ($K=3$, 20%), only the results for SOL in the ipCBTI condition (Hedges' $g=0.53$; mean difference=-11.5 minutes) reached statistical significance. At postintervention time points, in the ipCBTI condition, the ISI total score was, on average, improved by 9.0 points; the PSQI global score by 4.4 points; diary-based sleep efficiency by 12.1%; and diary-based SOL, WASO, and TST by -20.9, -23.5, and +21.3 minutes, respectively. The comparable results for eCBTI were 7.1 points, 3.5 points, 10.3%, -19.6 minutes, -19.5 minutes, and +16.3 minutes, respectively. As also seen in Table S3 in Multimedia Appendix 2, the within-participant improvements in fatigue, anxiety, and depression were all statistically significant and similar for both delivery formats at postintervention. Similar results were found for the secondary nonsleep outcomes at follow-up (data not shown).

Conventional Superiority Meta-Analysis

As presented in Table 2, when analyzed with conventional superiority meta-analysis, the pooled differences between ipCBTI and eCBTI reached statistical significance in 11 (34%) out of 32 comparisons. The effects generally favored ipCBTI but were small, for example, corresponding to a mean difference of 1.8 points on the ISI and 1.9% in sleep efficiency. The pooled difference for total sleep disturbance corresponded to a small ES (Hedges' $g=0.32$). The forest plots are shown in Figures 2-4 [69-85] and Figures S2-S11 in Multimedia Appendix 2. Concerning the secondary nonsleep outcomes of fatigue, anxiety, and depression, no differences in the conventional superiority analyses reached statistical significance (Table S4 in Multimedia Appendix 2).

Figure 2. Forest plot of postintervention differences (Hedges' g) between the effects of eHealth cognitive behavioral therapy for insomnia (eCBTI) and in-person-delivered cognitive behavioral therapy for insomnia (ipCBTI) on total sleep disturbance (red lines denote the equivalence margin).

Figure 3. Forest plot of postintervention mean differences (%) between the effects of eHealth cognitive behavioral therapy for insomnia (eCBTI) and in-person-delivered cognitive behavioral therapy for insomnia (ipCBTI) on sleep efficiency (red lines denote the equivalence margin).

Figure 4. Forest plot of postintervention mean differences (min) between the effects of eHealth cognitive behavioral therapy for insomnia (eCBT) and in-person-delivered cognitive behavioral therapy for insomnia (ipCBTI) on total sleep time (red lines denote the equivalence margin).

Table 2. Results of a meta-analysis of studies directly comparing the efficacy of in-person–delivered cognitive behavioral therapy for insomnia (ipCBTI) and digitally delivered eHealth CBTI (eCBTI), including tests of nonzero differences and tests of statistical equivalence.

^aThe test of equivalence tests whether the CI falls within an equivalence interval. The equivalence test is based on the largest *P* value from two 1-sided tests [44].

^bK: number of studies.

^cN: total number of participants.

^dAnalyses were conducted for outcomes with K≥3 for mean differences (% , min) and standardized mean difference (SMD; adjusted for small sample bias; Hedges' *g*) [53], with positive values of Hedges' *g* indicating a difference of effects in favor of ipCBTI compared with eCBTI.

^e2-tailed *P* values.

^fPI: prediction interval.

^g95% prediction interval is the interval in which 95% of future observations from the same family of studies will fall [61].

^hMID: minimal important difference (or clinical significance threshold) [54].

ⁱStatistically significant *P* values (*P*<.05) indicate equivalence.

^jSMD=0.50, as suggested by Edinger et al [54].

^kISI: Insomnia Severity Index.

^l2.6 point difference on the Insomnia Severity Index (ISI), corresponding to 0.5 × SD found in the original validation study (SD 4.2) [48] (average ISI baseline SD across studies in this review=4.1).

^mPSQI: Pittsburgh Sleep Quality Index.

ⁿ4.4 point difference on the Pittsburgh Sleep Quality Index (PSQI), as suggested by Longo et al [55].

^oSleep efficiency (%; total sleep time/time in bed × 100).

^pDiary: sleep parameters based on sleep diaries, for example, the Consensus Sleep Diary [92].

^qNot applicable.

^r5% difference, as suggested by Edinger et al [54].

^sSOL: sleep onset latency (min).

^t10-minute difference in sleep onset latency, as suggested by Edinger et al [54].

^uWASO: wake after sleep onset (min).

^v15-minute difference in wake after sleep onset, as suggested by Edinger et al [54].

^wWhen no minimal important differences are available, we chose 0.5 SD, as suggested by Norman et al [58].

^xTST: total sleep time (min).

^y15 minutes difference in total sleep time, as suggested by Edinger et al [54].

Equivalence Meta-Analysis

As shown in [Table 2](#), the 95% CI for total sleep disturbance was included in the prespecified equivalence interval for this outcome, and, based on the largest p-value of two one-sided tests, the null hypothesis of nonequivalence was rejected ($P=.04$). As shown in [Table 2](#), when examining the various sleep outcomes, ipCBTI and eCBTI were statistically significantly equivalent for 25 (78%) out of 32 calculations. Furthermore, ipCBTI and eCBTI emerged as statistically significantly equivalent for all 3 secondary nonsleep outcomes at both time points ([Table S4 in Multimedia Appendix 2](#)).

Publication Bias and Outliers

Inspecting the funnel plot and Egger's test for total sleep disturbance, which included data from all included studies (15/15, 100%), did not indicate publication bias (Egger test, $P=.56$; refer to the funnel plot in [Figure S12 in Multimedia Appendix 2](#)). Considering ESs, larger or smaller than 2 SDs beyond the pooled ES, revealed no outliers.

Heterogeneity and Moderator Analyses

As seen in [Table 2](#), heterogeneity analyses suggested that varying proportions of the variance in postintervention effects stem from between-study differences beyond random error. The I^2 values were highest for the questionnaire-based sleep outcomes (62%-70%) and generally lower for the sleep diary and actigraphy-based outcomes (0%-31.2%). The data also suggested relatively high levels of heterogeneity for outcomes at follow-up. As shown in [Table 3](#), when exploring possible explanations for the heterogeneity with meta-regression, 2 (18%) of the 11 analyzed moderators reached statistical significance. Differences between the proportions of dropouts in the eCBTI and ipCBTI moderated the between-group effects, with higher dropout rates in eCBTI compared with ipCBTI being associated with larger differences in favor of ipCBTI at both postintervention and follow-up, explaining 50% and 74% of the variation, respectively. Longer overall treatment duration was associated with larger differences in favor of ipCBTI compared with eCBTI at both time points. No statistically significant effects were found for the remaining moderators analyzed.

Table 3. Results of moderator analyses based on standardized mean differences (Hedges' *g*) in total self-reported sleep disturbance outcomes between in-person–delivered cognitive behavioral therapy for insomnia (ipCBTI) and eHealth cognitive behavioral therapy for insomnia (eCBTI) at postintervention and follow-up time points.

^aK: number of studies in the analysis.

^bMeta-regression (maximum likelihood method), conducted when K≥10.

^c2-tailed *P* value.

^dDifference in dropout (%) between conditions (eHealth cognitive behavioral therapy for insomnia [eCBTI] dropout minus in-person–delivered cognitive behavioral therapy for insomnia [ipCBTI] dropout). Positive values correspond to a higher dropout rate in eCBTI than in ipCBTI. Combined self-reported sleep quality outcomes include measures of insomnia severity (Insomnia Severity Index) and sleep quality (Pittsburgh Sleep Quality Index).

^eSignificant values (*P*<.05) are italicized.

Results of Supplementary Bayesian Analyses

As presented in Table S5 in [Multimedia Appendix 2](#), the Bayesian meta-analyses favored the alternative hypothesis of equivalence, that is, a zero difference between ipCBTI and eCBTI, for 4 (67%) out of 6 sleep outcomes at postintervention time points. The Bayes factors (BFs), that is, the probabilities of the alternative hypotheses relative to the null hypotheses, ranged from 1.7 (PSQI) to 9.9 (TST), indicating that a zero difference between ipCBTI and eCBTI is 1.7 to 9.9 times more likely than a nonzero difference. The level of evidence [93] ranged from anecdotal (BF=1-3) for PSQI to moderate (BF=3-10) for SOL, WASO, and TST. A 0 and nonzero difference for sleep efficiency appeared equally likely (BF=1.2). Insomnia severity assessed with the ISI was the only outcome for which the current evidence clearly favored a nonzero difference, with this result being 10.5 times more likely than the null hypothesis. Concerning heterogeneity, the data provided strong (BF=13.0) and anecdotal evidence (BF=2.3) for heterogeneous ISI and PSQI ESs, respectively. Nonheterogeneity was slightly more likely for the remaining outcomes (BF=1.9-3.5).

Discussion

Sleep Outcomes

When pooling the results of the 15 unique randomized trials directly comparing eCBTIs with ipCBTIs using conventional meta-analysis, the observed differences generally favored ipCBTI. Specifically, the postintervention results revealed statistically significant advantages for ipCBTI across several dimensions, including overall sleep disturbance (encompassing both insomnia severity and sleep quality), insomnia severity assessed independently, and sleep efficiency. While ipCBTI was statistically significantly superior to eCBTI for these outcomes, the magnitudes of these differences were modest, corresponding to small ESs (Hedges' *g*) and small mean, nonstandardized differences. For example, concerning the latter, the pooled mean differences in favor of ipCBTI for insomnia severity and sleep efficiency were only 1.8 points (on the ISI) and 1.9%, respectively. Furthermore, for total sleep disturbance and sleep efficiency, the CIs fell within the suggested equivalence margins of 0.5 SD and 5%, respectively [54].

Regarding the remaining self-reported sleep outcomes at postintervention, none yielded statistically significantly superior results in favor of either delivery type. Furthermore, with the exception of Hedges' *g* for the PSQI, all remaining analyses showed the 2 delivery types to be statistically significantly equivalent; that is, the CIs of the pooled effect parameter fell within the suggested equivalence margin for that parameter. The same general pattern was observed for the results obtained at the (on average) 21-week follow-up. On the basis of the available data, eCBTI and ipCBTI were statistically significantly equivalent for almost all self-reported sleep outcomes, except for the ES for sleep quality assessed with the PSQI and the mean difference in minutes for TST.

While equivalence indicates similar efficacy, if one only examines the between-group differences, it cannot be determined whether the equivalence stems from similar small or similar

large improvements in both conditions. Therefore, we also calculated the within-group effects for each delivery format. The results revealed that both ipCBTI and eCBTI were associated with statistically significant within-condition improvements in all self-reported outcomes at both postintervention and follow-up. The largest effects were seen in both conditions for total sleep disturbance, insomnia severity, sleep quality, and sleep efficiency. Small-to-medium effects were observed for the remaining self-reported sleep outcomes. Therefore, it may be concluded that both delivery formats appear efficacious, displaying improvements at postintervention corresponding to 9- and 7-point reductions on the ISI, 12% and 10% improvements in sleep efficiency, 21- and 20-minute reductions in SOL, 24- and 20-minute reductions in WASO, and 21- to 16-minute increase in TST for ipCBTI and eCBTI, respectively. These effects are all clinically relevant and well beyond the suggested MIDs and minimal important changes for these outcomes, that is, a 6-point within-person change on the ISI [56] and 10, 15, and 15 minutes for SOL, WASO, and TST, respectively [54]. In addition, these clinically relevant, positive improvements were sustained over time, supporting previous findings that CBTI, regardless of the delivery format, yields robust long-term effects [28].

Only 3 (20%) of the 15 studies assessed sleep objectively, that is, with actigraphy. Despite the small number of studies, the results for sleep efficiency and SOL showed the 2 delivery formats to be statistically significantly equivalent. In contrast, the results for actigraphy-assessed TST appeared to be in favor of eCBTI, with eCBTI resulting in increased TST and ipCBTI in reduced TST. However, neither the conventional nor the equivalence analyses reached statistical significance. When examining the within-group effects, statistically significant improvements were seen for actigraphy-based SOL in the ipCBTI group. The remaining effects for TST and sleep efficiency failed to reach statistical significance. Such discrepancies between effects on self-reported and objectively assessed sleep outcomes, especially concerning estimates of sleep duration, are a well-recognized issue in sleep research and clinical practice [94].

Nonsleep Outcomes

It is well known that insomnia can lead to various physical and mental symptoms, including increased levels of fatigue [95], and that it is a significant predictor of later onset of mental disorders such as depression and anxiety [8]. Therefore, we also explored the effects on the secondary nonsleep outcomes of fatigue, anxiety, and depression. The 2 delivery formats of CBTI were statistically significantly equivalent in their effects on these symptoms, and both yielded statistically significant medium-to-large within-condition improvements of almost identical magnitude in all 3 outcomes. Thus, our results add to the more general findings that CBTI may not only improve insomnia itself but also associated psychological and physical symptoms such as depression, anxiety, and fatigue [96-98], with our findings indicating that both delivery formats appear equally efficacious in reducing these symptoms.

Heterogeneity and Its Sources

When exploring possible heterogeneity of the postintervention effects, the relatively large I^2 statistics observed for both insomnia severity and sleep quality and the combined outcome of total sleep disturbance indicate that a considerable proportion of the variance is due to systematic differences between the study characteristics. In contrast, the differences in effects on sleep diary outcomes displayed little or no signs of heterogeneity. When we investigated possible sources of heterogeneity for the combined total sleep disturbance outcome, 2 study characteristics emerged as statistically significant moderators at both postintervention and follow-up.

First, higher dropout rates in eCBTI than in ipCBTI were significantly associated with larger differences in favor of ipCBTI in effect on total sleep disturbance. At postintervention time points, on average, 30% more participants in eCBTI had dropped out compared to ipCBTI. While we do not know the reasons for the higher dropout rates in eCBTI, this factor, which explained between 50% and 74% of the variance in between-condition differences in effect, could represent an important, potentially modifiable factor that needs to be addressed if the efficacy of eCBTI is to be further increased. While the research on adherence to electronically adapted interventions for insomnia is still limited, studies in this [99] and other clinical populations suggest that common factors influencing dropout and adherence across such interventions include engagement and motivation; technical issues and usability; and demographic factors such as age, educational level, and digital literacy [100,101]. Second, while there was no difference in the mean duration of the 2 delivery formats, interventions with longer duration favored ipCBTI. The moderating effect of intervention duration persisted when adjusting for study dropout. We have no clear explanation for this finding, but longer treatment duration may allow for increased trust and improved therapeutic alliance in personally delivered CBTI, which, in turn, will increase the effect.

None of the remaining moderators analyzed reached statistical significance, including demographic characteristics such as mean sample age and percentage of women in the sample; study characteristics such as time to follow-up; and treatment characteristics such as therapist contact versus no contact, the number of treatment sessions, and the number of CBTI components. Some of the nonsignificant results could be viewed as surprising. For example, one might have expected larger differences between ipCBTI and fully automated eCBTI than between ipCBTI and eCBTI with some degree of therapist contact. One would also have expected age to play a role, for example, that older sample age would be associated with larger between-condition differences. Possible reasons for nonsignificant findings could be insufficient between-study variation, for example, in sample age, and inadequate statistical power due to the relatively small number of studies. Further research is needed to identify the common and different factors associated with the increased efficacy of the 2 delivery formats.

Limitations

Our findings should be interpreted cautiously for several reasons.

First, the interpretability is challenged by between-study heterogeneity, for example, by considerable between-study differences in eCBTI formats, with some eCBTIs delivered with direct therapist contact via telephone or videoconferencing; some delivered on the web with asynchronous therapist contact, for example, through email; and others offered as fully automated programs. While we attempted to explore the possible moderating role of such variations and found no indication of a moderating effect of the degree of therapist contact involved, the relatively small number of studies may have limited our ability to identify the influence of such characteristics.

Second, as demonstrated by the results of the Bayesian analyses, the small number of studies restricts the strength of the evidence. While the currently available evidence favored equivalent effects for 4 (67%) out of 6 outcomes (sleep quality, SOL, WASO, and TST), the level of evidence was weak (ie, anecdotal) to moderate. The evidence for sleep efficiency was inconclusive, and while the level of evidence for a nonzero difference in favor of ipCBTI was characterized as *strong*, the BF was only just above the lower limit (ie, ≥ 10) [93].

Third, interpreting the differences between eCBTI and ipCBTI as equivalent or nonequivalent clearly depends on the chosen equivalence margins. While we chose the MIDs suggested in the literature, for example, 2.6 points, 4.4 points, 5%, 10 minutes, 15 minutes, and 15 minutes for ISI, PSQI, sleep efficiency, SOL, WASO, and TST, respectively [48,54,55], specific MIDs have not been identified for all the corresponding ESs. While we used the 0.5 SD suggested in the literature [54,58], the clinical relevance of this value has yet to be established for several of the sleep outcomes investigated in this review.

Finally, assessed with the revised Cochrane Risk of Bias tool [51,102], one-third of the studies were characterized as having an overall *high risk* of bias, and the remaining two-thirds were characterized as having *some concerns*. Among the main reasons for these categorizations were high rates of missing outcome data and the use of self-reported outcomes. These issues cannot easily be amended. For example, it is not too surprising that behavioral interventions, in general, and eHealth interventions, in particular, have higher dropout rates than pharmacological trials. In addition, while sleep characteristics such as SOL, WASO, and TST can be assessed with both self-report and objective measures, insomnia is inherently a subjective outcome, which can be evaluated only with self-report. Furthermore, ensuring blinding is another factor that is difficult to obtain with behavioral interventions and not possible when comparing in-person and electronically delivered interventions. Other reasons for the identified risks of bias can be addressed more easily, including the failure to include sensitivity analyses correcting for missing outcome data and insufficient preregistering of analytical plans.

Conclusions

This, to our knowledge, first systematic review and meta-analysis of randomized head-to-head comparisons of eCBTI and ipCBTI suggests that while the effects tended to be in favor of the latter, the mean differences were generally of small magnitudes, with several approaching 0. Furthermore,

the 2 CBTI delivery formats were statistically significantly equivalent for most outcomes examined. Statistically significant equivalence means that the CIs of the differences fell within the prespecified equivalence margins, with the latter being based on the minimal clinically relevant differences suggested in the literature for each of the outcomes in question. Importantly, when examining the within-condition effects, both delivery formats yielded large and clinically relevant effects on most

outcomes, including the nonsleep outcomes of fatigue, anxiety, and depression. Although the results should be interpreted cautiously due to the currently limited evidence base, they support eCBTI, including fully automated programs, as clinically relevant alternatives to ipCBTI. These results are promising for people with insomnia, given the challenges of meeting population needs with conventional treatment formats.

Abstract

Background: Digital mental health technologies (DMHTs) have the potential to enhance mental health care delivery. However, there is little information on how DMHTs are evaluated and what factors influence their use.

Objective: A systematic literature review was conducted to understand how DMHTs are valued in the United States from user, payer, and employer perspectives.

Methods: Articles published after 2017 were identified from MEDLINE, Embase, PsycINFO, Cochrane Library, the Health Technology Assessment Database, and digital and mental health congresses. Each article was evaluated by 2 independent reviewers to identify US studies reporting on factors considered in the evaluation of DMHTs targeting mental health, Alzheimer disease, epilepsy, autism spectrum disorder, or attention-deficit/hyperactivity disorder. Study quality was assessed using the Critical Appraisal Skills Program Qualitative and Cohort Studies Checklists. Studies were coded and indexed using the American Psychiatric Association's Mental Health App Evaluation Framework to extract and synthesize relevant information, and novel themes were added iteratively as identified.

Results: Of the 4353 articles screened, data from 26 unique studies from patient, caregiver, and health care provider perspectives were included. Engagement style was the most reported theme (23/26, 88%), with users valuing DMHT usability, particularly alignment with therapeutic goals through features including anxiety management tools. Key barriers to DMHT use included limited internet access, poor technical literacy, and privacy concerns. Novel findings included the discreteness of DMHTs to avoid stigma.

Conclusions: Usability, cost, accessibility, technical considerations, and alignment with therapeutic goals are important to users, although DMHT valuation varies across individuals. DMHT apps should be developed and selected with specific user needs in mind.

Introduction

Background

Digital health comprises a broad range of technologies, including mobile health, health information technology, wearable devices, and personalized medicine, which serve as tools to enhance health care delivery. Recently, several digital mental health (MH) therapeutics, a category of digital MH technologies (DMHTs), have received US Food and Drug Administration (FDA) approval to prevent, manage, or treat a medical disorder or disease based on evidence from superiority trials and compliance with technical guidelines [1,2]. However, most DMHTs, particularly apps, fall outside FDA jurisdiction because they are not intended to diagnose, treat, or prevent disease and because they are “low risk” in that they would not cause harm in the event of malfunction [3]. Due to this lack of regulatory framework, few DMHTs are supported by published efficacy studies. One study found that only 16% of MH apps recommended by college counseling centers were supported by efficacy studies published in peer-reviewed journals [4].

Nonetheless, many health care providers (HCPs) use MH apps in clinical practice. Up to 83% of behavioral health providers in a small study covering the Greater Boston area reported using apps as part of their clinical care, particularly mindfulness apps for patient anxiety management [5]. As many DMHTs are currently widely used in clinical practice without undergoing any formal assessment for quality or relevance, understanding how DMHTs should be assessed based on factors impacting their value from the perspective of key stakeholders, such as patients, caregivers, providers, payers, and employers, could improve the selection of DMHTs for use by patients, thereby increasing care quality and outcomes for those seeking MH support.

Objective

To address identified gaps, a systematic literature review (SLR) was conducted using a published framework to synthesize emerging themes from mixed methods evidence in order to understand how digital health solutions, encompassing both digital therapeutics and direct-to-consumer digital health technologies, are valued, with a focus on MH disorders, Alzheimer disease, epilepsy, autism spectrum disorder (ASD), and attention-deficit/hyperactivity disorder (ADHD) in the United States.

Methods

Overview

The SLR was performed in accordance with a prespecified protocol and reported in line with the Enhancing Transparency in Reporting the Synthesis of Qualitative Research and PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [6,7]. The protocol was not registered.

Search Strategy

Electronic databases, encompassing MEDLINE (including MEDLINE In-Process, MEDLINE Daily, and MEDLINE Epub

Ahead of Print); Embase; the Cochrane Library (including Cochrane Database of Systematic Reviews and Cochrane Central Register of Controlled Trials); PsycINFO; and the Health Technology Assessment Database, were selected in alignment with this SLR’s target indications and were searched on June 17, 2022. The search terms included combinations of free-text and Medical Subject Heading or Emtree terms related to indications of interest, DMHTs, and relevant outcomes or assessment types (eg, technology assessments and cost; Tables S1-S5 in [Multimedia Appendix 1](#)). Searches were limited to studies performed in the United States and to those published from 2017 onward.

Manual hand searches of gray literature, namely, the bibliographies of relevant SLRs identified from the electronic database searches and key conference proceedings (2019-2022), were performed to identify additional studies of relevance (Table S6 in [Multimedia Appendix 1](#)). The FDA website was also searched to identify factors involved in the FDA’s appraisal of relevant MH apps, which could supplement the factors identified in this SLR (Table S7 in [Multimedia Appendix 1](#)).

Study Selection

Studies were included in the SLR if they met prespecified criteria defined using the SPIDER (Sample, Phenomenon of Interest, Design, Evaluation, Research type) framework, which is appropriate for mixed methods research questions. Eligible studies were published in the English language, were set in the United States, and reported quantitative or qualitative outcomes relating to the factors considered in the evaluation of DMHTs. Only studies published in 2017 or later were included because of the rapidly evolving research area. Eligible studies reported on MH, Alzheimer disease, epilepsy, ASD, or ADHD from user, payer, or employer perspectives (Table S8 in [Multimedia Appendix 1](#)). While the primary focus of the SLR was MH, neurological conditions were also of interest because their pathologies, symptoms, and treatment strategies can overlap with those of mental illnesses. Alzheimer disease, epilepsy, ASD, and ADHD were selected because they are highly researched and represent diverse types of neurological conditions.

The titles and abstracts of records were assessed for inclusion against these eligibility criteria by 2 independent reviewers, and discrepancies were resolved by consensus, with arbitration by a third reviewer if necessary. Full texts of potentially relevant articles were acquired and screened using the same methodology.

Study Prioritization

Due to the large volume of the evidence identified, additional eligibility criteria were applied to prioritize primary research on theoretical DMHT valuation factors. In line with the thematic framework synthesis objective, *theoretical valuation factors* were defined as user or DMHT attributes that impact interaction with or perception of DMHTs; therefore, studies that reported only efficacy outcomes, such as mental illness symptom improvement, were deprioritized for full-text review. Secondary research was also deprioritized for full-text review. Studies that reviewed a select app against a framework and studies that

reported only the outcomes specific to a select app were deprioritized for data extraction. For example, a study reporting the usability of a *specific* app's features would have been deprioritized, while a study reporting what *types* of features increase MH app usability *in general* would not.

Data Extraction

All relevant data were extracted into a prespecified Microsoft Excel grid, and a quality assessment was performed for each study. Studies that reported only qualitative data were assessed with the Critical Appraisal Skills Program Qualitative Studies Checklist. Studies that reported only quantitative data were evaluated with the Critical Appraisal Skills Program Cohort Study Checklist, and studies reporting both qualitative and quantitative data were evaluated with both checklists [8]. Data extractions and quality assessments were performed by a single individual for each study, with the information verified by a second independent individual. Discrepancies were resolved by consensus, with arbitration by a third individual if necessary.

Framework Synthesis

A framework synthesis approach was undertaken to synthesize qualitative and quantitative data identified from the SLR. In line with the "best fit" framework synthesis approach, data were indexed deductively against an existing framework where possible, and novel themes were added inductively as needed [9,10]. The American Psychiatric Association (APA) Mental Health App Evaluation framework was considered the most appropriate framework to address the research objectives of this SLR because its key valuation themes were developed using psychiatrist and patient input, are broadly shared by other evaluation frameworks, are widely acknowledged in the literature, and have been described as durable and adaptable [11-13].

The APA model follows a hierarchical and chronological order whereby the evaluator moves through the framework using prompting questions (eg, "Does the app work offline?"). For this SLR, these questions were either thematically grouped into subthemes or left as prompting questions, as appropriate. The framework was therefore ultimately adapted into 3 levels: themes, subthemes, and more granular valuation criteria. It should be emphasized that this SLR did not aim to formally develop an updated framework to be used in practice by HCPs and their patients but rather was used to form a theoretical basis

for understanding DMHT valuation factors, for which novel themes were expected to emerge.

A data-based convergent approach was used to synthesize quantitative and qualitative data [14]. Data were initially indexed deductively against the prespecified themes within the data collection instrument and then further synthesized within Docear [15], a mind-map software used to organize and connect data and concepts. Indexing was performed by 1 reviewer and checked by a second independent reviewer. New themes and subthemes that emerged from the literature through inductive coding were added post hoc to the thematic framework, with all extracted data then considered against both the prespecified and novel themes. The evidence identified for each theme was synthesized narratively, taking into consideration the context and design of each study.

Results

Included Studies

A total of 4974 records were retrieved from the electronic databases. Of the 3374 (67.83%) unique records identified following deduplication across the databases, 2891 (85.68%) were excluded based on the eligibility criteria, and an additional 456 (13.52%) were deprioritized because they were not directly related to the topic of interest for this SLR. Excluded and deprioritized full texts are listed in Tables S9 and S10 in [Multimedia Appendix 1](#), respectively. Therefore, 27 (0.54%) articles were included from the electronic database searches. In addition, 1 article reporting on the same study as an already-included conference abstract was identified during supporting targeted searches and included as a supplementary record, resulting in a total of 28 articles reporting on 26 unique studies (Figure S1 in [Multimedia Appendix 1](#)). No relevant FDA appraisals were identified in the supplementary search.

Of the 26 included studies, 8 (31%) were quantitative, 12 (46%) were qualitative, and 6 (23%) used a mixed methods approach. While 5 (19%) studies assessed prospective cohorts, 22 (85%) used a cross-sectional approach, including 1 (4%) study that contained both a prospective cohort and a cross-sectional cohort ([Table 1](#)). All studies (26/26, 100%) investigated a user perspective, with none specifically investigating payer or employer perspectives. Only 1 (4%) study, which examined ingestible sensor pills and smart pill dispensers to track adherence, investigated a DMHT that was not an app [16].

Table 1. Summary of included study characteristics and outcomes.

Study (author, year)	Design ^a	Perspective and population ^a	Objectives	Data collection methods ^a
Afra et al [17], 2018	Cross-sectional, quantitative	<ul style="list-style-type: none"> Patients with epilepsy who were regular smartphone users recruited from the University of Utah Adult Comprehensive Epilepsy Clinic (N=40) 	To develop a drug-device combination product using an app in combination with antiseizure medications as an epilepsy treatment	Custom survey
Beard et al [18], 2019	Cross-sectional, quantitative	<ul style="list-style-type: none"> Patients treated at a partial hospitalization program located in a nonprofit, insurance-based psychiatric hospital; diagnoses included MDD^b, BD^c, anxiety, OCD^d, stress-related disorders, and psychotic disorders (N=322) 	To characterize general smartphone app and social media use in an acute transdiagnostic psychiatric sample with high smartphone ownership, characterize current engagement and interest in the use of smartphone apps to support MH ^e , and test demographic and clinical predictors of smartphone use	Custom survey
Borghouts et al [19], 2022	Cross-sectional, mixed methods	<ul style="list-style-type: none"> General users^f: members of the Center on Deafness Inland Empire, comprised people with lived experience as members of the deaf or hard-of-hearing community (N=10) 	To investigate the MH needs of the deaf or hard-of-hearing community and how MH apps might support these needs	Custom survey; focus group
Boster and McCarthy [20], 2018	Cross-sectional, qualitative	<ul style="list-style-type: none"> Speech-language pathologists experienced in augmentative and alternative communication using a device in children with ASD^g recruited through social media and professional listserves (N=8) Parents (caregivers) of children with ASD recruited through national organizations (N=5) 	To gain insight from speech-language pathologists and parents of children with ASD regarding appealing features of augmentative and alternative communication apps	Focus groups; poll questions
Buck et al [21], 2021a	Cross-sectional, quantitative	<ul style="list-style-type: none"> Caregivers of young adult family members who experienced early psychosis (onset before age 35) recruited through HCP^h referrals or ads (N=43) 	To assess caregivers' interest in an array of specific potential mHealth ⁱ functions to guide the development of mHealth for caregivers of young adults with early psychosis	Custom survey
Buck et al [22], 2021b	Cross-sectional, quantitative	<ul style="list-style-type: none"> Users: young adults (aged 18-30 years) with a diagnosis of a psychotic disorder or self-reported history of psychotic symptoms recruited through HCP referrals or ads (N=77) 	To understand the needs, interests, and preferences of young adults with early psychosis regarding mHealth by surveying interest in mHealth features and delivery modalities and by collecting information about their digital and web-based behaviors	Custom survey
Carpenter-Song et al [23], 2018	Prospective cohort, qualitative	<ul style="list-style-type: none"> Patients at a community MH center (N=15) 	To examine current practices and orientations toward technology among consumers in 3 mental health settings in the United States	Semistructured interviews
Casarez et al [24], 2019	Cross-sectional, qualitative	<ul style="list-style-type: none"> Caregivers: spouses or partners of patients with BD recruited from a local outpatient psychiatry clinic or psychiatric hospital (N=13) 	To explore how the well-being of spouses and partners of patients with BD can be improved through mHealth technology	Focus groups; minimally structured, open-ended individual interviews
Connolly et al [25], 2018	Cross-sectional, qualitative	<ul style="list-style-type: none"> Patients: US military veterans (aged 18-70 years) who screened positive for PTSD^j, alcohol use disorder, or MDD during the previous year at 9 community-based VA^k outpatient clinics (N=66) 	To examine veterans' attitudes toward smartphone apps and to assess whether openness toward this technology varies by age or rurality	Semistructured interviews informed by the State of the Art Access Model

Study (author, year)	Design ^a	Perspective and population ^a	Objectives	Data collection methods ^a
Cummings et al [26], 2019	Cross-sectional, qualitative	<ul style="list-style-type: none"> Parents and grandparents with children or grandchildren (caregivers) enrolled in a public health insurance program who received ≥ 2 months of ADHD¹ treatment at 4 safety-net clinics (N=37) Administrators at the same clinics (N=41) 	To examine stakeholder perspectives regarding whether mHealth tools can improve MH treatment for low-income youth with ADHD in safety-net settings and what functions would improve treatment	Focus groups (caregivers) and interviews (HCPs and staff), both semistructured and including open-ended questions and targeted probes
Dinkel et al [27], 2021	Cross-sectional, qualitative	<ul style="list-style-type: none"> Adult patients (aged ≥ 19 years) with a current or prior diagnosis of depression recruited during medical visits from 2 integrated primary care clinics (N=17) HCPs and staff at the same clinics (N=15) 	To explore patient and clinic-level perceptions of the use of depression self-management apps within an integrated primary care setting	Semistructured focus groups; semistructured interviews
Forma et al [16], 2022	Cross-sectional, quantitative	<ul style="list-style-type: none"> Caregivers of patients with BD, MDD, or schizophrenia who believed their patients had adherence issues to second-generation oral atypical antipsychotic medication (N=184) 	To assess caregivers' preferences and willingness to pay for digital (ingestible sensor pill, medication containers with electronic monitoring, mobile apps, and smart pill dispensers) and nondigital (medication diary and simple pill organizer) tools	Custom discrete choice experiment survey
Hoffman et al [5], 2019	Prospective interventional, mixed methods	<ul style="list-style-type: none"> HCPs (N=24) in a routine primary care behavioral health setting who reported their own and patients' (sample size not reported) MH app use and feedback; patient conditions included anxiety, stress, depression, and substance use 	To test the feasibility of using mHealth apps to augment integrated primary care services, solicit feedback from patients and providers to guide implementation, and develop an MH app toolkit for system-wide dissemination	Custom survey
Huberty et al [28], 2022	Cross-sectional (current Calm (Calm.com, Inc) users) and prospective interventional (nonusers of Calm, HCPs), qualitative	<ul style="list-style-type: none"> General users^f: patients with cancer and survivors of cancer with smartphones, some of whom were current subscribers of Calm, a meditation app (N=17) HCPs, staff, and not-for-profit partners in cancer care with smartphones (N=10) 	To develop a mobile meditation app prototype specifically designed for patients with cancer and survivors of cancer	Custom surveys; focus groups
Kern et al [29], 2018	Cross-sectional, quantitative	<ul style="list-style-type: none"> General users^f: students from a midwestern university with smartphones (N=721) 	To investigate the potential usefulness of MH apps and attitudes toward using them	Custom survey
Knapp et al [30], 2021	Prospective cohort, qualitative	<ul style="list-style-type: none"> Clinical staff members who provide behavioral health care for children and adolescents with conditions, including ADHD and depression, at a large community service organization in a midwestern state (N=37) 	To learn about considerations and perspectives of community behavioral HCPs on incorporating digital tools into their clinical care for children and adolescents	Focus groups
Kornfield et al [31], 2022	Prospective cohort, qualitative	<ul style="list-style-type: none"> Users: participants with at least moderate levels of depression or anxiety symptoms on the PHQ-9^m or GAD-7ⁿ questionnaires, but without serious mental illnesses (eg, BD, schizophrenia), who were not receiving formal care and recruited upon completing free web-based MH self-screening surveys hosted by Mental Health America (N=28) 	To investigate how digital technologies can engage young adults in self-managing their MH outside the formal care system	Web-based asynchronous discussion; synchronous web-based design workshop

Study (author, year)	Design ^a	Perspective and population ^a	Objectives	Data collection methods ^a
Lipschitz et al [32], 2019	Cross-sectional, quantitative	<ul style="list-style-type: none"> Users: veterans enrolled in care at the VA Boston Healthcare System diagnosed with an anxiety disorder (including OCD), unipolar depressive disorder, or PTSD and who had at least 1 encounter in the local primary care clinic (N=149) 	To assess patients' interest in mHealth interventions for MH, to identify whether provider endorsement would impact interest, to determine reasons for nonuse of mHealth interventions for MH, and to identify what mHealth content or features are of most interest to patients	Custom survey
Mata-Greve et al [33], 2021	Cross-sectional, mixed methods	<ul style="list-style-type: none"> General users^f: essential workers during the COVID-19 pandemic or workers who were unemployed or furloughed because of the COVID-19 pandemic, recruited from a web-based research platform (N=1987) 	To document psychological stress, to explore DMHT ^o use in response to COVID-19-related stress, to explore the usability and user burden of DMHTs, and to explore which aspects and features of DMHTs were seen as necessary for managing stress during a pandemic by having participants design their own ideal DMHTs	Survey combining custom and validated measures (System Usability Scale, Use Burden Scale)
Melcher et al [34], 2022 and Melcher and Torous [4], 2020	Cross-sectional, mixed methods	<ul style="list-style-type: none"> General users^f: college students aged 18-25 years, recruited through social media and word of mouth (N=100) 	To examine why college students show poor engagement with MH apps and how apps may be adapted to suit this population	Custom survey; interviews
Schueler et al [35], 2018	Cross-sectional, mixed methods	<ul style="list-style-type: none"> General users^f: smartphone owners recruited from a research registry (N=827) 	To understand where users search for MH apps, what aspects of MH apps they find appealing, and what factors influence their decisions to use MH apps	Custom survey; focus group interviews
Schueler et al [36], 2021	Cross-sectional, qualitative	<ul style="list-style-type: none"> General users^f: participants who had used an app that allowed them to track their mood, feelings, or mental well-being for ≥2 weeks, recruited from a research registry (N=22) 	To understand motivations for and experiences in using mood-tracking apps from people who used them in real-world contexts	Semistructured interviews
Stiles-Shields et al [37], 2017	Cross-sectional, qualitative	<ul style="list-style-type: none"> General users^f: participants recruited from web-based postings; approximately equal numbers of participants were above and below the criteria for a referral for psychotherapy for depression (N=20) 	To identify the barriers to the use of a mobile app to deliver treatment for depression and to provide design implications on the basis of identified barriers	Card sorting task
Storm et al [38], 2021	Cross-sectional, qualitative	<ul style="list-style-type: none"> Patients with diagnoses of schizophrenia, schizoaffective disorder, BD, or persistent MDD in active treatment at a community MH center (N=17) Peer support specialists at the same center (N=15) 	To identify stakeholders' perspectives on partnering to inform the software development life cycle of a smartphone health app intervention for people with serious mental illness	Semistructured interviews
Torous et al [39], 2018	Cross-sectional, quantitative	<ul style="list-style-type: none"> Outpatients attending psychiatric clinics; one clinic primarily treated mood and anxiety disorders, and the other primarily treated psychotic disorders (N=185) 	To understand how individuals with mental illness use their mobile phones by exploring their access to mobile phones and their use of MH apps	Custom survey
Zhou and Parman-to [40], 2020	Cross-sectional, mixed methods	<ul style="list-style-type: none"> Users: participants with mild or moderate depression with local privacy concerns when using MH apps, recruited from a research registry (N=40) 	To determine user preferences among the several privacy protection methods used in current mHealth apps and the reasons behind those preferences	Custom survey; interview

^aOnly information relevant to this systematic literature review is reported in this table.

^bMDD: major depressive disorder.

^cBD: bipolar disorder.

^dOCD: obsessive-compulsive disorder.

^eMH: mental health.

^fGeneral users are participants who were not necessarily diagnosed with indications of interest.

^gASD: autism spectrum disorder.

^hHCP: Health care provider.

ⁱmHealth: mobile health.

^jPTSD: posttraumatic stress disorder.

^kVA: Veterans Affairs.

^lADHD: attention-deficit/hyperactivity disorder.

^mPHQ-9: Personal Health Questionnaire-9.

ⁿGAD-7: Generalized Anxiety Disorder-7.

^oDMHT: digital mental health technology.

Most frequently, studies focused on indications for mood, anxiety, or psychotic disorders (15/26, 58%), with other indications of focus including ADHD (2/26, 8%), ASD (1/26, 4%), and epilepsy (1/26, 4%). No relevant studies focused on Alzheimer disease were identified.

A total of 8 (31%) studies assessed the perspectives toward DMHTs of general population participants who were not necessarily diagnosed with relevant conditions [19,28,29,33-37]. Of these populations, several were identified as having an increased risk of MH conditions, such as patients with cancer [28], college students [29,34], deaf or hard-of-hearing individuals [19], and people who were unemployed or furloughed during the COVID-19 pandemic [33]. In addition,

1 (4%) study included a mix of patients who were above and below the referral criteria for psychotherapy for depression [37].

Thematic Analysis

Overview

Evidence was identified for all 5 themes included in the APA framework: engagement style (23/26, 88%), background and accessibility (16/26, 62%), privacy and security (13/26, 50%), therapeutic goal (12/26, 46%), and clinical foundation (8/26, 31%; Table 2). Five novel criteria were identified and added to the framework post hoc, 1 each under engagement style (forgetting or feeling unmotivated to use DMHTs) and privacy and security (personal image and stigma) and 3 under background and accessibility (willingness to pay, insurance restrictions, and cost savings compared with professional care).

Table 2. Studies reporting on each theme, subtheme, and criterion.

Subtheme	Criteria (study reference)
Engagement style	
Short-term usability	<ul style="list-style-type: none"> Ease of use [5,25,34,35] Available engagement styles [20-22,24,25,30,31,34,37]
Long-term usability	<ul style="list-style-type: none"> Alignment of app with needs and priorities [5,16-22,24,26,28-34,36-39] Forgot or unmotivated to use^a [5,25,31,37]
Customizability	<ul style="list-style-type: none"> No further stratification [20,24,28,31,32,34,35]
Background and accessibility	
Technical	<ul style="list-style-type: none"> Offline functionality [19,23,25,27,30,37] Compatibility with different operating systems^b Accessibility [5,19,25,27-29,32,35,38]
Business model ^b	<ul style="list-style-type: none"> Funding sources or conflicts of interest^b
Costs	<ul style="list-style-type: none"> Additional or hidden costs [26,37] Willingness to pay^a [16,25,34,35] Insurance restrictions^a [20] Cost savings compared with professional care^a [29] No further stratification [25-27,34]
Medical claims ^b	<ul style="list-style-type: none"> Specific medical claims^b Trustworthiness of source^b
Stability	<ul style="list-style-type: none"> Frequency of software updates [35,37]
Privacy and security	
No specific subtheme	<ul style="list-style-type: none"> No further stratification [34,36,37]
Data collection and storage	<ul style="list-style-type: none"> Ability to opt out of data collection or delete data^b Data storage location^b Security associated with collection, use, and transmission of sensitive data (including personal health information) [5,19,27,29,32]
Privacy policy	<ul style="list-style-type: none"> Transparency and accessibility of privacy policy [34,35,38] Declaration of data use and purpose [34] Data sharing with third parties [25] Systems to respond to potential harms or safety concerns^b
Personal health information	<ul style="list-style-type: none"> Description of use of personal health information [34] Personal image and stigma^a [5,25,29,40]
Security measures	<ul style="list-style-type: none"> Security systems used [30,35,40]
Clinical foundation	
Impressions of use	<ul style="list-style-type: none"> Accuracy and relevancy of app content [25,26] Alignment in app appearance and its claimed purpose^b
User feedback	<ul style="list-style-type: none"> Evidence of specific benefit from user feedback or user research studies [27,35] Validation of app usability and feasibility^b
Clinical validity	<ul style="list-style-type: none"> Supporting sources or references for use cases of the app [34,35] Evidence of specific benefit [27,34-36] Evidence of effectiveness or efficacy [32,34,37] Clarity in functional scope^b
Therapeutic goal	

Subtheme	Criteria (study reference)
Clinically actionable	<ul style="list-style-type: none"> Positive change or skill acquisition [5,18,26-28,30,31,34,36] Ease of sharing and interpretation of data [25-27,30]
Therapeutic alliance	<ul style="list-style-type: none"> Possibility for collaboration with an HCPc [5,21,22,27,34,36] The therapeutic alliance between patient and HCP [5,26]
Data ownership, access, and export ^b	<ul style="list-style-type: none"> User ownership of data^b Opportunity for sharing of data with electronic medical records and other data tools (Apple HealthKit, Fitbit)^b Opportunity for use with a provider and ability to export or transfer data^b

^aNovel findings that emerged from this systematic literature review.

^bThese subthemes and criteria were included in the American Psychiatric Association's framework but were not reported on by studies included in this systematic literature review.

^cHCP: health care provider.

Theme 1: Engagement Style

Engagement style was the most reported theme, with evidence identified from 23 (88%) of the 26 studies. Engagement style encompasses how and why users do or do not interact with DMHTs. The long-term usability subtheme was reported by 96% (22/23) of studies, short-term usability by 12 (52%) studies, and customizability by 7 (30%) studies. Findings from short- and long-term usability subthemes were highly interconnected.

A total of 4 studies reported that ease of use promoted short-term DMHT engagement. In the study by Schueller et al [35], 89.6% of a general population of smartphone users reported ease of use for MH apps as "important" or "very important," and users qualitatively reported dislike of "overwhelming," difficult-to-navigate apps. In addition, users valued apps that were "simplistic" [34], fit into their daily schedules, and were available when needed (eg, during acute symptom experiences) [5,25]. Select supporting qualitative data are presented in Table 3.

Table 3. Select key quotes identified for systematic literature review findings.

Subtheme and criteria: findings	Key quotes
Engagement style	
Short-term usability	
Ease of use	<ul style="list-style-type: none"> “I like short exercises. I can use them in different places.” [Patient in routine behavioral health care] [5] “Whenever I have one of those outbursts and frustration, I can just open it up, say ‘Okay, what’s my first step?’” [Male veteran, aged 26 years] [25]
Available engagement styles: use of animation and visuals	<ul style="list-style-type: none"> “They love badges. And decorating their avatars, like getting a new hat...So, they’re very motivated to get through their modules when they get to earn something at the end.” [Pediatric behavioral health clinician] [30] “It could become visually distracting—children preferring the animation rather than actually creating genuine, communicative messages.” [Caregiver or speech-language pathologist for children with ASD^a] [20]
Long-term usability	
Alignment of app with needs and priorities: gamification	<ul style="list-style-type: none"> “I’ve seen some kid clients come alive because they’re excited because they wanna beat their score. And just helping them like, ‘How do you have to communicate? You have to keep talking. You have to keep going.’ It’s helped with that.” [Pediatric behavioral health clinician] [30]
Alignment of app with needs and priorities: anxiety management	<ul style="list-style-type: none"> “App features that could help to reduce anxiety, for example, guided meditation, breathing exercises, or positive affirmation [may be] useful.” [Community MH^b center peer support specialist] [38] “Stuff that’s purely motivational...can feel alienating if I’m depressed...but focusing on something specific, like doing a breathing exercise...would be cool.” [Patient with anxiety or depression] [31]
Alignment of app with needs and priorities: tracking mood, symptoms, or sleep	<ul style="list-style-type: none"> “They [the adolescent] can bring it up on their phone...and we look at just is she daily fluctuating? If so, what happened during that day?” [Pediatric behavioral health clinician] [30] “I don’t know...if he’s good or he’s getting better or worse or anything like that. Just everything being simple in one place, and just hit a couple of buttons and not have to write anything down will be very good.” [Caregiver of a child with ADHD^c] [26]
Alignment of app with needs and priorities: social media-like features	<ul style="list-style-type: none"> “I like hearing other people’s stories and what they did, and it kind of helps me feel a little better. And I kind of like bounce off it and do what they did and try these new things that they’re doing.” [User with anxiety or depression] [31]
Alignment of app with needs and priorities: peer support and chat functions	<ul style="list-style-type: none"> “Incorporating lived experiences into a [smartphone] app and organize the [intervention] process to address lived experience because that’s what it’s all about.” [Community MH center peer support specialist] [38] “So maybe the bipolar individual also has access to the same app and then so they talk to each other...That way when I get home, I know ahead of time, it was an okay day today...Or if it was not a good day ok, so I know that I need to come in a little more reserved.” [Spouse of an individual with BD^d] [24]
Forgot or unmotivated to use ^e	<ul style="list-style-type: none"> “For someone who may be severely depressed, or someone who needs help, [writing messages] is almost like hard to do. Because if they’re having a hard time motivating or encouraging themselves, they might not feel like this is something they could do.” [User with anxiety or depression] [31] “I notice a good number of patients mentions they did not continue using in home. [...] Maybe because this area is still new for patients?” [Routine behavioral health care staff] [5] “[My son] has one of those crazy little phones that you can do everything with. I just don’t have an interest.” [Female veteran aged 57 years] [25]
Background and accessibility	
Technical considerations	
Accessibility: mobility barriers	<ul style="list-style-type: none"> “They can’t figure out why my hands shake so bad...so trying to use a smartphone [is frustrating]...I don’t have a whole lot of feeling in my hands.” [Male veteran aged 40 years] [25]
Accessibility: technical literacy	<ul style="list-style-type: none"> “I haven’t gotten acclimated to a smartphone yet...the technology is kind of difficult to navigate.” [Male veteran aged 66 years] [25]
Offline functionality: internet and mobile data access as a barrier to use	<ul style="list-style-type: none"> “[A young person’s smartphone] is normally one of the first things that get taken away if they do have a bad day. So, this is the thing you can use when you’re having a bad day to calm down, but then mom and dad won’t let you use it because you had a bad day.” [Pediatric behavioral health clinician] [30] “There have been times I think people have suggested, ‘Check this app out, check that app out,’ and for the most part I don’t think I have...I do only have so much data.” [Patient receiving psychiatric care] [23]

Subtheme and criteria: findings	Key quotes
Costs	
Willingness to pay ^e	<ul style="list-style-type: none"> “If they don’t have the free trial and they want money, I’m not even gonna look at it. I’m not gonna pay for something before I’ve gotten the chance to see if it’s gonna work for me or not.” [General user, smartphone owner] [35] “...[T]hey gave the option to pay \$50.00 a year. And I did that, because I liked the idea of what they were trying to do.” [General user, smartphone owner] [35]
Privacy and security	
Data collection and storage	
Security associated with collection, use, and transmission of sensitive data (including personal health information)	<ul style="list-style-type: none"> “I’m worried about my data.” [Patient in routine behavioral health care] [5] “Any apps that terms and conditions you’re forfeiting your information as soon as you click to that to anything so and I’m not worried about getting identity theft.” [Patient with current or prior depression diagnosis] [27]
Privacy policy	
Transparency and accessibility of privacy policy	<ul style="list-style-type: none"> “To use a smartphone app with a client I would want to make sure it’s secure before going any further.” [Community MH center peer support specialist] [38]
Personal health information	
Personal image and stigma ^c	<ul style="list-style-type: none"> “I worry about my virtual image. I’d feel more comfortable using an app from CHA^f that is protected in the same way my EMR^g is protected.” [Patient in routine behavioral health care] [5]
Security measures	
Security systems used	<ul style="list-style-type: none"> “The app doesn’t read as something like, My Personal Diary...it reads as something that you might just pass by if you don’t know what its intention is, which can be good for teenagers who are afraid of people looking into their stuff.” [Pediatric behavioral health clinician] [30]
Therapeutic goal	
Clinically actionable	
Positive change or skill acquisition: apps that impart skills and encourage positive change, in an easy way	<ul style="list-style-type: none"> “Great way to have patients practice exercises between sessions; both provider and patient happy to have concrete tool.” [Routine behavioral health care staff] [5] “I almost wonder, like, if you logged in, what would you like to address today, like, symptom management versus stress...You almost need, like, an emergency toolkit and then you almost need, like, your day-to-day stuff.” [HCP^h in cancer care] [28]
Ease of sharing and interpretation of data: increase of engagement and symptom reporting	<ul style="list-style-type: none"> “[I] feel like sometimes I’ll give parents follow up things to do while I’m not there, and they’ll forget about it throughout the week, but because they’re on their phone or whatever so much throughout the week, I feel like we could send them reminders or this is what we need to do before the next week. I think that that would encourage them to be more engaged, at least in the process.” [Pediatric behavioral health clinician] [30]
Therapeutic alliance	
Therapeutic alliance between patient and HCP	<ul style="list-style-type: none"> “Sometimes I think my training in behavioral medicine allows me to create a different tool with the patient that is more specific to them.” [Routine behavioral health care staff] [5]
Clinical foundation	
Clinical validity	

Subtheme and criteria: findings	Key quotes
Evidence of specific benefit: HCP recommendations	<ul style="list-style-type: none"> • “My doctor tells me to use an app, I’m probably going to use it.” [Patient with current or prior depression diagnosis] [27]
Evidence of specific benefit: increased usage if supported by research, academic institution, or reputable professional society	<ul style="list-style-type: none"> • “I would trust an app supported by my university more than a random app I found online.” [General user, college student] [34] • “I think it would be helpful, too, to have like the American Psychiatric Association or something, one of those, the licensure bodies or whatever—if they had official recommendations or backing.” [General user, smartphone owner] [35]

Users valued DMHT features that aligned with their needs and priorities, as reflected by findings within the long-term usability subtheme. Across 9 studies, quantitative and qualitative findings demonstrated high interest in anxiety management features such as relaxation tools, breathing exercises, and mindfulness or meditation activities, and 10 studies identified interest in mood, symptom, or sleep tracking (Tables 3 and 4). While most studies (24/26, 92%) focused on MH, patients with epilepsy also reported high interest in features to record seizure dates and

types [17]. Importantly, users in 2 studies emphasized the need for developers to tailor DMHTs to the needs and priorities of the target population (Table 3) [28,31]. Relatedly, mixed attitudes were reported toward positive affirmations and words of encouragement, with many users expressing interest but others emphasizing the value of a human component to DMHTs or cautioning against blanket encouragement and automated messages that could feel insincere [19,25,31].

Table 4. Quantitative evidence related to anxiety management and mood, symptoms, or sleep tracking features.

^dMH: mental health.

^eDMHT: digital mental health technology.

^fMDD: major depressive disorder.

^gPTSD: posttraumatic stress disorder.

Both patients and caregivers expressed interest in psychoeducational content that aligned with their needs and priorities. When surveyed, >60% of veterans with anxiety or major depressive disorder (MDD), patients with epilepsy, young adults with psychosis, and essential and furloughed workers during the COVID-19 pandemic expressed interest in relevant psychoeducational content [17,22,32,33]. In contrast, only 4% of college students in another study reported using an MH app for information about MH, although an MH diagnosis was not required for study participation [29].

Caregivers of young adults with psychosis, caregivers of children with ADHD, and spouses and partners of people with bipolar disorder (BD) were all interested in information related to caring for the individual with the given disorder, such as information on psychological and pharmacological treatments, symptoms and symptom changes, and the MH system [21,24,26]. Comparatively smaller, but still notable, proportions of caregivers of patients with psychosis were interested in caregiver-focused information; for instance, 62% to 69% were interested in relaxation exercises, stress and mood management, and community events for caregivers, while 85% to 90% were interested in the aforementioned patient-focused information [21].

Information delivery–style preference was captured under the short-term usability subtheme. One study in young adults with psychosis and another study with their caregivers revealed that delivering information in a variety of formats was important; when presented with nonmutually exclusive options, >50% of both populations were interested in text content, video content, audio content, and discussion boards [21,22].

Social interaction promoted long-term engagement. Qualitatively, 3 studies found that users valued learning about similar experiences from others via social media–like features, which normalized their experiences and could provide new

symptom management strategies (Table 3) [28,31,36]. Similarly, 67% of both young adults with psychosis and deaf or hard-of-hearing survey participants (N=9) reported interest in peer support via chat features [19,22]. However, a comparatively smaller proportion of veterans with anxiety or MDD (48.3% of the full cohort and 51.3% of the smartphone user subgroup) were interested in peer support [32].

Overall, users endorsed social features to support their MH. In the study by Casarez et al [24], spouses and partners of people with BD likewise desired features to communicate with other caregivers and also emphasized that DMHTs could facilitate conversation and understanding with patients, a sentiment echoed by peer support specialists by Storm et al [38] (Table 3). However, one oncology HCP cautioned that similar to support groups, “very strict guidelines of what is said” should be implemented to manage potential risks from shared social media–like content, although little additional context was provided [28].

Spouses and partners of people with BD also suggested both in-app information on accessing professional resources and direct counseling for the patient at times when other support might be inaccessible [24]. More than half of all workers, employed or unemployed during the COVID-19 pandemic, likewise endorsed links to resources, counseling, and crisis support as DMHT features, and 81.6% of young adults with psychosis endorsed a feature to communicate with professional experts [22,33]. Importantly, compared with patients attending public clinics, patients attending private psychiatric clinics expressed a higher comfort level for in-app communication with HCPs, suggesting demographic differences in the valuation of access to professional support through DMHTs [39].

A total of 9 studies reported an interest in DMHT reminders and notifications. Across 3 studies, >70% of patients or caregivers were interested in appointment reminders [17,21,22].

In addition, 73% and 68% of patients with epilepsy reported interest in reminders for medication refills and adherence, respectively [17]. Beyond apps, caregivers of patients with MDD, BD, and schizophrenia preferred an ingestible pill sensor that tracked medication adherence, physical activity, mood, and rest 9.79 (95% CI 4.81-19.9), 7.47 (95% CI 3.81-14.65), and 6.71 (95% CI 3.29-13.69) times more than a nondigital pill organizer, respectively [16]. Qualitatively, patients and caregivers also appreciated reminders, especially if reasonably timed or delivered via text messages [27,31].

Short-term DMHT engagement was also supported by games and graphics, which could communicate information in an accessible way [24], provide tools for stress management [17,33], and be used therapeutically with children [20,30]. However, some HCPs and caregivers expressed concerns that graphics and games may be distracting for certain children (Table 3) [20].

In a novel finding, 3 studies reported forgetfulness or lack of motivation as an influence on DMHT engagement. In some cases, disuse was related to stress, other MH symptoms, or poor technical literacy (Table 3) [5,25,31]. In contrast, “forgetting to use” DMHTs and “lack of motivation” were perceived as relatively small barriers to use in the study by Stiles-Shields et al [37].

The third subtheme under engagement style was customizability, which was generally valued by users; 70.9% of a general population of smartphone users noted customization was an important factor [35]. Similarly, 9.4% of all surveyed veterans and 10.9% of those with smartphones reported disliking a prior DMHT due to a lack of personalization [32]. Users specifically wanted to be able to opt out of irrelevant features, customize audiovisual and design elements, add personal notes to tracked mood data, and provide ongoing feedback to facilitate personalization [20,24,28,31,34].

Theme 2: Background and Accessibility

A total of 16 (62%) studies reported findings related to DMHT background and accessibility, which considers the developer of the DMHT, as well as functionality and accessibility. Of these, 12 (75%) studies reported on the technical considerations subtheme, 9 (56%) on costs, and 2 (13%) on stability.

Under technical considerations, 9 studies assessed diverse accessibility concerns. Broadly, Storm et al [38] emphasized that DMHTs should be developed in consideration of patients’ social, cognitive, and environmental needs to avoid overwhelming users. Specifically, 2 studies reported language as a barrier. Deaf or hard-of-hearing participants recommended visual content presentation, such as videos and icons, alongside text and American Sign Language translations where possible [19]. Similarly, when discussing English-only apps, 1 provider stated as follows: “language is a barrier for some [patients]” [5]. Mobility issues related to MH symptoms or other conditions and technical literacy, such as difficulties remembering passwords and navigating smartphones or apps, created accessibility barriers as well (Table 3) [5,25,27,28]. Additional concerns included apps that restricted use based on geographic location [19], user difficulty in finding relevant, useful apps

[32], and limited mobile device memory for downloading apps [5,19].

Offline functionality, reported by 6 studies, was also captured under the technical considerations subtheme. A majority (5/9, 56%) of participants included in the study by Borghouts et al [19] expressed concern about their mobile data plans when using their devices. Correspondingly, “availability of Wi-Fi” was noted as a top barrier to the use of apps for depression by Stiles-Shields et al [37], and several veterans in another study reported that home Wi-Fi connectivity facilitated app use by eliminating cellular data fees [25,37]. Quotes from patients and HCPs echoed the concern about apps without offline functionality (Table 3) [23,30].

Data fees were also captured under the costs subtheme, with hidden or additional costs described as a barrier to app use by 2 studies [26,37]. Parents of children with ADHD reported that difficulty paying phone bills could result in their phones being shut off, limiting DMHT use; one MH clinic administrator stated as follows: “We often encounter parents’ phones being shut off because they haven’t paid their bill...If the app were free or low cost, I imagine it could be very helpful” [26]. In addition to hidden costs, this quote identifies up-front app costs as a barrier. Quantitatively, more than half of a general population of surveyed college students expressed that cost was a top concern for the use of MH apps [34]. Qualitative findings from 2 additional studies likewise identified cost as a barrier to DMHT use [25,27].

Three novel cost attributes were identified by this SLR: willingness to pay, insurance restrictions, and cost savings compared with professional care. Four studies, 3 of which focused on apps, explored willingness to pay for DMHTs from a user perspective. Willingness to pay varied based on user preference; some surveyed college students and smartphone users among general populations valued free apps due to financial restrictions or uncertainty around app effectiveness, although 1 student commented that the quality of free trials might be inferior [34,35]. Some smartphone users also voiced a limit on how much they would be willing to spend for an app subscription (Table 3) [35]. Forma et al [16] found that caregivers were willing to pay US \$255.04 (95% CI US \$123.21-US \$386.86) more per month for a pill with an ingestible sensor that tracked medication adherence, physical activity, and rest and could connect to an app that also collected self-reported mood data. Moreover, the caregivers were willing to pay US \$124.50 (95% CI US \$48.18-US \$200.81) more per month for an app-connected pill organizer alone than for a nondigital pill organizer [16]. In contrast, some veterans expressed total disinterest in paid apps, with 1 user citing poor technical literacy (“don’t have the knowledge”) in addition to cost as affecting willingness to pay [25].

In another novel finding, a speech-language pathologist working with children with ASD preferred a single app including multiple features over separate apps for particular features due to insurance restrictions: “I agree that teaching Apps should be an in-App feature versus their own app because sometimes insurance doesn’t allow us to open the iPads purchased through insurance” [20]. Although no further detail was provided for

this finding, it suggests that there may be restrictions on the use of other apps on devices purchased under insurance, which may have implications for DMHT use in formal care settings due to the lack of financial support.

In a third novel cost-related finding, a small number of participants from a general population of students (3.6%) in one study preferred using an MH app to seeing an MH professional due to cost savings [29].

A total of 13% (2/16) of studies reported on the subtheme of app stability and technical difficulties, with crashes and poor display quality decreasing DMHT value [35,37]. Participants in the study by Schueller et al [35] reported that technical difficulties were often an issue for apps developed by medical institutions, which might be effective and safe but less usable than apps from other developers.

Theme 3: Privacy and Security

A total of 13 (50%) out of 26 studies reported findings related to the privacy and security theme, which covered the use and protection of user data by DMHTs. Subthemes were reported relatively equally: data collection and storage (5/13, 38%), personal health information (PHI; 5/13, 38%), privacy policies (4/13, 31%), general privacy (3/13, 23%), and security measures (3/13, 23%).

Quantitative and qualitative findings on general privacy (ie, evidence not categorized under any specific subtheme), the data collection and storage subtheme, and the privacy policies subtheme revealed heterogeneous concerns (Table 3). A total of 74% of a general population of college students reported privacy as a top concern for MH apps, although further details on the specific area of concern were unclear [34]. In the study by Stiles-Shields et al [37], participants were highly concerned with data access but less so with general privacy. Echoing the concerns about data collection and storage, 59.1% of veterans with anxiety or MDD in 1 study were concerned about in-app PHI protection [32]; however, a qualitative study in veterans with posttraumatic stress disorder, alcohol use disorder, or MDD reported that a relatively small number of participants expressed privacy concerns. In the latter study, reasons for the concerns included distrust in Veterans Affairs, belief that digital data are inherently not confidential, and fear of phone hacking [25]. From an HCP perspective, none of the surveyed behavioral health HCPs agreed with the statement “My patients are concerned about data security,” despite multiple patients within the same study reporting privacy concerns [5].

Still, privacy policies were important overall, with 70.5% of smartphone MH app users rating having a privacy policy as “very important” or “important” [35]. Melcher et al [34] found that although users valued data protection, some reported a lack of awareness about data privacy, and others were concerned about obscure privacy policies and PHI use. As noted in the data collection and storage subtheme, veteran concerns about government use of PHI were heterogeneous [25].

A novel valuation factor not included in the APA framework related to user concern with PHI privacy and security regarding MH diagnoses and MH app use is a desire to upkeep their personal image or avoid stigma (Table 3) [5,25,29,40]. For

instance, 21.1% of a general college student population preferred MH app use to seeing an MH professional due to anonymity or reduced stigma [29]. One participant in a study of Veterans Affairs health service users described access to professional care via MH apps as convenient because they could avoid disclosing their use of MH services to explain leaving work early for an appointment [25].

In line with the overarching concern about PHI privacy and security, users valued app security measures. Schueller et al [35] reported that 74.2% of users rated data encryption as “important” or “very important.” Users in another study perceived the level of privacy protection as the highest for apps using a combination of a generic app name (ie, not reflecting the indicated MH disorder); easily hidden modules; and secure, user-authenticated web portals for making module changes [40]. Behavioral health clinic staff echoed the importance of discreet MH app names (Table 3) [30].

Theme 4: Therapeutic Goal

There were 12 (46%) studies that reported on the factors relating to the integration of DMHTs with users’ therapeutic goals. The clinical actionability and therapeutic alliance subthemes were reported by 83% (10/12) and 58% (7/12) of studies, respectively.

A total of 9 studies reported the value of clinically actionable insights from apps where the users could acquire and practice new skills to make positive changes in their lives (Table 3). For instance, patient and caregiver app users reported interests in “daily tips,” “new ideas,” and “solutions or recommendations” for symptom management [26,27,36]. Furthermore, an app that could serve as a resource for multiple management strategies was preferable [26,28,31]. Quantitatively, 4% of patients receiving acute treatment in a partial hospitalization program for MH conditions, including mood and psychotic disorders, reported that the primary purpose of their DMHT use was therapy skills practice [18]. HCPs similarly appreciated that DMHTs could facilitate patients practicing skills outside of formal treatment sessions [5]. In particular, clinicians from a youth behavioral health clinic noted that DMHTs might be especially beneficial for young users because they could be conveniently and discreetly incorporated into their daily lives [30].

Users valued easy data sharing with clinicians, particularly for mood- or symptom-tracking features, which could improve communication and the accuracy of symptom reporting during clinical visits [5,25-27,34,36]. For instance, 53% of a general college student population believed that the potential to share information with their clinician was “one of the top benefits” of using DMHTs [34]. In addition, many HCPs reported active use or interest in the use of DMHTs in clinical practice to facilitate asynchronous communication and increase patient engagement with treatments outside of formal appointments; however, some preferred traditional care strategies for their personalization and flexibility (Table 3) [5,26,30].

Theme 5: Clinical Foundation

A total of 8 (31%) studies reported findings related to the clinical foundation of DMHTs, that is, their utility and appropriateness for patients. Clinical validity was the most reported subtheme,

with evidence identified from 6 (75%) studies; 2 (25%) studies reported on the user feedback subtheme and 2 (25%) on the impressions of use subtheme, which captured users' perceptions of app content as accurate and relevant.

Across subthemes, users valued evidence of DMHT benefit or efficacy from various sources. A total of 71.8% of surveyed veterans said that they would use a DMHT if they "saw proof that it worked" for their MH conditions [32]. Similarly, among the 811 general population participants surveyed, 69.5% ranked direct research evidence as "important" or "very important" for DMHT, and 66.8% ranked indirect research evidence the same [35]. Qualitative data identified recommendations from HCPs or academic institutions, as well as evidence of DMHT benefit from publications or research studies, as specific sources for clinically valid evidence of benefits (Table 3) [27,34,35].

In addition to academic and professional support, the user feedback subtheme captured user interest in whether DMHTs were beneficial for peers or recommended by other trusted individuals. Patients with depression reported that other users' experiences influenced their app use, with one user wanting to know "...if other people had success using it" [27]. Quantitatively, user ratings and user reviews were ranked as "important" or "very important" factors in DMHT use by 59.4% and 58.7% of the general population participants, respectively [35].

Quality Assessment

The risk of bias was overall moderate. Of the 14 studies including quantitative components, only 1 (7%) used relevant validated outcome measurement instruments [33]; all others used custom questionnaires. Of the 18 studies with qualitative components, 4 (22%) were at risk of selection bias due to participants being exclusively recruited using web-based postings and research registries [33-35,37], and only 1 (6%) considered the relationship between researcher and participant when interpreting the results [36]. Full quality assessments for qualitative and quantitative study components can be found in Tables S11 and S12 in [Multimedia Appendix 1](#), respectively.

Discussion

Principal Findings

This SLR aimed to identify and synthesize qualitative and quantitative evidence on how DMHTs are valued by users, payers, and employers in the United States. Evidence from users with or without diagnosed relevant disorders, caregivers, and HCPs was captured across a wide range of demographics. No study reported evaluating an app from a payer or employer perspective. Furthermore, all but one included study focused on mobile apps.

No relevant appraisals of DMHTs were identified from the FDA website searches; however, 8 relevant FDA approval labels or notifications for MH apps or guidance documents for industry and FDA staff were identified. The content of these materials overlapped with some valuation factors identified in this SLR, including evidence of clinical efficacy and safety, app maintenance, and privacy and security.

Engagement style, although not covered by the FDA materials, was the most reported theme by the studies included in this SLR and was found to overlap heavily with other themes. Engagement may be a key consideration for app developers, as app user retention can be low: 1 study showed that >90% of users had abandoned free MH apps within 30 days of installation [41]. Engagement is also a key clinical concern in terms of DMHT efficacy; one meta-analysis of 25 studies showed that increased use of DMHT modules was significantly associated with positive outcomes regardless of the target MH condition [42]. The findings of this SLR may therefore be informative to both DMHT designers and HCPs who integrate DMHTs into clinical care by providing insight on DMHT valuation and thus how use and benefit can be improved. For instance, users valued DMHTs that were easy to use and aligned with their needs and priorities, particularly through features that supported their therapeutic goals. In addition, content presented through multiple delivery modes, such as both text and visuals, promoted engagement as well as accessibility.

However, engagement and feature preference varied across populations. For instance, DMHT valuation was affected by technical literacy, which may relate to user demographics; in this SLR, veterans repeatedly emphasized technical literacy as a barrier to DMHT use [25]. Similarly, offline functionality may be more important for some users. Although 85% of the total United States population owns smartphones, only 59% of Medicare beneficiaries have access to a smartphone with a wireless plan. Moreover, beneficiaries who are older, less educated, disabled, or Black or Hispanic have even lower digital access [43,44]. These findings emphasize the importance of customizability and suggest that app development and selection in the clinical setting should consider the demographics of the target population, particularly in relation to ease of use and offline functionality.

Background and accessibility findings also identified up-front and hidden costs as barriers to DMHT use, with the willingness to pay varying among individuals. This has important implications for app development, considering that many MH apps currently on the market are direct-to-consumer sales and require out-of-pocket payment. App developers often take this approach as it does not require the accumulation of formal evidence of clinical benefit for FDA approval [45], but it may present a financial barrier to use for consumers.

Privacy and security, reported by 13 (50%) out of 26 studies, was a prevalent theme, with users primarily concerned with data and PHI security within apps. This finding reflects wider research; a 2019 review of 116 depression-related apps retrieved from iTunes and Google Play stores in 2017 found that only 4% of the identified apps had acceptable transparency in privacy and security, with many completely lacking a privacy policy [46]. Similarly, 39% of MH apps recommended by college counseling centers had no privacy policy, and of those with a policy, 88% collected user data, and 49% shared that data with third parties [4]. Most evidence identified in this SLR under this theme, as well as findings previously published in the wider literature, focuses on these remote privacy risks. However, local privacy concerns are also important to users. In particular, inconspicuous naming and the ability to hide sensitive modules

within MH apps were rated as highly important by both patients and HCPs to maintain user privacy. Users emphasized a desire to avoid the stigma associated with mental illness, which was also reflected by the findings in the engagement style theme: more young adults with psychosis were more interested in in-app messaging with other patients in psychosis recovery (67.1%) than a provider and family member together (47.3%) or their personal support network (59.8%) [22]. Similarly, youths were interested in apps that could be used discreetly in school or other public settings to avoid potential MH stigma. This is a key, novel finding of this SLR, considering that many app or DMHT components on the market are named after their target disorder.

The use of DMHTs to achieve therapeutic goals was discussed from patient, caregiver, and HCP perspectives, all of which valued DMHTs that had evidence of efficacy, presented clinically actionable information, and facilitated patient-clinician relationships. Of the 5 studies that explored how HCPs value DMHTs in clinical practice, 2 (40%) were restricted to the oncology or ASD settings and were not readily generalizable to wider MH settings [20,28]. In other studies, providers reported interest in using DMHTs to facilitate asynchronous communication with patients and their caregivers, promote patient skill practice, and improve care for children through the use of games and visuals [26,30]. However, while HCPs overall believed that DMHTs improved care, some believed that their clinical training allowed for care personalization beyond what DMHTs could provide. Feature customizability and receipt of input from HCPs and users during app development and testing may be a way to mitigate these concerns, as well as concerns about safety and efficacy, as many available apps do not appropriately address user health concerns [47].

Findings additionally suggested that training and resources on DMHTs would be beneficial to ensure that HCPs were equipped to integrate DMHTs into their practices [5]. Collaboration between DMHT specialists and HCPs, along with a shift from randomized controlled trials to effectiveness-implementation hybrid trials, may be a way to streamline the integration of DMHTs into clinical care and provide more training and resources for HCPs [30,48].

Strengths

This review followed a prespecified protocol and used systematic methods in line with the York Centre for Reviews and Dissemination guidelines [49] to conduct an exhaustive search of the literature, identifying evidence relevant to the review objectives from multiple databases and supplementary sources. The framework synthesis approach allowed for the inclusion and analysis of both qualitative and quantitative data, providing a detailed picture of not only what DMHT features users value but *why* they value them, especially in areas where valuation varies across patient demographics. In addition, the

APA framework is a robust model created with patient and HCP input that incorporates key valuation themes broadly shared by other frameworks and widely acknowledged in the literature [11-13].

Limitations

Methodological limitations should be considered when interpreting the findings of this SLR. Only publications in English and in United States populations were included. As perceptions of value are influenced by factors including cultures, laws, and health care settings, the findings of this SLR should not be generalized to other countries. For instance, trust in HCPs and rates of longstanding relationships between patients and primary care providers are lower in the United States than in many European nations [50,51], which could impact the type of support users want from DMHTs (ie, engagement style) or interest in DMHT integration with therapeutic goals.

In addition to the prespecified eligibility criteria, deprioritization strategies were implemented due to the large volume of the identified evidence, and this may have resulted in missing relevant articles. In particular, the deprioritization of secondary research and opinion pieces likely led to the exclusion of relevant discussion around payer perspectives and reimbursement, for which no evidence was included in this SLR. Furthermore, although unlikely, there may have been reporting biases in the included studies due to missing results, which this SLR was not able to assess.

This SLR identified no evidence for 3 subthemes included in the APA framework: business model (background and accessibility), which covers DMHT funding sources and potential sources of conflict, medical claims (background and accessibility), which examines whether DMHTs claim to be medical and the trustworthiness of their creators, and data ownership, access, and export (therapeutic goal), which includes sharing data with eHealth records or wellness devices (eg, Apple HealthKit [Apple Inc], Fitbit [Google LLC]). The valuation of these subthemes should be evaluated in future research.

Conclusions

In summary, app usability, cost, accessibility and other technical considerations, and alignment with therapeutic goals were the most reported valuation factors identified by this SLR. Many studies also reported user preference for apps that incorporated privacy and security features that provided protection from stigma. However, individual DMHTs and their features are valued differently across individuals based on demographics and personal preferences. MH apps should be developed and selected with these specific user needs in mind. Feature customizability and input from users and HCPs during development may improve app usability and clinical benefit.

Abstract

Background: In this digital age, children typically start using the internet in early childhood. Studies highlighted that young children are vulnerable to internet addiction due to personal limitations and social influence (eg, family and school). Internet addiction can have long-term harmful effects on children's health and well-being. The high risk of internet addiction for vulnerable populations like young children has raised questions about how best to prevent the problem.

Objective: This review study aimed to investigate the existing interventions and explore future directions to prevent or reduce internet addiction risks in children younger than 12 years.

Methods: The systematic review was conducted following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. We searched for relevant literature from 4 research databases (Scopus, Web of Science, PubMed, and PsycINFO). We included 14 primary studies discussing the interventions to prevent or reduce internet addiction risks in young children and their efficacy outcomes.

Results: The preventive interventions identified were categorized into four approaches as follows: (1) children's education, (2) parenting strategy, (3) strategic physical activity, and (4) counseling. Ten interventions showed promising efficacy in preventing or reducing internet addiction risks with small-to-medium effect sizes. Interventions that enhance children's competencies in having appropriate online behaviors and literacy were more likely to show better efficacy than interventions that force children to reduce screen time. Interventions that shift children's focus from online activities to real-world activities also showed promising efficacy in reducing engagement with the internet, thereby preventing addictive behaviors. We also identified the limitations of each approach (eg, temporariness, accessibility, and implementation) as valuable considerations in developing future interventions.

Conclusions: The findings suggest the need to develop more sustainable and accessible interventions to encourage healthy online behaviors through education, appropriate parenting strategies, and substitutive activities to prevent children's overdependence on the internet. Developing digital tools and social support systems can be beneficial to improve the capability, efficiency, and accessibility of the interventions. Future interventions also need to consider their appropriateness within familial context or culture and provide adequate implementation training. Last, policy makers and experts can also contribute by making design guidelines to prevent digital product developers from making products that can encourage overuse in children.

Introduction

Internet Addiction in Young Children

The internet provides powerful functions and benefits in supporting human lives and work. Globally, people spend more than 6.5 hours daily on online activities, meaning we spend almost a third of our lives using the internet [1]. In this digital age, most children begin using the internet since early childhood (younger than 5 years) [2-5]. The existing guidelines suggest that parents do not give their children access to internet devices before they are 2 years old [6,7]. The increasing access to the internet for young children raises concern about the negative impacts of internet overuse that could lead to addictive behavior. This emerging phenomenon is often referred to as internet addiction [8,9]. Behavioral disorders related to the internet and gaming activities have been recognized as a diagnosable mental health condition that needs further studies in the *International Statistical Classification of Diseases* and the *Diagnostic and Statistical Manual of Mental Disorders* [10,11].

Internet addiction is identified as a behavioral disorder caused by the excessive and uncontrolled use of the internet and digital devices, which can lead to physical, mental, and social problems [12,13]. Internet addiction could bring many negative consequences for children, including mental health problems such as anxiety, emotional instability, and depression [14,15]; physical health problems such as headaches, eye problems, and musculoskeletal pains [16,17]; declining performance [18,19]; sleep disorder [20]; antisocial behavior [21,22]; speech delay [23]; and hindering child growth and development [24]. Prior studies highlighted that children are considered vulnerable to internet addiction [8,9,25]. In 2022, the estimated global prevalence of internet addiction in children was 13.82% [26]. Multiple studies highlighted some reasons that underlie the high risks of internet addiction in young children, such as limited self-control [18], incomplete brain development [20], parental limitations [27,28], and influence from children's environment [29,30].

According to the Interactional Theory of Childhood Problematic Media Use, some distal, proximal, and maintaining factors jointly contribute to determining the risks of internet addiction in children younger than 12 years [31]. For context, the media referred to in the model is digital media that can be accessed and distributed through the internet [31]. The distal factors include the family socioeconomic conditions, family dysfunctions (eg, behavioral, academic, and social dysfunctions), and digital environments (eg, types of devices used, online activities, and content accessed). The proximal factors include the access, behavior, and attitude toward the internet and media use from the children, their family, and their peers. The maintaining factors include parent-child relationships, peers' influence on the internet and media use, and self-efficacy and self-regulation in children. Internet addiction in young children becomes more complex than in adults since the people around them (eg, parents, siblings, or peers) may significantly influence their online behavior [31,32]. In addition, prior studies were concerned about product features that could encourage children

to have more screen time, which can exacerbate the problem [33,34].

Related Work and the Objective of This Study

This review study was conducted to fill gaps in the discussion of the current state and future directions of preventive interventions for internet addiction in young children. We identified the gaps from the prior studies. Vondráčková and Gabrhelík [25] and Lee et al [35] conducted review studies about the prevention of internet addiction. They discussed the topic from several aspects, such as conceptual model, target groups, specific skills, characteristics, and environmental (or social). However, they did not discuss the preventive interventions and their outcomes. They highlighted that research into and development of preventive interventions for internet addiction are still scarce, especially for vulnerable populations like children. The finding from Vondráčková and Gabrhelík [25] suggested the need for more intervention studies of children by involving their environment (eg, parents, teachers, and peers). Young children typically have unique characteristics related to their internet use and risky online behavior, thus requiring appropriate intervention developed for them [31,36]. The previous findings indicate the need to conduct more investigation on appropriate preventive interventions for internet addiction in children.

Prior studies reviewed the existing internet addiction treatments for various target groups. Xu et al [37] and Kuss and Lopez-Fernandez [9] discussed psychological treatments and therapies for internet addiction. Ayub et al [38] discussed treatment modalities for addressing internet addiction in children and adolescents. Those studies similarly investigated internet addiction treatments' methods, domains, and effectiveness. The use of psychotherapies like cognitive behavioral therapy and electro-acupuncture were reported as promising treatments for reducing the symptoms of internet addiction [9,37,38]. However, there is a lack of studies discussing the preventive interventions for internet addiction in young children. Preventive interventions are essentially needed for children to prevent them from experiencing the negative consequences of internet addiction [8,25].

The high risks and prevalence of internet addiction in young children raised the urgency in exploring how best to prevent this problem. There is a need to understand how the existing preventive interventions have been developed, implemented, and assessed to prevent or reduce the risks of internet addiction in young children. Young children are categorized as persons 12 years and younger based on the theory of child cognitive development [39,40]. Children older than 12 years are generally classified as adolescents with different characteristics and internet behavior than younger children [31,40-42]. Therefore, this review study aimed to investigate the existing interventions and explore future directions to prevent or reduce internet addiction risks in children younger than 12 years. This review study contributed to filling the gaps in understanding the current approaches, efficacy outcomes, and strengths and limitations of preventive interventions to address internet addiction in young children. In addition, this study provided recommendations on

future intervention study opportunities to overcome the limitations of the existing interventions.

Methods

Overview

This review was conducted following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines to identify, report, and synthesize the evidence systematically [43]. We performed the systematic literature review in six key stages as follows: (1) determining the research questions, (2) defining the search strategy and conducting the literature search, (3) selecting the relevant studies, (4) assessing the risk of bias, (5) extracting the data, and (6) analyzing and reporting the data.

Research Questions

We formulated two research questions to achieve the objective of this study as follows: (1) What intervention approaches have been developed, and what are their efficacy outcomes to prevent or reduce internet addiction risks in children younger than 12 years? and (2) What are the strengths and limitations of the existing interventions to prevent internet addiction in children younger than 12 years?

Search Terms and Strategy

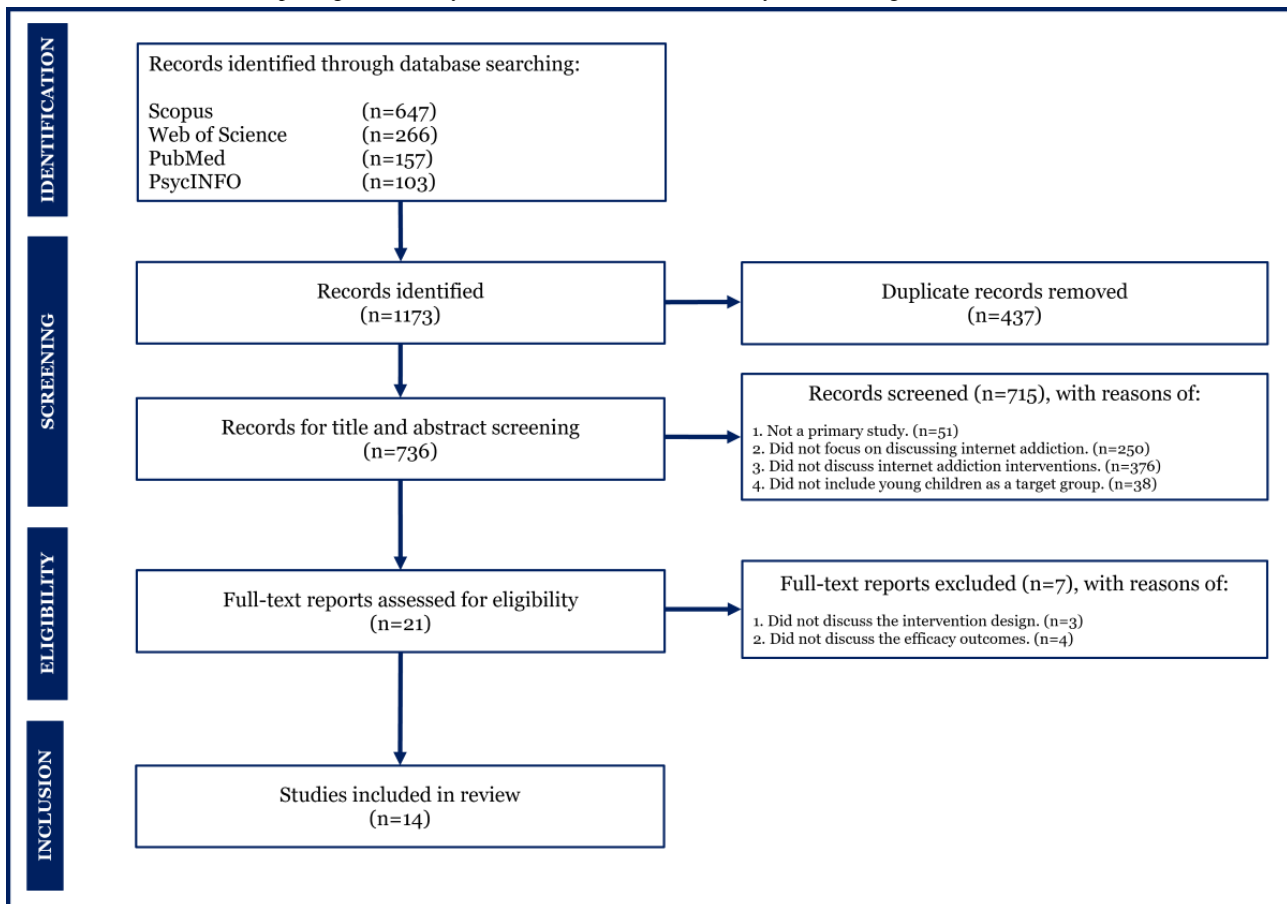

This study reviewed primary studies discussing interventions to prevent internet addiction in young children and their efficacy outcomes. In addition, some terms are commonly used to refer to the phenomenon that could lead to internet addiction, such as problematic internet use, compulsive internet use, and excessive internet use [9,12,44-46]. In this study, we also included those related terms in the literature search to obtain comprehensive evidence on the current state of preventive interventions.

We searched for relevant literature from 4 credible research databases (Scopus, Web of Science, PubMed, and PsycINFO). The literature search was conducted within the title and abstract from the databases with the following search string: internet AND (addiction OR problematic OR compulsive OR excessive) AND (prevent* OR intervention) AND (child*). We searched for peer-reviewed journals or conference articles written in English. The search was conducted on January 5, 2024. The term “internet addiction” was initially introduced in around 1996, and the conceptualization remained relevant to date [47,48]. Therefore, we searched for relevant literature using the publication timeframe between 1996 and January 2024.

Inclusion Criteria for Study Selection

The literature search used inclusion and exclusion criteria to select relevant studies. The inclusion criteria were as follows: (1) the intervention discussed in the study was intended to prevent internet addiction in children younger than 12 years; (2) the study discussed the intervention design and its efficacy outcomes—various types of efficacy assessments were allowed in our evidence search, such as randomized controlled trials [RCTs], quasi-experimental designs (QEDs), or other quantitative study designs; (3) the study was available in a full-text article; (4) the study was peer-reviewed; and (5) the study was written in English.

In this systematic review, we focused on discussing the evidence from primary studies. Therefore, we excluded some types of articles: (1) editorial, (2) review, (3) study protocol, and (4) commentary. Two authors (YT and AAM) performed the study selection, and all the authors checked the results. The screening and selection processes in this study are shown in the PRISMA flow diagram in [Figure 1](#).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram.

Risk of Bias Assessment

To assess the risk of bias, we evaluated each study using the Mixed Methods Appraisal Tool (MMAT; version 2018; McGill University) [49]. This tool has been proven valid and reliable for assessing the methodological quality of empirical studies with various study designs [50]. MMAT is suitable in this study since we included primary studies with multiple study designs.

The MMAT consists of 2 screening indicators for all study types and 5 unique quality indicators for each type of study (eg, quantitative RCT, quantitative nonrandomized, quantitative descriptive, qualitative, and mixed methods) [49]. Therefore, each study design has 7 indicators to assess. However, for a mixed methods study, there are 17 indicators to assess (2 screening indicators + 5 mixed methods indicators + 5 quantitative indicators + 5 qualitative indicators). The risk-of-bias assessment was conducted on the studies that had passed the screening and selection process. The assessment was initially performed by 2 authors (YT and AAM), and the final decisions were made based on the authors' consensus.

Data Extraction

The data extraction aimed to summarize the included studies systematically. The PICOS (Population, Intervention, Comparison, Outcome, and Study type) framework was used to systematically report the key evidence of each study [51]. The critical information of each included study was collected, such as authors, year, country, study design (including measurement scale and timeframe), participants, intervention

design, control condition, and key outcomes (Multimedia Appendix 1 [52-66]).

Data Analysis

The included studies in this review were thematically analyzed based on their intervention characteristics, approaches, and efficacy outcomes [67]. The mechanisms, strengths, and limitations of each intervention approach were also investigated to identify gaps and directions for future preventive interventions to address the problem. Recommendations for future studies were provided based on the findings of this study. The data extraction and analysis were performed by 2 authors (YT and AAM).

Results

Overview of the Studies

The initial literature search found a total of 1173 articles. After screening and selecting relevant articles (Figure 1), we included 14 studies that met all the inclusion criteria. The summary of included studies based on the PICOS framework is shown in Multimedia Appendix 1.

Although we searched publications using a timeframe between 1996 and 2024, all included studies that suited our criteria were conducted after 2013. The sample size ranged from 10 to 3141. Most studies (13/14, 93%) focused on children aged between 9 and 12 years (or older) as the target group. Only 1 study was intended for children younger than 7 years. The final samples came from Europe (7/14, 50%), Asia (6/14, 42.9%), and the

Middle East (1/14, 7.1%). Based on the country, most of the included studies were conducted in Turkey (n=5) and Hong Kong (n=3). The rest of the studies came from various countries, including South Korea (n=1), Germany (n=1), Lebanon (n=1), Norway (n=1), Taiwan (n=1), and Thailand (n=1).

This review explored the existing preventive interventions that have been assessed to understand the efficacy outcomes of the intervention discussed. Four testing designs were used in the studies, including RCT (n=5), QED (n=5), single-arm trial (n=3), and cross-sectional study (n=1). There was variability in the implementation duration, measurement timeframe, and scale used to measure the efficacy outcomes. The implementation of the interventions discussed in this study varied between 1 week and 6 months. The measurement timeframe was also varied between 1 week and 12 months. Some common internet addiction scales were used, such as Young's Internet Addiction Scale (n=3) [8] and Korean Internet Addiction Proneness Scale (n=2) [68].

The interventions discussed in the included studies were aimed at preventing or reducing the risks of internet addiction (n=9), internet gaming addiction (n=6), and problematic internet use (n=1). Two studies claimed that their interventions were intended to prevent internet addiction and internet gaming addiction [57,58], and 1 study developed an intervention to prevent both internet addiction and smartphone addiction [59]. The included studies involved children's environment (eg, families and schools) in their intervention design, such as teachers (n=7), parents (n=4), peers (n=2), and school nurses (n=1).

The included studies mentioned the theoretical underpinnings that underlie their intervention designs. The interventions used various well-established theories related to parenting (eg, parental mediation [52], positive parenting [55], and parenting styles [58]), psychosocial (eg, self-regulation [60], social cognitive [61], self-determination [62], ecological systems [62], family systems [59], and operant conditioning [58]), and learning (eg, participatory learning [60], media literacy [57], and gamified learning [53]).

Risk of Bias Assessment

The risk of bias assessment was conducted on the 14 studies (Multimedia Appendix 2). All included studies passed the 2 screening indicators for clear research questions and data collection to address the questions. Five RCT studies were assessed based on 5 quality indicators in terms of randomization, baseline comparison, outcome data, outcome assessor, and intervention adherence. Four studies provided adequate explanations of all required quality indicators. One study did not clearly explain one indicator about the comparison of the baseline conditions between intervention and control groups [52].

Nine studies were assessed using 5 quality indicators for quantitative nonrandomized studies (including QED, single-arm trial, and cross-sectional study designs). This includes participants' representativeness, measurement appropriateness, outcome data, confounders' accountability, and intervention or exposure administration. Seven of 9 studies met all the quality

indicators. Two studies did not provide adequate rationale about the representativeness of their samples to the target population [53,54]. One study did not clearly describe the potential confounders in their studies [54].

According to the risk of bias assessment results, 11 studies met all quality indicators, 2 did not meet 1 indicator, and 1 did not meet 2 indicators. We decided to include all the studies by taking into account their methodological limitations in extracting and analyzing the data.

Preventive Intervention Approaches and Their Outcomes

Overview

The preventive interventions included in this study were categorized based on the similarity of the working mechanism to achieve the objective. Four different approaches were identified from the existing interventions. These were children's education, parenting strategy, strategic physical activity, and counseling.

Children's Education (n=5)

The interventions in this category aim to prevent or reduce internet addiction risks in young children by enhancing their knowledge or skills. The educational materials provided through this approach can be divided into two main goals as follows: (1) improving children's digital literacy and encouraging healthy internet use (n=4) and (2) developing children's competencies in combating addictive behavior (n=1). The interventions in this category were developed as school materials or curricula, thus involving teachers in delivering the materials to their students in classes.

Three educational interventions developed limited meetings (4-8 sessions, 30-90 minutes each) for children to enhance their knowledge and skills about digital literacy and healthy internet use: School-Based Media Literacy [57], School- and Family-based Intervention [60], and Healthy Internet Use [61]. These programs were delivered as offline seminars, training, or classes to educate children about internet use, risky online behavior, and how to prevent and anticipate internet addiction. Although the goals were similar, they used different theoretical underpinnings to develop the intervention, such as media literacy, social cognition, self-regulation, and participatory learning. Based on the efficacy assessment, these interventions showed promising efficacy in lowering the risks of internet addiction or internet gaming addiction [57,60,61].

One intervention (Wise IT-use) used a hybrid format (combining 3-month online training and an offline workshop) to deliver similar materials [53]. This intervention was developed based on gamification learning and flow theory. It provided multimedia learning and flexible online training to enhance children's experience in learning the materials. This program showed promising efficacy in lowering the risks of internet gaming addiction ($\chi^2_4=42.89, P<.001; d=.5$) [63].

The last intervention in this category (B.E.S.T. Teen) aimed to equip children with youth development competencies to combat addictive behavior, including cognitive, emotional, social, and

behavioral competencies [63]. Similar to 3 other interventions in this category, it consisted of limited offline meetings (10 sessions, 30 minutes each) to deliver the materials in school settings. This intervention significantly lowered the odds of addictive behavior ($B=-0.61$, SE 0.19; odds ratio 0.55; $P<.002$).

Parenting Strategy (n=4)

This approach provides parental rules, skills, or guidelines to support parents in regulating children's internet use. Two studies in this category developed learning materials to improve parenting knowledge and skills to prevent risky internet use in children [55,62]. The Positive Parenting Program (Triple P) provided a set of seminars (3 sessions, 2 hours each) to educate parental guidelines on how to cope with online behavior problems and health care services in young children [55]. Developed based on the positive parenting theory, this program showed promising efficacy in reducing children's screen time and improving minor psychiatric disorders and family perception [55]. The Game Over Intervention was developed based on self-determination and ecological systems theories to provide parents with parental monitoring, parental care, and psychoeducation skills [62]. This intervention could reduce children's screen time and addiction risks. However, the control group also showed a similar reduction, so there was not enough evidence that the intervention was better than the control group [62].

Two other studies in this category developed and discussed parenting strategies to reduce children's internet use. The e-Discipline program used screen time as a discipline tool for parents to manage children's behavior and attitude [58]. This program was based on parenting styles and operant conditioning theories. Through this intervention, parents reward and punish their children by adding or reducing their children's screen time. Ironically, this intervention made their children more likely to exceed recommended screen time (2 hours a day) than before [58]. Therefore, this strategy was not promising in preventing risky internet use in children. The other intervention (Guardian Guidelines to Prevent Problematic Gaming) was developed based on the parental mediation theory [52]. This is a set of guidelines for parents or caregivers to manage children's device use at home (eg, children should not use digital devices in their bedrooms, children should not use digital devices more than 5 days a week, and no screen time during meals). This intervention was not promising because it showed no significant difference between the intervention and control group [52]. In addition, many parents involved in this study could not understand how to implement the guidelines properly and were not consistent in implementing the guidelines.

Strategic Physical Activity (n=4)

The strategic physical activity approach encourages children to do more physical activities in order to become less attached to online activities. This approach could also provide many positive developments for children, such as self-regulation, executive functions, and social engagement [56,59,64].

Two interventions used sports activities to reduce the risks of internet addiction in young children. The first intervention (Intensive Sports Activity) was a program based on optimism

theory where children were involved in multiple types of intensive sports activities for 12 consecutive weeks [54]. This study reported promising efficacy in reducing addiction risks ($t(185)=20.091$, $P<.001$), improving optimism ($t(185)=-13.205$, $P<.001$), and improving communication skills ($t(185)=-14.903$, $P<.001$) [54]. One similar program (Strategic Physical Activity) was a 12-week strategic basketball activity [56]. The intervention was developed based on the principle that increasing children's executive functions would reduce their addictive behavior. However, although the intervention successfully improved motor competencies ($P=.04$; $r=-0.38$), there was not sufficient evidence that the intervention reduced the risks of addiction.

The other 2 programs in this category focused on preventing addiction by encouraging children's physical activities through play and art activities with peers. Peer Relationship Enhancement and Traditional Children's Game interventions were developed to encourage children to interact with their peers through playing and making art [59,64]. The first intervention used social systems and family systems theories to build the intervention, whereas the second used the psychosocial development theory as a framework. Promising efficacy was reported by the Peer Relationship Enhancement ($P<.05$; $d=.4$) and Traditional Children's Game ($P<.05$; $d=.77$) interventions [59,64].

Counseling (n=1)

Counseling is professional assistance that gives advice or recommendations for coping with particular personal problems [69]. The intervention in this category prevents internet addiction through professional counseling sessions to help children reflect on their internet use, recognize their internet use problems, and find appropriate solutions. One study (Solution-Focused Intervention) was developed based on positive psychology theory to guide children in identifying problems, setting goals, and finding appropriate solutions relating to their internet use [65]. This short-term intervention (3-month implementation) consisted of 6 group interviews every 2 weeks. The intervention showed promising efficacy in lowering internet addiction risks ($P<.01$; $d=.5$) [65].

Strengths and Limitations of the Existing Approaches

The most frequent intervention approach to prevent internet addiction in young children is children's education ($n=5$). This approach showed great potential since all included studies in this category reported promising efficacy in preventing or reducing internet addiction risks. The main strength of this approach is that it provides children with understanding rather than forces them to engage in particular online behaviors (eg, reducing screen time and avoiding specific apps). In addition, this approach is flexible and can be attached to children's daily activities, such as at school or a child community center. The challenges may appear in providing appropriate materials for the children, training the provider to deliver the materials in exciting ways, and increasing awareness to educate healthy internet use in children [8]. Besides, the family's or parent's roles in educating and modeling healthy internet use could also significantly influence how children can implement the materials [27,28,70]. Educational interventions typically need initial

awareness and active commitment from children to be involved. In addition, the educational interventions included in this study are temporary programs (limited seminar, training, or workshop sessions).

Parents had a significant influence in providing internet access and controlling children's online behavior [31,71,72]. However, some parenting strategy interventions included in this study were not efficacious [52,58,62]. Parents can contribute significantly to preventing internet addiction through education, role modeling, or positive relationships with children [8,27,28]. Some limitations of the parenting approach may support the outcomes of the existing interventions: (1) parents had limited capacity, capability, and consistency in implementing the strategy [52,62]; (2) children with better knowledge about technology might outsmart their parents so that they could violate parental rules easily [27,62]; (3) forcing children's online behavior by implementing restrictions and limitations without giving proper understanding might not be effective and favorable [52,58,73]; and (4) harnessing screen time as a tool for rewarding or punishing children's behavior might not work to prevent internet addiction [58,74].

The strategic physical activity approach showed promising efficacy outcomes in preventing addictive behavior in children. The strengths of this approach are its ability to enhance peer relationships and smoothly shift children's attention to physical activities to reduce children's engagement with online activities. In addition, the interventions in this approach could bring additional positive values for children, such as self-regulation, executive functions, and social engagement [56,59,64]. However, all interventions in this approach provided limited physical activity sessions for children; thus, we could not determine the sustainable effects of the interventions. Matching the physical activities with children's interests would also be crucial because children may have various activity preferences (eg, some children may not like sports or arts).

The counseling approach utilized the capability of health practitioners to provide children with proper advice or recommendations to address internet addiction [8]. The intervention included in this review used a solution-focused approach in the counseling sessions to achieve the objective [65]. The use of counseling or psychotherapy approaches was common and promising in reducing the symptoms of internet addiction [37,38]. Several common approaches exist, such as cognitive behavioral therapy and family therapy [9,37]. However, there is a lack of discussion about the application and outcomes of those in preventing internet addiction in young children. The counseling approach needs the commitment of children and their parents or guardians to spend time, money, and energy attending the sessions. In addition, this intervention needs to be delivered by professional health practitioners, who may not always be available or accessible, especially in low-resource or rural areas [75]. Some parents or children may also have a negative stigma towards counseling or therapy because they may be considered different or "abnormal" [76].

Discussion

Principal Findings

This review study has provided an exploration of the current approaches, efficacy outcomes, and strengths and limitations of the existing interventions to prevent or reduce the risks of internet addiction in young children. Ten (71%) out of 14 preventive interventions for young children reported promising efficacy in preventing or reducing the risks of internet addiction. Those interventions showed small to medium effect sizes of their interventions [77]. However, 3 studies with promising efficacy did not provide effect size information in their articles (we have tried to follow up this information with the corresponding author via email).

According to the outcomes, interventions that enhance children's knowledge and skills in having appropriate digital literacy and healthy online behavior were more likely to show promising efficacy than interventions that force children to reduce screen time. Interventions with this objective showed promising efficacy, regardless of the approaches used (eg, children's education, parenting strategy, and counseling) [53,55,57,60,61,63,65]. Another study (Game Over Intervention) with a similar aim also reported a significant risk reduction [62]. However, there was insufficient evidence because a similar reduction was also found in the control groups. In contrast, interventions that forced children to restrict their screen time without proper education and communication were not efficacious [52,58]. It showed that instilling an awareness of healthy online behavior in children had a better effect than enforcing restrictions. Previous studies similarly found that shaping children's behavior would be more effective than forcing them to do certain behaviors [27,78]. Forcing the children too much may also provide a negative experience [74].

Interventions that shift children's focus from online activities to real-world activities also showed promise in reducing children's engagement with the internet, thereby preventing addictive behavior [54,59,64]. Those interventions leveraged children's social relationships with peers through various activities (eg, sports, plays, and arts) to prevent overengagement with online activities. Prior studies also highlighted the importance of improving peer relationships and encouraging more real-world activities in combating internet addiction in children [79-82]. In addition, it may be beneficial if the intervention can suit the physical activities with children's or families' preferences to increase its acceptability.

Prior studies highlighted the vital role of parents in preventing internet addiction in young children [27,28]. However, 3 parenting strategy interventions included in this study did not show promising efficacy [52,58,62]. We identified that the interventions might be ineffective for two main reasons: (1) inappropriate strategies and (2) the parents' failure to implement the intervention as intended. Regardless of the outcomes, involving parents is essential in developing interventions to encourage healthy internet use in children [27,83]. To overcome the first limitation, we suggest further studies to collaborate with related experts and health practitioners to develop appropriate parental guidelines. Technology may also be used

to provide tailoring or personalized strategies for parents based on their preferences or conditions [84,85]. To overcome the second limitation, we suggest further studies to provide adequate training and understanding for parents in implementing the strategies. Appropriate strategies would not be useful if parents cannot apply them well. Therefore, we should also consider the motivation, usability, and learnability factors when parents apply the strategies to their children.

According to the Interactional Theory of Childhood Problematic Media Use model, internet addiction in young children could be significantly influenced by factors related to the family and peers (eg, relationships, behavior, attitude, and media influence) [31]. The role of children's environment may improve or exacerbate the risks of internet addiction in young children. Therefore, involving people who can influence children's online behavior may be beneficial for the success of preventive interventions. The existing interventions in the included studies also involved children's families or schools in delivering the intervention. For instance, parents were trained to manage children's internet use, teachers delivered education materials and physical activity programs, peers collaborated to do physical activities together, and health practitioners provided professional counseling. However, no single intervention involved more than 1 stakeholder. Therefore, we recommend that the intervention design and implementation involve stakeholders that can significantly influence children's behavior. They should be used to reinforce positive online behavior in children and prevent negative influence [86]. For example, parents or teachers can be role models or educators, peers or siblings can be social facilitators, and health practitioners can create educational materials to combat addictive behavior. Their combined contributions will create positive environments for children to prevent addictive behavior.

The findings of this study showed that each intervention approach has some limitations in design and implementation that need to be further improved. Although some interventions reported promising efficacy outcomes, most of them were temporary programs with limited sessions and accessibility (eg, seminar or training, professional counseling, and strategic physical activity). Sustainable interventions may be needed to improve long-term effects in young children [87,88]. In addition, interventions that need much money or expert involvement (eg, counseling) may not always be accessible in low-resource regions [89]. Therefore, we suggest developing interventions with better accessibility to reach various families with different backgrounds.

Combining multiple approaches may improve efficacy in overcoming the limitations of each approach [90]. For example, we may develop an integrated intervention that facilitates families in educating healthy internet use, determining appropriate internet use regulations, and suggesting attractive physical activities to prevent their children from over-engagement with online activities. The use of digital technology may be beneficial in achieving these goals [91]. Digital technology can increase the capability, efficiency, and accessibility of the intervention in encouraging children to have healthy online behavior [92,93].

Some digital tools, such as parental control or digital well-being software, have been developed to support managing children's device use [88,92]. Parental control software could be beneficial in improving children's online safety and parental mediation [74,94]. However, in this study, we did not find studies that investigated the design and efficacy outcomes of digital interventions or digital tools to prevent internet addiction in young children. Some studies developed digital tools to manage children's internet use, but they were not developed specifically to prevent internet addiction, and their efficacy outcomes have not been tested [74,88,95]. Therefore, further studies are needed to investigate, develop, and evaluate appropriate digital tools to prevent internet addiction in young children.

The interventions discussed in this study mainly focused on educating or regulating young children as problem owners. However, there were concerns about digital product features or content that could encourage children to have more online activities [22,33,34]. Considering that excessive and uncontrolled online activities can cause internet addiction, we suggest future studies to investigate how product developers for children can contribute to preventing addictive behavior in their users. We encourage product developers, related experts, or policy makers to consider safe child-computer interaction in supporting internet addiction prevention in children. This can be manifested in various forms, such as making child-friendly design guidelines, interaction strategies, or policies.

In this study, we searched for evidence of the existing interventions for preventing internet addiction in children younger than 12 years. However, the interventions identified in this study mainly focused on children aged 9-12 years. There is a lack of intervention studies intended for children younger than 8 years. Since today's children start using the internet from early childhood (1-5 years old) [3-5], we suggest investigating more intervention studies focusing on children younger than 8 years. It is crucial to ensure children do not have addictive behavior in early childhood since optimal cognitive development typically starts from that period [96,97].

Limitations of the Study

This study may have some possible limitations. This systematic review focused on investigating relevant evidence about preventive interventions to address internet addiction in children. To date, the conceptualization between internet addiction and other related terminologies (eg, digital addiction and smartphone addiction) is still under debate due to some similarities in symptoms, mechanisms, and harmful effects [13,98,99]. Consequently, interventions for preventing related problems like digital or smartphone addiction may also have the prospect of preventing internet addiction. However, we did not include other related terms in this study to avoid biases. Future studies are needed to define and standardize this conceptualization issue before considering them as similar constructs.

In this study, we did not limit the regions where the studies were conducted to avoid selection biases. However, the studies included in this review mainly came from European and Asian countries. In this review, we did not get samples from some regions (eg, North America and Australia) due to our inclusion criteria to achieve the objectives of this particular study, which

might be a limitation of our study. For instance, we initially found 15 studies with relevant topics (preventing internet addiction in young children) from North America and Australia. However, we excluded them because they did not report their intervention design or efficacy outcomes. Accordingly, this study might have limited generalizations that must be considered when applying the findings. This limitation also indicated the need for future studies to develop, implement, and evaluate new or existing preventive interventions in different regions to extend our knowledge on preventing the problem effectively in multiple contexts.

Although the existence of addiction to the internet and online gaming has been recognized as a diagnosable mental condition (eg, in *Diagnostic and Statistical Manual of Mental Disorders* and *International Statistical Classification of Diseases*), the diagnosis may have a cultural limitation. For example, in the United States, internet addiction was considered a comorbid condition, not a primary diagnosis [100], and approximately 86% of internet addiction cases were comorbid with other conditions [101]. Other studies similarly reported the possible comorbidity of internet addiction with other diagnoses such as attention deficit and hyperactivity disorder and depression [102,103]. We recognize that considering the comorbid conditions of the participants is essential to have a more accurate diagnosis of internet addiction. However, only 1 study [56] in our sample screened the participants' comorbid conditions, which might be a limitation of our study. We suggest further internet addiction studies to pay attention to this comorbidity issue to have better results and validity.

The variability of the measurement scale and timeframe in the included studies raised challenges in comparing the efficacy outcomes of the interventions. Therefore, we could not perform a comparative analysis of the interventions in this study. Nevertheless, we have provided a deep exploration and discussion of the potential preventive intervention mechanisms and approaches as valuable insights to address this problem better in the future.

Conclusions

There is a growing concern about internet addiction in young children due to the increasing number of childhood internet users and their vulnerability to this problem. This review study has investigated and discussed the current approaches, efficacy outcomes, and strengths and limitations of the existing

interventions to prevent or reduce the risks of internet addiction in young children. This study identified 14 preventive interventions categorized into 4 groups based on their approaches to achieving the objective. This includes children's education, parenting strategy, strategic physical activity, and counseling. Ten interventions showed promising efficacy outcomes in preventing or reducing internet addiction risks in young children with small-to-medium effect sizes.

Overall, preventive interventions that enhance children's competencies in having appropriate online behavior and literacy were more likely to have better efficacy than interventions that force children to reduce screen time. Interventions that shift children's focus from online activities to real-world activities also showed promise in reducing children's engagement with the internet, thereby preventing addictive behavior. In this study, we have also identified the limitations of each intervention approach as valuable considerations in developing future interventions to address the problem. The current limitations include several domains, such as the temporariness of the program, accessibility, parental capability, and implementation.

The findings of this study suggest the need to develop more sustainable and accessible interventions in educating healthy internet use, determining appropriate internet use regulations for children, and suggesting attractive activities to prevent children from overengagement with online activities. Involving children's stakeholders (eg, parents, teachers, and peers) can be beneficial in reinforcing positive online behavior in children and preventing negative influence. The use of technology-mediated interventions is recommended to improve the capability, efficiency, and accessibility of the intervention. Further studies are needed to investigate, develop, and evaluate appropriate digital tools to prevent internet addiction in young children. In developing parental control interventions, we must consider the appropriateness of the strategies with familial contexts or cultures and provide adequate training or understanding for parents to apply the strategies as intended. Future interventions may also emphasize the role of product developers, related experts, or policy makers by developing child-friendly product design guidelines to prevent developers from making products that can encourage overuse. Last, future studies may be needed to develop preventive interventions for children younger than 8 years. This was lacking in the current literature but urgently needed, given that today's children start interacting with technology at a very young age.

Acknowledgments

We would like to thank the Indonesia Endowment Fund for Education and the Indonesian Center of Higher Education Funding for funding the research project associated with this study.

Abstract

Background: Smartphone-delivered attentional bias modification training (ABMT) intervention has gained popularity as a remote solution for alleviating symptoms of mental health problems. However, the existing literature presents mixed results indicating both significant and insignificant effects of smartphone-delivered interventions.

Objective: This systematic review and meta-analysis aims to assess the impact of smartphone-delivered ABMT on attentional bias and symptoms of mental health problems. Specifically, we examined different design approaches and methods of administration, focusing on common mental health issues, such as anxiety and depression, and design elements, including gamification and stimulus types.

Methods: Our search spanned from 2014 to 2023 and encompassed 4 major databases: MEDLINE, PsycINFO, PubMed, and Scopus. Study selection, data extraction, and critical appraisal were performed independently by 3 authors using the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. When necessary, we pooled the standardized mean difference with a 95% CI. In addition, we conducted sensitivity, subgroup, and meta-regression analyses to explore moderator variables of active and placebo ABMT interventions on reducing symptoms of mental health problems and attentional bias.

Results: Our review included 12 papers, involving a total of 24,503 participants, and we were able to conduct a meta-analysis on 20 different study samples from 11 papers. Active ABMT exhibited an effect size (Hedges g) of -0.18 ($P=.03$) in reducing symptoms of mental health problems, while the overall effect remained significant. Similarly, placebo ABMT showed an effect size of -0.38 ($P=.008$) in reducing symptoms of mental health problems. In addition, active ABMT (Hedges g -0.17 ; $P=.004$) had significant effects on reducing attentional bias, while placebo ABMT did not significantly alter attentional bias (Hedges g -0.04 ; $P=.66$).

Conclusions: Our understanding of smartphone-delivered ABMT's potential highlights the value of both active and placebo interventions in mental health care. The insights from the moderator analysis also showed that tailoring smartphone-delivered ABMT interventions to specific threat stimuli and considering exposure duration are crucial for optimizing their efficacy. This research underscores the need for personalized approaches in ABMT to effectively reduce attentional bias and symptoms of mental health problems.

Introduction

Background

Smartphone-delivered attentional bias modification training (ABMT) has emerged as a promising intervention for alleviating symptoms of mental health conditions amid a notable increase in their prevalence [1]. As mental health problems, such as anxiety, depression, and substance use disorders, continue to rise globally, traditional treatment options face challenges of accessibility and scalability [1,2]. In response to this growing concern, researchers are exploring innovative approaches such as ABMT, leveraging the ubiquity of smartphones to provide convenient and flexible support for individuals experiencing psychological distress. This systematic review and meta-analysis aimed to evaluate the efficacy of smartphone-delivered ABMT in addressing attentional biases and symptoms of mental health problems, with a particular focus on exploring the impact of different design approaches and methods of administration.

Statistical records have supported a substantial rise, with the number of people with mental health problems increasing from 80.8 million to 125.3 million between 1990 and 2019 [3]. This upward trend has prompted a growing inclination among individuals to seek in-person treatment options for addressing their mental health problems. However, face-to-face therapy also presents societal challenges, including heightened demands on health care systems, a pressing need for additional mental health professionals, and the potential for disparities in access to care [4-6]. Furthermore, various forms of stigma emanate from diverse sources, including families and friends [7]. People's increasing recognition of the significance of addressing mental health problems explains the urgent requirement for comprehensive and accessible mental health services to effectively tackle the broader societal implications of these conditions, alongside the need to protect individuals' privacy when seeking mental health assistance.

In addressing the rise in mental health problems, researchers have come up with evidence-based treatments such as pharmacotherapy and psychological interventions that involve medications and behavior modification, respectively [8]. For example, cognitive behavioral therapy (CBT) focuses on modifying behaviors and maladaptive thoughts through language and communication to address dysfunctional cognitions, fostering behavioral change and proving highly effective and versatile across various mental health conditions. Despite the effectiveness of CBT in addressing mental health problems among young individuals, approximately 40% do not exhibit a positive response to this intervention [9,10]. One of the key possible factors of ineffective CBT is the limitation of the youth's language and communication skills [8]. Therefore, there is continued interest in developing novel interventions.

As options for mental health treatment continue to develop, traditional modalities, such as cognitive restructuring and behavioral activation [11], along with newer approaches, such as third-wave acceptance and mindfulness [12] and ABMT,

have been widely used. Prioritizing attentional bias is crucial because it is an automatic process [13]. As such, ABMT can not only be effective in itself but also enhance the effectiveness of other therapeutic interventions and provide a targeted, evidence-based strategy for improving mental health outcomes [14-16].

ABMT stands out as a promising alternative, targeting cognitive processes using visual cues, such as directing attention away from threat-related or addiction-related stimuli. This stimuli-design approach allows ABMT to be more accessible and effective for individuals with limited language and communication skills, overcoming challenges posed by linguistic barriers in the CBT interventions [14,17,18]. Unlike traditional therapies such as CBT, which often involve interpreting complex sentences and verbal interactions, ABMT uses visual and cognitive tasks. For instance, patients respond to visual stimuli rather than needing to interpret text or verbal instructions. This approach reduces the cognitive load and makes it easier for patients to engage effectively in therapy sessions, regardless of their language proficiency or communication abilities. Research indicates that modifying attentional biases through ABMT can have long-lasting effects on emotional regulation and anxiety reduction [19]. ABMT can also be a fully automated, computer-based intervention designed to modify attentional preferences, making it highly scalable and easily accessible for clinical use [16]. In addition, ABMT does not require language communication, which can be particularly advantageous in treating patients who have language barriers or communication impairments.

Recent years have borne witness to a growing interest in ABMT as an empirically supported treatment strategy for an array of mental health problems, including anxiety, posttraumatic stress disorder (PTSD), depression, and substance use. ABMT revolves around the fundamental tenet of training attention away from threat-related stimuli for anxiety, depression, and PTSD and from addictive-cue stimuli for substance use, thereby fostering an internal competition between stimuli that evoke threats or cravings, respectively, and those that are neutral. This internal contest induces a recalibration of attentional mechanisms, leading to a diminished bias toward threat stimuli. The common application of ABMT, grounded in phenomenological characteristics, involves 4 primary experimental tasks: Posner task, Stroop task, dot-probe task, and visual search task [20].

In the context of psychological research, ABMT involves 2 key paradigms: active and placebo ABMT. Active ABMT strategically redirects attention by consistently guiding individuals to focus on neutral stimuli, thereby modifying attentional biases and reducing symptoms associated with anxiety and other mental health issues. In contrast, placebo ABMT serves as a control condition, maintaining the same task structure as active ABMT but placing the cue on both neutral and negative stimuli. This distinction allows researchers to assess the specific therapeutic effects of actively pacing cues to neutral stimuli in ABMT interventions while controlling for

nonspecific factors, such as task engagement or participant expectations. These 2 paradigms are pivotal in evaluating the effectiveness of computer-based ABMT and understanding its potential clinical applications [21,22].

The medium through which ABMT is administered has experienced a transformative evolution, aligning itself with the digital tapestry of contemporary health care. While traditionally executed through computer-based platforms, ABMT has recently embarked on a trajectory toward smartphone-mediated delivery [23,24]. This paradigm shift holds great promise, poised to address several pivotal challenges associated with the in-person mode of delivery. The use of smartphones as a conduit for ABMT promises to revolutionize the accessibility and privacy of mental health interventions. The ubiquity of smartphones transcends geographical constraints, rendering mental health support accessible to individuals across diverse locations. In addition, smartphone-based delivery holds the potential to attenuate the omnipresent specter of stigma, an entrenched barrier that has historically dissuaded individuals from engaging with traditional, in-person therapeutic interventions. The discrete and private nature of smartphone-delivered ABMT may sidestep potential stigma, potentially fostering a more expansive adoption of mental health interventions [25]. Furthermore, the incorporation of gamification within smartphone apps enhances user engagement, potentially bolstering treatment adherence and overall efficacy [26]. The gamified interface capitalizes on users' inherent motivation to participate, cultivates sustained engagement, and optimizes treatment outcomes.

Given the advantages of enhanced accessibility, reduced stigma, increased engagement through gamification, extensive customization, real-time feedback, and seamless integration into daily routines, this review focused on ABMT delivered through smartphones and not ABMT delivered through computers. Recent advancements in psychiatry have seen significant contributions from smartphone-delivered interventions for mental health problems. The previous meta-analyses used a narrow lens for the evaluation of smartphone-delivered ABMT, focusing on specific conditions [27-29]. They found that such interventions were effective in addressing mental health problems, improving quality of life, and reducing symptoms of depression and anxiety. The previous studies focused on smartphone-delivered ABMT on reducing the symptoms of specific mental health problems; however, understanding how ABMT operates across a spectrum of mental health symptoms can help evaluate its effectiveness more comprehensively in reducing symptoms of mental health problems. This review not only assessed the impact of ABMT on a wide range of symptoms of mental health problems but also delved into the mechanisms by which ABMT reduces attentional bias. This investigation included both the active and placebo forms of ABMT. By adopting this comprehensive approach, our review provides insights into how smartphone-delivered ABMT affects not only various mental health symptoms but also attentional bias, offering a more holistic perspective on its effects.

Objectives

This systematic review and meta-analysis aimed to analyze the efficacy of smartphone-delivered ABMT in reducing mental health symptoms and attentional biases and to understand how different ABMT design strategies influence these outcomes. The mechanisms by which ABMT operates are directly related to these objectives, as ABMT works by retraining the brain to reduce automatic attention to negative stimuli, thus alleviating symptoms of anxiety, depression, and other mental health issues. By modifying attentional patterns through repetitive training tasks, ABMT aims to improve emotional regulation. Different design strategies, such as the type of stimuli, delivery method, and training frequency, may impact the effectiveness of this retraining, making the exploration of these mechanisms essential for optimizing ABMT interventions and achieving better mental health outcomes.

Methods

Overview

Our systematic literature review adhered to the Cochrane recommendations [30] and followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines for the planning, execution, and reporting of this study (Multimedia Appendix 1) [31]. In addition, our review protocol was registered with PROSPERO (CRD42023460749).

Ethical Considerations

In this review, there was no need for informed consent or ethics approval because the data were extracted from previously published studies.

Search Strategy and Study Selection

In February 2023, MEDLINE, PsycINFO, PubMed, and Scopus were searched systematically for eligible studies published between 2014 and 2023 using keywords related to attentional bias and mobile apps: “attention bias” OR “cognitive bias” AND “smartphone” OR “smartphone application” OR “smartphone app” OR “mobile phones” OR “mobile application” OR “mobile app” OR “personal digital assistant.” These keywords and databases were chosen based on a related prior study [26]. This decision was made to extend their research on the efficacy and design characteristics of ABMT. The rationale behind starting the search in 2023 was based on 2 similar reviews on smartphone-delivered cognitive bias modification interventions, which indicated that the first smartphone-delivered ABMT was developed in 2014 [32,33]. In addition, while other internet-based ABMT interventions can be accessed on mobile phones, our focus is exclusively on interventions developed specifically for mobile phones. Recognized articles were exported to the web-based systematic review software Rayyan (Rayyan Systems, Inc) [34], and duplicates were removed. The remaining articles were reviewed for inclusion by 3 independent authors using Rayyan.

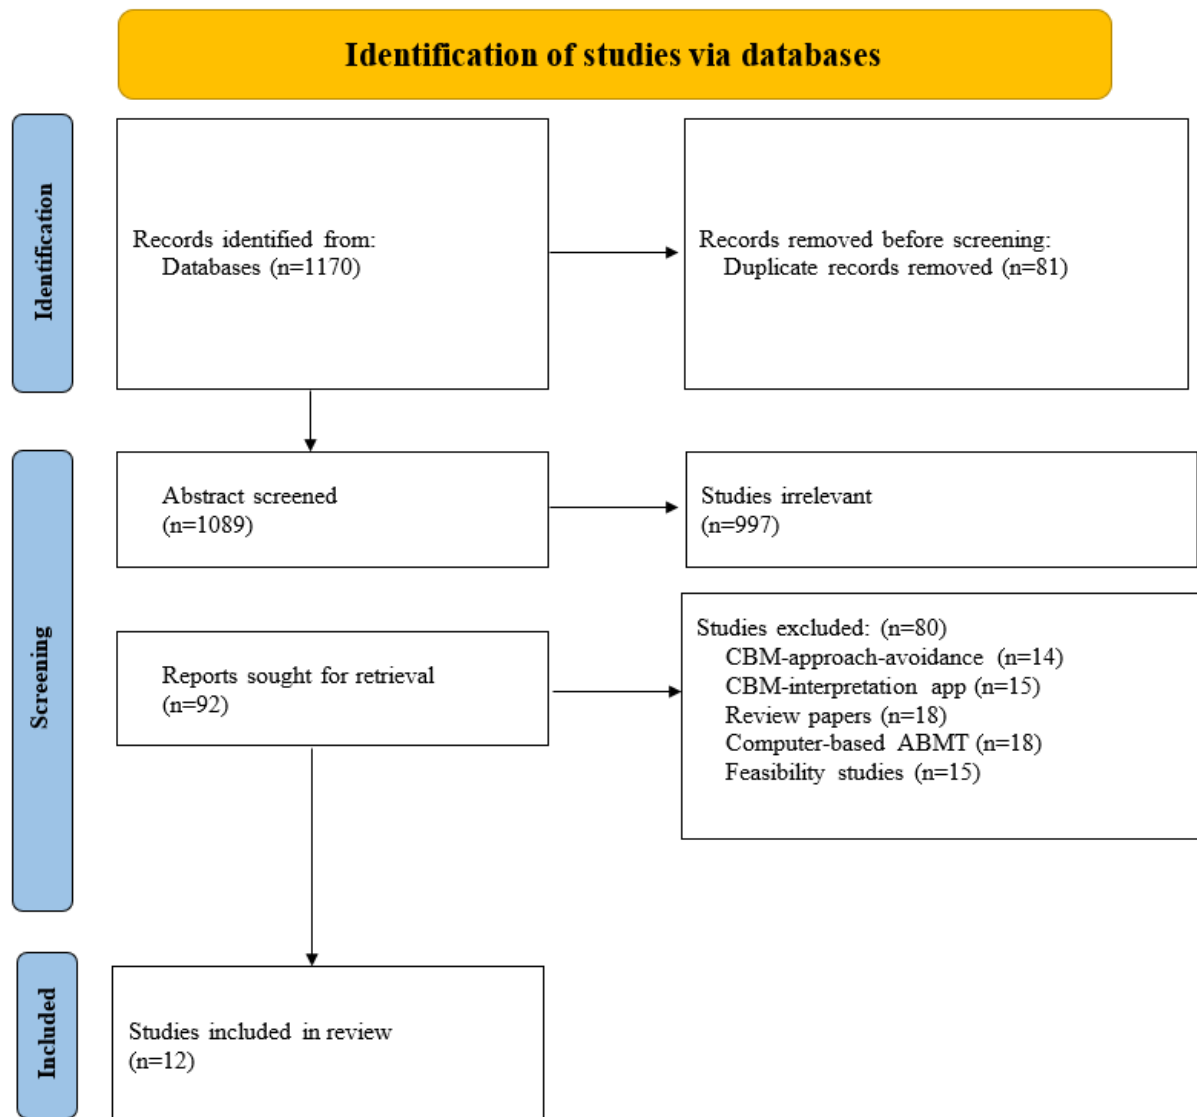

Inclusion and Exclusion Criteria

To be considered for inclusion in this review, studies had to satisfy the following criteria: they had to be written in English and assess ABMT for mental health symptoms, such as anxiety,

depression, stress, PTSD, or substance use (eg, smoking and alcohol consumption). ABMT interventions were explicitly defined and limited to those delivered exclusively through mobile devices. We included studies that met the following conditions: (1) ABMT was administered using a mobile device, such as a mobile phone, smartphone, or PDA, and (2) the delivery method took the form of a dedicated app or game. Articles that met any of the following criteria were excluded: (1) reviews, (2) interpretation bias modification delivered in any format, (3) avoidance bias modification delivered in any format, (4) web-based ABMT, and (5) computer-based ABMT. Web-based and computer-based ABMT interventions are similar in that both aim to modify attentional biases by training

individuals to shift their focus away from negative stimuli. They offer interactive tasks and can be accessed remotely. However, web-based ABMT is accessed through an internet browser, making it more flexible and accessible across various devices, whereas computer-based ABMT usually requires specific software installed on a computer, potentially limiting accessibility. The objective of this review was to investigate ABMT that can be accessed only through smartphones, excluding the option of using other types of devices, to understand its unique effectiveness and accessibility. Therefore, ABMT interventions delivered through other platforms were excluded from this review. Figure 1 provides a visual representation of the inclusion and exclusion processes.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Review and Meta-Analyses) flowchart. ABMT: attentional bias modification training; CBM: cognitive bias modification.

Data Extraction and Risk-of-Bias Assessment

We used the Rayyan management software to initially screen studies based on their titles and abstracts. Subsequently, 3 authors (BB, MO, and HB) independently performed data extraction based on the predetermined eligibility criteria. The disagreements that arose during this process were effectively resolved through collaborative discussion among the authors.

The data extracted from each included study encompassed several key elements: author information, publication date, sample size, the delineation of sample groups (active and placebo), the description of the type of treatment, specifics regarding experimental tasks (dot-probe task, Stroop task, or visual search task), the type of threat stimuli (faces, pictures, or words), characteristics of threat stimuli, details about the

number of stimuli and the type of stimulus array presented, the number of trials and sessions, stimulus presentation duration, and the outcome measurements used. Of the 5 authors, 2 (BB and YM) independently used the Cochrane risk-of-bias assessment tool to evaluate the risk of bias in the selected studies for the meta-analyses [35]. We also discussed the discrepancies to reach a consensus.

Data Analysis

We used the R Studio analysis packages (The R Foundation) [36] to conduct the meta-analyses. To perform these analyses, we used sample sizes for each group (active and placebo), along with means and SDs of mental health symptoms and attentional biases observed before and after the intervention (preintervention and postintervention assessments). These data were instrumental in calculating meta-estimates for both attentional bias levels and the reduction in mental health symptoms, encompassing anxiety, depression, stress, PTSD, or substance use. These meta-estimates were derived through random-effects meta-analyses.

The rationale for choosing random-effects meta-analyses is the anticipated substantial heterogeneity and aim to obtain a comprehensive overview of the true effect size while accounting for the variability among studies. Random-effects meta-analyses, fixed-effects meta-analyses, and Bayesian meta-analyses are common types of meta-analyses, each with distinct characteristics [37]. The choice of a random-effects model is often preferred when conducting a meta-analysis due to several key reasons. First, it is a flexible approach that can accommodate significant heterogeneity, which is common in meta-analyses involving diverse study populations and research questions. By allowing for varying effect sizes between studies, the random-effects model acknowledges the inherent variability in study results and provides more conservative estimates with wider CIs. This conservative approach is valuable, as it acknowledges the uncertainty associated with the underlying effect sizes and is less influenced by potential outliers.

The primary meta-analysis aimed to compute a comprehensive Hedges g effect size, accompanied by 95% CIs. This effect size was computed for both active and placebo ABMT interventions across all the studies included in our analysis. To interpret the effect sizes, we applied the Hedges g values of 0.20, 0.50, and 0.80, which correspond to small, moderate, and large effect sizes, respectively [38]. Heterogeneity was quantified using the I^2 statistic, and $I^2 > 50\%$ was considered evidence of substantial heterogeneity. We also used the inverse variance approach, a restricted maximum-likelihood estimator for τ^2 , and the Q-profile method to establish CIs for τ^2 and τ , ensuring a robust analytical framework. Publication bias was examined using funnel plots, and the presence of asymmetry was assessed using the Egger regression test [39]. If the Egger test yields a

significant result (indicating asymmetry), it suggests potential publication bias in the meta-analysis.

In addition, we performed separate sensitivity analyses using meta-regression with random-effects models in cases where there were enough study samples (at least 3), drawing reference from a previous study [27]. Sensitivity analysis is crucial for assessing the robustness of meta-analysis results and understanding the impact of potential sources of bias or variability, particularly in the presence of significant heterogeneity [40]. Moderators refer to specific factors or variables that can influence the relationship between the use of the smartphone-delivered ABMT intervention and its impact on mental health symptoms or attentional bias. These moderators can help researchers better understand the conditions under which the smartphone-delivered ABMT is effective and provide insights into the nuances of its outcomes. These meta-regression analyses allowed us to explore the influence of 5 moderators identified from the ABMT design characteristics reviewed, namely type of threat stimuli (face, images, or words); stimulus array type (left right or top down); design style (gamified or not gamified); display duration (200 ms or 500 ms) where applicable, along with the risk of bias (low or some concerns); and treatment groups (mental health and attentional bias) as additional considerations. These factors were identified as potential moderators.

Results

Study Selection

The initial search produced 1170 results, and we reduced this number to 1089 (93.08%) by eliminating duplicates. We excluded 997 (91.55%) articles after reviewing their titles and abstracts. Moving on to the full-text level, we reviewed the remaining 92 (8.4%) articles. Out of these 92 articles, we retained only 12 (13%) articles that were relevant to this paper. During the extraction process, we excluded 80 (87%) articles out of the initially considered 92. The article screening process is detailed in Figure 1. In Table 1, we have summarized the characteristics of the included studies. The sample sizes varied, ranging from 18 to 22,993 participants across different studies. The studies evaluated active and placebo interventions for 5 different symptoms identified in 24,503 participants. These 5 symptoms include anxiety, depression, stress, PTSD, and substance use. The treatments involved tasks used include dot-probe, Stroop, and visual search tasks, with threat or addictive-cue stimuli, including faces, words, and images. The duration of stimulus presentation was typically 500 milliseconds, and the number of stimuli varied between 2 and 16 per array type. The number of trials conducted in these studies ranged from 60 to 800. Overall, these studies encompassed a diverse range of sample sizes and characteristics, reflecting their focus on different mental health problems and intervention strategies.

Risk of Bias in the Studies

The risk-of-bias assessment for the included studies was conducted across 5 specific domains (Figure 2 [23,24,41-47,49,50] and Figure 3): *randomization, deviation from intended intervention, missing outcome data, measurement of the outcome, and selection of the reported result*. Among the 11 studies analyzed, the majority demonstrated a low risk of bias across all these domains, indicating a generally robust methodology in these investigations. Specifically, 9 (82%) out

of 11 studies were categorized as having a low overall risk of bias, implying a high level of confidence in their research findings. However, 1 (9%) out of 11 studies raised some concerns, primarily in the domains of randomization, deviation from intended intervention, and missing outcome data. In addition, 1 (9%) out of 11 studies showed a high risk of bias, particularly in the domain of measurement of the outcome. Our assessment of the risk of bias in individual studies is presented in Multimedia Appendix 2 [23,24,41-47,49,50]. These findings underscore the overall quality and reliability of the studies, with

the majority (9/11, 82%) exhibiting a low risk of bias in their design and execution, while a small proportion raised some concerns (1/11, 9%) or demonstrated a high risk of bias (1/11, 9%) in specific domains.

Figure 2. Risk-of-bias domains.

Study	Risk of bias domains					Overall

Figure 3. Overall risk of bias.

Effectiveness of Smartphone-Delivered Active ABMT for Mental Health Symptoms

In this comprehensive analysis involving 20 study samples (Figure 4 [23,24,41-45,47,50]), the pooled effect size for the study samples reflected a significant effect of active ABMT on mental health symptoms (Hedges $g = -0.18$, 95% CI -0.340 to -0.02 ; z score $= -2.27$; $P = .03$). Specifically, the negative value of the effect size suggests that the symptoms decreased after

the intervention. In addition, the statistical tests conducted confirm that this reduction is unlikely to have occurred by chance, suggesting that active ABMT can be effective in alleviating mental health symptoms. Significant heterogeneity was observed among the study samples ($Q = 6526.76$; $P < .001$; $I^2 = 99.7\%$). The subgroup meta-analysis revealed diverse effects of interventions across 5 distinct symptom categories, namely anxiety, depression, stress, substance use, and PTSD, with the varying impacts of interventions and heterogeneity. Sensitivity

analysis of the compiled *P* values presented in Multimedia Appendix 3 [23,24,41-47,49,50] showed that specific studies, including the studies by Dennis-Tiwary et al [43] (*P*=.02) and Robinson et al [50] (*P*=.005), emerged as influential contributors to the overall significance. Despite their exclusion, the

meta-analysis maintained statistical significance, reaffirming the primary findings' solidity. The test of the asymmetry funnel plots presented in Multimedia Appendix 4 showed no evidence of publication bias ($t_{18}=0.31, P=.76$).

Figure 4. Forest plots for active attentional bias modification training for mental health symptoms. PTSD: posttraumatic stress disorder; TE: treatment effect.

Effectiveness of Smartphone-Delivered Placebo ABMT for Mental Health Symptoms

In this analysis involving 14 study samples (Figure 5 [24,41-43,45,47,50]), the outcomes revealed a significant effect size (Hedges *g*=-0.381, 95% CI -0.8307 to 0.0403; *z* score=-2.66; *P*=.008), and significant heterogeneity was

observed among the samples ($Q=559.83; P=.002; I^2=99.7\%$). In essence, the negative value of the effect size suggests that the symptoms decreased after the intervention. In addition, the statistical tests conducted confirm that this reduction is unlikely to have occurred by chance, suggesting that placebo ABMT can be effective in reducing mental health symptoms. In the subgroup analysis, diverse effects of interventions across 5

distinct symptom categories, namely anxiety, depression, stress, substance use, and PTSD, were observed. Sensitivity analysis of the compiled *P* values presented in Multimedia Appendix 3 revealed that among the 14 study samples considered, the exclusion of 2 specific study samples, short active AMBT (*P*=.009) and long active AMBT (*P*=.006) from the study by Dennis and O’Toole [41], was found to exert substantial influence, significantly impacting the overall statistical

significance. Notably, even with the removal of these influential study samples, the overall analysis sustained its statistical significance. The results of the test of the asymmetry funnel plots are displayed in Multimedia Appendix 4. The results of the linear regression test conducted to assess funnel plot asymmetry yielded a nonsignificant outcome ($t_{12}=-0.35, P=.73$), indicating that there was no publication bias.

Figure 5. Forest plots for placebo attentional bias modification training for mental health problems. PTSD: posttraumatic stress disorder; TE: treatment effect.

Effectiveness of Smartphone-Delivered Active ABMT for Attentional Bias

In the analysis involving 11 study samples evaluating attentional bias, we observed a significant outcome using a random-effects model (Figure 6 [24,41-45]). The pooled effect size analysis for the study samples showed a significant effect of active

ABMT on attentional biases (Hedges $g=-0.17, 95% CI -0.28$ to $0.05; z score=-2.87; P=.004$). In summary, the negative value of the effect size suggests that the attentional bias decreased after the intervention, and the statistically significant effect did not occur by chance, suggesting that active ABMT is effective in reducing attentional bias.

Figure 6. Forest plots for active attentional bias modification training for attentional bias.

Significant heterogeneity was observed among all the samples ($Q=559.83$; $P=.004$; $I^2=98.2\%$). The analysis of the subgroups within the study samples showed different effects and significant heterogeneity among the 2 different category symptoms: anxiety and substance use. Sensitivity analysis of the compiled P values presented in Multimedia Appendix 3 revealed that even after the removal of specific study samples, the overall analysis maintained statistical significance, reaffirming the efficacy of ABMT in reducing attentional bias. The test of the asymmetry funnel plot is displayed in Multimedia Appendix 4. The Egger regression test found no evidence of publication ($t_9=-0.09$, $P=.93$).

Effectiveness of Smartphone-Delivered Placebo ABMT for Attentional Bias

In this analysis comprising 8 study samples, as shown in Figure 7 [24,41-43,45,50], the pooled effect size did not reflect a significant effect of placebo ABMT on attentional biases

(Hedges $g=-0.04$, 95% CI 0.200-0.13; z score=-.44; $P=.66$). The negative value of the effect size suggests that the attentional bias decreased after the intervention; however, the effect size was not statistically significant, suggesting that placebo ABMT is not effective in reducing attentional bias. Significant heterogeneity was observed among the study samples ($Q=779.84$; $P<.001$; $I^2=99.1\%$). The subgroups within the random-effects model unveiled varying effects and heterogeneity linked to the different symptom categories of anxiety and substance use. The sensitivity analysis based on the compiled P values in Multimedia Appendix 3 indicated that even when certain studies were excluded, the overall analysis did not attain statistical significance. The test of asymmetry funnel plot is displayed in Multimedia Appendix 4; however, the analysis was not conducted because the study samples were too small to be included in the meta-regression, but the funnel plot showed asymmetry.

Figure 7. Forest plots for placebo attentional bias modification training for attentional bias.

Moderator Analyses

The moderator analysis focused exclusively on anxiety and depression, given the limited samples in other subgroups. Only the anxiety subgroup is discussed, as the depression subgroup did not exhibit significant effects on all the moderating parameters, as shown in [Multimedia Appendix 5](#) based on the raw data provided in [Multimedia Appendix 6](#) [23,24,41-47,49,50]. Results of the moderator analysis using meta-regression showed that the choice of “stimuli” played a significant role in shaping treatment outcomes. Specifically, when “images” were used as stimuli for individuals with anxiety symptoms, a significant effect on anxiety reduction was observed, suggesting that this stimulus type may be particularly effective in this subgroup. In contrast, the use of “face” stimuli for patients with primary anxiety symptoms and “word” stimuli for those with anxiety and PTSD did not yield significant effects on reducing anxiety symptoms, and the use of “word” stimuli for those with anxiety related to PTSD did not yield significant effects on anxiety outcomes.

Moreover, the “display duration” of 200 milliseconds emerged as a significant moderator ($\beta = .436$; $P = .002$), indicating that shorter exposure durations may lead to more substantial reductions in symptoms, while a longer duration of 500 milliseconds showed a negative effect on outcomes ($\beta = -.537$; $P < .001$). The other factors, such as “stimulus array type,” “design style,” and “risk of bias,” did not exhibit significant moderating effects on anxiety outcomes within ABMT interventions. These findings illustrate the importance of tailoring ABMT interventions based on the specific type of threat stimuli and the characteristics of the target population to optimize their efficacy, thus highlighting the nature of ABMT’s impact on anxiety reduction.

Discussion

Principal Findings

Overview

This paper presents a systematic review and meta-analysis of 12 individual studies including 20 independent samples. The overarching goals were to (1) compute the overall effect sizes for active ABMT and placebo ABMT on the reduction of attentional bias and symptoms of mental health problems and (2) separately evaluate which ABMT design characteristics moderate the effect sizes in reducing mental health problems and attentional bias. Importantly, this analysis included only randomized controlled trial designs and study samples that included pre-post modification comparisons of mental health symptoms and attentional biases. Our study diverges from earlier reviews focused on gamification elements and commercialized apps by prioritizing the core phenomenological characteristics of ABMT: Posner task, Stroop task, dot-probe task, and visual search task. Embedding these established tasks in smartphone interventions ensures scientific rigor and enhances ABMT effectiveness. Furthermore, our research identifies current smartphone approaches and explores novel adaptations of these tasks for optimal integration into mobile platforms. This exploration provides practical insights for designers and developers, guiding interface design, interaction mechanics, and task presentation to boost engagement and adherence among mobile users. These insights are pivotal for advancing mobile-based ABMT, ensuring interventions are scientifically grounded and efficacious in enhancing mental health outcomes. In addition, our study represents the first meta-analysis focused on smartphone-based ABMT. Unlike previous reviews, we included both placebo and active designs to rigorously assess the efficacy of smartphone-based ABMT interventions. Using a randomized controlled trial design with a diverse participant

sample, we enhanced methodological robustness and applicability. These contributions set a high standard for future research in smartphone-based ABMT, aiming to improve the accessibility and effectiveness of mental health interventions broadly.

Overall Effect

Overall, this review found that using ABMT through smartphones had a small but significant impact (Hedges $g=0.17$), whereas Hakamata et al [51] reported a larger effect size (Cohen $d=0.51$). The studies by Heeren et al [52] and Hang et al [53] reported small effect sizes for computer-based ABMT in reducing anxiety, with Hedges $g=0.41$ for social anxiety and Hedges $g=0.26$ for anxiety disorders, respectively. It is important to note that the study by Hakamata et al [51] encompassed various delivery methods without a specific focus, while the studies by Heeren et al [52] and Hang et al [53] concentrated on the computer-based medium. In contrast, this review's investigation specifically centered on ABMT via smartphones. These results highlight that both smartphone-based and computer-based ABMT interventions can be effective in reducing social anxiety symptoms, despite variations in effect size. The effect size variation across media may be due to the difference in screen sizes between computers and smartphones. Exploring the differences in platforms for the delivery of ABMT will be insightful intervention for mental health problems. Despite variations in effect size between studies, the findings by Hakamata et al [51] reinforce the notion that design characteristics play a crucial role in determining the effectiveness of ABMT interventions, aligning with the observations of this study. This suggests that while the magnitude of the effect may differ, the underlying factors contributing to the efficacy of ABMT remain consistent across different research contexts. In essence, the emphasis on design characteristics highlights the need for the careful consideration of intervention parameters to optimize outcomes in ABMT research and practice. Furthermore, the meta-analysis of combined ABMT and CBT also showed small but significant effects on clinician-rated anxiety symptoms and attentional bias toward threat [54]. Smartphone-delivered ABMT showed similar effects to other mental health apps for anxiety and depression [27,55,56]. In contrast, the placebo ABMT showed a small and not significant effect size for reducing attentional bias toward negative stimuli (Hedges $g=-0.04$; $P=.66$), but there was a significant small to moderate effect size for reducing mental health for anxiety and depression (Hedges $g=-0.38$; $P=.008$).

Our findings on placebo ABMT revealed a significant and moderate effect size in reducing mental health problems but not attentional bias. Other studies have shown that both active and placebo ABMT interventions significantly reduce mental health problems [21,45,57], which supports our findings. These findings regarding symptom reduction across active and placebo ABMT interventions suggest a potential placebo effect, emphasizing the need for further investigation into the mechanisms driving these outcomes and the broader implications for understanding placebo treatment effects in therapeutic interventions.

The significant effects of both active ABMT and placebo ABMT on symptoms of mental health problems can be explained through several mechanisms supported by previous studies. Active ABMT works by specifically targeting and modifying attentional biases toward threat-related stimuli, which are often implicated in anxiety and other mental health conditions. This modification reduces cognitive load and emotional reactivity, leading to symptom reduction [58,59]. In addition, active ABMT enhances emotional regulation by training individuals to redirect their attention away from negative stimuli. In contrast, placebo ABMT may improve symptoms through expectation effects, where participants' belief in receiving effective treatment triggers neurobiological responses contributing to symptom improvement [60]. Moreover, the structured nature of placebo ABMT improves therapeutic engagement and support, enhancing feelings of control and self-efficacy [42]. Finally, the cognitive engagement involved in placebo ABMT tasks can improve cognitive functioning, indirectly benefiting mental health. These mechanisms collectively explain the significant effects observed in both treatment conditions.

The significant heterogeneity observed in the effectiveness of smartphone-delivered active ABMT for mental health symptoms across studies could be attributed to several factors. First, there are variations in study populations and sample sizes, ranging from small groups of 29 participants [43] to large samples of 22,993 participants [48], which could affect the generalizability and robustness of the results. Second, the type of mental health conditions addressed varies, with studies targeting anxiety, depression, PTSD, alcohol use, and substance use disorders, potentially leading to different outcomes based on the specific symptoms being treated. Third, the intervention protocols differ significantly; for instance, while most studies use the dot-probe task with face stimuli, others use the Stroop task with images or words or a visual search task. In addition, the duration of exposure to stimuli and the number of trials vary widely, from 60 trials [49] to 800 trials [44], which might influence the effectiveness of the intervention. These methodological differences, including those in the type of stimuli, the structure of the tasks, and the specific parameters of the intervention, contribute to the observed heterogeneity in the outcomes of these studies.

However, sensitivity analysis emerged as a critical tool in navigating this heterogeneity, allowing for a thorough examination of the robustness of the findings [27]. Despite the significant observed heterogeneity among the study samples, sensitivity analysis revealed that the meta-analysis maintained its statistical significance even after excluding influential studies. This indicates that the overall findings remained robust and reliable, despite the presence of variability across the included studies. By systematically assessing the impact of individual studies or study characteristics on the overall results, sensitivity analysis provided valuable insights into the stability of the meta-analysis outcomes.

Comparison of Smartphone-Delivered ABMT With Computer-Delivered ABMT

The current findings on smartphone-delivered ABMT and its effects on attentional bias and mental health symptoms,

particularly for anxiety and depression, are compared with mixed significant effects reported in other meta-analyses on ABMT delivered through other platforms, that is, computer-based (internet-based) ABMT interventions.

Considering computer-based ABMT platforms, the study by Heeren et al [52] primarily focused on their application for social anxiety disorder. The meta-analysis reported small but significant effect sizes for ABMT in reducing attentional bias (Hedges $g=0.30$) and social anxiety disorder symptoms (Hedges $g=0.41$ for training toward neutral stimuli vs control condition) after multiple sessions. The study also noted that the control conditions often performed similarly to the ABMT, suggesting a potential placebo effect or the nonspecific benefits of participating in a study. Similarly, the study by Hang et al [53] focused on computer-based ABMT but extended the discussion to children and adolescents with anxiety disorders. This meta-analysis found that ABMT had small but significant effects on clinician-rated anxiety symptoms (Hedges $g=0.26$) and attentional bias toward threat (Hedges $g=0.21$) but not on self-reported or parent-reported anxiety measures (Hedges $g=-0.08$). The control conditions used in these studies, such as attention control training, did not show significant effects, which contrasts with the significant effects seen in this study for placebo ABMT on reducing mental health symptoms for anxiety and depression.

This review's findings suggest a potential advancement in the delivery method of ABMT. The use of smartphones could increase accessibility and adherence to ABMT protocols, potentially enhancing their effectiveness. These results build upon the findings from the studies by Heeren et al [52] and Hang et al [53] by suggesting that the delivery method of ABMT (eg, via smartphone) and the nature of the control condition can significantly influence the outcomes of ABMT interventions. They also highlight the importance of considering placebo effects in the design and interpretation of ABMT studies, as nonspecific factors can sometimes produce significant improvements in mental health symptoms. This underscores the need for well-designed studies to carefully assess the specific contributions of ABMT techniques to changes in attentional bias and mental health outcomes.

Moderating Factors of ABMT Intervention

The moderator analysis conducted in this review comprehensively evaluated the effectiveness of ABMT design characteristics across various mental health problems, including anxiety, depression, PTSD, and substance use disorders. The analysis shows that certain characteristics, such as the threat stimulus type, spatial arrangement of stimuli, and duration of stimuli display, have an influence on ABMT's effectiveness. This finding is consistent with a previous meta-analysis that showed that the use of ABMT interventions may be owing to their varying design characteristics and optimal protocols (eg, task types, target stimuli, stimulus directions, and display settings) [61]. However, due to the limited number of study samples (<3) available in the other mental health problem categories, the analysis focused only on anxiety and depression. Delving into the intricacies of ABMT, we first explored the role of its design characteristics, including the type of threat stimuli,

the spatial arrangement of stimuli, and the duration of stimuli display, in influencing ABMT's effectiveness.

Given the findings from our moderator analyses highlighting the significant influence of various design characteristics on ABMT's effectiveness, there is a compelling rationale for exploring personalized approaches in future smartphone-based ABMT interventions. While our review did not directly analyze personalized ABMT due to the limited studies with personalized features, the identified moderating factors offer valuable insights into potential avenues for customization. For example, the choice of stimuli, spatial arrangement, and the duration of stimulus display emerged as critical factors influencing treatment outcomes. Building on these insights, future research could investigate how tailoring ABMT protocols to individual preferences and needs, based on these design characteristics, could enhance treatment efficacy. By developing personalized ABMT interventions that align with patients' specific attentional biases and cognitive profiles, we may optimize treatment outcomes and improve overall engagement and adherence. Therefore, we propose personalized approaches as a promising direction for further exploration in the field of smartphone-delivered ABMT interventions.

Personalization of ABMT Interventions on Smartphone Platforms

Personalization in the context of ABMT refers to the customization of intervention components to align with individual preferences, needs, and characteristics. This customization can encompass various aspects of the intervention, including the stimulus selection, presentation format, difficulty levels, and session duration. By tailoring the intervention to everyone, personalization aims to enhance engagement, relevance, and effectiveness, ultimately optimizing treatment outcomes.

The personalization of ABMT interventions on smartphone platforms and that of ABMT interventions on PCs can differ significantly due to the unique characteristics and capabilities of each device. However, the personalization of ABMT design can be achieved on both smartphones and PCs by adding the option of selecting the type of stimuli and duration of stimuli display. However, personalization on smartphone platforms tends to be more dynamic, context aware, and automated, leveraging the device's sensors and data processing capabilities to tailor ABMT interventions to the user's current context and needs.

Smartphone-based ABMT offers unique advantages for personalization compared to traditionally delivered (computer-based) ABMT. With smartphones, users have greater control and flexibility in customizing intervention parameters according to their preferences. For example, individuals with anxiety may respond differently to various types of stimuli, as highlighted by this study. Smartphone apps can allow users to select their preferred stimulus types, such as images, faces, or words, based on their personal preferences and comfort levels. This level of customization enables users to engage with stimuli that resonate the most with them, potentially enhancing their attentional training experience and improving treatment outcomes.

Similarly, smartphones can be leveraged to track personalized data, such as location and physical activity patterns, using their sensors. These data may be used to inform real-time feedback on user performance. In contrast, personalization on PCs may rely more on user input and manual customization, offering greater control but potentially limiting the adaptability and responsiveness of the intervention. The use of mobile sensors in personalizing mobile health interventions is highlighted in the meta-analysis by Tong et al [62]. The study found that interventions using system-captured data, which can be obtained from mobile sensors, were associated with higher effectiveness compared to those using user-reported data. Specifically, the standardized difference in means for interventions using system-captured data was 1.48 (95% CI 0.76-2.19), indicating a more substantial impact on lifestyle behavior outcomes when mobile sensors are used for personalization. Despite the advantages of the smartphone-delivery platform, it also comes with potential challenges, such as limited screen size, potential distractions, and variability in device capabilities across different users. It is essential to carefully consider these factors when designing smartphone-based ABMT interventions to ensure optimal effectiveness and user engagement.

The Impact of ABMT Characteristics on Anxiety and Depression Symptoms

Our research findings shed light on the impact of ABMT design characteristics on intervention outcomes for anxiety symptoms, providing valuable insights into the diverse factors that shape the efficacy of ABMT interventions. One pivotal aspect of these design characteristics is the influence of threat stimuli, a factor that significantly affects the effectiveness of ABMT. Our results align with previous studies, such as those conducted by Xia et al [61], emphasizing how the nature of these stimuli notably shapes the efficacy of ABMT interventions. Another critical factor is the spatial arrangement of stimuli, whether presented in a top-down or left-right fashion. Interestingly, the top-down arrangement is found to significantly reduce anxiety symptoms, echoing the findings of a previous meta-analysis that demonstrated the impact of spatial stimulus display on the outcome of ABMT treatment [61]. It is noteworthy that the design style, whether gamified or not, does not significantly impact ABMT outcomes. This finding can be linked to a recent review on gamified ABMT, where 2 (50%) out of 4 studies did not reduce mental health problems, while the other 2 (50%) studies did. These mixed results highlight the need for the further exploration of gamified ABMT, as identified in the review, given the limited number of studies conducted in this field [61].

Moreover, the duration for which stimuli are displayed significantly influences ABMT's effectiveness, with a 200-millisecond display duration emerging as a significant moderator compared to a 500-millisecond display duration. This indicates that shorter exposure durations may lead to more substantial reductions in anxiety symptoms. This aligns with prior research, such as the work by Charles et al [63], emphasizing the importance of optimizing stimulus presentation duration in ABMT protocols. In addition, a co-design study by Zhang et al [64], involving both health care professionals and patients, aimed to enhance conventional ABMT. Their recommendation to initiate training with a lengthier stimulus

presentation interval and then gradually reduce the interval has proven instrumental in enhancing engagement and reducing assessment time. Subsequently, Zhang et al [65] adopted this approach, reinforcing the effectiveness of a 200-millisecond duration by presenting participants with a 500-millisecond fixation cross, followed by images for 200 milliseconds.

From the ABMT protocol perspective, the risk of bias does not appear to impact ABMT outcomes, as evidenced by nonsignificant trends in both low and some concern categories. This corresponds with an existing meta-analysis study that has shown the role of bias risk and intervention types in determining the outcomes of ABMT interventions [27]. Finally, the findings from this study on the effect of intervention types (active and placebo) on ABMT outcomes reveal that the intervention types in the anxiety treatment group do not significantly impact ABMT outcomes. In summary, these significant moderators offer nuanced insights into optimizing the design and implementation of ABMT interventions for anxiety, establishing direct connections to existing literature and enhancing the understanding of the multifaceted influences on treatment effectiveness.

When considering threat stimuli, there is a nonsignificant negative effect for both face and words, suggesting a subtle reduction in depression symptoms. The stimulus array type shows no significant impact for either left-right or top-down arrangement. The design style, whether gamified or not, does not significantly influence ABMT outcomes for depression. Notably, within the depression treatment group, both active and placebo interventions exhibit negative but nonsignificant effects, indicating comparable impacts on ABMT outcomes. These findings provide a detailed understanding of the role of these moderators in shaping the effectiveness of ABMT interventions for depression.

Limitations

This meta-analysis provides valuable insights into the effectiveness of active and placebo ABMT interventions for reducing mental health problems, particularly anxiety and depression. However, it is crucial to acknowledge several limitations that should be considered when interpreting these findings. First, the study's reliance on small sample sizes within the selected studies limits the generalizability of the results. Future research with larger and more diverse samples could provide a more comprehensive understanding of the effects of ABMT on mental health problems, as current research has primarily focused on high-income countries. Second, the high heterogeneity observed among the included study samples poses a challenge to drawing definitive conclusions. This heterogeneity calls for further investigation into which specific elements of ABMT are the most impactful in reducing mental health problems and whether certain subgroups of individuals may benefit more than others. Despite the significant heterogeneity observed among the study samples, sensitivity analysis revealed that the meta-analysis maintained its statistical significance. The sensitivity analysis conducted in this study should be interpreted with caution. While it helps assess the robustness of the findings, it relies on assumptions that may not always hold. The role of moderators in influencing the effectiveness of

ABMT interventions deserves further attention. This meta-analysis highlights certain moderators, such as the type of threat stimuli and intervention duration, but the complex interplay of these factors requires more in-depth investigation to determine their precise impact on treatment outcomes. The availability of internet facilities could be considered an obstacle when contemplating smartphone-delivered ABMT, as it might limit access for certain patients. Last, most of the studies focused on symptoms of mental health conditions and not a formal diagnosis of mental health conditions; further research is needed to validate the use of smartphone-delivered ABMT in this patient collective.

Future Directions

The findings of this meta-analysis point toward several promising avenues for the future of ABMT research. First, there is a need for the further exploration of design styles in ABMT interventions, with a particular focus on creating engaging and gamified programs that enhance user engagement and motivation. Second, the personalization of ABMT based on individual characteristics and preferences holds significant potential, enabling tailored interventions that match specific symptom profiles and cognitive processes. The standardization of ABMT protocols, including stimulus types, array formats, trial numbers, and intervention durations, is crucial to address the heterogeneity among study samples. Long-term follow-up

studies are essential to assess the durability of ABMT's effects and its potential for preventing symptom relapse. Overall, the future of ABMT research should prioritize enhancing design styles, embracing personalization, addressing heterogeneity, and investigating long-term effects to maximize the effectiveness of ABMT in reducing mental health problems.

Conclusions

This systematic review and meta-analysis have shed light on the effectiveness of ABMT in addressing mental health symptoms. The findings reveal that active ABMT shows promise in reducing attentional biases, with a moderate overall effect size. However, its impact on directly alleviating anxiety and depression symptoms appears limited, as indicated by smaller and nonsignificant effect sizes within these subgroups. Interestingly, the placebo ABMT results emphasize the influence of belief and expectation in treatment outcomes, highlighting the importance of rigorous study designs to distinguish genuine effects from placebos. Moreover, moderator variables, such as the choice of threat stimuli, design style, and stimulus array type, emerge as critical factors influencing treatment efficacy, underscoring the need for personalized interventions. These findings provide valuable insights for tailoring and optimizing ABMT interventions for individuals with mental health problems.

Authors' Contributions

This study was conducted collaboratively by BB, MO, HB, YM, RO, and SM. BB, MO, and HB played pivotal roles in the study section, specifically in filtering and data extraction. YM investigated the risk of bias of the studies selected with BB. SM provided essential verification of the information and analysis methods used, while RO offered invaluable guidance in presenting the study. SM and RO made significant contributions, conducted a meticulous review, and approved the manuscript for publication.

Abstract

Background: The demand for mental health (MH) services in the community continues to exceed supply. At the same time, technological developments make the use of artificial intelligence–empowered conversational agents (CAs) a real possibility to help fill this gap.

Objective: The objective of this review was to identify existing empathic CA design architectures within the MH care sector and to assess their technical performance in detecting and responding to user emotions in terms of classification accuracy. In addition, the approaches used to evaluate empathic CAs within the MH care sector in terms of their acceptability to users were considered. Finally, this review aimed to identify limitations and future directions for empathic CAs in MH care.

Methods: A systematic literature search was conducted across 6 academic databases to identify journal articles and conference proceedings using search terms covering 3 topics: “conversational agents,” “mental health,” and “empathy.” Only studies discussing CA interventions for the MH care domain were eligible for this review, with both textual and vocal characteristics considered as possible data inputs. Quality was assessed using appropriate risk of bias and quality tools.

Results: A total of 19 articles met all inclusion criteria. Most (12/19, 63%) of these empathic CA designs in MH care were machine learning (ML) based, with 26% (5/19) hybrid engines and 11% (2/19) rule-based systems. Among the ML-based CAs, 47% (9/19) used neural networks, with transformer-based architectures being well represented (7/19, 37%). The remaining 16% (3/19) of the ML models were unspecified. Technical assessments of these CAs focused on response accuracies and their ability to recognize, predict, and classify user emotions. While single-engine CAs demonstrated good accuracy, the hybrid engines achieved higher accuracy and provided more nuanced responses. Of the 19 studies, human evaluations were conducted in 16 (84%), with only 5 (26%) focusing directly on the CA’s empathic features. All these papers used self-reports for measuring empathy, including single or multiple (scale) ratings or qualitative feedback from in-depth interviews. Only 1 (5%) paper included evaluations by both CA users and experts, adding more value to the process.

Conclusions: The integration of CA design and its evaluation is crucial to produce empathic CAs. Future studies should focus on using a clear definition of empathy and standardized scales for empathy measurement, ideally including expert assessment. In addition, the diversity in measures used for technical assessment and evaluation poses a challenge for comparing CA performances, which future research should also address. However, CAs with good technical and empathic performance are already available to users of MH care services, showing promise for new applications, such as helpline services.

KEYWORDS

conversational agents; chatbots; virtual assistants; empathy; emotionally aware; mental health; mental well-being

Introduction

Background

An escalation in mental health (MH) diagnoses in the community, inadequate facilities, and a MH care workforce that does not meet demand are placing extraordinary pressures on an already strained system [1]. This service gap creates a significant opportunity for MH care interventions, enhanced using recent advances in modern technologies. Conversational agent (CA) platforms using artificial intelligence (AI) via machine learning (ML) techniques have emerged within the MH care domain, providing additional functionalities and support to address this gap [2]. Examples of CAs that use ML include Woebot, providing cognitive behavioral therapy [3]; Wysa, providing MH support by checking depressive symptoms [4]; Saarthi, trained to provide personalized and empathic support to patients via therapeutic techniques [5]; and Empathetic Research IoT Network, a chatbot that provides access to MH resources for students in need [6]. However, the lack of acceptance of CAs in the MH domain remains a barrier to the uptake of these innovations, and the lack of empathy often displayed by CAs contributes to end-user mistrust [7].

Empathy in patient care has been defined by the World Health Organization as an understanding of the patient's experiences, concerns, and perspectives, combined with a capacity to communicate this understanding and an intention to help [8]. Counselor empathy is an essential feature that enhances therapeutic outcomes for patients and can be measured via therapeutic alliance [9,10]. The same is true for CA-human interactions, where empathy exhibited by a CA system helps build rapport, encouraging users to more frequently engage with the CA system [11]. Contextual awareness, which allows CAs to respond to a user's current emotional situation when suggesting appropriate interventions, also facilitates empathic CA communication [12]. Both trustworthiness of the CA (as perceived by the user) and contextual awareness of the user's situation (as detected by the CA) are, therefore, important considerations when building an empathic CA. Empathy serves to enhance the bidirectional interaction between the CA and the end user [13].

Assessment of the effectiveness of CA platforms has received little attention in the MH care sector [14]. For the impact of these systems to be fully realized, these platforms need to meet the requirements of end users, which suggests a key role for lived experience and coproduction. The validity and reliability of these new digital technologies also need to be reviewed by MH care decision-makers and professionals to ensure successful integration in the sector [15]. In addition, evaluations need to assess the ability of such platforms to reduce symptoms of mental illness [16] while also enhancing user well-being and ensuring that patients feel understood [13]. However, any such evaluation needs to be conducted in the context of the role envisaged for the CA, considering the success of the bidirectional interaction described earlier.

While there are existing reviews exploring the efficacy of CAs designed for MH care [10,17,18], to our knowledge, this is the first review to specifically examine how these empathic CAs

are designed and evaluated. A comprehensive systematic review and meta-analysis of AI-based CAs for promoting MH was conducted by Li et al [17], with a focus on the intervention and technical characteristics of effective CAs. The effectiveness of the CA designs was captured through user feedback. The meta-analysis explored the role of the CA, AI techniques, and delivery platforms that contributed to the success of these designs. In a similar review, Gaffney et al [18] targeted CA interventions for treating MH problems, with a specific focus on user experience outcomes as measures of efficacy. Another such study explored the evidence of effectiveness with regard to improving symptoms of MH conditions [19]. A critical finding of this review was that empathic response and personalization were significant facilitators of efficacy in these systems. However, the incorporation of this crucial empathy component within CAs has not been studied in any depth within the MH sector. Existing reviews have tended to focus on the inability of CAs to respond to unexpected user inputs rather than their ability to demonstrate empathy [19].

Objectives

This review aimed to assess the types of CA designs found in the MH care sector that are specifically tailored to convey empathy. It also aimed to describe the methods used to evaluate these empathic designs from a technical and implementation perspective. Therefore, this review considered how empathy has been engineered and the limitations identified with its use by a CA from a human perspective. There were three objectives: (1) to identify existing empathic CA design architectures within the MH care sector and to assess their technical performance in detecting and responding to user emotions appropriately; (2) to describe the approaches used to evaluate empathic CAs within the MH care sector in terms of their acceptability to users; and (3) to identify limitations and future directions for empathic CAs in MH care.

Methods

Database Search

A systematic literature search was conducted across 6 academic databases (Web of Science; Scopus; EBSCOhost: Academic Search Complete; CINAHL Complete; Computers and Applied Sciences Complete; and IEEE Xplore) for journal articles and conference proceedings from January 1, 2010, to September 30, 2023. The period of data capture dates from the time when AI-informed CA technology emerged as a distinct area of research [20], and conference proceedings were included to ensure that the most recent studies could be included.

The search terms covered 3 topics: "conversational agents," "mental health," and "empathy." Possible keywords were broadened using synonyms for each topic, pilot searching of existing literature, and discussion among research team members. Boolean operators combined different keywords and their synonyms to establish the final search strategy. Wildcards were included (eg, empath* = empathic). Medical Subject Heading terms were used where appropriate. An example of the search syntax is available in [Multimedia Appendix 1 \[4-6,21-36\]](#).

Eligibility Criteria

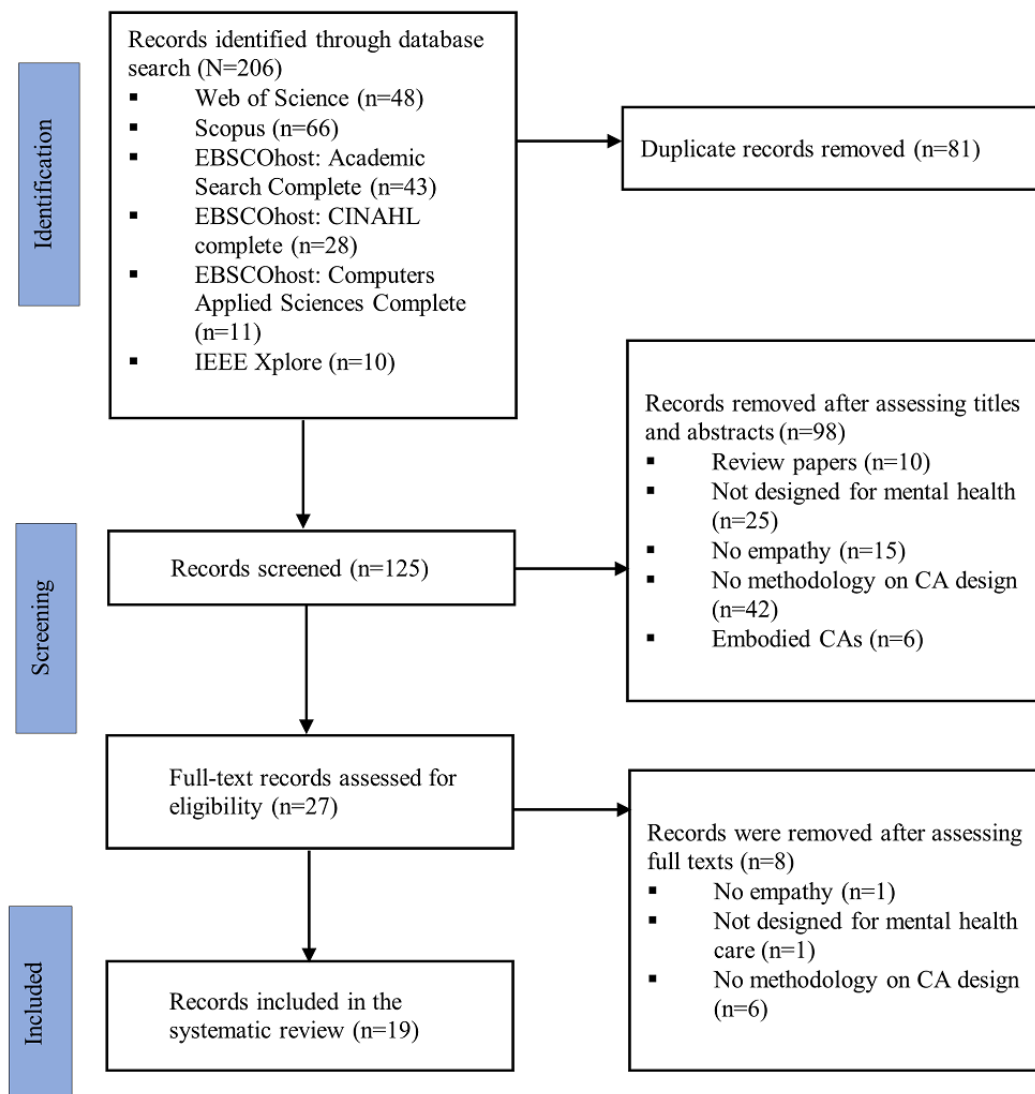

Publications discussing CA interventions for the MH care domain were eligible for the review. There were no restrictions on research design (eg, observational designs and narrative review). This review considered both textual and vocal modes of interaction with the CA. Publications were included if they referred to CA empathy or related terms (eg, emotional intelligence, emotional awareness, and compassion). Publications that did not feature a methodology section that detailed CA design, types of data sets, and participants were excluded. Systematic reviews, scoping reviews, and meta-analyses were excluded. Publications that used data inputs other than text and vocal cues (eg, facial recognition) were also excluded. [Multimedia Appendix 1](#) provides the full-text screening checklist.

Screening

Eligible references were exported to the EndNote (version 20; Clarivate) software [37], where duplicates were removed. The first author (RS) conducted the title and abstract search, mapping against the eligibility criteria. A full-text screening was then performed by the first author and by 2 other authors, DM and RI, independently. Any disagreements on full-text screening were discussed, and an agreement was reached before proceeding. [Figure 1](#) illustrates the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart describing the screening process. PRISMA checklist is reported in [Multimedia Appendix 2](#).

Data including details on the study designs, how empathy was evaluated, and the types of CA architectures used were extracted to obtain a summary of all findings ([Multimedia Appendix 1](#)).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) procedure applied. CA: conversational agent.

Quality Assessment

The Joanna Briggs Institute critical appraisal tool was used to assess the methodological quality of the papers shortlisted while also considering the extent to which each study addressed the possibility of bias in design, conduct, and analysis [38]. This

appraisal tool was specifically designed for the assessment of the variety of study designs encountered in this systematic review. Decisional criteria were answered with *yes*, *no*, *unclear*, or *not applicable*. The proportion of *yes* responses relative to the total number of assessment questions was used for quality assessment purposes. Separate quality assessments were

conducted for publications that included a description of the implementation as well as the design of the CA platform and for publications that included only a description of the design.

Risk of Bias

Risk of bias was assessed using the revised Cochrane risk-of-bias tool for randomized trials. This included risks of bias due to randomization, deviations from the intended intervention, missing data, the measurement of outcomes, and

the selection of results. The risk of bias in nonrandomized studies of interventions tool was used to evaluate the nonrandomized studies.

Results

Overview

A total of 19 studies met all the inclusion criteria. The study characteristics are summarized in [Table 1](#).

Table 1. Study characteristics.

Study	CA ^a	Training database	Aim of the study	Evaluation measures for detecting and responding to user emotions	Mode of exchange	Analysis model for generating empathic responses
Jiang et al [21], 2022	Replika	14 Chinese female users (aged 19-26 years)	Explore types of mediated empathy that occur in human-AI ^b interactions	In-depth interviews and survey results: user ratings of empathy	Text and voice	Transformer architecture
Brocki et al [22], 2023	Serena	Trained on "Pushshift" Reddit data set and tested on psychotherapy transcript	Help improve outcomes of counseling by lowering barriers to access	Survey results: user ratings of engagement and helpfulness	Text	Transformer architecture
Persons et al [6], 2021	ERIN ^c	15 undergraduate students	Help users with finding resources about sensitive issues	Survey results: user ratings for experience	Text	Rule-based architecture
Trappey et al [23], 2022	Virtual reality empathy-centric counseling CA	120 university students	Provide complementary support for students who were troubled	Survey results: user ratings of stress levels, life impact, and psychological sensitivity	Voice and text	Transformer architecture
Ghandeharioun et al [24], 2019	EMMA ^d	39 participants	Delivery of just-in-time MH ^e interventions	Survey results: user ratings of preference; behavioral metrics: user engagement	Text	Hybrid architecture
Meng and Dai [25], 2021	AI CA	278 participants from Midwestern University	Check whether the CA's emotional support was effective in reducing people's stress and worry	Survey results: user ratings of stress, worry, and perceived support	Text	Transformer architecture
Goel et al [26], 2021	Empathic CA with an attention mechanism	Trained with the Facebook AI Empathic Dialogue data set	Support users express their feelings and anxious thoughts	None	Text	Neural network architecture
Adikari et al [27], 2022	Empathic CA	Data set from Cancer Chat Canada	Provide empathic patient-centered MH care	Behavioral metrics for user engagement	Text	Hybrid architecture
Inkster et al [4], 2018	Wysa	129 users with self-reported symptoms of depression	Evaluation of the effectiveness and engagement levels of Wysa	Survey results for symptom assessment	Text	Unspecified ML ^f architecture
Beredo and Ong [28], 2022	Vhope	Senior high school and college students (aged 17-20 years)	Help the students maintain their well-being	Response ratings provided by experts	Text	Hybrid architecture
Rathnayaka et al [29], 2022	Bunji	Australian mobile users on Google Play Store	Remote health monitoring	Survey results for symptom and mood assessment	Text	Unspecified ML architecture
Morris et al [30], 2018	Koko	37,169 individuals who signed up for the Koko platform	A corpus-based approach to simulate expressed empathy	Response ratings provided by users	Text	Hybrid architecture
Ghandeharioun et al [31], 2019	A behavioral change CA	39 participants (n=7, 18% were female, and n=32, 82% were male)	Conduct experience sampling	Survey results: user ratings of likability and CA intelligence	Text	Rule-based architecture
Saha et al [32], 2022	Empathic CA	Data set: conversations between the support seekers who were depressed	Generate empathic and motivational responses	Response ratings by users for fluency, adaptability, and motivation	Text	Transformer architecture

Study	CA ^a	Training database	Aim of the study	Evaluation measures for detecting and responding to user emotions	Mode of exchange	Analysis model for generating empathic responses
Agnihotri et al [33], 2021	Topic-driven and affective CA	Data set: "ScenarioSA" with affective state labels	Tackle the emotional and contextual relevance for mental well-being	Response ratings for emotional relevance	Text	Transformer architecture
Rani et al [5], 2023	Saarthi	None	None	None	Text	Unspecified ML architecture
Alazraki et al [34], 2021	An empathic AI coach	23 participants recruited through crowd working websites	Achieve a high level of engagement during web-based therapy sessions	Survey results: user ratings of empathy and expert ratings of fluency	Text	Hybrid architecture
Gundavarapu et al [35], 2022	A CA companion	Data set: created using sources such as Wikipedia	Provide emotional support, without judgment	None	Text	Neural network architecture
Mishra et al [36], 2023	Counseling CA	A novel conversational data set	Provide MH and legal counseling	Survey results: user ratings of empathy	Text	Transformer architecture

^aCA: conversational agent.

^cERIN: Empathetic Research IoT Network.

^dEMMA: Emotion-aware mHealth agent.

^eMH: mental health.

^fML: machine learning.

Of the 19 studies, 6 (32%) were conducted in the United States and 6 (32%) in India. In addition, 1 (5%) study each from Australia, Canada, China, the Philippines, Poland, Switzerland, and the United Kingdom were also included. The year of publication is summarized in [Multimedia Appendix 3](#), indicating a sharp rise in the number of publications since 2022. Most studies, 14 (74%) out of 19, described both design and human

evaluations. The types of study designs among the 19 studies included are 9 (47%) cross-sectional studies, 5 (26%) randomized controlled trials (RCTs), 4 (21%) quasi-experimental designs, and 1 (5%) qualitative study. Only 5 (26%) of the 19 studies referred to an explicit definition of empathy, as summarized in [Textbox 1](#).

Textbox 1. Definitions of empathy.**Studies and definition of empathy**

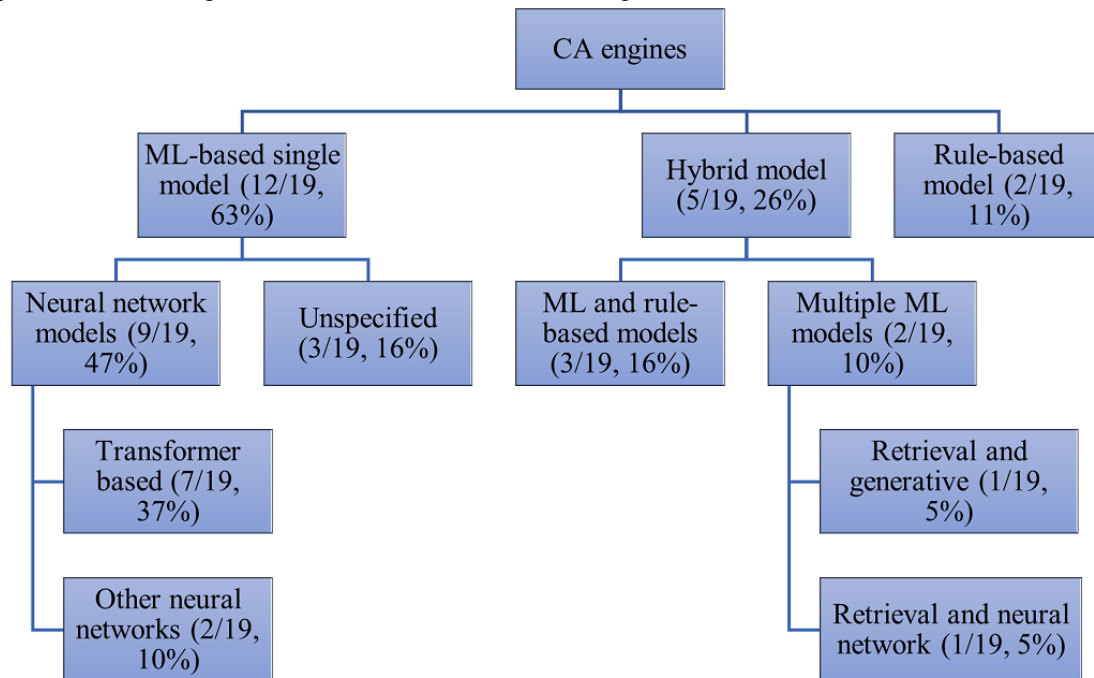

- Jiang et al [21], 2022
 - Empathy processing is a situation-specific, cognitive-affective state or process with the projection of oneself into another's feelings, actions, and experiences.
- Trappey et al [23], 2022
 - Roger's [39] definition of empathy:
 - Level 1: responding to an individual's explicitly expressed meaning and feelings with a simple repetition of basic understanding.
 - Level 2: responding to the implicit, half-expressed, or implied feelings of the person with corresponding emotional words to acknowledge them and bring their true feelings to the surface.
 - Level 3: recognizing the individual's confusing and contradictory feelings that subconsciously obscure what they really care about, capturing the core of the emotion, and then responding to the patient's desire with affirmations.
 - Level 4: when the person is suppressing their feelings or not expressing their feelings in the conversation, guessing their intentions from what they are describing, capturing the core of the emotion, and responding to it directly or indirectly in a way that is acceptable to the person.
- Rathnayaka et al [29], 2022
 - Empathic engagement means, "making the impression of a credible and trustworthy conversation partner that can hear you out and offer a detached point of view on things."
- Saha et al [32], 2022
 - Empathy or empathic interactions refer to the ability to feel the emotions and experiences of others [40].
- Alazraki et al [34], 2021
 - Definition of empathy by Barrett-Lennard [41]:
 - First phase: where the listener sympathizes and resonates with what is being expressed by the speaker.
 - Second phase: where the listener compassionately responds to the speaker. Third phase: where the speaker assimilates the listener's response.

Keywords used to identify a CA varied across studies from "chatbot" (9/19, 47%) to "conversational agent" (6/19, 32%) to "dialog system" (2/19, 11%) to "virtual assistant" (1/19, 5%) to "conversational AI agent" (1/19, 5%). The mode of interaction chosen by most of the CA designs, 17 (89%) out of 19, was text (eg, live chat, symptom checker, and text-based counseling), with voice interactions being used in interactive avatar and counseling roles in 2 (11%) studies.

In the *Technical Design of the CAs* section, we consider the technical designs used for these CAs and their performance in detecting and responding to user emotions before discussing how human-user evaluations were conducted and the conclusions reached from these evaluations.

Technical Design of the CAs

The types of CA architectures (or engines) considered by the authors included a mix of recent technologies, as summarized in [Figure 2](#), with ML-based architectures used in 12 (63%) out of 19 cases. The transformer-based engine, which learns meaning from context, was used in 7 of the 19 (37%) studies, sometimes in the form of a large language model (LLM). A minority of the papers, 3 (16%) out of 19, did not specify the type of engine used within the design. Hybrid or ensemble models use several models in parallel to improve the accuracy of the overall CA design. A more detailed breakdown of the CA engine types with explanations is shown in [Multimedia Appendix 4](#). Figures S1 and S2 in [Multimedia Appendix 4](#) also illustrate how a single engine and a hybrid engine work with user input to provide an empathic response.

Figure 2. Types of conversational agent (CA) architectures. ML: machine learning.

Transformer-based engines included Bidirectional Encoder Representations Transformer (BERT), Sentence-BERT, Robustly Optimized-BERT, Generative Pre-trained Transformer 2, and sequence-2-sequence models. Other neural network architecture-based CA designs were incorporated in 2 (11%) of the 19 papers [26,35].

Of the 19 publications, 5 (26%) considered hybrid models. Of these hybrid models, 2 applied a ML model to capture user emotion and then applied a rule-based algorithm to generate appropriate responses in dialogue management [24-27]. For example, EMMA gathered mobile sensor data to infer user mood and then assigned users to appropriate wellness interventions [24]. Once assigned, the CA then responded with emotionally expressive responses selected at random from a set of prescribed phrases using a rule-based approach [27]. In another example, VHope, an internet-based therapist, used a hybrid model containing a retrieval model that deciphered user input combined with a generative model to elicit empathic responses [28].

Among the 19 papers, the 3 (16%) papers using unspecified architectures commenced with natural language processing (NLP) before using various ML approaches. In one example,

continuous emotional support via remote MH care monitoring and personalized assistance was provided [29]. MH monitoring was performed by scheduling activities that were meaningful to each user, sending out reminders as encouragement, and forwarding satisfaction surveys to receive feedback.

Overall, 2 (11%) of the 19 publications implemented CA design approaches based on rule-based NLP architectures. For example, a mobile phone-based CA measured the level of emotion in user input and then selected an appropriate empathic response from a set of predefined scripts using a rule-based decision tree [31]. In the *Summary of the Results of the Assessment of the Technical Design of CAs in Terms of Classification Accuracy* section, we will discuss the technical performance of the CAs reviewed.

Summary of the Results of the Assessment of the Technical Design of CAs in Terms of Classification Accuracy

The accuracy of the designs in detecting and responding to user emotions appropriately is summarized in Table 2. Technical evaluations of the CA designs usually involved comparisons with a “gold standard,” using data not previously used for training the CA.

Table 2. Measures used for evaluating the technical performance of CA^a designs.

Type of CA assessment	Assessment of user emotions or CA responses	Accuracy measure
Classification of sentiment and issues	User emotions	<ul style="list-style-type: none"> • Mathews correlation coefficient=0.857 [23]
Classification of valence and arousal	User emotions	<ul style="list-style-type: none"> • Accuracy of valence=80.4% [24] • Accuracy of arousal=50.4% [24]

^dROUGE-L: Recall Oriented Understudy for Gisting Evaluation–Longest Common Sequence.

A technical evaluation of empathic CA performance was conducted in 17 (89%) of the 19 papers reviewed; however, only 10 (53%) papers reported these results. These studies conducted comprehensive assessments where technical performance was measured in terms of recognition, classification, prediction, and response generation abilities during interactions with end users. The assessments were

centered around the ability of the CA to discern user emotions correctly and to respond appropriately. Of the 19 papers, 4 (21%) focused on the CA responses during the technical assessments, while the rest of the studies (n=15, 79%) considered user emotions. A variety of measures were used for each such assessment, highlighting the diversity in evaluation methodologies across studies. These metrics are categorized in

detail under the type of CA performance in [Multimedia Appendix 5](#) [4-6,23-34,36].

In general, the performances of the CA designs were satisfactory. The highest classification accuracy for user emotions was reported by ML-based CAs. In one of these studies, a Robustly Optimized-BERT transformer model, which was built integrating 3 classifiers for politeness, counseling strategy, and empathic feedback, achieved good results overall. This empathy classifier achieved excellent performance with a weighted accuracy score of 0.977 and an F_1 -score of 0.972 [36]. In a second study, a topic-driven classification model used a Generative Pre-trained Transformer 2 model for generating controlled responses, and the classification model accomplished relatively high scores of accuracy (95%), precision (0.954), and recall (0.947) and an F_1 -score of 0.95 [33].

However, high accuracy and a more nuanced response generation were consistently apparent in all the CAs using

hybrid architectures [24,27,28,30,34], suggesting that hybrid models lead to enhanced performance in tasks requiring complex understanding of user emotions and the generation of contextual responses.

Human Evaluation of CAs

Most of the reviewed studies, 16 (84%) out of 19, conducted a human evaluation of the implemented CA designs. Acceptability by end users was evaluated in terms of user experience, satisfaction, and levels of engagement. A detailed summary of the human evaluations of these designs is presented in [Multimedia Appendix 5](#).

The human evaluation was performed by only CA users in most cases (13/16, 81%), while experts in the field of MH contributed to the process of assessing the CA in the remaining studies (3/16, 19%). [Table 3](#) summarizes the empathy measures used in these papers.

Table 3. Measurement of empathy in CAs^a.

^dMH: mental health.

Alazraki et al [34] conducted a cross-sectional study with 23 volunteers and 2 clinicians who engaged with a web-based chatbot platform using 4 prescribed conversations of different CA personas. An anonymous web-based questionnaire collected participant feedback regarding the level of empathy displayed by the chatbot, engagement levels, and the ability of the chatbot to identify emotions in the participant. The survey results revealed that 75% of users agreed that the CA persona Kai was empathic, 63% found it engaging, and 75% rated it as useful. In contrast, Beredo and Ong [28] asked 3 psychologists to provide feedback on chatbot user logs. Empathy was measured using the affect criterion, a measure of the ability of the CA to read and respond to users with empathy, along with performance and humanlike characteristics. On the basis of expert feedback, 67% of the CA responses were relevant, 78% seemed human, and 70% were empathic.

In an RCT, a group of 39 participants were randomly allocated to a treatment group interacting with the emotion-aware chatbot EMMA, while a control group (n=39) was assigned to an emotionally nonexpressive chatbot, with 2 weeks of monitoring in each case [24]. The participants engaging with EMMA showed higher frequency of interactions and responded quicker than the control group. The feedback of the users was useful in understanding how empathy was perceived during the study.

The only qualitative experimental study involved an AI-based chatbot, Replika, designed to improve resilience and user well-being [21]. The author followed an ethnographic approach for their study of empathy, asking users to download the Replika application and write down reflective notes on their conversations with Replika. The results of this study expand the empathy theories within human conversations to human-AI interactions through variations in cognitive empathy, affective empathy, and empathic responses. A list of technical terms used in the paper is further explained in [Multimedia Appendix 6](#).

Risk of Bias and Quality Assessment Results

The included RCTs showed a low risk of bias on the revised Cochrane risk-of-bias tool. Of the 14 nonrandomized studies included in the review, all showed a moderate to high risk of bias. A total of 5 (36%) studies [27,32-34,36] were moderately biased, and 1 (7%) study [28] was seriously biased according to the risk of bias in nonrandomized studies of interventions tool. The Joanna Briggs Institute quality assessment results were generally low when only the design component of the studies was assessed, with 32% (6/19) of the papers receiving a score of 0. However, an overall moderate quality was seen in publications when both the design and implementation stages were appraised. [Multimedia Appendix 7](#) [4-6,21-36] shows the quality assessment results.

Discussion

Principal Findings

The study and use of CA technology have been the subject of extensive research across many fields, such as education, customer service, and health care. Moreover, there are reviews focusing on AI-based CAs, their effectiveness, and their impact in the realm of MH care [17,18,42]. While these reviews offer

significant insights into AI-based CA designs in MH care, the importance of empathy is not central. Although these reviews suggest the need for empathy in CA innovations in MH care, they do not consider CA designs specifically aimed at generating and evaluating empathy. To address this gap, this review compares various empathic CA designs, their effectiveness in detecting and responding to user emotions, and their acceptability to users.

CA Designs

This review has found that most researchers used an ML-based transformer engine for designing empathic CAs, achieving excellent classification and prediction results. Surprisingly, several researchers used rule-based architectures and retrieval engines. While lacking the sophistication of transformer-based engines in terms of comprehension, rule-based approaches were able to efficiently identify keywords and themes, ensuring that consumer needs were addressed within a limited number of categories. Rule-based systems are comparatively easy to design and implement, allowing for a trade-off between classification accuracy and economic feasibility. However, rule-based systems tend to generate more predictable, inflexible, and repetitive responses compared to advanced LLM engines and, therefore, might be more suitable for providing simple information to managers and MH care workers, rather than responding to end users requiring more nuanced responses.

Hybrid architecture seems best suited to the detection of user emotion followed by the retrieval of a suitable response. Therefore, having >1 model appears to facilitate a more robust model output. This is supported by the superior accuracies achieved by hybrid architectures in the classification and prediction tasks. The hybrid model of Adikari et al [27] achieved the highest accuracy of 87% (F_1 -score=0.87) in recommending a resource based on the concerns expressed by the patients. However, the highest accuracy in emotion recognition (95% accuracy in identifying sadness, anger, fear, and happiness) was obtained by Alazraki et al [34]. The combined features of high accuracy and improved user experience probably make these the best performing CAs within the review.

While the use of such robust LLMs has significantly improved language-based CA technology, it is important to recognize that these models are not without disadvantages [43]. These models have been found to perpetuate biases with regard to gender, race, and MH conditions present in the training data [44,45]. Such biases can strengthen gender stereotypes and reduce response accuracy when dealing with users from diverse cultural backgrounds, potentially causing harm to users. Such issues may have serious impacts on user trust, the credibility of the empathic CA, and user well-being. Such biases can be mitigated by ensuring that the training data sets represent diverse gender categories, races, and cultural backgrounds and that advanced technical approaches are used to detect and minimize any such biases in the training data [46-48].

Ethical and privacy concerns associated with these LLMs are critical [49,50]. Following ethical guidelines centered around transparency, accountability, and adherence are pivotal to user privacy, while measures to maintain data security through strict access controls and regular security checks also need to be in

place. Privacy should be a core component of CA designs, with limitations placed on personal data collection whenever possible [7]. These strategies are especially important for an empathic CA design dealing with users seeking MH care. Any breaches of privacy and ethical guidelines pose a high risk to user mental well-being as well as users' trust in and acceptance of these new technologies [51]. The AI safety guidelines established by the European Union provide a key foundation for the creation of secure and ethical experiences for users [50].

Due to the complexity of LLMs and the many parameters involved, some models can have high latency in response time, which can cause potential challenges for a real-time CA dealing with vulnerable users waiting for a response. However, the use of parallel processing, optimization techniques, and hardware that supports the requirements of these AI models has facilitated a decrease in execution times [52].

Human Evaluations of CAs

Among the reviewed publications, human evaluation of chatbots was common. However, only 26% (5/19) of the studies used an RCT design to assess the CA platform. Random assignment to the treatment arm is known to reduce bias while improving the reliability of the experimental results. Any confounding factors are, therefore, likely to be controlled for in an RCT, making it important to overcome the practical difficulties these designs present in this context. RCTs provide the opportunity to observe user experiences with the CA designs over time. Ideally, future studies should consider RCT designs for their human evaluations, and ideally, the long-term effects of the CA can be examined over an extended timeline.

Previous experiences with CAs could be an important confounding factor. On the basis of these experiences, expectations of users regarding CA performance may affect actual engagement with the CA. Previous bad experiences may make it less likely that a user will try to engage fully with a CA, resulting in a less favorable evaluation and satisfaction levels [53]. Another confounding factor could be the rate at which the user likes to communicate. If the CA cannot automatically adapt its speed of response to that preferred by the user, it is likely that this will also impact evaluation results [54].

The human evaluations of CAs in this review focused on their ability to portray empathy, satisfy user needs, provide useful and contextually informed responses, and facilitate user engagement. Most CAs were evaluated as satisfactory by end users. However, among the 19 papers reviewed, only 5 (26%) papers provided quantitative evaluations of CA empathy, and only 5 (26%) papers provided a definition of empathy.

Because empathy has been defined in numerous ways in the literature, it is important that in future studies users are given a framework that guides their perceptions of empathy. Future research on empathic CA designs would, therefore, benefit from a clear and well-established definition of empathy, such as that provided by the World Health Organization [8]. Ideally, standardized scales for perceived empathy should be used to enhance the reliability, comparability, and validity of survey results. In this review, other self-report measures were used as surrogates for empathy, with considerable variation in the types

of scales used. However, self-report scales are subjective and prone to bias, with different meanings based on users' lived experiences [55]. Ideally, the impact of the CA on MH outcomes should also be assessed. Only 2 (11%) of the 19 papers in this review [4,29] used the Patient Health Questionnaire as their measure of MH outcomes, while 2 (11%) other papers considered stress levels in their evaluation [23,25].

Furthermore, the human evaluations were mostly conducted by study participants. Experts and professionals in the field of MH care were rarely consulted. There is a need for greater consultation with focus groups and user groups to ensure that the CA design best reflects the needs of all stakeholders [22]. Future research in this area should also consider an iterative design framework, incorporating the co-design and coevaluation of prototypes involving all stakeholders [22].

In summary, there were deficiencies in all the human evaluations included in this review. Only 5 (26%) of the 19 papers in this review included a direct evaluation of CA empathy in the design, while the rest (n=14, 74%) were more concerned with general user satisfaction. Only 2 (40%) of 5 these studies used multiple rating scales to measure the level of empathy portrayed by a CA, and only 1 (20%) of 5 these studies [34] considered evaluations by both users and clinicians. However, there were 4 studies that did consider the impact of the CA on MH outcomes.

Future Opportunities

A significant limitation of the CAs reviewed was the use of only textual input in all but 2 (11%) of the 19 studies where voice data were included, thus losing a valuable opportunity to leverage alternative and powerful forms of data input for evaluating empathy. A range of vocal characteristics have been associated with the detection of suicide risk and psychological distress, which suggests that vocal characteristics might provide a natural extension for the detection of levels of empathy [56,57]. The omission of voice data is surprising given that empathy is communicated predominately through vocal cues. However, textual information is not without its advantages. As we have shown in this review, NLP approaches have been used to successfully detect and convey empathy by CAs. A novel approach would be to leverage both streams of information to identify vocal characteristics indicative of different levels of empathy in addition to textual cues. Characteristics of vocal and textual cues that are associated with empathy could be combined to create a CA design to attend to users of MH care facilities such as helpline services, patient triage, and emergency services [21,23].

Creating a CA design that accurately portrays empathy and adjusts the level of empathy to match the emotional status of patients is a significant challenge. Effective vocal interaction often faces hurdles due to technical issues in voice analysis, including the smooth processing and interpretation of data. These challenges are compounded by poor audio quality [58]; the presence of overlapping psychological states in users; and linguistic variability influenced by culture, age, gender, and accents [59-61]. The use of high-quality audio devices to capture user voice [62, 63] and the use of training data sets reflecting diverse human demographic features are two challenges in

algorithm development aiming to provide effective vocal interaction in CAs in real time.

The integration of an empathic CA with voice analysis capabilities into crisis helpline services could benefit users and the service provider. Attending to callers during peak hours for the collection of demographic information, triage, and risk assessment of callers using their voice patterns are some of the possible roles that CAs could fulfill. The involvement of CAs in these capacities could help reduce caller wait times, streamline processes, and ensure 24-hour service availability while providing a nonjudgmental and sensitive interaction for users within a safe environment. Improved empathy portrayal by the CA would help enhance user engagement and CA acceptability, helping reduce the gap between the demand and supply of available crisis helpline services.

Summary

This review confirms that empathy is an important characteristic for CA implementation for MH care. It highlights the strengths of the ML-based architectures when it comes to CA design and provides evidence of both technical and human assessments of CA performance. The need for improvement in measures used for detecting the level of empathy exhibited by CAs is manifest. The importance of AI safety regarding ethical and privacy concerns is a neglected area and should be considered as a priority for future designs. The promise of empathic CA applications that use vocal inputs and outputs is another area warranting further research, with opportunities for crisis helpline services.

Limitations of the Review

The studies included in this review presented a mix of methods, which made it challenging to compare and analyze the results. This relates to the diversity in the CA designs included, along with the different data formats obtained through human evaluations, such as survey results, response ratings, and interview feedback. The methods used to assess the accuracy of the technical designs were also varied, and a lack of empathy definitions and standard measures for perceived empathy made study comparisons difficult.

The quality rating of the studies emphasized the need for the complete reporting of CA designs as well as rigorous evaluation. Deficiencies in these areas meant that the quality ratings for several papers were low. Evaluation guidelines were often missing, which made it challenging to appraise the performance of these systems. Classification accuracy and the accuracy of the responses generated were assessed using a variety of methods, further complicating this comparison.

Conclusions

The objective of this systematic review was to identify the existing architectures of empathic CA designs and the types of CA design assessments used in MH care. A further aim was to determine how CA empathy is evaluated and to examine the limitations and future ideas for CAs in this specific context. More than half of the selected papers used the latest technologies in CA architectures, including designs developed using ML-based transformer engines (eg, LLMs). Evaluations of technical capabilities were conducted in most of the papers and demonstrated good levels of accuracy.

This review suggests that a hybrid design is ideally used for the design of an empathic CA, allowing an initial assessment of user emotion before any CA response is developed. This review indicates that human feedback is required to assess the extent to which the CA is successful in demonstrating empathy. It is recommended that well-validated scales be used for this purpose. Further research on the portrayal of empathy in CAs for MH care would benefit by involving cocreation activities, explicit definitions of empathy, and effective evaluation of empathy using standardized empathy scales, as well as by using vocal features associated with empathy in addition to textual cues.

Despite its limitations, this review demonstrates that it is possible to design AI-empowered CAs that evoke empathy within MH care applications, with many of these CAs being rated as satisfactory by human users. This suggests that such CAs could prove beneficial in a range of settings, such as crisis helpline services, gathering data on user characteristics and emotions, and in postvention follow-up, helping to bridge the gap between the existing supply and demand for MH services.

Abstract

Background: Depression and anxiety have become increasingly prevalent across the globe. The rising need for treatment and the lack of clinicians has resulted in prolonged waiting times for patients to receive their first session. Responding to this gap, digital mental health interventions (DMHIs) have been found effective in treating depression and anxiety and are potentially promising pretreatments for patients who are awaiting face-to-face psychotherapy. Nevertheless, whether digital interventions effectively alleviate symptoms for patients on waiting lists for face-to-face psychotherapy remains unclear.

Objective: This review aimed to synthesize the effectiveness of DMHIs for relieving depression and anxiety symptoms of patients on waiting lists for face-to-face therapy. This review also investigated the features, perceived credibility, and usability of DMHIs during waiting times.

Methods: In this systematic review, we searched PubMed, PsycINFO, Cochrane, and Web of Science for research studies investigating the effectiveness of DMHIs in reducing either depression or anxiety symptoms among individuals waiting for face-to-face psychotherapy. The search was conducted in June 2024, and we have included the studies that met the inclusion criteria and were published before June 6, 2024.

Results: Of the 9267 unique records identified, 8 studies met the eligibility criteria and were included in the systematic review. Five studies were randomized controlled trials (RCTs), and 3 studies were not. Among the RCTs, we found that digital interventions reduced depression and anxiety symptoms, but the majority of interventions were not more effective compared to the control groups where participants simply waited or received a self-help book. For the non-RCTs, the interventions also reduced symptoms, but without control groups, the interpretation of the findings is limited. Finally, participants in the included studies perceived the digital interventions to be credible and useful, but high dropout rates raised concerns about treatment adherence.

Conclusions: Due to the lack of effective interventions among the reviewed studies, especially among the RCTs, our results suggest that waiting list DMHIs are not more effective compared to simply waiting or using a self-help book. However, more high-quality RCTs with larger sample sizes are warranted in order to draw a more robust conclusion. Additionally, as this review revealed concerns regarding the high dropout rate in digital interventions, future studies could perhaps adopt more personalized and human-centered functions in interventions to increase user engagement, with the potential to increase treatment adherence and effectiveness.

Introduction

Poor mental health is an increasing global challenge [1,2], with the prevalence of depression and anxiety reaching a peak during the COVID-19 pandemic [3-5]. Several meta-analyses have concluded that psychotherapies, such as cognitive behavioral therapy (CBT), acceptance and commitment therapy, and problem-solving therapy (PST), are as efficacious at treating depression and anxiety as pharmacotherapy, and that their effects are more enduring [6-8]. Compared to pharmacotherapy, psychotherapy is often the preferred treatment for depression and anxiety by most patients, as well as clinicians [8]. According to the latest Mental Health Gap Action Program guideline by the World Health Organization [9], psychotherapy, instead of medication, is usually recommended as a frontline treatment for common mental disorders.

However, access to psychotherapy treatment remains limited worldwide, even in high-income countries [1]. The insufficient number of clinicians has led to prolonged waiting times before face-to-face psychotherapy can begin. For example, in Germany, waiting times are on average 12.5 weeks for an initial consultation and 23.4 weeks for the first therapy session [10]. In the Netherlands, patients wait at least 6 weeks for the first treatment session [11]. In Hong Kong, while urgent and semiurgent cases wait for 1-4 weeks, stable cases, which are 76% of the total cases, wait for an average of 40 weeks [12]. A prolonged time spent on waiting lists for therapy can have negative impacts on the well-being of patients, demonstrated by increased symptoms of depression and anxiety, remission, deterioration in life quality, and even an increase in mortality [10,13-16]. This delay is also significant for most patients as their symptoms do not usually dissipate naturally with time [10,14].

Although waiting list interventions (ie, interventions that are implemented during the weeks or months before face-to-face treatment) are potentially important for patients who are waiting for treatment, few studies have investigated their impact on reducing depression and anxiety. However, Grünzig et al [17] conducted a systematic review of low-intensity interventions to reduce depressive symptoms before outpatient psychotherapy and found limited evidence of their effectiveness in reducing depressive symptoms. Among the reviewed studies, the interventions were a mix of face-to-face sessions, web-based training for self-help strategies, and supervised bibliotherapy with feedback via email or telephone [17]. Due to the wide range of intervention formats, Grünzig et al [17] also found that acceptance varied between the interventions.

Responding to this treatment gap, digital mental health interventions (DMHIs) are potentially a solution to the waiting list problem because they can be implemented digitally and with minimal input from a therapist [18]. Emerging evidence suggests that DMHIs are effective in improving a wide range of mental health conditions, including depression and anxiety [19,20]. Moreover, DMHIs have adopted psychotherapies, like CBT and acceptance and commitment therapy, and these have been found to be as effective as face-to-face therapies [21,22]. Due to the advantages of DMHIs, such as being more scalable, more accessible, and more cost-effective compared to face-to-face therapies [23,24], DMHIs offer the possibility to provide patients with a pre-face-to-face therapy intervention while they are on a waiting list. In addition, DMHIs can be used in a stepped care model as the frontline treatment, which steps up to more intense and advanced care if patients do not improve with the DMHIs.

However, although evidence shows that DMHIs are effective in treating depression and anxiety, it is unknown whether DMHIs are effective for patients on waiting lists. Unlike face-to-face psychotherapies that are usually delivered in a relatively standard procedure, DMHIs encompass diverse features, such as being available on multiple digital devices (website, computer, mobile apps) and offering many delivery formats (email, text message, virtual reality, games, self-help, or guided) [25-27]. It is unclear which of these features are critical for the creation and implementation of effective interventions. The typical factors undermining the effectiveness of DMHIs include low user engagement and low perceived credibility and usability; both of which are associated with poor treatment adherence and subsequently lower effectiveness [28-30]. In contrast, guided DMHIs have been found to be associated with higher user engagement [31], higher treatment adherence [32], and higher effectiveness compared to self-guided DMHIs [21,22]. In addition to user engagement, perceived credibility and usability are positively correlated with treatment outcomes [33]. Hence, it is important to investigate the perceived credibility and usability of DMHIs, as well as user engagement for patients on waiting lists in order to assess their effectiveness.

To our knowledge, there are no previous systematic reviews that synthesized the effectiveness of DMHIs for relieving symptoms of depression and anxiety for patients on waiting lists for face-to-face psychotherapy. Since depression and anxiety are the most prevalent mental health disorders globally [34], this review focused on DMHI's impacts on alleviating depression and anxiety. This review also investigated the features, perceived credibility, and usability of DMHIs during waiting times.

Methods

Overview

This systematic review was conducted following the guidelines of the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses; see [Multimedia Appendix 1](#) for PRISMA checklist) statement [35]. The study protocol was uploaded to the Open Science Framework prior to running the initial search and updates after the search have been documented.

Search Strategy and Selection Criteria

Searches were conducted in the following 4 web-based databases: PubMed, PsycINFO, Cochrane, and Web of Science. Backward and forward citation searching was manually conducted using the Web of Science. The search was carried

out in June 2024. Studies published before June 6, 2024, and that met the inclusion criteria were included in the review.

The search terms used were a combination of the population (ie, patients on the waiting lists for psychotherapy), treatment (ie, intervention), and outcome (ie, depression or anxiety, or both). The detailed search terms for each domain are shown in [Table 1](#). In addition, the language was limited to English, and the publication type was limited to peer-reviewed publications in scientific journals with full-text access.

To fulfill the objectives of this review, the inclusion criteria were (1) randomized controlled trials (RCTs), or clinical trials, or pilot studies, or feasibility studies (2) of any kind of digital intervention (3) for individuals on waiting lists (4) for psychotherapy (5) with clear psychological outcome measurements that included depressive or anxiety symptoms.

Table 1. Search terms.

Concept	Search terms ^a
Concept 1: population	“before psychotherapy” OR “before therapy” OR “pretreatment” OR “pretherapy” OR “before outpatient psychotherapy” OR “waiting time” OR “waiting list”
Concept 2: intervention	“digital intervention” OR “digital mental health” OR “DMH” OR “eMental health” OR “mobile mental health” OR “mobile psychiatry” OR “technology” OR “online” OR “mobile” OR “phone” OR “app” OR “web” OR “internet” OR “computer*” OR “ehealth” OR “mhealth” OR “guided” OR “self-help”
Concept 3: outcome	“depress*” OR “anxiety” OR “MDD” OR “anxious” OR “GAD” OR “generalized anxiety disorder”

^aSearch terms are based on the inclusion criteria (see eligibility criteria), targeting the population, intervention, outcome, and study type. The search terms were combinations of the keywords listed under categories 1, 2, and 3.

Screening and Data Extraction

Three of the coauthors (SH, GL, and TJN) independently completed the title and abstract screening of the retrieved study records, as well as the full-text reviews of the eligible studies. The web-based platform Covidence (SaaS Enterprise) was used in managing the screening process. The corresponding author resolved any screening disparities.

Data were extracted through Covidence following the same template for each study across three domains: (1) study characteristics (ie, study title, authors, publication year, country, study type, health care settings, recruitment, sample size and demographics, and inclusion and exclusion criteria); (2) intervention characteristics (ie, therapy type, components, duration, and outcome measurements); and (3) study results (ie, primary outcome: the reduction in depression and anxiety symptoms, secondary outcome: user engagement, intervention credibility, and usability).

Data Synthesis

The extracted data were first synthesized by the study characteristics and the features of interventions including sample size, recruitment methods, types of psychotherapy adapted, delivery formats, and outcome measures. Next, we synthesized the effectiveness of the digital intervention by analyzing the reduction of depression and anxiety symptoms, separately for different study types (ie, RCTs and non-RCTs). Finally, reports about user engagement and perceived credibility and usability were synthesized.

Results

Overview

Of the 10,066 study records retrieved from the databases, and after removing duplicates and non-English studies, a total of 9267 unique titles and abstracts were screened. Following the screening, a final 22 studies remained for full-text screening ([Figure 1](#)). After scanning the full texts, 8 studies met eligibility criteria and were included in the review.

Figure 1. PRISMA flow diagram outlining data set and study identification. PRISMA: Preferred Reporting Items for Systematic Reviews and Meta-Analyses.

Study Characteristics

The study characteristics are shown in [Table 2](#). In all the studies, the participants were informed about the digital intervention by their health care service providers and were recruited if they were interested in participating and passed screening. Five

studies used an RCT design, two studies were feasibility studies, and 1 study was a nonrandomized experimental study. Studies by Kenter et al [11] and Kolovos et al [36] used the same data collection for analysis and were therefore discussed together in the current review.

Table 2. Study characteristics.

Reference, study type, and location	Setting	Recruitment	Sample size	Demographics	Inclusion and exclusion criteria
Krämer et al (2021) [37], RCT ^a , Germany	Outpatient clinics	Individuals were informed about this study and provided with a screening questionnaire.	136	Age: mean 36.3 (SD 11.9); 78% female; 58% in a relationship	Included depressive patients on the waiting lists (age 18 years and older; CES-D ^b >22; BSI ^c item 9≤1). Excluded patients indicating suicidal ideation at baseline.
Villemare-Krajden and Myhr (2019) [38], RCT, Canada	A university clinical teaching unit in a tertiary care hospital	Participants were recruited from referrals for CBT ^d and instructions were sent by emails.	67	Age: mean 38.21 (SD 12.71); 67% female; 43% in a relationship	Unspecified, but included outpatients with all types of depressive disorders, anxiety, bipolar, insomnia, psychosis, adjustment disorder, personality disorders, and autism spectrum disorder.
Kenter et al (2016) [11], RCT, The Netherlands	Outpatient clinics	Recruited patients after their registration for regular face-to-face treatments. Screened by telephone.	269	Age: mean 38 (SD 11.4); 53.9% female; 24.2% in a relationship	Included outpatients waiting for face-to-face treatment at clinics with major depressive disorder diagnosed by <i>DSM-IV</i> ^e (age 18 years and older, waiting time >8 weeks). Excluded patients with suicidal ideation and antidepressant medication.
Kolovos et al (2016) [36], RCT, The Netherlands	Outpatient clinics	Recruited patients after their registration for regular face-to-face treatments. Screened by telephone.	269	Age: mean 38 (SD 11.4); 53.9% female; 24.2% in a relationship	Included outpatients waiting for face-to-face treatment at clinics with major depressive disorder diagnosed by <i>DSM-IV</i> (age 18 years and older, waiting time >8 weeks). Excluded patients with suicidal ideation and antidepressant medication.
Twomey et al (2014) [39], RCT, Ireland	A public health care provider in Dublin	Participants were invited by telephone, and instructions were sent by email.	149	Age: mean 35.3 (SD 10.3); 73.8% female; 41.6% in a relationship	Included adults on waiting lists with symptoms of depression, anxiety, or stress (as shown by their initial referral). Excluded those with psychosis or cognitive impairment.
Hentati et al (2022) [40], feasibility study, Sweden	A routine psychiatric care unit	Participants were informed by the health care personnel at the psychiatric care unit and self-registered digitally.	12	Age: mean 34.3 (SD 11.1); 50% female; 75% in a relationship	Included patients with symptoms of depression or anxiety on the waiting list (age 18 years and older; PHQ-9 ^f or GAD-7 ^g ≥5; MADRS-S ^h item 9<4). Excluded patients with severe suicidal ideation, and psychiatric or somatic difficulties.
Duffy et al (2019) [41], feasibility study, United Kingdom	Outpatient clinics	Participants were informed of the study through their clinician and discussed their participation with clinicians during the assessment appointment.	123	Age: 28% between 17 and 24, 46% between 25 and 44, 26% between 45 and 64, and 1% between 65 and 80; 69% female	Included clients with severe presentations of anxiety or depression, or both, requiring high-intensity treatment. Excluded clients requiring low-intensity treatment and those with substance abuse.
Whitfield et al (2006) [42], nonrandomized experimental study, United Kingdom	Outpatient clinics	Referred participants were invited to a screening appointment.	20	Age: mean 38.05 (SD 12.98); 45% female	Included patients with problems of depression and depression with anxiety (aged between 16 and 65, BDI-II ⁱ <2). Excluded patients with current active suicidal intent and psychosis.

ⁱBDI-II: Beck Depression Inventory Version II [48].

Among the 5 RCTs, only the intervention group in Krämer et al [37] reported a significant decrease in depressive symptoms, as well as improvements in psychological symptoms and quality of life, compared to the control group. In the other 4 RCTs, 3 RCTs provided the control groups with a self-help book and did not find the internet-based interventions more effective in reducing depression and anxiety symptoms than the control groups, and 1 RCT did not provide any intervention for the control group [11,36,38,39]. The 3 non-RCT studies, which did not have a control group, reported mixed findings. Two studies found that the effectiveness of the digital interventions was beneficial and reduced depression and anxiety symptoms during the waiting time and at follow-up [41,42]; however, after the intervention in the remaining study, only a few participants reached the threshold for clinical improvement in their symptoms of depression or anxiety [40].

Quality Assessment

We used the RoB 2 tool (a revised Cochrane risk of bias tool for randomized trials) to assess the risk of bias of the included RCTs. The RoB 2 evaluates five domains, including the randomization process, deviations from intended interventions (effect of assignment to intervention), missing outcome data, measurement of the outcome, and selection of the reported result [49]. In addition, the ROBINS-I (Risk of Bias in Nonrandomized Studies-of Interventions) tool by Cochrane was used to assess the risk of bias of the included non-RCTs. The ROBINS-I evaluates seven domains including confounding, selection of participants, classification of interventions, deviations from intended interventions, missing data, measurement of the outcomes, and selection of the reported results [50].

Out of the 5 included RCTs, 4 RCTs had low risk and 1 RCT had some concern with regard to the randomization process (due to significant baseline differences between the two groups). Two studies had low risk and three studies had some concerns regarding low intervention adherence. Regarding missing data,

2 studies had low risk and 3 studies had moderate to high risk due to dropouts. All 5 studies had some concerns due to it being unclear if the assessment method was double-blinded or not. Finally, all studies had a low risk of bias regarding the selection of the reported result. A detailed quality assessment for each study is presented in Table S1 in [Multimedia Appendix 2](#).

The 3 included non-RCTs all had moderate risks. A common serious risk factor among all studies was the consideration of confounders. None of the studies reported potential confounders, which contributed to the potential bias of the study results. In addition, intervention adherence was a concern in all studies. Due to the moderate to high dropout rates, the handling of the missing values was problematic in two of the three studies. Finally, similar to RCTs, the 3 non-RCTs also only included self-reported outcome measurements, and it was unclear if outcome assessors were aware of the intervention received by study participants. A detailed quality assessment for each study is presented in Table S2 in [Multimedia Appendix 2](#).

Randomized Controlled Trials

The intervention characteristics of RCTs are shown in [Tables 3 and 4](#). Krämer et al [37] found that the “GET.ON Mood Enhancer” that they used was effective in reducing depressive symptoms. The intervention group improved significantly after the intervention compared to the control group ($F_{2,121.5}=3.91$; $P<.05$; see mean, SD, and between-group effect size in [Table 5](#)). The control group remained on the waiting list and did not receive any intervention during the study period. These differences were also maintained at the 5-month follow-up, where the depressive symptoms were significantly reduced in the intervention group compared to the control group. In addition, Krämer et al [37] reported a significant difference in the decrease of both psychological symptoms ($F_{2,119.4}=4.37$; $P<.05$) and mental health quality of life ($F_{2,119.7}=3.36$; $P<.05$), indicating that the intervention group improved more than controls.

Table 3. Intervention characteristics of RCT^a studies.

Reference	Therapy	Delivery formats	Components	Duration and frequency
Krämer et al (2021) [37]	CBT ^b	Internet-based platform “GET.ON Mood Enhancer”	Six consecutive modules of 45 minutes, written semistandardized feedback by an e-coach (trained psychologist), homework assignments, a digital mood diary, and an optional text message coach	7 weeks
Villemaire-Krajen and Myhr (2019) [38]	CBT	Internet-based website “Good Days Ahead” accessible via computer	Nine lessons of 30 minutes, explanations for the CBT model and its application, vignettes presenting case examples, quizzes, exercises, introduction to a few behavioral techniques such as activity monitoring and scheduling	9 weekly lessons
Kenter et al (2016) [11]	PST ^c	Internet-based platform, email reminders if not finishing a session	Five sessions with structured homework assignments, adopting a structured 6-step approach: identifying the problem, finding solutions, selecting one solution, creating a plan to solve the problem with this solution, executing the plan, and evaluating the plan, plus web-based feedback by a coach	5 weekly sessions
Kolovos et al (2016) [36]	PST	Internet-based platform, email reminders if not finishing a session	Five sessions with structured homework assignments, adopting a structured 6-step approach: identifying the problem, finding solutions, selecting one solution, creating a plan to solve the problem with this solution, executing the plan, and evaluating the plan, plus web-based feedback by a coach	5 weekly sessions
Twomey et al (2014) [39]	CBT	Internet-based platform “MoodGYM,” weekly automated email reminders	A brief introductory session and five 20- to 40-minute sessions, containing written information, animations, human-centered exercises, and quizzes	32 days

^aITT: intention-to-treat.

^bNot applicable.

Villemaire-Krajden and Myhr [38] investigated the effectiveness of using computerized CBT to decrease symptoms of distress in outpatients during a waiting period for services. They did not find significant interactions between the intervention and control group, with a very small between-group effect size (Table 5). This indicates that compared to the control group, the intervention group did not score significantly better with regard to well-being, symptom severity, functioning, or motivation for CBT. In addition, depressive symptoms, anxiety symptoms, and life functioning difficulties were not found to have changed significantly between groups from baseline to the postintervention assessment. However, for both groups, the well-being (measured by Clinical Outcomes in Routine Evaluation Outcome Measure) of the participants significantly increased ($F_{1,37}=6.31$; $P<.05$), and the symptoms significantly decreased ($F_{1,37}=8.74$; $P<.05$) over time.

Both Kenter et al [11] and Kolovos et al [36] investigated the effectiveness of a web-based PST, self-help intervention in reducing depression symptoms. The intervention examined by Kenter et al [11] was effective in reducing depression and anxiety symptoms, but in comparison with the control group (who were provided with a self-help book), it was not more effective. They used intention-to-treat (ITT) analysis and found a significant reduction in depressive symptoms in both the

intervention group (see Table 5, within-group effect size: Cohen $d=0.75$) and the control group (within-group effect size: Cohen $d=0.69$) from baseline to posttreatment. Despite the moderate within-group effect size for both groups, the between-group effect size was small (Table 5). The between-group difference posttreatment was not significant in the regression analysis. Similarly, for anxiety, Kenter et al [11] reported moderate within-group effect sizes (intervention group: Cohen $d=0.41$; control group: Cohen $d=0.52$) and small between-group effect size (Table 5), and they found no significant difference between the intervention group and the control group. The clinical outcomes in Kolovos et al [36] were the same as Kenter et al [11] but Kolovos et al [36] focused on estimating the cost-effectiveness of the intervention in comparison with enhanced usual care. Kolovos et al [36] found that from a societal perspective, the intervention was not cost-effective in comparison with the enhanced usual care.

Twomey et al [39] examined the effectiveness of a self-help CBT intervention (“MoodGYM”) on reducing general psychological distress, stress, depression, anxiety, and impaired daily functioning symptoms. Twomey et al [39] found symptom improvement for the treated individuals with a within-group effect size of Cohen $d=0.4$ for depression and Cohen $d=0.14$ for anxiety. Nevertheless, similar to the studies conducted by Kenter et al [11] and Kolovos et al [36] they did not find

significant differences between the intervention group and the simply waiting control group (depression: $F_{1,64}=2.99$; $P>.05$; anxiety: $F_{1,64}=1.72$; $P>.05$) [39]. At posttreatment, small between-group effect sizes were found for both depression and anxiety (Table 5), suggesting that “MoodGYM” was not more effective than the control condition.

Non-RCTs

Intervention characteristics of non-RCTs are shown in Table 6. Hentati et al [40] tested the effectiveness of a self-guided PST

intervention. The results showed a 16% and 22% median for symptom improvement in depression and anxiety, respectively, from screening to posttreatment. However, from pretreatment to posttreatment, the improvement in depression was reduced by 3%, while anxiety symptoms were reduced by 3%. Hentati et al [40] concluded that there was insufficient evidence for the effectiveness of this digital intervention.

Table 6. Intervention characteristics of non-RCT^a studies.

Reference	Therapy	Delivery formats	Components	Duration and frequency	Measurement		
					Depression	Anxiety	Others
Hentati et al (2022) [40]	CBT ^b	Internet-based platform accessible via computer and mobile devices	Psychoeducational texts, treatment rationale, examples of problems and suggestions of solutions, illustrative pictures, instructions, and problem-solving exercises	4 weeks	PHQ-9 ^c	GAD-7 ^d	Treatment credibility (CEQ ^e), usability (SUS ^f), behavioral engagement, suicidal ideation (MADRS-S ^g), negative effects (NEQ ^h), post-study questionnaire on user experience
Duffy et al (2019) [41]	CBT	Internet-based platform “Silver-Cloud”	Eight modules including tools such as self-monitoring and thought recording, behavioral activation, cognitive restructuring, and challenging core beliefs	47 days, one review every 10 to 12 days.	PHQ-9	GAD-7	Work and social functioning (WSAS ⁱ)
Whitfield et al (2006) [42]	CBT	Computerized CD Rom	Six sessions of 45-60 minutes, including text, cartoon illustrations, animations, human-centered questions, sound, and video, as well as the offer of short support sessions by a self-help support psychiatric nurse	6 weekly sessions	BDI-II ^j	BAI ^k	Hopelessness (BHS ^l), social adaptation self-evaluation (SASS ^m)

^aRCT: randomized controlled trial.

^bCBT: cognitive behavioral therapy.

^mSASS: Social Adaptation Self-evaluation Scale [66].

Duffy et al [41] examined the outcomes of using iCBT as a prequel for patients requiring high-intensity treatment. The results indicated that 58% exhibited reliable improvement from baseline to iCBT exit and around 20% of the sample achieved reliable recovery in advance of starting face-to-face therapy. This was demonstrated by the decrease in depression

(within-group effect size: Cohen $d=0.61$) and anxiety (within-group effect size: Cohen $d=0.69$). In addition, the decrease in the WSAS score, which estimates the severity of work and social adjustment impairment, followed a similar pattern with a substantial reduction (mean 2.4, SD 8.7 points)

in the severity score at iCBT exit (within-group effect size: Cohen $d=0.31$).

Finally, Whitfield et al [42] investigated the effectiveness of the compact disc CBT self-help intervention. They adopted an ITT analysis where the last observation for the participant was carried forward if data were missing due to questionnaire nonresponse. The ITT analysis could possibly reduce any potential bias by accounting for the situation of those who had dropped out of the study. Although they did not calculate the effect sizes, the mean BDI-II scores for depression symptoms significantly decreased ($t_{19}=4.91$; $P<.001$), and the mean BAI score for anxiety symptoms significantly decreased as well ($t_{19}=2.51$; $P=.02$; Table 5). Furthermore, Whitfield et al [42] found the effectiveness of the intervention persisted at the 3-month follow-up.

Summary

To summarize, there is some evidence of the effectiveness of digital interventions to improve depression and anxiety symptoms in individuals waiting for psychotherapy. Seven of the eight studies reported digital interventions that led to a reduction in depressive and anxiety symptoms, with, on average, a moderate within-group effect size. However, only one study found that the waiting list intervention was effective in comparison with the control group. Moreover, due to the small between-group effect sizes in four of the five RCTs and the small sample sizes in the non-RCTs, it is difficult to conclude that the waiting list interventions were effective.

The secondary outcomes are shown in Table S3 in [Multimedia Appendix 2](#). In brief, the reviewed studies showed that the user engagement of the self-guided digital interventions was low, but the guided digital interventions appeared more engaging compared to the unguided ones. The low engagement and high dropout rates may have contributed to the interventions being less effective. The interventions were generally perceived as credible and useful, with moderate to high user satisfaction, suggesting that digital interventions have the potential to be adapted as a pretreatment for patients on waiting lists.

Discussion

Principal Findings

This systematic review identified 8 studies of digital interventions aimed at reducing the depression and anxiety symptoms of patients waiting for face-to-face psychotherapy. We found that waiting list interventions were effective in reducing symptoms of depression and anxiety, but not more effective compared to simply waiting for treatment or control groups who used a self-help book. Although the digital interventions were perceived as credible and useful, low user engagement was a major concern for treatment adherence and effectiveness.

Effectiveness and Features of the Waiting List Digital Interventions

We found that the DMHIs implemented with patients on waiting lists reduced depression and anxiety symptoms with moderate effect sizes. These effect sizes were similar to those of prior

meta-analyses on the effectiveness of DMHIs in general by Firth et al [22] and Moshe et al [28]. Nevertheless, this review did not find significant differences between the intervention group and the control group. Several factors might have reduced symptoms in the control groups. First, in the RCTs conducted by Kenter et al [11] and Kolovos et al [36], the control group was provided with a self-help book instead of merely waiting; the aim was to increase the participation rate. Even with small effect sizes, previous studies have shown that self-help books were effective in reducing depression symptoms [8]. In addition, some spontaneous improvements were found among the waiting control group, as demonstrated in Twomey et al [39]. This is in line with previous studies that show that spontaneous improvement does occur among some patients with depression and those with anxiety [16,67].

Concerning the features of the DMHIs, there was no difference between DMHIs implemented for patients specifically on waiting lists and general DMHIs. In addition, across the reviewed 8 studies, we did not find evidence of a specific technological platform (ie, using phone vs computer) or a specific psychological therapy (ie, CBT vs PST) having better effectiveness in DMHIs, which is consistent with previous studies [8,28].

While DMHIs have the potential to provide more scalable, more accessible, and more cost-efficient treatments compared to face-to-face therapies [23,24], it is important to acknowledge that DMHIs may not be suitable to address some patients' need for face-to-face psychotherapy, especially for those with severe symptoms [11,36]. Due to these concerns, Twomey et al [39] and Krämer et al [37] recommended that digital interventions should not be provided as a substitute for face-to-face psychotherapy but were better suited to being an additional or complementary treatment option that could bridge the waiting time. This is consistent with Cornish's [68] stepped-care model, where patients are able to receive timely digital interventions on the same day that they seek care, balancing out the treatment intensity and resources available.

User Engagement

As identified by earlier studies, guided interventions are more engaging compared to unguided ones [31,32], and general DMHIs implemented during the waiting time exhibited lower user engagement and treatment adherence compared to face-to-face psychotherapies [28-30]. In this review, Krämer et al [37] show that there was a lower dropout rate and higher treatment adherence compared to the other self-guided studies. This might be explained by the participants' demographics. For example, Twomey et al [39] reported that although 85% of the males dropped out of the study, the number of females that dropped out was only 8%. In contrast, Kenter et al [11] and Kolovos et al [36] reported that 64.7% of the participants who did not complete the study were female. They also found that participants who were younger, less educated, and had lower incomes were more likely to drop out [11,36]. In addition, as Farrington et al [69] suggest, technical difficulties experienced by certain age groups (ie, older people) and incompatibility between different digital device systems may also have been barriers to user engagement.

Another factor for low user engagement might be related to how the digital intervention was promoted. In all the studies reviewed, the interventions were presented to the participants as an additional or temporary treatment rather than a replacement for the face-to-face psychotherapy they were waiting for. Promoting the interventions in this way might have lowered the expectancy of participants as regards the effect of the treatment and they may also have perceived it as less important. For instance, Hentati et al [40] reported that the participants were not convinced that the digital intervention would result in any major reduction in their symptoms although they perceived the intervention as credible. Kenter et al [11] found that the completion rate was positively associated with participants' expectancy and perceived credibility of the intervention. Therefore, changing the way digital interventions are promoted may increase the engagement rate.

Limitations and Future Studies

Due to the understudied nature of the topic, the first limitation of this systematic review was the restricted number of randomized control studies (n=5), which reduces the possibility of drawing a robust conclusion concerning the effectiveness of waiting list interventions. In addition, according to the quality assessment, the reviewed studies had some shared concerns about using self-report data and missing values due to dropouts. In future studies, once a sufficient number of high-quality studies with adequate sample sizes are available, conducting a meta-analysis will be crucial to provide a more comprehensive synthesis of the evidence in this area. Second, various instruments were adopted to measure depression and anxiety symptoms, posing challenges when controlling for baseline differences and when comparing the effectiveness of the studies. Moreover, the psychological outcomes were self-reported in most studies, and these might be less sensitive to symptom changes compared to a clinician's assessment [37]. Third, this study was limited to patients with depression and those with anxiety with relatively stable conditions. Patients with severe suicidal ideation and psychosis were excluded, even though

these groups are at a higher risk for symptom deterioration while waiting for psychotherapy. Ketner et al [11] reported one case of suicide in the control group, suggesting that future waiting list interventions could target individuals with less stable conditions. Additionally, when considering future studies, we recommend the use of multiple research protocols for RCTs in the field of digital interventions for patients on waiting lists that target a wider range of symptoms (ie, phobic disorders and eating disorders) [70-72]. Moreover, we recommend that researchers adopt more therapies (ie, exposure therapy) and include larger samples [73,74]. Finally, it is also important for future studies to consider the use of digital interventions in different populations. We acknowledge that this review only included English studies, which may have missed valuable studies conducted in non-English speaking countries. The reviewed studies in this study were also conducted in high-income Western countries. It is unclear whether resource-limited areas may benefit more from low-cost, web-based interventions for mental health issues.

Conclusions

As a potential solution to the problem of prolonged waiting lists for psychotherapy, this systematic review examined the effectiveness of DMHIs in reducing anxiety and depression symptoms of patients on waiting lists for psychotherapy. Our results showed that among the RCTs, DMHIs were overall not more effective when compared with simply waiting or the control groups who used a self-help book. Among the non-RCTs, although the intervention reduced depression and anxiety symptoms, the study design with no control group made it difficult to conclude the effectiveness of the intervention. Waiting list DMHIs may prove to be an adequate treatment for some patients, but low user engagement remains a concern for treatment adherence and effectiveness. Despite patients rating DMHIs as credible and useful, it is nevertheless evident that as yet DMHIs might not fully replace face-to-face psychotherapies for all patients.

Authors' Contributions

All authors designed the study protocol together, contributed to writing, as well as reviewed and revised the final manuscript. SH, YW, GL, and TJN conducted the literature search, data extraction, and synthesized the data. SH and YW made [Figure 1](#). SH and TJN made all the tables. TJN supervised the research project.

Abstract

Background: Depression affects 5% of adults and it is a major cause of disability worldwide. Digital psychotherapies offer an accessible solution addressing this issue. This systematic review examines a spectrum of digital psychotherapies for depression, considering both their effectiveness and user perspectives.

Objective: This review focuses on identifying (1) the most common types of digital psychotherapies, (2) clients' and practitioners' perspectives on helpful and unhelpful aspects, and (3) the effectiveness of digital psychotherapies for adults with depression.

Methods: A mixed methods protocol was developed using PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. The search strategy used the Population, Intervention, Comparison, Outcomes, and Study Design (PICOS) framework covering 2010 to 2024 and 7 databases were searched. Overall, 13 authors extracted data, and all aspects of the review were checked by >1 reviewer to minimize biases. Quality appraisal was conducted for all studies. The clients' and therapists' perceptions on helpful and unhelpful factors were identified using qualitative narrative synthesis. Meta-analyses of depression outcomes were conducted using the standardized mean difference (calculated as Hedges *g*) of the postintervention change between digital psychotherapy and control groups.

Results: Of 3303 initial records, 186 records (5.63%; 160 studies) were included in the review. Quantitative studies (131/160, 81.8%) with a randomized controlled trial design (88/160, 55%) were most common. The overall sample size included 70,720 participants (female: *n*=51,677, 73.07%; male: *n*=16,779, 23.73%). Digital interventions included "stand-alone" or non-human contact interventions (58/160, 36.2%), "human contact" interventions (11/160, 6.8%), and "blended" including stand-alone and human contact interventions (91/160, 56.8%). What clients and practitioners perceived as helpful in digital interventions included support with motivation and accessibility, explanation of task reminders, resources, and learning skills to manage symptoms. What was perceived as unhelpful included problems with usability and a lack of direction or explanation. A total of 80 studies

with 16,072 participants were included in the meta-analysis, revealing a moderate to large effect in favor of digital psychotherapies for depression (Hedges $g=-0.61$, 95% CI -0.75 to -0.47 ; $Z=-8.58$; $P<.001$). Subgroup analyses of the studies with different intervention delivery formats and session frequency did not have a statistically significant effect on the results ($P=.48$ and $P=.97$, respectively). However, blended approaches revealed a large effect size (Hedges $g=-0.793$), while interventions involving human contact (Hedges $g=-0.42$) or no human contact (Hedges $g=-0.40$) had slightly smaller effect sizes.

Conclusions: Digital interventions for depression were found to be effective regardless of format and frequency. Blended interventions have larger effect size than those involving human contact or no human contact. Digital interventions were helpful especially for diverse ethnic groups and young women. Future research should focus on understanding the sources of heterogeneity based on intervention and population characteristics.

Introduction

Background

Globally, depression affects >280 million people including 5% adults [1]. It is a leading cause of disability worldwide and a major contributor to the overall global burden of disease [2]. In the United Kingdom, for example, depression affects 3% to 6% of people [3] from diverse socioeconomic, educational, and cultural backgrounds.

In view of the prevalence of depression across different groups, the 2022 National Institute for Health and Care Excellence (NICE) guidelines for depression [3] have been revised to include a range of interventions as a first line of treatment, thus meeting diverse needs while widening clients' choices. The interventions include behavioral activation, exercise, mindfulness, cognitive behavioral therapy (CBT), counseling for depression, psychodynamic psychotherapy, and couples therapy. In addition, the NICE guidelines [3] recommended antidepressant medication but for severe depression only, placing an emphasis on clients' preferences and the role of psychological and physical interventions over drug treatment.

In the past, interventions for depression were provided predominantly face to face, and digital psychotherapies were available only to a limited degree. However, the outbreak of COVID-19 and consequent lockdowns, social distancing, and isolation rules have led to many people struggling with anxiety and depression [4]. The National Health Service had to adapt to provide therapy in a more flexible way, including digital delivery [5], which was in line with the policies outlined in the UK Government's Five Year Forward View for Mental Health [6] and the National Health Service Long Term Plan [7]. This has led to a need for more research in relation to the provision of digital psychotherapies.

The need for guidance in digital psychotherapies has given rise to recent systematic reviews on depression. However, the reviews are limited to formal diagnoses of unipolar depression [8] or relate to chronic health conditions [9-11]. The available reviews also focus on specific modes of delivery (eg, smartphone apps [12]) or specific client groups (eg, perinatal clients [13] or children and young people [14-17]). Another limitation of most of the published systematic reviews is a focus

on CBT only [11,18-20] ignoring the fact that a range of interventions are being offered for depression [3]. A broader review of evidence in relation to a range of digital approaches and psychotherapeutic theories is needed, and this systematic review aims to address this gap.

Most recent meta-analyses highlighted that there is no difference between technology-based and in-person treatments for depression [21], and there are some indications [22] that this is reflected in clients' preferences for treatment: 55.5% of adults choose digital psychotherapy for depression. However, practitioners draw attention to the therapeutic relationship in digital psychotherapies, which is important to consider [21]. There is some evidence that working digitally does not reduce the quality of the therapeutic relationship [23], but therapists are often concerned that they do not have the same access to the clients' experience as in face-to-face interactions. Researchers argue that most therapeutic activity is grounded in the body involving body-to-body communication, attunement, and coregulation of feelings in the shared physical space, which cannot be replaced by a web-based treatment [24]. A preliminary literature search revealed no systematic reviews highlighting service users' perspectives on digital psychotherapies for depression. This would seem essential when discussing individual preferences and ethical considerations of web-based treatments especially in terms of safety and privacy [25]. This current systematic review aims to address this gap and present service users' perspectives within the existing research on digital psychotherapies for depression, highlighting their needs and preferences.

An additional problem in existing literature is a lack of clarity in the terminology used for the digital modes of delivery, leading to confusion in relation to what is effective and what is not [26]. Delivery can be, for example, asynchronous, synchronous, self-guided, with a therapist, or blended. Types of media can include telephone, videoconferencing, emails, websites, or apps. In the literature, terms are often used inconsistently. Therefore, the current systematic review will review the terminology and summarize current evidence using consistently defined terms.

Moreover, it is important to understand the specific factors impacting the effectiveness of digital interventions for depression. There are arguments that effectiveness depends on

the duration of the intervention, baseline severity, adherence, and the level of human guidance [19]. This current systematic review will focus on these and other important factors within the data set, aiming to provide more specific guidance in relation to the digital psychotherapies for depression.

Research Questions

Taking the above issues into account, this systematic review will aim to answer the following 3 research questions that have not yet been addressed in other systematic reviews. The research questions will include:

1. What are the most common types of digital psychotherapeutic interventions for adults with depression?
2. What are the clients' and practitioners' perspectives on helpful and unhelpful factors in digital psychotherapeutic interventions for adults with depression?
3. What is the effectiveness of digital psychotherapeutic interventions for adults with depression?

Step 2: "online" OR "remote" OR "tele-therap*" OR "digital" OR "e-mental health" OR "e-therap*" OR "mobile*" OR "internet-administered" OR "web-based" OR "app*" OR "digital*" OR "technolog*" OR "computer*" OR "tablet*" OR "m-health*" OR "mobile health" OR "e-health" OR "electronic health" AND

Step 3: "Psychotherap*" OR "psychologic*" OR "therap*" OR "counselling" OR "counseling"

The search was limited to the 2010-to-2024 time frame in order to focus on the latest advances in digital psychotherapies.

Screening

Search results were independently screened by 4 reviewers (SA, SL, JO-T, and RC) at the title and abstract level. The full texts were then assessed for eligibility based on the predetermined

Methods

Overview

A mixed methods systematic review protocol was developed using PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [27] and registered with PROSPERO (2021; CRD42021238462). Unlike traditional systematic reviews, this review combined both quantitative and qualitative studies. The intention was to maximize the findings not only by examining the effectiveness of digital psychotherapies but also by mapping the utility, impact, and the ability of those findings to inform policy and practice.

Search Strategy

The search strategy was developed using 3 key concepts: population, intervention, and context (population: people with depression, intervention: digital interventions, and context: psychotherapy) using Boolean operators and truncation marks (Textbox 1). The following data bases were searched up to February 12, 2024: CINAHL, PsycArticles, PsycINFO, PubMed, BASE, Academic Search Premier, and ProQuest Health Research Premium Collection.

criteria that were set using a combination of the Population, Intervention, Comparison, Outcomes and Study Design (PICOS) framework [28] (Table 1) and other factors such as context, time period, and the type of publication. Where data needed for eligibility assessment were missing, the authors were contacted to provide the information. Unclear or unresolved cases were discussed and moderated during the weekly team meetings.

Table 1. Eligibility criteria.

Criteria	Inclusion	Exclusion
Population	Participants with a mean age of ≥ 18 years, any gender, ethnicity, country, and with any severity and chronicity of depression. $\geq 75\%$ of participants in the study should have a diagnosis of depression or self-report depression or low mood as a primary reason for being involved in the study. The diagnosis could involve MDD ^a , dysthymic disorder, peripartum depression (previously postpartum depression), seasonal affective disorder, or premenstrual dysphoric disorder.	Studies where depression is not a primary outcome (comorbid with psychotic or other medical and mental health conditions) and acute phase of depression.
Intervention	Studies with digital psychotherapeutic intervention as the main intervention, including all forms of verbal psychotherapies and counseling (eg, humanistic, psychoanalytic or psychodynamic, cognitive or behavioral, and integrative); creative or arts psychotherapies (eg, dance, drama, art, music, and poetry); and any combination of the above delivered in any digital format (eg, websites, apps, telephone, videoconferencing, emails, etc)	Studies where $\geq 50\%$ sessions are delivered nondigitally (eg, face-to-face consultation in the therapy room). Studies with advice, guidance, signposting, coaching, psychoeducation, and peer support. Studies focused on only screening, assessment, prevention, and follow-up.
Comparators	All types of comparators such as waiting list, treatment as usual, face-to-face psychological therapies, pharmacological interventions, physical interventions, or studies with no comparators	None
Outcomes	Depressive symptoms measured using any validated instruments (self-rated or observational tools) is considered as the primary outcome. In addition, views or perspectives of clients and practitioners on the processes and helpful and unhelpful factors or aspects of digital psychotherapies for adults with depression	None
Study design	Any type of empirical research with quantitative, qualitative, mixed, or arts-based approaches using surveys, pilot studies, intervention protocols, and quasi-experimental studies, RCTs ^b , interviews, and other methods with people experiencing depression is considered.	Systematic reviews, secondary sources, opinion-based articles, editorials, policy reviews and statements, and commentaries. Unpublished masters or doctoral level dissertations, unpublished conference presentations, conference proceedings where full-length articles are not available, clinical case examples without explicit research methodology, and narrative articles.
Context	Psychotherapeutic interventions delivered “digitally” by qualified and registered therapists or web-based interventions or apps informed by psychotherapeutic approaches.	Nontherapeutic studies, educational videoconferences, workshops, and self-help programs that involve exclusively chats or support groups.
Time period	2010-2024	Before 2010 and unpublished ongoing studies
Publication type	Peer-reviewed	Editorials, conference presentations, and opinion-based articles

^aMDD: major depressive disorder.

^bRCT: randomized controlled trial.

Extraction

Studies involving both therapeutic processes and outcomes of digital psychotherapies were included to aid further understanding of the digital contribution to psychotherapies for depression. An extraction form based on a Microsoft Excel spreadsheet was developed to gather information for each research question. The review authors piloted 8 initial studies to refine the extraction form. A total of 10 authors independently extracted data from approximately 10 to 30 studies each, and 4 authors (SA, SL, JO-T, and RC) cross-checked and verified all the extracted data. Disagreements were resolved by discussion in weekly meetings, and when issues remained unclear, the members of the review team arbitrated. In the first instance, the team extracted demographic data related to the studies and population characteristics. To answer the first research question in relation to the most common types of digital interventions for depression, we used the Template for Intervention Description and Replication (TIDieR), which is a commonly

used intervention description and replication checklist [29]. Furthermore, clients' and practitioners' perceptions on helpful and unhelpful factors of digital psychotherapies were gathered to answer the second research question. Finally, numeric data related to the primary outcomes of depression were documented for the third research question.

Quality Assessment

Randomized controlled trials (RCTs) were evaluated using the Cochrane risk-of-bias assessment tool [30] to identify risks such as selection bias (random sequence generation and allocation concealment), performance bias (blinding of participants and personnel), detection bias (blinding of outcome assessment), attrition bias (incomplete outcome data), and reporting bias (selective reporting). Studies with non-RCT designs (eg, controlled trials, pretest-posttest design, mixed methods, and qualitative studies) were evaluated using the Mixed Methods Appraisal Tool (MMAT; version 2018) [31]. The review authors

working in pairs answered the questions that covered various aspects of the quality of execution and reporting of the studies.

Data Synthesis and Analysis

All the studies that met the inclusion criteria were considered for qualitative narrative synthesis [32] to present the characteristics of digital psychotherapies. The synthesis began with the “mapping” of the available relevant evidence against the specific research questions. Intervention-specific and person-specific factors influencing digital psychotherapy were explored and thematically analyzed using a modified behavior change model [33], which provides a useful classification of the barriers and facilitators in digital interventions [34]. Moreover, the quantitative data from studies with RCT components were analyzed to evaluate the pooled robustness of the digital psychotherapy outcomes.

Meta-analyses of depression outcomes were conducted using the standardized mean difference (SMD, calculated as Hedges g) of the postintervention change between digital psychotherapy and control groups to accommodate for expected methodological and intervention design variations [35]. Analyses were conducted for all depression outcomes combined, and the precision of the SMD was calculated for each trial by the 95% CI. A negative SMD implied better therapeutic effects over time in the digital psychotherapy group compared to the control group. All the analyses were performed using Comprehensive Meta-Analysis software. The pooled effect sizes were interpreted using the same rule for describing Cohen d effect sizes as applied to Hedges g . SMDs of ≤ 0.30 , 0.30 to 0.60, and >0.60 were considered as small, moderate, and large effect sizes, respectively.

We intended to include crossover trials but only the first active treatment period. For studies with multiple arms, only those with the digital intervention and the control arms were included in the analysis [36]. If there were 2 digital intervention arms with a single control group, then the sample size of the control group was halved before the meta-analysis to avoid counting the same participants twice. When studies presented data from >1 depression measurement tool, we prioritized data in the following order: Beck Depression Inventory, Patient Health Questionnaire-9, and Hamilton Depression Rating Scale based on the most frequently used tools identified in this review.

Dealing With Missing Data

For meta-analysis where mean, SD, and sample size were missing from the end of intervention scores, we looked for alternate formats available on Comprehensive Meta-Analysis to compute the missing data. If we lacked sufficient information to extrapolate missing information, we contacted the study authors to obtain the missing data and the reason for the missing data. Where this was not possible, we excluded the study from the meta-analysis but used the descriptive information to answer other research questions and qualitative synthesis.

Assessment of Heterogeneity

We initially explored heterogeneity across studies using a visual inspection of forest plots (potential heterogeneity was considered where CIs were not overlapping). Furthermore, to assess the

presence and extent of between-study variation I^2 statistic with 95% CIs (uncertainty), Q statistics were used. The Q test was performed to check if there was any variance in the true effect size across studies with an α criterion set at a low statistical power of .100 for a better possibility to reject the null hypothesis and identify if the effect sizes varied across studies. The I^2 test was performed to identify what proportion of the variance in observed effects shows variance in true effects rather than a sampling error.

Assessment of Reporting Bias

For evaluating the risk of publication bias, funnel plots for overall depression outcomes were visually inspected for asymmetry (ie, SMDs charted against their SE). As ≥ 10 studies were pooled, we formally tested funnel plot asymmetry using Egger test of the intercepts [37]. A positive intercept indicates that studies with smaller sample sizes tend to report more positive results than large-sample studies. When the test found notable asymmetry ($P=.10$), we reported primary outcomes based on a fixed effects model along with a random effects model. This strategy gave more weight to larger trials and helped to counterbalance a possible inflation of the therapeutic effect by discussing a more conservative effect estimate [38].

Subgroup Analysis

Subgroup meta-analyses were conducted to investigate between-study variability, explore the reasons for heterogeneity, and recognize intervention design components that may moderate observed efficacy. Subgroup analyses were based on a mixed effects model, which used a random effects model to generate within-subgroup variance and a fixed effects model to compare effects between subgroups [39]. Between-subgroup heterogeneity was tested using Cochrane Q statistic and was considered significant at the $P=.05$ level. The following moderating factors related to the intervention were included in our analysis plan: delivery format of the digital intervention (contact with human, no contact with human, and blended) and session frequency (once per week and more than once per week).

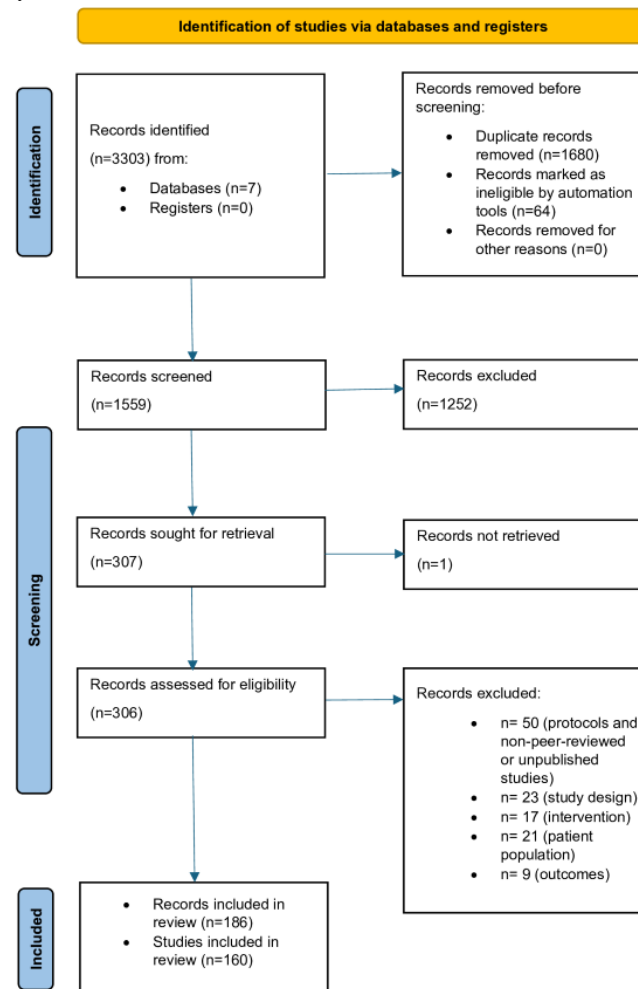

Results

Overview

As shown in the PRISMA flow diagram (Figure 1), the comprehensive search of 7 academic databases resulted in 3303 records. After duplicates were removed, the remaining 1559 (47.2%) records were screened at the title and abstract level, excluding 1252 (80.31%) records. Out of the remaining 307 articles, 306 (99.7%) were read in their entirety, while 1 (0.3%) study was not retrieved. A total of 23 (7.5%) records were excluded based on the study design, 21 (6.9%) in relation to population, 17 (5.5%) due to intervention, 9 (2.9%) based on outcomes, and 50 (16.3%) due to the type of publication. The remaining 186 (60.8%) records (Multimedia Appendix 1 [40-224]), corresponding to 160 studies, were included for data extraction. Of these, 25 (13.4%) records constituted sibling studies that formed 18 groups of studies using the same samples. To avoid double counting of data, only the main publication was considered for demographic data extraction and research questions. Data from sibling studies were mainly extracted in

relation to clients' and practitioners' perspectives on helpful and unhelpful aspects of digital psychotherapies. In terms of meta-analysis of the overall efficacy of the digital psychotherapy for adults with depression, data from 80 RCTs were considered.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 flow diagram for new systematic reviews that included searches of databases and registers only.

General Characteristics of Included Studies

Study Characteristics

Year of Publication

This systematic review covers the period between 2010 and February 2024. Most papers were published in 2018 (21/160, 13.1%) and 2020 (18/160, 11.2%). In the years 2023, 2021, 2013, and 2014, a total of 13 (8.1%) or 14 (8.8%) papers were published each year. The remaining years saw 3 to 10 papers yearly.

Country

A total of 31 countries were covered in the studies (n=160) including the United States (n=49, 30.6%), the United Kingdom (n=18, 11.2%), Australia (n=15, 9.4%), Germany (n=13, 8.1%), the Netherlands (n=12, 7.5%), Canada (n=9, 5.6%), and others (n=40, 25%). Most of the studies (n=116, 72.5%) were conducted in countries from the global north (eg, the United States, the United Kingdom, the Netherlands, Australia, Germany, and Canada). Furthermore, 2 (1.25%) studies included

2 sites, Australia and the United States, and 3 (1.8%) studies were multinational.

Methodological Approach

The studies (n=160) were conducted using a range of approaches but predominantly adopted quantitative approaches (n=131, 81%), out of which more than half of the studies (n=88, 55% were RCTs. A total of 15 (9.4%) studies were conducted using mixed methods designs where 3 (20%) studies had an RCT component. Only 13 (8.1%) of the studies provided solely a qualitative view of the digital therapeutic process.

Place of Recruitment

A total of 61 (38.1%) studies recruited participants from health care settings, 44 (27.5%) used online methods, 15 (9.4%) were from community settings, 12 (7.5%) from educational settings, 14 (8.8%) from other settings, and 14 (8.8%) from a combination of the above.

The “other” category included a telephone service, postal invitations, emailed letters, and places of employment. The most common combination of recruitment places was “online and other” with 3 (1.9%) studies using this combination (Table 2).

^aRace and ethnicity in the included studies: not reported, n=84 (52.5%); reported, n=76 (47.5%).

Age

Age data were analyzed in relation to means and age ranges (where stated). Most studies (138/160, 86.2%) provided mean age data, with an average of 38.52 (SD 10.87) years. Moreover, 45.6% (73/160) of the studies provided a minimum age, and 41.2% (66/160) of the studies provided a maximum age, with an average age range of 38.52 years. In terms of specific age groupings (18-24, 25-39, 40-64, and >65 years), 15.6% (25/160) studies spanned all 4 categories, and 41.2% (66/160) studies included >1 category.

Gender

Of the 160 studies (participants, n=70,720) reviewed, 51,677 (73.07%) of the participants were women, 16,779 (23.73%) were men, and 2147 (3.04%) participants did not report their gender. The diversity of gender generated 7 different categories, including transgender (n=18, 0.03%), queer (n=9, 0.01%), nonconforming (n=9, 0.01%), variant (n=5, 0.007%), gender expansive (n=2, 0.002%), gender fluid (n=1, 0.001%), and nonbinary (n=1, 0.001%). A total of 72 (0.1%) participants did not specify their gender. Most of the studies (145/160, 90.1%) had a mixture of men and women in their sample. However, 14 (8.8%) studies recruited women only while, 1 (0.6%) study men only; 8 (5%) studies recruited more men than women. While 4 (2.5%) studies had an equal number of men and women participants in the sample, 2 (1.2%) studies did not report gender characteristics.

Race and Ethnicity

Of the 160 studies (participants, n=70,720), 84 (52.5%) did not report race and ethnic data, leaving 30,197 (42.7%) participants

not accounted for. In the remaining studies, there was no information about the race and ethnicity of an additional 10,511 (14.86%) participants, which brings the overall number of participants who did not report their race and ethnicity to 40,708 (57.56%). A total of 76 (47.5%) studies considered race and ethnicity in their analysis involving 40,523 (57.3%) participants and groups such as Asian (n=713, 1.76%; Asian American, Asian, Chinese, New Zealand Indian, Iranian, Han, and Middle Eastern); Black (n=741, 1.83%; Black African American, African American, African, African Canadian, and Black); Hispanic (n=16,684, 41.17%; Mexican, Hispanic Latino, and Latin American); Indigenous (n=851, 2.1%; First Nations or Metis, American Indian or Alaska Native, Maori, Indigenous Australians, Native Americans, Hawaiian Pacific Islander, and Indigenous); White (n=7291, 17.99%; White, Caucasian, European, European New Zealander, Dutch, and American); other (n=3560, 8.79%; non-Hispanic or Latino, non-Dutch, Other, non-Aboriginal Torres Strait Islander, and minority groups); and mixed (n=172, 0.42%; Black and White, mixed or >1).

Clinical Characteristics and Severity

There was a spread in terms of the severity of depression among the 160 studies, with 36 (22.5%) studies focusing on mild and above, 31 (19.4%) studies focusing on mild to moderate, and 27 (16.9%) on moderate to severe depression. A smaller number of studies (n=20, 12.5%) focused on severe depression only. Some studies (n=21, 13.1%) included major depressive disorder, perinatal depression (n=12, 7.5%), and (n=3, 1.9%) depression in older adults. A group of studies (n=35, 21.9%) focused on both depression and anxiety, and 3 (1.9%) studies included

multiple categories. There were also studies (n=9, 5.6%) that discussed other concerns such as suicidal ideation or alcohol misuse; diverse populations such as lesbian, gay, bisexual, and transgender communities; and different contexts such as workplace or rural communities.

Research Question 1: Mapping the Types of Digital Interventions

MoodGYM was the most popular named digital intervention (15/160, 9.4%), which used an interactive workbook (Table 4).

Beating the Blues was also common (8/160, 5%) and involved an 8-session course supported by a counselor. Other interventions included Good Days Ahead (4/160, 2.5%), a 9-lesson psychoeducational program, and Mindful Mood Balance (3/160, 1.9%), an 8-week course integrating mindfulness meditation with CBT. Furthermore, 5% (8/160) studies used a combination of digital interventions. Some interventions involved apps; for example, Project EVO (3/160, 1.9%) was a video game training app.

Table 4. Frequency of named interventions (n=70).

Named intervention	Frequency, n (%)
MoodGYM ^a	15 (21)
Beating the Blues ^b	8 (11)
Good Days Ahead	4 (6)
GET.ON Mood Enhancer, Health tips ^c , iPST ^c Meru health program, Mindful Mood Balance, Project EVO ^c	3 (4)
BluePages ^d , Cognitive Bias Modification Imagery, Deprexis, Intellicare, Living to the Full, Mom Mood Booster, My Compass ^e , My Strength Inc, The Journal, This Way Up	2 (3)
Ascent, BAML, BetterHelp, Bluewatch, Colour Your Life, Cooperation After Divorce, Dario Behavioural Health, e-SMART, Empower@Home, Feel Stress Free, Feeling Better, Get Happy, Good Life Compass, Gratitude Visit ^f , Happy@Work, HappyMom, Hdep, iFightDepression, Just In Time Adaptive Intervention, LifeApp'tite, Life Flex, Making the Golden Years Golden Again, MamaKits, Man Central, MARIGOLD, Master your Mood, MasterMind, Mindbalance, Mindfulness Virtual Community, MindWise 2.0, Moodbuster, MoodHacker, Mood Manager, MoodGarden ^g , Motherly, NexJ Health Inc, OctaVis, Online Life Review, Online Writing, Op Koers Online, OPTT, Overcoming Thoughts, PaarBalance, Pacifica, Peak, PRIME-D, Signature Strength ^f , Sinasprite, Sokoon, SPARX, Talkspace, TAPI, Three Good Things, Three Funny Things ^f , Thrive, Todac, VIDA, Wellness Workshop	1 (1)

^aUsed in combination with other named interventions (n=4).

^bUsed in combination with MoodGYM (n=1).

^cProject EVO, iPST, and Health tips used in combination (n=3).

^dUsed in combination with MoodGYM (n=2).

^eUsed in combination with MoodGYM (n=1).

^fGratitude visit, Three Good Things, Three Funny Things, and signature strength used in combination (n=1).

^gUsed in combination with MoodGYM (n=1).

Of the 160 studies reviewed, most interventions (n=132, 82.5%) used CBT as their framework, 6 (3.8%) referred to positive psychology interventions, and only 1 (0.6%) adopted a psychoanalytic and psychodynamic approach. In 8 (5%) studies, the interventions were based on an integrative framework such as combining CBT with positive psychology, while 13 (8.1%) studies described interventions in which the theoretical models were either not clearly defined or did not fall within the 4 main approaches to psychotherapy (ie, cognitive-behavioral, humanistic, psychoanalytic and psychodynamic, and integrative). Table 5 shows the definitions of specific types of interventions.

Out of the 160 studies reviewed, 93 (58.1%) were web based, 25 (15.6%) used mobile apps, 13 (8.1%) used computer

programs, 1 (0.6%) involved virtual reality, and 1 (0.6%) was avatar based. Moreover, 26 (16.2%) studies used a combination of the above methods.

The interventions included messaging, emails, and calls (17/160, 10.6%), online peer support (11/160, 6.9%), online face-to-face contact (7/160, 4.4%), and virtual or augmented reality (1/160, 0.6%). Interventions were also delivered via participants watching videos (19/160, 11.9%) and listening to audio (11/160, 11.9%).

In terms of psychotherapeutic approaches, the digital interventions were mainly based on CBT (132/160, 82.5%). A small number of interventions used integrative approach (8/160, 5%), positive psychology (5/160, 3.1%) and psychodynamic and psychoanalytic psychotherapy (1/160, 0.6%).

Table 5. Definitions of the types of interventions (n=160).

Type of intervention	Definition	Studies, n (%)
No human contact and stand-alone	No human involvement in the therapeutic process, for example, an app that was fully automated and sent reminders to users via notifications or emails, but the participants did not have any contact with a human therapist	58 (36.2)
Human contact	Participants had web-based or offline sessions with the therapist. The contact could be synchronous (eg, a Zoom video call) or asynchronous (eg, an email), but the therapist was involved in the clients' journey. For example, the contact could include live Zoom video calls only or Zoom video calls and then text follow-up with the therapist. However, the contact had to be with a therapist, not a researcher	11 (6.9)
Blended	Both "stand-alone" and "human contact" interventions were used. For example, the participant worked through modules independently on a website and then met with a therapist via a Zoom video call or in person. The degree of contact with the therapist varied	91 (56.9)

Most of the therapeutic activities (86/160, 53.8%) involved web-based psychoeducation drawn primarily from CBT, including cognitive restructuring (34/160, 21.3%), behavioral activation or activity planning (23/160, 14.8%), mood rating (14/160, 8.8%), problem-solving (16/160, 10%), goal setting (5/160, 3.1%), and graded exposure or behavioral experiments (4/160, 2.5%). Some interventions (22/160, 13.8%) were delivered using creative means such as games or quizzes, music, journal writing, comic books, stories, animations, singing, bibliotherapy, and graphics. Homework with therapeutic tasks also featured (19/160, 11.9%). Different forms of relaxation (17/160, 10.6%) including visualization, guided relaxation, body scan, yoga, self-hypnosis, deep breathing, and progressive muscular relaxation were mentioned. Mindfulness and meditation (16/160, 10%) and acceptance and commitment therapy or values-based interventions (7/160, 4.4%) were also common. Less-common approaches included working with emotions or emotion regulation strategies (5/160, 3.1%), social skills learning (5/160, 3.1%), relapse prevention (2/160, 1.2%), coping skills training (2/160, 1.2%), cognitive training for memory improvement (1/160, 0.6%), neuroplasticity principles (1/160, 0.6%), and an emotional faces memory task (1/160, 0.6%).

Where reported, the most common dosage for interventions was 6 to 12 weeks in length (73/160, 45.6%), 6 to 12 sessions (44/160, 27.5%), and 6 to 12 modules (30/160, 18.6%). A further 23 (14.4%) studies lasted for <6 weeks, while 6 (3.6%) took >12 weeks. Most commonly, the interventions included 8 (mean 9.66) sessions of 60 (mean 43.35) minutes and were spread over 8 (mean 8.29) weeks, taking place once a week. However, due to variation, the average frequency per week was 2.18 sessions. At least 17 (10.6%) studies stated access as "ad libitum" or "self-paced."

Research Question 2: Clients' and Practitioners' Perspectives on Helpful and Unhelpful Factors Identified in Qualitative and Mixed Methods Studies

Overview

Qualitative (13/160, 8.1%) and mixed methods (15/160, 9.4%) studies were used to identify clients' and practitioners' perspectives on helpful and unhelpful factors in digital psychotherapeutic interventions for depression. In line with the categorization above, these interventions were divided into 3 groups: with no human contact or stand-alone, with human

contact (via digital means), and a combination of human contact with stand-alone approach (blended).

In order to identify the specific helpful and unhelpful factors within each of the above groups, 4 authors used a modified behavior change model [33] as applied by Liverpool et al [34], outlining the barriers and facilitators to engagement in digital mental health interventions including person-specific and intervention-specific influencing factors. In terms of person-specific factors, motivation, opportunity, and capability were listed as the influencing factors. In terms of intervention-specific influencing factors, suitability, usability, and acceptability were identified.

Interventions That Did Not Involve Human Contact or Stand-Alone Interventions

The interventions included in this category involved 11 fully automated programs. Of these 11 interventions, 10 (91%) were delivered through dedicated websites [40-49] and 1 (9%) was delivered through a fully automated app [50].

A total of 9 (82%) studies discussed helpful and unhelpful factors from the clients' perspectives. In addition, 1 (9%) study [46] was interested in consulting the public, as potential users, to better understand how interventions for depression could be improved for lesbian and gay users. Another study [50] involved collecting data from potential users and 2 groups of experts formed by researchers and health care professionals.

For the interventions delivered via websites, the most frequently reported (6/10, 60% studies) helpful factors related to "motivation." Examples of what "motivated" people to engage included gaining improvement in mental health, learning coping skills in difficult situations (eg, when anxious), achieving behavioral change, gaining awareness and insight, learning self-reflection skills, and having a sense of achievement and self-efficacy [44,49]. According to participants in the reviewed studies, digital psychotherapies also provided an "opportunity" to engage in online approaches, which was seen as equally valid as seeing a professional [47]. Reference was also made to the "suitability" of the interventions, as it allowed clients to undertake therapy at their own pace, time, and place [41], and "acceptability," when participants liked working in private due to discomfort related to working with personal issues [49].

Unhelpful factors related to the interventions delivered via website included issues with "acceptability," involving comments that the exercises were overwhelming, disconnected

from experiences, “typical” advice [48], and repetitive. Participants also commented that they would have preferred a more engaging interactive format [49]. Unhelpful factors also related to the limitations of “opportunity,” as the intervention was too flexible and consequently easy to avoid or too difficult to sustain as it required personal initiative. Users also reported the tasks were too demanding and felt like “work,” which decreased their inclination to engage [42].

The study that focused on a fully automated app [50] discussed “acceptability,” including an appealing visual layout and organization of content of the app, as well as the offer of a wide range of psychological strategies. End users also reported satisfaction with the increased self-awareness promoted by the app, which kept them “motivated” to continue engaging with the intervention.

Some unhelpful factors included the lack of contact with the therapist, which made the therapy “unacceptable” and ineffective [42], and a lack of guidance, making it difficult for participants to know whether they had used the content appropriately [41] or wasted their “opportunity.”

Interventions That Involved Human Contact

There were 4 qualitative or mixed methods studies that focused on interventions involving human contact; 2 (50%) studies used a website [40,51], 1 (25%) study used a combination of digital formats (eg, videoconferencing and self-help materials) [52], and 1 (25%) study used videoconferencing as a primary mode of delivery [53]. Helpful and unhelpful factors were reported from the clients’ perspectives.

In terms of websites, helpful factors focused mainly on “usability,” such as explanations that helped with engagement and managing expectations [51]. Improved symptoms of anxiety and social support increased the “motivation” to continue using the intervention [40]. However, intervention “usability” problems were also mentioned as an unhelpful factor. For example, some clients indicated that when there were no attempts to manage the expectations of tasks, this led to difficulties and uncertainty how to respond [51]. No significant change in depression or dysfunctional thinking led to decreased “motivation” for engagement in therapy; this was also seen as an unhelpful factor [40].

When videoconferencing was used, participants reported feeling satisfied, as they were able to engage in therapy from their own environment and adapt it to their own needs (acceptability) [53]. However, they appreciated having an in-person assessment before the digital intervention. Initially, participants were worried that they would feel separated from the therapist, but they did not experience this during the intervention. In terms of unhelpful factors, participants reported “usability” issues especially when there were no technical explanations, and their privacy was compromised. In 1 study that implemented a combination of virtual reality and email [52], the intervention seemed “acceptable,” as the self-help materials provided a calming and structured way to reflect on difficulties without a therapist’s input [52]. Unhelpful aspects related to “usability” issues and uncertainty about the function of the group (where the intervention included online peer support) [52].

In addition, 1 study [54] highlighted the need for collaborative platforms in old age as older participants (aged > 65 years) used media less often than younger participants.

Interventions That Combined Human Contact With Automated Interventions (Blended)

Qualitative and mixed methods studies within the “blended” category (20/28, 71%) used mainly human contact alongside noncontact automated interventions.

Human contact methods included face-to-face appointments, telephone or video calls, emails, or asynchronous messaging (eg, via a forum). The most common approach was to use a combination of ≥ 2 different contact methods (8/28, 29%). In terms of the automated intervention component, 39% (11/28) studies used a website.

In these blended interventions, the use of daily practices, reminders, and likable content were viewed as “helpful” since they “motivated” clients to engage with the intervention [222]. Similarly, learning skills that focused on new ways of relating to negative thoughts, emotions, and sensations [55] and using likable content and helpful activities [56] “motivated” clients to engage. Other “motivating” factors included resources and tools to help manage stress and anxiety [57]; tools for soothing and helping to improve mood [58]; insights and resources offered by a coach [57]; and interventions interrupting the downward spiral of negative thinking [59], increasing the awareness of personal warning signs of impending relapse [222]; and confrontations by therapists in relation to completing more online sessions [60].

Other examples of helpful factors included the “opportunity” to access additional sources of social support, which made some clients feel more connected and less lonely [56,58]. Examples of “suitability,” from the therapists’ perspective, included the freedom to work anywhere at any time [61]. Clients, too, favored flexible scheduling [62]. Blended approaches were also viewed as addressing the issue of inadequate access to specialist care [63].

Examples of unhelpful factors included comments that the modules were not engaging and too lengthy and that certain program features were complicated and hard to follow; these issues had an impact on “usability” [62,64,65]. Other examples of unhelpful factors included an interface that felt less “acceptable”; some clients commented that the programs were not advanced enough [66], too structured [60], and not user-friendly [56]. In some cases, clients felt that they were asked to write “essays,” which was not useful [59]. Clients also commented on the costs related to data charges [58], time and scheduling issues [222], and technical difficulties with access [65], which challenged the “suitability” of the interventions. From practitioners’ perspectives, the constraints of hectic practice, inadequate knowledge, and competing tasks made it more difficult to use [63].

A lack of human contact, real-time interaction, dialogue, and guidance left users feeling a responsibility that required too much from them and sometimes left them feeling lonely [58,61]. The absence of synchronous group interaction led to feeling a

loss of interpersonal learning [222], which again seemed like a lost “opportunity” of meaningful therapeutic interaction.

Research Question 3: Effectiveness of the Interventions

Overall Efficacy of Digital Psychotherapies on Depression

A total of 80 studies (intervention group, $n=8444$; control group, $n=7628$; total $n=16,072$) were included in the meta-analysis to examine the effects of digital psychotherapy interventions plus standard care compared to control groups (standard care alone, waiting list, or active controls) for depression in adult participants. The overall effect of digital psychotherapies on depression was moderate to large and statistically significant in favor of digital psychotherapies (Hedges $g=-0.61$, 95% CI -0.75 to -0.47 ; $Z=-8.58$; $P<.001$) immediately after the intervention (Figure 2 [40,52,59,65,68-80,82,87,89,91,93,94,101,106,109,113,114,116-136,138-146,149-152,156-158,161-166,168,170-174,177,178,181,189,191,195,198,201,206,212,213,216,218,223,224]). The resulting funnel plot from the overall depression outcomes (Figure 3) did not appear to have significant asymmetry (Egger intercept= 0.07 ; $P=.94$).

The Q test revealed a value of 1348.221 with 79 degrees of freedom and $P<.001$. Using a criterion α of .100, the null hypothesis that the true effect size is the same in all these studies was rejected. The I^2 statistic indicates that 94% of the variance in observed effects reflects the variance in true effects rather than a sampling error. As shown in Figure 4, assuming that the true effects are normally distributed (in g units), it was estimated that the prediction interval falls within -1.811 to 0.587 , indicating that the true effect size in 95% of all comparable populations falls in this interval.

To explore the potential sources of heterogeneity, subgroup analyses (Figure 5; delivery format: blended [40,59,69,71,75-78,80,94,106,109,113,116,120,123,130,132,136,138,163,178,

182,186,187,195,198,201,212,213,216,218], contact with human [52,65,68,82,118,121,127,144,157,161,167,170,174,175,188,223], no human contact [67,70,72-74,79,87,89,91,93,101,122,125,126,128,134,139,141-143,145,149,151,164,165,171,177,181,191,206,224], session frequency: more than one per week [40,52,59,69,71,74-77,79,80,87,89,91,93,101,106,113,120,121,123,125,128,130,132,134,138,139,144,145,151,157,164,165,168,170,172,174,181,182,186,188,195,201,213,216], once per week [65,67,68,70,72,73,78,82,94,116,118,122,136,141-143,161,163,171,175,177,178,187,191,212,223,224]) were conducted based on the intervention characteristics of the studies using a sufficient number of trials (80 for deliver format; 74 for session frequency) and participants. Therefore, the covariate distribution was not concerning in the subgroups. The type of delivery of the intervention (eg, blended, contact, or no contact with humans) did not have statistically significant modifying effects on the results of digital psychotherapies in comparison with the control group ($P=.48$). The intervention effects however are consistently in favor of digital psychotherapies for trials delivered in the 3 different formats studied, although the intervention effect is slightly greater for the trials delivered through a blended format (Hedges $g=-0.73$) than for the trials using contact with human (Hedges $g=-0.42$) or no contact with humans (Hedges $g=-0.40$). Similarly, the frequency of the intervention (once per week or more than once per week) did not have statistically significant modifying effects on the results of digital psychotherapies in comparison with the control group ($P=.97$). However, the intervention effect is slightly greater for trials that delivered the intervention more than once per week (Hedges $g=-0.60$) than for trials offering once per week intervention (Hedges $g=-0.40$). As the residual unexplained heterogeneity between the trials within all these subgroups is still persistent, the validity of the intervention effect is uncertain and requires further exploration to discuss the potential confounding variables.

Figure 2. Overall efficacy of digital psychotherapies on depression outcomes in adults.

Figure 3. Funnel plot for overall effects without removal of outliers.

Figure 4. Distribution of true effects of the overall efficacy of digital psychotherapies for depression in adults. The mean effect size is -0.61 (95% CI -0.75 to -0.47). The true effect size is 95% of all comparable populations falls in the interval -1.81 to 0.59.

Figure 5. Subgroup analyses. *Q-test for between-group heterogeneity, mixed-effects model. **Six studies that did not offer session frequency data or did not fit into these two categories were excluded from this analysis. .

Quality Appraisal

Methodological quality varied across the included studies (Multimedia Appendix 3).

Most of the qualitative studies (12/13, 92%) were assessed as meeting all 5 MMAT criteria [31] (marked as “yes”), 2 (15%) studies were judged as not using appropriate qualitative approaches to answer the research question, and the findings did not seem adequately derived from the data (judged as “no” and “can’t tell/unclear”). In 2 (15%) studies, the interpretation of] the results was judged as not being sufficiently substantiated by data.

Out of 15 nonrandomized quantitative trials (eg, quasi-experimental studies), 1 (7%) study was assessed as meeting all 5 MMAT criteria and 14 (93%) studies were assessed as “no” or “unclear” in terms of meeting at least 1 MMAT criteria, including presenting complete outcome data or appropriately accounting for confounder (n=8, 53%), administration of the intervention (n=7, 47%), having representative target samples (n=5, 33%), and using appropriate measurement tools (n=1, 7%).

Out of 25 quantitative descriptive studies, only 4 (16%) were judged as meeting all 5 criteria on MMAT; 13 (52%) studies were judged as “no” or “unclear” in terms of having representative samples, 5 (20%) for appropriate sampling strategies, and 4 (16%) in relation to measurement tools. A total of 18 (72%) studies were judged as “no” or “unclear” in terms of low risk of nonresponse bias, and 2 (8%) studies were judged as not having appropriate statistical analysis.

Most of the mixed methods studies without an RCT component were judged as not meeting at least 1 MMAT criteria (12/15, 80%). Only 2 (13%) studies met all 5 MMAT criteria, while 2 (13%) studies were judged as “no” or “unclear” for having adequate rationale for using mixed methods design. All studies (15/15, 100%) were judged as having qualitative and quantitative components of the study effectively integrated, but 4 (27%) studies were judged as “no” or “unclear” for providing adequate interpretation of the integration. A total of 10 (67%) studies were judged as “no” or “unclear” for adequately addressing divergences and inconsistencies between the quantitative and qualitative results, and 8 (53%) studies were judged as “no” or

“unclear” for adherence to quality criteria for each type of methods.

Regarding the RCTs and mixed methods studies with an RCT component (83 studies) following Higgins and Green’s [30] risk-of-bias assessment tool, random sequence allocation was judged as having a low risk of bias for most of the studies (n=74, 89%). Studies used methods such as software-generated block random sequence [223], algorithm-generated sequence [67], web-based sequence generator [68], computer random number generator [69], manual random sequence generation written in sealed envelopes [70,71], and via independent researchers [72]. A total of 9 (11%) studies, while identified as randomized trials, did not offer sufficient information on how the randomization took place [52,73], and therefore, they were marked as having an “unclear” risk of bias. Many authors did not adequately report their method of concealment, and therefore the risk of bias for this criterion was evaluated as “unclear” for 47% (n=39) of the studies and “high” for 18% (n=15) of the studies. Only 34% (n=29) of the studies clearly reported their method of concealment. When done successfully, authors used blocked randomization delivered in sealed envelopes from a centralized point instead of dividing participants across multiple recruitment centers [23]. Blinding was assessed with respect to participants, personnel, and outcome assessors. We judged only 9% (n=8) of the studies as having implemented blinding successfully with a “low” risk of bias [74,75]. Many studies were not explicit in their reporting of this procedure (“unclear”; n=32, 39%). In some contexts, authors reported that it was difficult or impossible to blind the participants in relation to the type of intervention. In other studies [76,77], blinding of personnel involved in the study was not possible (“high”; n=41, 49%). The risk of bias for blinding of outcome assessment was marked as “unclear” for 38 (46%) studies [78,224] and “high” for 22% (n=18) of the studies. Only 32% (n=27) of the studies were judged as having “low” risk of bias in terms of blinding of outcomes [79,80].

There were some important differences between the outcome assessment measurements across the studies. Blinding of assessors was often not feasible when depression was assessed as a self-reported measure rather than a clinician-rated measure. In many instances, authors reported the reasons for dropout, offered transparent reporting of attrition, and used

intention-to-treat analysis (n=74, 89%). This was “unclear” in 10% (n=8) of the studies, and the risk of bias was “high” in only 1% (n=1) of the studies. The risk of selective reporting of the results (including depression outcomes) was judged as “low” for 80% (n=66) of the studies, as the differences within and between intervention groups were given regardless of the direction, magnitude, or statistical significance. The risk of selective reporting was judged as “high” and “unclear” only in 10% (n=8) and 11% (n=9) of the studies, respectively. Overall, selection bias and performance bias were identified as very likely to influence the quality of the results in the included studies.

Discussion

The systematic review identified the current literature on the topic of digital psychotherapies for adults experiencing depressive symptoms, including the most common types of interventions, the clients’ and practitioners’ views on helpful and unhelpful factors, and the effectiveness of the digital interventions for depression.

Characteristics of Reviewed Studies

A total of 186 eligible papers (160 primary studies and 26 sibling studies) met the inclusion criteria for this review. The studies accounted for 70,720 participants, including 51,677 (female: 73.07%) participants, which constituted a 3:1 female-to-male participants ratio. When age was reported, a relatively young mean age was present (mean 38.52 years). It therefore appears that women and younger people were overrepresented in the sample. This is reflected in the mental health literature reporting that women are twice as likely to report depression than men [225-227], including postnatal depression. The impacts of social inequalities and gender-based oppression on mental health and depression are well documented by the World Health Organization’s Women’s Mental Health report [228] as well as more recently by other researchers [229-231], highlighting that younger women are particularly susceptible to depression, especially in parts of the world where women struggle with additional burdens linked with unequal division of labor based on gender roles. Other predisposing factors to depression include social roles, cultural norms, and higher vulnerability to violence. Furthermore, women may be attracted to using digital devices, as they can give easier and quicker access as well as more privacy and anonymity. It is possible that digital interventions are particularly attractive to younger women especially in postnatal periods [13], and it might be useful to tailor the developments of these interventions to this group in particular.

The fact that fewer men were included in the review may be closely linked with fixed gender roles. For example, it is possible that, for men, admitting that they have depression is seen as a sign of weakness [232], which may prevent them from accessing psychological help [233]. Studies also show differences between men and women in terms of externalizing and internalizing mental health issues [234]. It seems that men are likely to show depression in an external way, for example, by outbursts of anger [235], smoking [236], physical inactivity [237], or alcohol abuse [238]. For women, depression may be more internalized and linked with social isolation [239] and loneliness [236], and

they are more likely to seek psychological help. It is possible that different ways of working with men, and young men in particular, may be needed in psychological therapies for depression by involving more physical or creative approaches to psychological support.

More than a half of the studies (105/160, 65.6%) recruited participants from health care settings or used online methods. In terms of the severity of depressive symptoms, participants had depression as their primary diagnosis with a wide range of severity from mild to severe. It was noticeable, however, that fewer studies focused on severe depression and that these studies tended to have smaller sample sizes. It is possible that because digital interventions are in early stages of development, participants with mild to moderate depression might be more suitable for these studies. It is also possible that digital psychotherapies may be less useful for people with severe depression where face-to-face or more individualized therapy may be more appropriate due to the need for careful monitoring of factors such as suicidal ideation or withdrawal. Köhnen et al [8] reported large heterogeneity of studies with acute depression (eg, due to treatment duration) as well as a higher likelihood of negative events during treatment (eg, deterioration, withdrawal, and dropout), which makes it more difficult to research.

Most studies (133/160, 83%) took place in countries from the global north (ie, the United States, Europe, Australia, and Canada), locations where digital technologies and attention to people’s mental health are prominent. However, the impact of race and ethnicity on mental health was often overlooked. As a result, >50% (84/160) of the studies did not report ethnic data about their participants. These omissions are salient in a context where inequalities in health care have been observable among ethnically diverse groups [240], although efforts have been made to adapt treatments for depression for different cultural groups [241,242]. The lack of collection and reporting of ethnic data in the sampled studies demonstrate that researchers need to engage with current debates on the usefulness, desirability, and feasibility of cross-sectional analysis of mental health issues concerning ethnic data.

Nevertheless, ethnicity data were gathered from 57.3% (40,523/70,720) of the participants included in this systematic review. Hispanic, Latino, or Mexican were the most common group of participants (n=16,684, 41.17%), but most of these participants came from 1 study that was conducted in Mexico [56]. Other studies reported fairly diverse race and ethnicity, including 1.76% (n=713) Asian, 1.83% (n=741) Black, 2.1% (n=851) Indigenous, 17.99% (n=7291) White, 8.79% (n=3560) other, and 0.42% (n=172) mixed. It is possible that the diversity in race and ethnicity in the studies where these data were collected suggests a high need for psychological support among non-White groups [240,243-246]. It is important to note, however, that the prevalence of depression and comorbid psychiatric disorders is not uniform across racial and ethnic groups [247,248]. Ongoing debates question the extent to which existing treatments are effective for diverse ethnic populations [249].

The multiple interpretations of the terms further complicate the report of race and ethnicity data. *Race* and *ethnicity* were

sometimes used interchangeably, and *nationality* was used at times as a substitute. The 64 studies incorporating race and ethnicity data in their analysis showed a complex spectrum of classification, as evidenced by >30 reported ethnic groups within what could be considered as homogenous groups. Beyond observable physical characteristics (eg, blackness, brownness, or whiteness), studies referred to finer distinctions such as being African, African American, or African Canadian, which indicate how context can impact the experience of depression in individuals of a seemingly homogenous racial group. Similar findings were observed in the category of indigeneity where studies provided further descriptors such as Native Hawaiian, Pacific Islander, American Indian, Maori, and Aboriginal. The use of subgroups suggests the potential for a detailed examination of how ancestry, culture, and geographical context shape the understandings of depression.

Summaries of the key findings are presented in the subsequent sections in relation to the research questions of the study.

Research Question 1: What are the Most Common Types of Digital Psychotherapeutic Interventions for Adults With Depression?

The most common types of digital psychotherapeutic interventions were MoodGYM and Beating the Blues, followed by Good Days Ahead, Health Tips, Mindful Mood Balance, and Project EVO. There were several programs with no human contact (58/160, 36.3%), but more than half of the studies (91/160, 56.9%) referred to blended versions. Over half of the programs (n=93, 58.1%) were web based with only a few involving virtual reality and avatars. Some included relaxation and mindful techniques and others included creative means such as games, music, and comic books. Therapeutically, the vast majority (132/160, 82.5%) used CBT as their framing approach delivered in 6 to 12 weeks in a self-paced manner.

Research Question 2: What Are the Clients' and Practitioners' Perceptions on Helpful and Unhelpful Aspects of Digital Psychotherapeutic Interventions for Adults With Depression?

Clients' and practitioners' perspectives on helpful and unhelpful factors were examined for interventions that did not involve human contact (automated interventions), those that involved human contact (via digital media), and those that combined human contact with automated interventions (blended).

Non-human contact and automated interventions facilitated motivation and offered an opportunity, which otherwise would not have been available. Engaging in one's own time, place, and overall pace was also named as a helpful factor. It was, however, easy for participants to feel overwhelmed and disconnected and to believe that they had simply received generic, common-sense advice. The interventions were experienced as too flexible in some cases, making engagement difficult to sustain over time. In other cases, the tasks were experienced as tedious work.

For interventions that involved human contact, for example, via a website, the most helpful factors from a client's perspective related to usability, which included explanations about tasks.

However, "usability" was at times experienced by participants as unhelpful, especially when explanations were not available and there was confusion about how a client should respond. Experience of social support and the perception that their symptoms were improving helped motivate clients to continue using the intervention. However, when they felt no significant changes in their symptoms, clients often became less motivated and even disengaged from the intervention.

For blended approaches, the use of daily practices, reminders, and resources to manage stress and anxiety were seen as motivating. Learning skills to deal with negative thoughts and feelings was also helpful. However, participants commented that they appreciated and felt more attracted to contents that were likable. Blended approaches also provided opportunities to engage with peers (online) and with the therapist; both sets of interactions were seen as helpful. Participants appreciated the flexibility of blended approaches, especially given the difficulty in accessing face-to-face services. The adaptability of blended approaches to patients' needs and preferences has been noted in literature as different interventions can be easily tailored [250]. However, many unhelpful factors were also identified. These included difficulties with the usability of the interventions (eg, lengthy modules and limited attractiveness) and limited acceptability (not all the digital material made immediate sense; some were too structured or too challenging). In terms of opportunity, participants would have liked face-to-face interactions and synchronous groups, which were not available.

Research Question 3: What is the Effectiveness of Digital Psychotherapeutic Interventions for Adults With Depression?

The meta-analysis that included 80 studies with 16,072 participants suggested that there is some certainty in the evidence showing moderate to large effects supporting that digital psychotherapies are likely to reduce depression in comparison with control conditions (Hedges $g=-0.61$). Furthermore, subgroup analysis revealed a positive effect of digital psychotherapies to reduce scores of depression across all delivery formats. The blended approach appeared to have the greatest positive effects (Hedges $g=-0.73$ over -0.42 for human contact or -0.40 for no human contact). These findings highlight the benefits of digital interventions. The high impact of the blended approach may be the result of combining the benefits of both human and automated engagement. The value of this type of intervention is also reflected in the range of helpful and unhelpful factors identified in the qualitative and mixed methods studies reviewed and discussed in the *Research Question 2: Clients' and Practitioners' Perspectives on Helpful and Unhelpful Factors Identified in Qualitative and Mixed Methods Studies* section. However, we do not know if there is a statistically significant difference between the different digital approaches since they all indicate moderate and high impact. Further investigation on the differences between these approaches will be needed.

It is also worth considering the group of participants targeted by the different interventions. For example, a recent systematic review and meta-analysis of RCTs of smartphone app-based

psychological interventions [16] found greater reduction of symptoms in moderate to severe depression than in mild to moderate depression. However, they commented that the findings might be related to the groups of clients that normally do not access mental health services (eg, health care staff during the COVID-19 pandemic). Our systematic review revealed participants with a range of mild to severe symptoms of depression (with less focus on severe depression), and, as highlighted above, it is possible that blended approaches are more relevant for this group of participants. These interesting findings highlight the need to combine the growth of digital interventions with user preferences and personalized care.

Our subgroup analysis also revealed that all forms of delivery, regardless of the frequency and duration of the sessions, were likely to support the reduction of depression in comparison with control groups. However, there was a greater effect size for interventions delivered more often than once per week (Hedges $g = -0.60$ vs -0.40 for interventions delivered once per week), a format of delivery that is more easily provided digitally, minimizing cost and human effort. This challenges the common practice of in-person psychotherapy that tends to be once a week. Although there is evidence that higher session frequency could lead to faster recovery, this is not common practice in in-person psychotherapy. These findings [251] provide useful information that could have a direct impact on future digital developments.

Although we were unable to perform a subgroup analysis for digital psychotherapies with different types of delivery and content due to the diversity of interventions, it is well established that creative tools such as creative writing or use of music as well as yoga or relaxation can impact the levels of engagement [252]. Further exploration is needed in this area to develop digital interventions that do not rely so heavily on CBT and focus on meeting the needs of clients from diverse cultural, socioeconomic, or educational backgrounds [253,254]. An example of this could be Arts for the Blues, a creative therapy for depression that has been offered in a digital format [255].

Comparison With Other Reviews

The review examines all digital forms of psychotherapy for depression; this is a new contribution to the existing evidence base, creating a cohesive picture. Unlike other reviews that have focused on specific client populations such as those with severe depression [8], chronic health conditions [9-11], and perinatal depression [13] or children and young people [14-17], this review examines digital forms of psychotherapy for all types of depression affecting all populations. Unlike systematic reviews conducted on specific psychotherapeutic approaches such as CBT only [11,18-20] or specific types of delivery (eg, smartphone app [12]), this review included all forms of psychotherapy and gathered information about different types of digital interventions. Given the increase in mental health concerns and depression worldwide, and the growth of digital psychotherapies in recent years, by bringing all populations, approaches, and digital products together in one review, we have been able to acquire a comprehensive picture of the field. This enables more insight and breadth to identify useful interventions as suggested by the recent NICE [3] guidelines.

As per other reviews [256], this review found that the evidence base would benefit from more diverse study participants, higher quality quantitative studies, and more detailed studies concerning which mechanisms within specific interventions lead to a change of outcomes.

Limitations

The comprehensive nature of the review is certainly one of its major strengths. However, at the same time, depth may have been compromised to accommodate for this “broad stroke” approach. It is possible, for example, that this could be achieved in future studies if qualitative and quantitative studies were reviewed separately.

By contrast, if the aim is to acquire a greater bird’s eye view of this rich and fast-growing field, it is possible that future studies may also consider umbrella reviews (ie, overviews of systematic reviews) including multivariate analysis to obtain a better understanding of how the different reviews relate to each other.

Another limitation relates to the quality of the reviewed studies. Although most qualitative studies (12/13, 92%) were regarded as of “good enough” quality, meeting all MMAT criteria, over a third of the quantitative studies (55/146, 37.6%) had no randomization. In terms of quantitative studies with RCT design (83/146, 56.8%) most studies (80/83, 96%) did not meet all 5 of the MMAT criteria; they were of poor quality and therefore were given less significance in this review.

Despite the risk of bias identified in the RCTs, findings from the meta-analysis and the subgroup analyses offer an invaluable overview of the field, which has not been presented before. The inclusion of 80 studies with 16,072 participants suggests a degree of precision since it is likely that the total sample reaches powered levels (eg, in Grading of Recommendations, Assessment, Development, and Evaluations terms it reached an optimal information size).

Potential Biases in the Review Process

All aspects of the review were checked by >1 reviewer to minimize possible biases. The initial general data extraction was completed by 4 people. This was followed by data extraction focused on specific characteristics of the studies, which was completed by most of the reviewers. Any issues and discrepancies were discussed in weekly meetings. The reviewers came from different professional backgrounds and research skills. The team comprised psychotherapists and arts therapists, for example, with specialized knowledge in the field and qualitative research skills essential for investigating clients’ and practitioners’ perspectives of helpful and unhelpful factors. It also comprised psychologists and allied health professionals with quantitative research skills, essential for calculating effect sizes.

Implications for Practice, Policy, and Research

In the current context of a shortage of and increasing demand for mental health interventions, digital approaches hold great promise. However, this review demonstrates that while digital interventions offer flexibility and autonomy for both providers and participants, blended interventions seem important for a positive experience in the treatment of depression and related

conditions. Some of the reviewed studies documented limitations with asynchronous interventions and interventions that have no human contact [41,42,48]; these should not be ignored, especially for susceptible and at-risk populations.

Blended approaches delivered more than once a week seem to be particularly useful for the participants, giving the opportunity for a contact with a therapist as well as a platform that can be used between sessions supporting engagement. Digital interventions seem to be helpful for people from diverse ethnic groups and young women in particular. It will be important to tailor and target the digital interventions specifically for this group, and more research is needed in this area.

Most of the reviewed studies focused on CBT, and it seems important to use alternative theoretical approaches for digital psychotherapies, including creative interventions that can accommodate a range of service users' preferences especially minority populations. In addition, we agree with Fordham et al [257] that new research in the treatment of depression and other disorders ought to shift emphasis from investigating the general effectiveness of interventions to understanding how to achieve a greater effect size for specific populations.

Given the importance of clients' perceptions of what is helpful in digital psychotherapies, it is paramount that interventions that have high levels of acceptability and usability and prioritize a positive user experience are investigated further.

The fact that this review found that motivation to engage in a treatment was one of the most helpful factors from the clients' perspective suggests that digital interventions can have a useful auxiliary role to encourage clients to engage in treatments for depression and mitigate against the risk of dropout.

In the context of the COVID-19 pandemic, it is widely accepted that digital approaches show great promise as treatments for mental health problems [258]. However, this review found more research from the perspectives of clients rather than practitioners and therefore, further research is needed to assist practitioners to be aware of the evidence and efficacy of digital interventions they may use in clinical practice [258].

Nondigital interventions could consider the inclusion of a digital option to encourage participants to remain in treatment for depression. Further research could be done to understand the role of digital interventions for enhancing motivation and the

mechanisms by which patients can be encouraged to stay in treatment, thus reducing dropout rates.

Conclusions

The review examines the digital forms of psychotherapy for depression, which is a new contribution to the existing evidence base. Unlike other reviews that have focused on specific client populations and specific psychotherapeutic approaches or modes of delivery, this review included all forms of delivery and gathered information about different types of digital interventions for depression. Given the increase in mental health concerns and depression worldwide and the growth of digital psychotherapies in recent years, by bringing all populations, approaches, and digital products together in 1 review, we have been able to acquire a comprehensive picture of the field, which enables more insights and breadth to identify useful interventions as suggested by the recent NICE guidelines. The review aimed to answer three research questions in relation to digital psychotherapies for depression: (1) the most common types of interventions, (2) the clients' and practitioners' perspectives of helpful and unhelpful aspects, and (3) the effectiveness of the interventions. Digital interventions fell into 3 categories including interventions with no human contact and stand-alone interventions, interventions with human contact, and blended including both stand-alone and "human contact" interventions. Blended interventions formed the biggest group of studies. Most of the digital interventions were web based and involved online psychoeducation drawn primarily from CBT delivered once a week. Blended approaches seem to be particularly useful for participants, giving the opportunity for contact with a therapist as well as a platform that can be used between sessions supporting engagement. In terms of the effectiveness of the digital interventions for depression, meta-analysis revealed a moderate to large effect on depression. Analysis of studies with blended approaches revealed the largest effect size in comparison to interventions involving human contact only or no human contact. In addition, the review found that digital interventions seem to be particularly helpful for people from diverse ethnic groups and young women and therefore new research in the treatment of depression ought to shift emphasis from investigating the general effectiveness of interventions to understanding how to achieve a greater effect size for specific populations.

Acknowledgments

This systematic review was funded by the UK Research and Innovation Strategic Priorities Fund (2020-2021) administered by the University of Salford, Greater Manchester, the United Kingdom.

Abstract

Background: Digital mental health is a rapidly growing field with an increasing evidence base due to its potential scalability and impacts on access to mental health care. Further, within underfunded service systems, leveraging personal technologies to deliver or support specialized service delivery has garnered attention as a feasible and cost-effective means of improving access. Digital health relevance has also improved as technology ownership in individuals with schizophrenia has improved and is comparable to that of the general population. However, less digital health research has been conducted in groups with schizophrenia spectrum disorders compared to other mental health conditions, and overall feasibility, efficacy, and clinical integration remain largely unknown.

Objective: This review aims to describe the available literature investigating the use of personal technologies (ie, phone, computer, tablet, and wearables) to deliver or support specialized care for schizophrenia and examine opportunities and barriers to integrating this technology into care.

Methods: Given the size of this review, we used scoping review methods. We searched 3 major databases with search teams related to schizophrenia spectrum disorders, various personal technologies, and intervention outcomes related to recovery. We included studies from the full spectrum of methodologies, from development papers to implementation trials. Methods and reporting follow the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines.

Results: This search resulted in 999 studies, which, through review by at least 2 reviewers, included 92 publications. Included studies were published from 2010 to 2023. Most studies examined multitechnology interventions (40/92, 43%) or smartphone apps (25/92, 27%), followed by SMS text messaging (16/92, 17%) and internet-based interventions (11/92, 12%). No studies used wearable technology on its own to deliver an intervention. Regarding the stage of research in the field, the largest number of publications were pilot studies (32/92, 35%), followed by randomized control trials (RCTs; 20/92, 22%), secondary analyses (16/92, 17%), RCT protocols (16/92, 17%), development papers (5/92, 5%), and nonrandomized or quasi-experimental trials (3/92, 3%). Most studies did not report on safety indices (55/92, 60%) or privacy precautions (64/92, 70%). Included studies tend to report consistent positive user feedback regarding the usability, acceptability, and satisfaction with technology; however, engagement metrics are highly variable and report mixed outcomes. Furthermore, efficacy at both the pilot and RCT levels report mixed findings on primary outcomes.

Conclusions: Overall, the findings of this review highlight the discrepancy between the high levels of acceptability and usability of these digital interventions, mixed efficacy results, and difficulties with sustained engagement. The discussion highlights common patterns that may underscore this observation in the field; however, as this was a scoping review, a more in-depth systematic review or meta-analysis may be required to better understand the trends outlined in this review.

Introduction

Background

Research on digital mental health care in groups with serious mental illness (SMI), including schizophrenia spectrum disorders (SSDs), has grown slowly compared to other mental health conditions such as anxiety and depression [1,2]. Historically, this has been due to concerns about the ability to afford and use technology (ie, device ownership, access to the internet, and cellular data plans), understand the limitations of the technology (ie, privacy, crisis planning, and digital literacy), and make effective gains from digitally delivered content.

Recent research shows that cell phone and smartphone ownership and internet access are high in populations with SMI with and without psychosis [3,4] and have shown to be an adequate means of service delivery over the COVID-19 pandemic. Leveraging personal technologies (ie, laptops, tablets, smartphones, and wearable technologies) has also been framed as a critical measure to address access to specialized mental health care in remote areas and populations identified as marginalized, as access to smartphones and the internet is improving in these communities [5-7]. In addition, it has the potential to address barriers to stigma, time, and cost that limit the frequency and duration of available mental health care [8,9]. Given the potential to overcome such significant barriers, experts predict the use of personal technologies to deliver or assist with mental health care to continue to grow and hope to capitalize on the burst of enthusiasm brought about by the COVID-19 pandemic [10-12].

Although technologically delivered and assisted care is steadily gaining credibility and acceptability among mental health care professionals, there remain questions about the efficacy, safety and potential limitations of technologically delivered care in SSDs [13]. In fact, research has found that out of the publicly available technology advertised for mental health care, only 3% have scientific evidence supporting their use [14]. In schizophrenia and psychosis, a commercial review found that only 6 publicly available apps out of 700 were supported by scientific evidence, and many contained stigmatizing themes and misinformation [15].

To this end, it is critical to identify evidence-based digital mental health tools available for use on personal technologies by individuals with SSDs and evaluate the state of research in the field and readiness for implementation. Previous reviews in this area have tended to focus on 1 technical modality (eg, mobile apps [16] and SMS text messaging [17]) or 1 aspect of recovery (eg, relapse prevention [18]) but have yet to examine the field collectively across technological platforms, treatment targets,

and therapeutic approaches to provide a high-level snapshot of the extant literature.

This Study

This study is a scoping review examining the use of personal technologies to deliver digital mental health interventions in the treatment of SSDs. The overarching aim was to examine the state of the existing evidence supporting digital health tools for individuals with SSDs. Specifically, we identified gaps in the literature and explored the next steps for future research as the field moves toward implementation. To this end, we examined studies across the research stage, from development papers to implementation studies, using various types of commonly owned personal technologies that may be used to support clinical outcomes and recovery in populations experiencing SSDs. Personal technologies were chosen as the target technology for this review, as it can be argued that this may be the most efficient way to increase access to specialized information and care for individuals who cannot access traditional care consistently. It is also plausible that personal technologies may be the most accessible and cost-effective technological aid to traditional care.

Methods

Overview

Given the complex and broad nature of our research question, our results are presented in alignment with the scoping review methodology, focusing on the state of research and identification of key concepts and gaps [19,20]. Our methods are structured according to PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) principles endorsed by the Cochrane Collaboration [21] and the scoping review reporting framework [22].

Inclusion Criteria

The included studies were published in English, examined the use of digital health tools in populations with SSDs, and published between 2010 and 2023 (given the evolution of technology during this period). Population, Intervention, Comparison, and Outcome principles guided the formulation of the inclusion criteria using the categories population, intervention, and outcome of interest (control type was not applicable as we included a range of study types; refer to [Textbox 1](#) for details). Studies were excluded if no full text was available (eg, editorials and conference presentations), if not published in English, if examined in a population with health challenges other than SSDs (eg, depression, substance use, and physical health conditions), if they did not use technology to deliver an intervention, or if they did not examine clinical targets related to SSDs. We also did not include studies that examined

the pivot to virtual care (eg, phone, video, or other communication technology-based care) during the COVID-19 pandemic and virtually delivered care more broadly, as the only technological component was videoconferencing or telephone

delivery of treatment as usual (TAU). The included studies sought to enhance the delivery of TAU (ie, technologically supported TAU) or deliver adjunct interventions (ie, interventions not included in TAU).

Textbox 1. Study inclusion criteria following the Population, Intervention, Comparison, and Outcome principles.

Population diagnosis

- Schizophrenia
- Schizophreniform
- Schizoaffective
- Psychotic disorder not otherwise specified
- Psychosis

Type of technology

- Mobile apps
- SMS text messaging
- Web based
- Videoconferencing
- Wearables
- Blended interventions

Outcome target

- Symptoms
- Functioning
- Service engagement
- Illness management

Study methodology

- Randomized controlled trials
- Pilot trials
- Qualitative studies
- Feasibility studies
- Protocol papers

Search Strategy

A total of 3 core databases were searched: PsycINFO, Embase, and MEDLINE. In addition, Cochrane and PROSPERO databases were searched for existing reviews and protocols. References of resulting included studies were hand searched.

Search strategies used for general databases were as follows:

- Population: Psychosis OR Schizophrenia OR Schizoaffective OR Schizophrenia Spectrum OR Psychotic Disorders OR First-Episode Psychosis OR Early-Episode Psychosis
- Intervention: SMS OR Short Message Service OR SMS-Survey OR Texting OR Text Message OR SMS Based System OR SMS Reminder OR Text Message Reminder OR Digital Health OR Telehealth OR Mobile Apps OR Mobile Applications OR Mobile Health OR eHealth OR mHealth OR Wearable Technology

Search strategies used for databases powered by OVID were as follows: schizophrenia spectrum.mp. OR psychotic disorder.mp. OR exp psychosis/AND (sms or short message* service* or texting or text message*).mp. OR (mobile apps* or smartphone app* or telehealth) OR (eHealth or mHealth or mobile health or internet intervention or web-based treatment or web-based intervention or wearabl*).mp.

Reviewer Protocol

Studies resulting from the initial search were exported into a reference manager (EndNote; Clarivate) [23], where the initial deduplication occurred, and then transferred into a web-based review management system, where the system again identified duplicates (Covidence; Veritas Health Innovation) [24]. This platform also allowed for the independent review of each study for inclusion. Authors (JD, MI, LT, AZ, and TA) conducted the review using the title, abstract, and full text. Review conflicts were reviewed by the first author (JD) and team and, if needed,

by the last authors (SK and GF). At least 2 reviewers reviewed each publication.

Data Extraction

Both qualitative and quantitative data were extracted from the included studies. First, methodological information was collected, including research design and publication type, sample size, diagnostic group, length of study, and outcome measures. Second, intervention information was collected on the digital intervention target, the type of technology used, the evidence-based approach used, and the length of the intervention. Third, study outcome data were extracted, including qualitative or descriptive and quantitative data regarding primary outcomes. Both qualitative and quantitative data are reported descriptively.

Analysis

The reported results are descriptive, in line with scoping review methods, and provide a high-level overview of key findings. Extracted data are charted according to the type of technology used, followed by subcategories regarding the stage of research (eg, development, pilot feasibility and efficacy, and effectiveness and implementation trials), themes, and issues uncovered through data synthesis. Of note, we distinguish between blended care and multitechnological interventions. Blended care is

defined as integrating technology into traditionally delivered care (ie, in-person care) [25], whereas we define multitechnology interventions as using >1 technological platform and may be integrated with traditional or virtual care. Furthermore, given the large number of included studies, findings report on primary outcomes. A more detailed review would be required to investigate secondary and tertiary findings. Primary outcomes pertaining to feasibility use highly varied measures; therefore, we provided a high-level description of outcomes.

Results

Overview

Our search yielded 999 studies, of which, through careful review, 92 (9.21%) studies were included (refer to Figure 1 for details of the search exclusion), investigating approximately 50 unique interventions. It is difficult to know the exact number of unique interventions as this is not always clearly reported. Included studies were published in a range of countries, predominately in North America (40/92, 43%), Europe (33/92, 36%), Australia (13/92, 14%), and East Asia (7/92, 7%). Studies were published from 2010 to 2023, with the majority published between 2018 and 2020 (50/92, 54%; Figure 2).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) breakdown of search results. Description of the review process that determined the included and excluded studies.

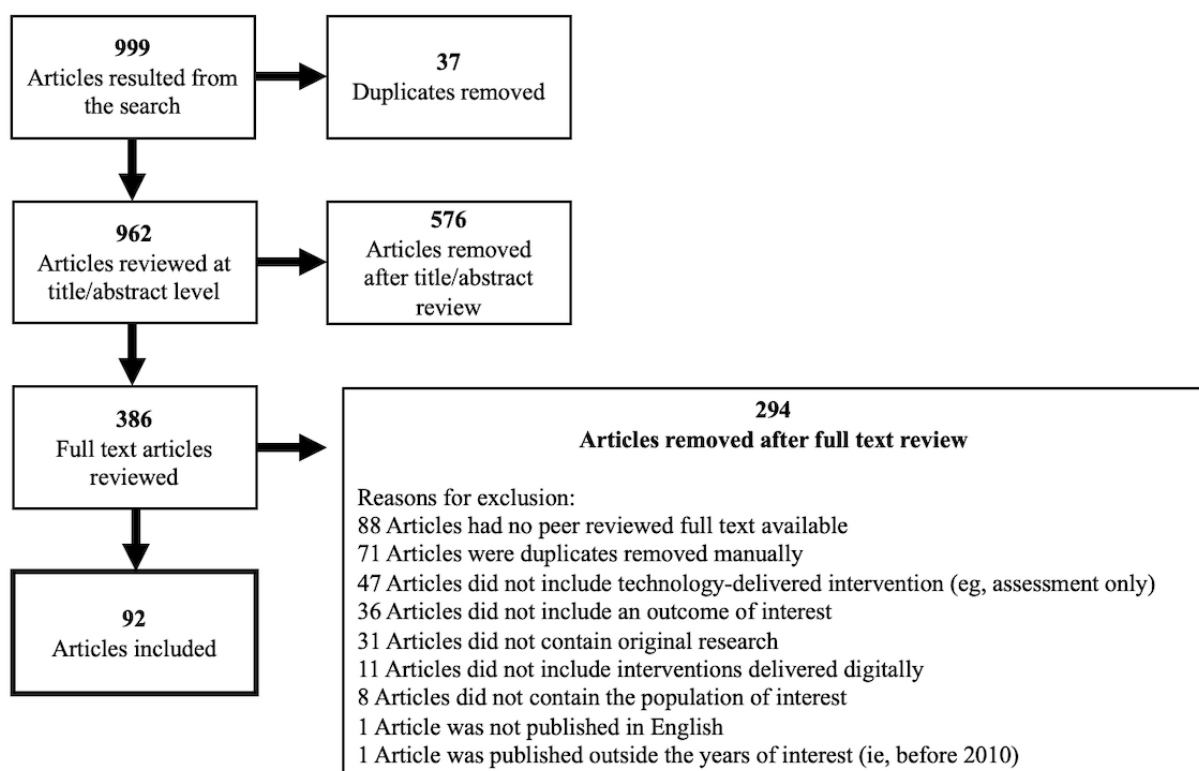

Figure 2. Number of publications over time by technological modality.

We primarily examined results through the intersecting lens of technology type and stage of research (ie, study design and aim). Among the 92 included studies, 11 (12%) focused on web or internet-based interventions, 25 (27%) examined smartphone apps, 16 (17%) investigated SMS text messaging, and 40 (43%) used multiple types of technology to deliver the interventions. No included studies used wearable technology to deliver an intervention. Studies included in this review that used videoconferencing or phone calls did so in combination with other types of technologies and are thus counted under multitechnology interventions.

Regarding the stage of the included research, of 92 studies, there are 5 (5%) qualitative studies investigating development and patient experiences, 32 (35%) pilot trials (26/32, 81% open trials and 6/32, 19% randomized control trials [RCTs]), 13 (14%) protocol papers, 23 (25%) conducted RCTs, 16 (17%) secondary analyses (both quantitative and qualitative), 3 (3%) nonrandomized trials, and no implementation trials. Given the number of secondary analyses, it is important to note the number of unique technologies being studied to reflect a potentially more accurate picture of the spread of digital mental health that is leveraging personal technologies in this population. There are 50 unique technologies studied within the 92 included studies. Several unique technologies (19/50, 38%) are investigated in >1 publication, with several published protocols suggesting ongoing investigations using these interventions. Contextually, it is important to note that all included trials recruited from mental health care clinics and institutions providing traditional care, and as such, all interventions included in this study can be considered blended or integrated to varying degrees with traditional care.

Overall Feasibility

Factors of feasibility in included studies vary, such as measures of acceptability, usability, technology engagement, and user

feedback. The vast majority of included studies report high levels of acceptability and usability. Technology and user feedback are mixed and reveal several high-level themes. First, technology engagement tends to decrease over time regardless of technology type. Second, many studies report self-reflection and therapeutic rapport as positive features of using these technologies. Third, various types of prompts were used with varying success to enhance engagement.

Safety and Privacy Outcomes

Across all technologies and all study designs, 60% (55/92) of the studies did not report on any safety indices at all. The most common indicator (31/92, 34%) of safety used was reporting serious adverse events (SAE) and adverse events (AE). Most studies reported that no SAEs or AEs were related to the technological intervention, and if there were any present, they provided a short description of the SAE or AE. Furthermore, the vast majority of the studies (64/92, 70%) did not comment on the privacy measures taken by the study team or built into the technology used to deliver the intervention.

Overall Efficacy

There were 16 RCTs and 1 pilot RCT examining the efficacy of the technological intervention as its primary outcome; see [Table 1](#)). Regarding methodology, most RCTs use TAU (10/17, 58%) as their comparison group, with others using varying active comparisons, including phone calls, films, sham apps, and other therapies. RCTs were most commonly reported using single-blind designs (7/17, 41%); however, 2 (12%) were double blinded, and 8 (47%) did not use blinding procedures for their assessors or participants. Approximately 52% (9/17) of the trials showed a positive change (ie, improvement in target) during the course of the intervention in favor of the technology, with another showing positive change in 1 primary outcome but not both [26] and another showing no overall change but a change in the positive symptom subscale scores [27]. Compared to the

control, 47% (8/17) of the RCTs show significant group differences in their primary outcome, with the same 2 studies reporting significant group differences in part of their primary outcomes [26,27]. Only 4 studies reported effect sizes, with 3 being interpretable as medium to high and 1 as low [28-31]. The type of effect sizes reported were inconsistent across studies

and thus were interpreted as low, moderate, and high based on suggested interpretation guidelines for each type of effect size to aid in comparison. A more detailed examination of efficacy, which includes all study types with primary efficacy outcomes, can be found in the sections below divided by technology type.

Table 1. Included original randomized control trials with primary efficacy outcomes.

Author, year	Technological intervention information					Study design information				Study outcomes

Detailed results are outlined in the subsequent sections and focus on the stage of research and notable results. Key gaps and future directions are explored in the *Discussion* section. A summary of the included studies can be found in [Multimedia Appendix 1](#) [26-120].

Multiple Technology Interventions

Overview

The largest proportion (40/92, 43%) of the included studies investigated interventions that leveraged multiple types of personal technologies. Multiple distinct personal technologies within 1 intervention were identified if they served (1) distinct purposes or (2) two distinct modes of communication. For example, an ecological momentary assessment (EMA) embedded with a mobile app would be considered 2 distinct technologies as an EMA collects information, whereas the mobile app shares information. In contrast, an addition of modules to an already existing web platform serves the same

purpose as the original web platform and would count as 1 technology. Most commonly, interventions combined the use of a smartphone app and a web page that could be accessed by either a clinician or peer support [29,33,34,43-49], with some additionally combined with targeted in-person intervention sessions [33,47]. Other technology combinations included smartphone apps to deliver resources with added EMA and intervention approaches [50] and a web page [51] or wearable technology [52] to help users self-manage their mental health. Other combinations still included using a smartphone app or web page in combination with communication technology such as SMS text messaging [29,53,54], phone calls, videoconferencing [32], and email [55]. Finally, 2 interventions engage various communication strategies, such as SMS text messaging and phone calls [35,56] and a smartphone app, SMS text messaging, and telemedicine [42].

Of the 40 included studies investigating interventions leveraging multiple personal technologies 2 (5%) were development papers

[57,58], 14 (35%) were pilot studies [42,43,45,49,51,53,54,59-65], 6 (15%) were RCT protocols [47,48,52,56,66,67], 8 (20%) were RCTs [28,29,33-36,64], 9 (23%) were secondary analyses [44,55,68-72,74,75], and 1 (2%) was a nonrandomized trial [46]. There are 17 unique multitechnology interventions investigated using the 40 included studies. Targets of the multitechnology interventions included illness self-management (5/17, 29%) [43,52,55,58,62], relapse prevention (3/17, 18%) [46,47,49], medication adherence (2/17, 12%) [51,56], general symptom severity (2/17, 12%) [29,34,48], social functioning (1/17, 6%) [42], motivation (1/17, 6%) [53], coping with auditory hallucinations (1/17, 6%) [50], negative symptoms (1/17, 6%) [54], and cognitive function (1/17, 6%) [70]. Evidence-based approaches are reported by 77% (13/17) of these interventions, including cognitive behavioral therapy (CBT; n=3, 23%); peer support (n=1, 8%); cognitive remediation (n=1, 8%); information motivation behavioral skills (n=1, 8%); connectedness, hope and optimism, identity, meaning, and empowerment (n=1, 8%); social cognitive theory (n=1, 8%); and mixed approaches (n=6, 46%). For all studies (29/92, 32%) that investigated any of the 17 multitechnology intervention, the trial lengths ranged from 1 visit to 60 months, with a mode of 3 months.

Feasibility

Studies (23/40, 58%) investigating feasibility-related variables as the primary outcome reported varying measures of engagement, including study retention, intervention retention, and various means of measuring technology engagement (eg, number of log-ins per period, number of tasks completed, and number of responses). Regarding study retention, included studies reported good retention rates of 78% to 100% [28,43]. However, technology or intervention retention tended to decrease over time and was 42% to 52% at the end of the intervention periods [43,60]. Technology use over time also tended to decrease over time regardless of the measurement [28,43,60]. Despite this, studies reported high levels of response or completion throughout the study period (70%-84%) [49,51,53,59]. One study reported a relatively low response rate (22%); however, this represented a homework completion rate of at least once per week [54]. Another study reported on clinician engagement with the connected clinician portal (67% log-in rate), which was much lower than patient engagement (80% response rate) [49]. Some studies reported on factors impacting intervention engagement, which included low mood or depression [44,68], negative symptoms and low motivation [44], and fluctuations in wellness [71]. Technological factors were also reported to impact engagement. Specifically, ease of navigation, accessibility of resources, the fit of technology [44,71], and concerns regarding privacy [69] impacted engagement, whereas coaching facilitated engagement [53,55] as long as it did not feel too scripted [53]. Overall, patients tended to endorse the technologies as easy to use and helpful and were satisfied with the technology or interested in continued use [43,49,51,53,117].

Of note, 7 (30%) feasibility studies of the 23 included multitechnology studies focused on 1 intervention [58,61,63-65,72,75] in varying populations (ie, psychotic and mood disorders), in different contexts (ie, outpatient, assertive

community treatment, and veteran association hospital), and with different comparison groups and augmentations (ie, the addition of video content and phone calls from interventionists). Throughout these studies, participants and clinicians rated the acceptability and usability of the intervention as high. Participants could access the app at any time, and the app sent out prompts and phone calls to support app engagement. Participants responded to most prompts [64,65] and phone calls from the mobile case manager or interventionist [65]. Despite this, patient app engagement over time declined in the studies that measured use over time [63,64] but reported better engagement over time compared to an in-person group [64]. One study reported on cost-effectiveness and found that the technologically supported intervention was significantly less costly, with no significant differences in efficacy compared to a fully clinician-delivered intervention [73].

Efficacy

Studies examining the efficacy of multitechnology interventions as a primary outcome (10/40, 25%) [29,32-36,42,46,70,74] reported mixed findings across a wide range of specific outcomes. One study examining self-guided CBT did not report an overall significant difference in symptom severity compared to TAU [29]. Another study investigating technology-assisted, clinician-delivered CBT for paranoid thinking found that the intervention significantly reduced paranoia across 3 measures at the end of a 3-month intervention compared to TAU [33]. Studies investigating social-cognitive-functional domains reported significant impacts on aspects of global cognition, attention [28], motivated behaviors (ie, anticipatory pleasure and improved effort expenditure for future social interaction) [32], improvements in affective symptoms [34], the identification of correct answers and cognitive fatigue [70], and social functioning [42]. A smartphone app-clinician portal alert system reported significant reductions in relapse, rates of hospitalization, and urgent care needs [46]. An intervention comprising biweekly clinician phone calls and weekly SMS text message check-ins showed improvements in medication adherence compared to controls [36]; however, it did not show improvements in other areas such as global functioning or quality of life [35].

Smartphone App Interventions

Overview

Of the 92 included studies, research investigating the use of smartphone apps included 25 (27%) publications, of which 2 (8%) were development papers [76,77], 8 (32%) were pilot studies [76,78-84], 1 (4%) was a nonrandomized study [85], 6 (24%) were protocol papers for RCTs [50,86-90], 3 (12%) were RCTs [30,91,92], and 5 (20%) were secondary analyses [93-97]. The average length of interventions was 4 months (range: 1 visit to 12 months and modes: 3 and 12 months). Pilot feasibility studies typically lasted 1 to 2 months; pilot efficacy trials lasted 2 to 6 months; and randomized trials lasted 3 or 12 months, including protocols. Sample size within trials is also highly variable (mean 41.65; median 31, range 8-229).

There were 15 unique smartphone app interventions investigated in the 25 included studies. Most of the included smartphone

interventions were positioned as adjunctive to traditional mental health care or TAU and were aimed at illness self-management [76,80,88,91]; medication adherence [30]; and symptom severity [81,86,89,92], including specific domains such as auditory hallucinations [84,90], social skills [79,82], and metacognition [85]. Most apps reported evidence-based foundation therapeutic approaches, most commonly CBT (6/15, 40%) [76,78,81,83,84,89], followed by social skills training (1/15, 7%) [77], positive psychology (1/15, 7%) [82], acceptance and commitment therapy (1/15, 7%) [76], metacognitive intervention for schizophrenia (1/15, 7%) [85], or report mixed approaches (3/15, 20%) [88,91]. However, some (2/15, 13%) [30,80,90] interventions do not report following a specific evidence-based approach or omit this information. Two (2%) of the 15 included app interventions were specifically blended with in-person care [84,92].

Feasibility

Of the 25 studies investigating apps, there were 12 (48%) studies that reported primary outcomes related to the feasibility of apps [78,80-84,91-96]. All feasibility studies investigating apps reported high levels of acceptability, usability, and satisfaction. Studies using a prompt or EMA system reported medium to high response rates of 33% to 81% [33,92,93]. Studies reporting on task or module completion also reported medium to high completion rates of 42% to 95% [78,81,82,92]. Of 12 feasibility studies, 2 (17%) studies reported that engagement with apps decreased over time [91,94], 1 of which reported that 50% stopped using the app within 3 months [91]. Facilitators of app engagement were functions allowing synchronous communication with clinicians [81], integration of face-to-face sessions [96], and stronger therapeutic alliance [94], whereas barriers to engagement were lack of clinician support using the app, concerns regarding therapy [91], feeling the app was not personable, and there were too many sessions or prompts [81,83]. Some studies found participant factors associated with app engagement, such as age, employment status, race, and smartphone ownership [93,94].

Efficacy

Of 25 studies, 4 (16%) examined the efficacy of interventions delivered via smartphone apps [30,79,85,98], of which study examined an app delivering self-guided CBT [98]. Regarding overall symptom severity, a pilot study found significant changes across recovery and symptom outcomes [98]. Another pilot study examined the delivery of self-guided social skills training and found a moderate impact on social functioning at the end of the intervention; however, it found that gains were not maintained at follow-up [97]. A nonrandomized control comparison study found that a smartphone-delivered metacognitive therapy augmented by weekly mentoring sessions found positive impacts on metacognition, delusions, general pathology, and negative symptoms [85]. Finally, an RCT examined the effect of medication reminders sent through a smartphone app and reported that compared to TAU, those receiving reminders showed significantly better medication adherence, with large effect sizes reported [30].

SMS Text Messaging Interventions

Overview

In this review of 92 studies, 16 (17%) were included in which an intervention using SMS text messaging was investigated. Of the 16 papers, 1 (6%) was a development paper [99], 2 (12%) were protocol papers [100,118], 4 (25%) were pilot trials (ie, 2 (12%) were open trials [101,102] and 2 (12%) were pilot RCTs [103,104]), 6 (38%) were RCTs [26,27,31,37-39], and 3 (19%) were secondary analyses [105-107]. The sample sizes varied greatly between 14 and 1139 (mean 181, SD 274.7); however, most were <100 participants (10/16, 62%). The length of the intervention varied from 1 to 18 months, with a mean of 4 months and a mode of 6 months.

There were 11 unique SMS interventions investigated within the included 16 studies. Most (n=9, 82%) did not report following a specific evidence-based model, with one reporting the use of CBT [102], and another Self-Determination Theory [39]. Interventions using SMS text messaging targeted a variety of outcomes, mainly in the form of reminders, such as medication adherence (4/16, 25%) [26,31,37,102], appointment attendance (1/16, 6%) [100], and relapse and rehospitalization rates (1/16, 6%) [27]. Beyond service engagement, some studies aimed to support clinical outcomes, such as auditory hallucinations [102], social skills [102], goal attainment [38], and general support [39,101,103,105]. Most SMS-based interventions were framed as adjunctive care, and only 1 was reported as being intentionally blended with traditional care [103]. Most SMS-based interventions did not report to follow a specific evidence-based approach. One intervention was based on CBT [102], and another was based on self-determination theory [39].

Feasibility

Of the 16 studies investigating SMS text messaging, 5 (31%) reported feasibility as the primary outcome. Studies reported high text message response rates (69% to 87%) [101,103,104] and high levels of satisfaction, ease of use, and helpfulness of SMS text messages [103,104,107]. One of the 5 feasibility studies even found that therapeutic alliance was higher with the SMS text message interventionists compared to participants' community-based clinicians [101]. Another study explored areas that participants found useful to discuss with SMS text message interventionists, including mental health symptoms, coping strategies, lifestyle or well-being, social or leisure activity, motivation, and independent living skills [106].

Efficacy

Of the 16 included studies that investigated SMS text messaging, 13 (81%) reported on efficacy outcomes. The reported efficacy of SMS text messaging interventions seemed to vary depending on the outcomes measured. Most studies investigating SMS interventions aimed at medication adherence were associated with greater rates of adherence [31,37,102,105], especially among individuals with schizophrenia who were living independently [102]. Effects on medication adherence may be bolstered by the addition of phone check-ins by clinicians [26]. However, drop-off effects may occur once the reminders are no longer delivered [119]. In addition, there seemed to be

potential positive effects on rehospitalization rates [31]; however, results were mixed as other researchers did not find evidence of a reduction in hospital admission rates, the time between hospitalizations, or time spent in a psychiatric hospital [39]. Regarding changes in recovery and symptom severity, some studies reported improvements in negative symptoms, positive symptoms [27], cognition, and global clinical symptoms [37]. These results were strengthened when the SMS text messaging intervention was coupled with a secondary intervention (eg, telephone intervention or assertive community treatment) [26,103]. Other researchers did not find significant improvements in symptom severity [39]. Mixed outcomes were reported for social and community functioning [38,104,105]. Studies reported mixed findings regarding service engagement. One study reported improved therapeutic alliance with their mobile clinician compared to in-person clinician visits, and participant feedback results reflected a sense of support among users when receiving daily SMS text messages [101,106].

Internet-Based Interventions

Overview

Of the 92 included studies, 11 (12%) described internet-based interventions that were not paired with other technology. Of these 11 papers, 1 (9%) was a cross-sectional study [108], 5 (45%) were pilot trials [109-112,120], 2 (18%) were RCT protocols [113,114], 2 (18%) were RCTs [40,41], and 1 (9%) was a secondary analysis [115]. The sample size of included studies examining internet-based interventions ranged from 10 to 300, with approximately 50% being >100 (mean 97). The length of the intervention ranged from 2 to 26 (mean 9; modes 2 and 18) months. There were 8 unique interventions investigated within the included 11 studies. The internet-based intervention treatment targets included recovery [110,113], cognition [112,120], working memory [111], symptom severity [40,41], and illness self-management [108]. Most internet-based interventions reported to be based on an evidence-based framework, including connectedness, hope and optimism, identity, meaning, and empowerment [110]; cognitive remediation [111,112,120]; CBT [41]; peer support [40]; and mixed approaches [113].

Feasibility

Of the 11 studies examining internet-based interventions, 6 studies examined feasibility using varied measures of feasibility and engagement. Study attrition was reported between 64% and 100% [109,112,114,120]. Given the range of interventions delivered, intervention engagement was measured differently in each study based on the intervention design. Of the 11 studies, 1 (9%) reported the number of log-ins (eg, mean 39.2 over the intervention) [109], 1 (9%) reported the mean time spent on the website per week (eg, 3 h/wk) [120], another (9%) reported percentage of participants completing at least 80% of modules according to a predetermined meaningful completion rate (eg, 70% of participants completed 80% of modules) [112], and 1 (9%) reported the percentage of participants that used the website (eg, 41% of participants used the website) [108]. Of the 11 studies, 2 (18%) reported that participant factors impacted engagement, such that younger age [108,120], higher education

[108], being employed [108], and lower cognitive symptoms [120] led to better engagement.

One study specifically reported integrating a website into regular therapy sessions and found that the website was used in 95% of therapy sessions [114]. Qualitative feedback related to the use in sessions included that the website helped facilitate conversation and reflection in their sessions and was a key tool for engagement, leading to increased perceived recovery [114]. However, only 60% of participants reported use outside of sessions [114]. Another study presented findings related to a self-guided website [115] and found that the self-guided nature to some was motivating and cultivated a sense of autonomy in recovery, whereas others found the self-guided nature overwhelming, which interrupted engagement. Positive aspects reported related to the self-guided website were having at-demand resources more so than any clinician-driven service, having the means to distract from distress in a meaningful, positive way, and having the ability to interact with peers and psychoeducation was a normalizing experience [115].

Efficacy

Of the 11 studies examining internet-based interventions, there were 3 (27%) that reported primary outcomes pertaining to the efficacy of internet-based interventions [40,41,111]. Each of these interventions focused on different evidence-based approaches. One study examined the impact of online peer support (ie, comparing anonymous listserv group email communication or communication with peers via web-based bulletin board compared to TAU) on subjective recovery, quality of life, empowerment, and social support [40]. No significant group differences were found with regard to online peer support and the control group for either the listserv or bulletin board communication types [40]. Another study investigated remote cognitive remediation (ie, web-based computerized tasks, psychoeducation, and strategy development paired with weekly clinician calls) targeting working memory [111]. Compared to TAU, remote cognitive remediation was associated with improved working and episodic memory, with medium effect sizes reported [111]. Finally, another study looked at the effects of self-guided CBT for psychosis on various psychotic symptoms compared to a waitlist condition [41]. Individuals receiving self-guided CBT for psychosis demonstrated greater improvements in symptoms overall and self-reported hallucinations compared to the waitlist condition, with a small to medium effect size reported [41]. However, the study did not find significant differences in other positive psychotic symptoms [41].

Discussion

Principal Findings

The primary aim of this review was to provide a high-level overview of the use of personal technologies in research on digital mental health interventions for individuals with SSDs. Publication patterns show rapid growth in the area over the past 5 to 7 years, highlighting increasing interest in this area [10-12]. The lower number of publications reported for 2021 to 2023 is likely partly attributable to a combination of the large number of protocols published in 2020, as many of these trials may still

be underway, and research challenges related to the COVID-19 pandemic. Personal technologies leveraged most often included the use of smartphone apps or an app in combination with other technology, such as a clinician web portal.

Our review confirms that personal technologies have already garnered acceptance among individuals with SSDs, as evidenced by consistently high ratings of acceptability, usability, and satisfaction. Some studies even report that augmenting care with technology improved engagement in traditional in-person or remote care [44,101,106]. In included studies which report participant feedback, participants typically report that these technologies facilitate self-reflection and understanding, better communication with their clinical teams, improved access to evidence-based resources, and support in times of need. Findings related to feasibility presented in this review are similar to findings reported elsewhere for groups with SMI [121].

Despite the high levels of acceptance and interest, sustained engagement in technological interventions is an ongoing concern [122] and is not well understood. Measures of engagement are highly inconsistent across studies, and include module completion, response rates, skills and homework completion, and number of posts, making it almost impossible to understand a cohesive story regarding engagement with digital tools in groups with SSDs. While simple metrics such as screen clicks or the number of days or hours used are commonly reported, the field lacks an understanding of clinically meaningful engagement for this metric [123]. Beyond access metrics, there is no consistent measure of technology use. The challenge of heterogeneity in engagement metrics is already well known [124], but a lack of progress in agreement around these common metrics hinders future advances in the field [125]. Furthermore, likely in part owing to a lack of definition in this area, means of addressing technology disengagement are also poorly understood. A review examining the use of persuasive system design (design features designed to address or enhance engagement) in technologies designed for use in depression and anxiety reported that persuasive system design efforts did not systematically lead to improved engagement but are associated with improved efficacy [126].

Moreover, some ongoing challenges may impact the feasibility of using such technologies in practice, including understanding the link between privacy protections embedded in these technologies and meaningful engagement. Privacy concerns are seldom outlined in the included publications, which may result from the dearth of available guidelines, policies, and reporting standards. Privacy concerns are often cited by health care providers as a key barrier to the use of technology in practice [127], and as such, to encourage technological adoption, more data on privacy features needs to be made available. There is also a dearth of information regarding patient safety and urgent or crisis resources and support. In this review, most of the included studies (55/92, 60%) did not report on safety at all, which is well above the proportions reported across the field of digital mental health (35%) [128]. The most common safety indicators reported in this review and across the field [128] were SAEs and other AEs, which are often mandatory reporting standards for ethics boards and do not provide nuanced information regarding technology use and patient well-being.

Furthermore, there are promising early results regarding efficacy, but overall findings are mixed. Pilot studies tend to show more optimistic outcomes across a range of mental health outcomes; however, once studies reach the RCT phase, findings become more mixed. Similar descriptions are found in other areas of SMI, such as bipolar disorder [129]. In areas such as depression and anxiety, where more research on efficacy has been conducted, clearer conclusions about effectiveness can be drawn [130]. In the included RCTs, it does not appear that study procedures, such as blinding, type of technology, or sample size, systematically impact outcomes, as no obvious patterns have emerged between study type or methodology. However, with few studies featuring an active control group, any assessment of efficacy is still preliminary. Future studies should consider the active intervention when planning a control group and the purpose of the technology (eg, if testing an evidence-based treatment that is typically delivered in person and not included in TAU, then TAU would not be an active control group, such as an in-person service delivering the evidence-based treatment would better represent an active control). However, there are some interventions that have garnered significant support and exhibit positive early results [33,53,60,84,86,113].

Of note, all included studies used samples of individuals currently in treatment and thus were all offered adjunctly to traditional clinician-delivered care. However, few studies described how the technology was blended or integrated into the care structure. As such, the field provides little direction on the role of technology and its integration into existing care models. Furthermore, there were few clinical integration and effectiveness studies, underscoring the next frontier for this research in SSDs. It is important to understand how external factors, including primary treatment methods, may impact engagement, efficacy, and effectiveness. For example, the included studies that described the role of technology within the clinical context described technology-forward (ie, self-guided and clinician-supported) and clinician-forward (ie, clinician-delivered and technology-supported) interventions. Clinician-forward interventions, in our small sample of studies that described clinical integration, seemed to demonstrate better engagement [96] and better outcomes [33,84,96] than technology-forward interventions, depending on the target and treatment approach [29].

Other reviews reported mixed findings in relation to blended (technology-supported) approaches. One review and meta-analysis of digital mental health interventions across disorders suggested that technology-supported interventions outperform (Hedges $g=0.16$; $P<.001$) traditional TAU (solely clinician-delivered) [131]. However, this review did not report on the more nuanced technological differences that we highlight in this review regarding whether the intervention was delivered by the technology (ie, technology-forward) or supported clinician-delivered care (ie, clinician-forward). Another review and meta-analysis suggested that technology engagement was associated with efficacy regardless of intervention type (ie, guided or unguided) [132], suggesting that engagement may be the underlying mechanism for effectiveness in these trials rather than the level of clinician involvement. Therefore, more research

is needed to define the role of technology within clinical spaces to understand the implementation and best practices related to technology-assisted care.

Future research in this promising area should focus on the identified key gaps to move the field toward implementation readiness. First, studies should clarify the technology's intended role, intervention targets, and functionality. This is important for understanding implementation into existing clinical structures and interpreting study outcomes. Second, given the significant barriers of safety and privacy to clinical adoption, a more detailed exploration of safety and privacy indices is critical. Finally, a better understanding of barriers to participating in and disengagement from digital interventions is crucial for understanding its usefulness and scope in clinical settings.

Limitations

There are several limitations to this review. First, as a scoping review, we could not provide a detailed review of each study but rather a high-level examination of the findings in the field to date. Therefore, data have been synthesized and presented in accordance with outlined scoping review guidelines, and, as such, the methodological quality of each study was not rigorously reviewed. Second, we limited our search to using personal technologies to deliver or support specialized care for individuals with SSDs. Other technologies are being used in SSD treatment that this review did not include, such as virtual reality, avatar therapy, cognitive remediation, brain stimulation, and more. Third, we restricted this review to outcomes directly related to general recovery (ie, core symptoms and functioning) and treatment engagement and did not focus on specific domains such as cognitive deficits. Fourth, other interventions exist for comorbid conditions, such as substance use and smoking cessation [133], physical activity [134], and resources for family

and social support [135]. Finally, we only included technologies that were used to deliver interventions; we did not include studies that were used to improve the understanding of SSDs, such as observational methods (eg, technology-assisted EMA or health services-based interventions, including those that are embedded in electronic medical records for medication algorithms, symptom monitoring, or other purposes). Future reviews may consider focusing on these additional areas of digital mental health to understand how other technologies may support the recovery of individuals with SSD diagnoses.

Conclusions

Overall, using personal technologies to deliver specialized care requires more careful consideration before advocating for broad implementation, highlighting the same challenges as other psychotherapeutic intervention research. Namely, the prolonged time between investigation and implementation is due to varied findings and a lack of cohesive targets and direction. Despite these challenges, as evidenced by this review, there is great promise for leveraging personal technology in mental health care to help provide pieces of the holistic care necessary for recovery in SSDs. Multifaceted mental health conditions such as SSDs are highly heterogeneous and may require multifaceted and flexible interventions. Although the exact nature of meaningful technological support is still being discovered, the studies in this review overwhelmingly demonstrate how flexibly personal technologies can support recovery from medication adherence to potentially delivering complex psychosocial interventions such as CBT. Furthermore, studies clearly demonstrated the feasibility of personal technologies to extend access to specialized information beyond traditional care and into everyday life. Therefore, these technologies are well suited to be integrated into existing specialty care structures for individuals with SSD diagnoses.

Acknowledgments

This study is funded by the Canadian Institute of Health Research. The first author (JD) is also supported by a Canadian Institute of Health Research Vanier Graduate Scholarship.

Conflicts of Interest

JT is the editor in chief of *JMIR Mental Health*. Research examining the App4Independence (A4i) is included in this review. A4i was developed and owned by the joint for-profit venture A4i. A4i is jointly owned by MEMOTEXT, the Centre for Addiction and Mental Health, and SK – hence having author engagement in this company.

Multimedia Appendix 1

Supplemental table of included studies divided by technology type.

Abstract

Background: Large language models (LLMs) are advanced artificial neural networks trained on extensive datasets to accurately understand and generate natural language. While they have received much attention and demonstrated potential in digital health, their application in mental health, particularly in clinical settings, has generated considerable debate.

Objective: This systematic review aims to critically assess the use of LLMs in mental health, specifically focusing on their applicability and efficacy in early screening, digital interventions, and clinical settings. By systematically collating and assessing the evidence from current studies, our work analyzes models, methodologies, data sources, and outcomes, thereby highlighting the potential of LLMs in mental health, the challenges they present, and the prospects for their clinical use.

Methods: Adhering to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines, this review searched 5 open-access databases: MEDLINE (accessed by PubMed), IEEE Xplore, Scopus, JMIR, and ACM Digital Library. Keywords used were (*mental health OR mental illness OR mental disorder OR psychiatry*) AND (*large language models*). This study included articles published between January 1, 2017, and April 30, 2024, and excluded articles published in languages other than English.

Results: In total, 40 articles were evaluated, including 15 (38%) articles on mental health conditions and suicidal ideation detection through text analysis, 7 (18%) on the use of LLMs as mental health conversational agents, and 18 (45%) on other applications and evaluations of LLMs in mental health. LLMs show good effectiveness in detecting mental health issues and providing accessible, destigmatized eHealth services. However, assessments also indicate that the current risks associated with clinical use might surpass their benefits. These risks include inconsistencies in generated text; the production of hallucinations; and the absence of a comprehensive, benchmarked ethical framework.

Conclusions: This systematic review examines the clinical applications of LLMs in mental health, highlighting their potential and inherent risks. The study identifies several issues: the lack of multilingual datasets annotated by experts, concerns regarding the accuracy and reliability of generated content, challenges in interpretability due to the “black box” nature of LLMs, and ongoing ethical dilemmas. These ethical concerns include the absence of a clear, benchmarked ethical framework; data privacy issues; and the potential for overreliance on LLMs by both physicians and patients, which could compromise traditional medical practices. As a result, LLMs should not be considered substitutes for professional mental health services. However, the rapid development of LLMs underscores their potential as valuable clinical aids, emphasizing the need for continued research and development in this area.

Introduction

Mental Health

Mental health, a critical component of overall well-being, is at the forefront of global health challenges [1]. In 2019, an estimated 970 million individuals worldwide experienced mental illness, accounting for 12.5% of the global population [2]. Anxiety and depression are among the most prevalent psychological conditions, affecting 301 million and 280 million individuals, respectively [2]. In addition, 40 million people experienced bipolar disorder, 24 million experienced schizophrenia, and 14 million experienced eating disorders [3]. These mental disorders collectively contribute to an estimated US \$5 trillion in global economic losses annually [4]. Despite the staggering prevalence, many cases remain undetected or untreated, with the resources allocated to the diagnosis and treatment of mental illness far less than the negative impact it has on society [5]. Globally, untreated mental illnesses affect 5% of the population in high-income countries and 19% of the population in low- and middle-income countries [3]. The COVID-19 pandemic has further exacerbated the challenges faced by mental health services worldwide [6], as the demand for these services increased while access was decreased [7]. This escalating crisis underscores the urgent need for more innovative and accessible mental health care approaches.

Mental illness treatment encompasses a range of modalities, including medication, psychotherapy, support groups, hospitalization, and complementary and alternative medicine [8]. However, the societal stigma attached to mental illnesses often deters people from seeking appropriate care [9]. Influenced by the fear of judgment and concerns about costly, ineffective treatments [10], many people with mental illness avoid or delay psychotherapy [11]. The COVID-19 crisis and other global pandemics have underscored the importance of digital tools, such as telemedicine and mobile apps, in delivering care during critical times [12]. In this evolving context, large language models (LLMs) present new possibilities for enhancing the delivery and effectiveness of mental health care.

Recent technological advancements have revealed some unique advantages of LLMs in mental health. These models, capable of processing and generating text akin to human communication, provide accessible support directly to users [13]. A study analyzing 2917 Reddit (Reddit, Inc) user reviews found that conversational agents (CAs) powered by LLMs are valued for their nonjudgmental listening and effective problem-solving advice. This aspect is particularly beneficial for individuals considered socially marginalized, as it enables them to be heard and understood without the need for direct social interaction [14]. Moreover, LLMs enhance the accessibility of mental health services, which are notably undersupplied globally [15]. Recent data reveals substantial delays in traditional mental health care delivery; 23% of individuals with mental illnesses report waiting for >12 weeks for face-to-face psychotherapy sessions [16],

with 12% waiting for >6 months and 6% waiting for >1 year [16]. In addition, 43% of adults with mental illness indicate that such long waits have exacerbated their conditions [16].

Telemedicine, enhanced by LLMs, offers a practical alternative that expedites service delivery and could flatten traditional health care hierarchies [17]. This includes real-time counseling sessions through CAs that are not only cost-effective but also accessible anytime and from any location. By reducing the reliance on physical visits to traditional health care settings, telemedicine has the potential to decentralize access to medical expertise and diminish the hierarchical structures within the health care system [17]. Mental health chatbots developed using language models, such as Woebot [18] and Wysa [19], have been gaining recognition. Both chatbots follow the principles of cognitive behavioral therapy and are designed to equip users with self-help tools for managing their mental health issues [20]. In clinical practice, LLMs hold the potential to support the automatic assessment of therapists' adherence to evidence-based practices and the development of systems that offer real-time feedback and support for patient homework between sessions [21]. These models also have the potential to provide feedback on psychotherapy or peer support sessions, which is especially beneficial for clinicians with less training and experience [21]. Currently, these applications are still in the proposal stage. Although promising, they are not yet widely used in routine clinical settings, and further evaluation of their feasibility and effectiveness is necessary.

The deployment of LLMs in mental health also poses several risks, particularly for groups considered vulnerable. Challenges such as inconsistencies in the content generated and the production of "hallucinatory" content may mislead or harm users [22], raising serious ethical concerns. In response, authorities such as the World Health Organization have developed ethical guidelines for artificial intelligence (AI) research in health care, emphasizing the importance of data privacy; human oversight; and the principle that AI tools should augment, rather than replace, human practitioners [23]. These potential problems with LLMs in health care have gained considerable industry attention, underscoring the need for a comprehensive and responsible evaluation of LLMs' applications in mental health. The following section will further explore the workings of LLMs and their potential applications in mental health and critically evaluate the opportunities and challenges they introduce.

LLMs in Mental Health

LLMs represent advancements in machine learning, characterized by their ability to understand and generate human-like text with high accuracy [24]. The efficacy of these models is typically evaluated using benchmarks designed to assess their linguistic fidelity and contextual relevance. Common metrics include Bilingual Evaluation Understudy for translation accuracy and Recall-Oriented Understudy for Gisting Evaluation (ROUGE) for summarization tasks [25]. LLMs are characterized

by their scale, often encompassing billions of parameters, setting them apart from traditional language models [26]. This breakthrough is largely due to the transformer architecture, a deep neural network structure that uses a “self-attention” mechanism developed by Vaswani et al [27]. This allows LLMs to process information in parallel rather than sequentially, greatly enhancing speed and contextual understanding [27]. To clearly define the scope of this study concerning LLMs, we specify that an LLM must use the transformer architecture and contain a high number of parameters, traditionally at least 1 billion, to qualify as “large” [28]. This criterion encompasses models such as GPT (OpenAI) and Bidirectional Encoder

Representations from Transformers (BERT; Google AI). Although the standard BERT model, with only 0.34 billion parameters [29], does not meet the traditional criteria for “large,” its sophisticated bidirectional design and pivotal role in establishing new natural language processing (NLP) benchmarks justify its inclusion among notable LLMs [30]. The introduction of ChatGPT (OpenAI) in 2022 generated substantial public and academic interest in LLMs, underlining their transformative potential within the field of AI [31]. Other state-of-the-art LLMs include Large Language Model Meta AI (LLaMA; Meta AI) and Pathways Language Model (PaLM; Google AI), as illustrated in Table 1 [32-35].

Table 1. Comparative analysis of large language models (LLMs) by parameter size and developer entity. Data were summarized with the latest models up to June 2024, with data for parameters and developers from GPT (OpenAI) to Large Language Model Meta AI (LLaMA; Meta AI) adapted from the study by Thirunavukarasu et al [32].

Model name	Publication date	Parameters (billion)	Developer

LLMs are primarily designed to learn fundamental statistical patterns of language [36]. Initially, these models were used as the basis for fine-tuning task-specific models rather than training those models from scratch, offering a more resource-efficient approach [37]. This fine-tuning process involves adjusting a pretrained model to a specific task by further training it on a smaller, task-specific dataset [38]. However, developments in larger and more sophisticated models have reduced the need for extensive fine-tuning in some cases. Notably, some advanced LLMs can now effectively understand and execute tasks specified through natural language prompts without extensive task-specific fine-tuning [39]. Instruction fine-tuned models undergo additional training on pairs of user requests and appropriate responses. This training allows them to generalize across various complex tasks, such as sentiment analysis, which previously required explicit fine-tuning by researchers or developers [40]. A key part of the input to these models, such as ChatGPT and Gemini (Google AI), includes a system prompt, often hidden from the user, which guides the model on how to interpret and respond to user prompts. For example, it might direct the model to act as a helpful mental health assistant. In addition, “prompt engineering” has emerged as a crucial technique in optimizing model performance. Prompt engineering involves crafting input texts that guide the model to produce the desired output without additional training. For example, refining a prompt from “Tell me about current events in health care” to “Summarize today’s top news stories about technology in health care” provides the model with more specific guidance, which can enhance the relevance and accuracy of its responses [41]. While prompt engineering can be highly effective and reduce the need to retrain the model, it is important to be wary of “hallucinations,” a phenomenon where models confidently generate incorrect or irrelevant outputs [42]. This can be

particularly challenging in high-accuracy scenarios, such as health care and medical applications [43-46]. Thus, while prompt engineering reduces the reliance on extensive fine-tuning, it underscores the need for thorough evaluation and testing to ensure the reliability of model outputs in sensitive applications.

The existing literature includes a review of the application of machine learning and NLP in mental health [47], analyses of LLMs in medicine [32], and a scoping review of LLMs in mental health. These studies have demonstrated the effectiveness of NLP for tasks such as text categorization and sentiment analysis [47] and provided a broad overview of LLM applications in mental health [48]. However, a gap remains in systematically reviewing state-of-the-art LLMs in mental health, particularly in the comprehensive assessment of literature published since the introduction of the transformer architecture in 2017.

This systematic review addresses these gaps by providing a more in-depth analysis; evaluating the quality and applicability of studies; and exploring ethical challenges specific to LLMs, such as data privacy, interpretability, and clinical integration. Unlike previous reviews, this study excludes preprints, follows a rigorous search strategy with clear inclusion and exclusion criteria (using Cohen κ to assess the interreviewer agreement), and uses a detailed assessment of study quality and bias (using the Risk of Bias 2 tool) to ensure the reliability and reproducibility of the findings.

Guided by specific research questions, this systematic review critically assesses the use of LLMs in mental health, focusing on their applicability and efficacy in early screening, digital interventions, and clinical settings, as well as the methodologies and data sources used. The findings of this study highlight the

potential of LLMs in enhancing mental health diagnostics and interventions while also identifying key challenges such as inconsistencies in model outputs and the lack of robust ethical guidelines. These insights suggest that, while LLMs hold promise, their use should be supervised by physicians, and they are not yet ready for widespread clinical implementation.

Methods

This systematic review followed the PRISMA (Preferred Reporting Items for Systematic Review and Meta-Analyses) guidelines [49]. The protocol was registered on PROSPERO (CRD42024508617). A PRISMA checklist is available in [Multimedia Appendix 1](#).

Search Strategies

The search was initiated on August 3, 2024, and completed on August 6, 2024, by 1 author (ZG). ZG systematically searched 5 databases: MEDLINE, IEEE Xplore, Scopus, JMIR, and ACM Digital Library using the following search keywords: (*mental health OR mental illness OR mental disorder OR psychiatry*) and (*large language models*). These keywords were consistently applied across each database to ensure a uniform search strategy. To conduct a comprehensive and precise search for relevant literature, strategies were tailored for different databases. All metadata were searched in MEDLINE and IEEE Xplore, whereas the search in Scopus was confined to titles, abstracts, and keywords. The JMIR database used the criteria *exact match* feature to refine search results and enhance precision. In the ACM Digital Library database, the search focused on full text. The screening of all citations involved four steps:

1. Initial search. All relevant citations were imported into a Zotero (Corporation for Digital Scholarship) citation manager library.
2. Preliminary inclusion. Citations were initially screened based on predefined inclusion criteria.
3. Duplicate removal. Citations were consolidated into a single group, from which duplicates were eliminated.
4. Final inclusion. The remaining references were carefully evaluated against the inclusion criteria to determine their suitability.

Study Selection and Eligibility Criteria

All the articles that matched the search criteria were double screened by 2 independent reviewers (ZG and KL) to ensure that each article fell within the scope of LLMs in mental health. This process involved the removal of duplicates followed by a detailed manual evaluation of each article to confirm adherence to our predefined inclusion criteria, ensuring a comprehensive and focused review. To quantify the agreement level between the reviewers and ensure objectivity, interrater reliability was calculated using Cohen κ , with a score of 0.84 indicating a good level of agreement. In instances of disagreement, a third reviewer (AL) was consulted to achieve consensus.

To assess the risk of bias, we used the Risk of Bias 2 tool, as recommended for Cochrane Reviews. The results have been visualized in [Multimedia Appendix 2](#). We thoroughly examined each study for potential biases that could impact the validity of the results. These included biases from the randomization

process, deviations from intended interventions, missing outcome data, inaccuracies in outcome measurement, and selective reporting of results. This comprehensive assessment ensures the credibility of each study.

The criteria for selecting articles were as follows: we limited our search to English-language publications, focusing on articles published between January 1, 2017, and April 30, 2024. This timeframe was chosen considering the substantial developments in the field of LLMs in 2017, marked notably by the introduction of the transformer architecture, which has greatly influenced academic and public interest in this area.

In this review, the original research articles and available full-text papers have been carefully selected, aiming to focus on the application of LLMs in mental health. To comply with the PRISMA guidelines, articles that have not been published in a peer-reviewed venue, including those only available on a preprint server, were excluded. Owing to the limited literature specifically addressing the mental health applications of LLMs, we included review articles to ensure a comprehensive perspective. The selection criteria focused on direct applications, expert evaluations, and ethical considerations related to the use of LLMs in mental health contexts, with the goal of providing a thorough analysis of this rapidly developing field.

Information Extraction

The data extraction process was jointly conducted by 2 reviewers (ZG and KL), focusing on examining the application scenarios, model architecture, data sources, methodologies used, and main outcomes from selected studies on LLMs in mental health.

Initially, we categorized each study to determine its main objectives and applications. The categorization process was conducted in 2 steps. First, after reviewing all the included articles, we grouped them into 3 primary categories: detection of mental health conditions and suicidal ideation through text, LLM use for mental health CAs, and other applications and evaluation of the LLMs in mental health. In the second step, we performed a more detailed categorization. After a thorough, in-depth reading of each article within these broad categories, we refined the classifications based on the specific goals of the studies. Following this, we summarized the main model architectures of the LLMs used and conducted a thorough examination of data sources, covering both public and private datasets. We noted that some review articles lacked detail on dataset content; therefore, we focused on providing comprehensive information on public datasets, including their origins and sample sizes. We also investigated the various methods used across different studies, including data collection strategies and analytic methodologies. We examined their comparative structures and statistical techniques to offer a clear understanding of how these methods are applied in practice.

Finally, we documented the main outcomes of each study, recording significant results and aligning them with relevant performance metrics and evaluation criteria. This included providing quantitative data where applicable to underscore these findings. We used a narrative approach to synthesize the information, integrating and comparing results from various studies to emphasize the efficacy and impact of LLMs on mental

health. This narrative synthesis allowed us to highlight the efficacy and impact of LLMs in mental health, providing quantitative data where applicable to underscore these findings. The results of this analysis are presented in Tables S1-S3 in [Multimedia Appendix 3](#) [14,50-131], each corresponding to 1 of the primary categories.

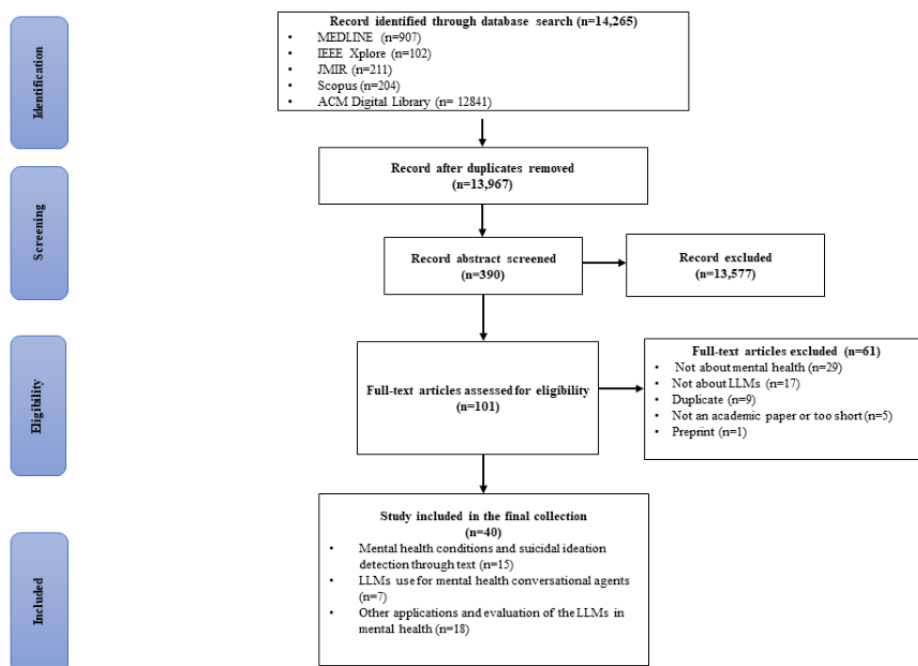

Results

Strategy and Screening Process

The PRISMA diagram of the systematic screening process can be seen in [Figure 1](#). Our initial search across 5 academic

databases, namely, MEDLINE, IEEE Xplore, Scopus, JMIR, and ACM Digital Library, yielded 14,265 papers: 907 (6.36%) from MEDLINE, 102 (0.72%) from IEEE Xplore, 204 (1.43%) from Scopus, 211 (1.48%) from JMIR, and 12,841 (90.02%) from ACM Digital Library. After duplication, 97.91% (13,967/14,265) of the unique papers were retained. Subsequent screening was based on predefined inclusion and exclusion criteria, narrowing down the selection to 0.29% (40/13,967) of the papers included in this review. The reasons for the full-text exclusion of 61 papers can be found in [Multimedia Appendix 4](#).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow of the selection process. LLM: large language model.

In our review of the literature, we classified the included articles into 3 broad categories: detection of mental health conditions and suicidal ideation through text (15/40, 38%), LLMs' use for mental health CAs (7/40, 18%), and the other applications and evaluation of the LLMs in mental health (18/40, 45%). The first category investigates the potential of LLMs for the early detection of mental illness and suicidal ideation via social media and other textual sources. Early screening is highlighted as essential for preventing the progression of mental disorders and mitigating more severe outcomes. The second category assesses LLM-supported CAs used as teletherapeutic interventions for mental health issues, such as loneliness, with a focus on evaluating their effectiveness and validity. The third category covers a broader range of LLM applications in mental health, including clinical uses such as decision support and therapy enhancement. It aims to assess the overall effectiveness, utility, and ethical considerations associated with LLMs in these settings. All selected articles are summarized in Tables S1-S3 in [Multimedia Appendix 3](#) according to the 3 categories.

Mental Health Conditions and Suicidal Ideation Detection Through Text

Early intervention and screening are crucial in mitigating the global burden of mental health issues [132]. We examined the

performance of LLMs in detecting mental health conditions and suicidal ideation through textual analysis. Of 40 articles, 6 (15%) assessed the efficacy of early screening for depression using LLMs [50,57,60,61,66,68], while another (1/40, 2%) simultaneously addressed both depression and anxiety [60]. One comprehensive study examined various psychiatric conditions, including depression, social anxiety, loneliness, anxiety, and other prevalent mental health issues [69]. Two (5%) of the 40 articles assessed and compared the ability of LLMs to perform sentiment and emotion analysis [75,81], and 5 (12%) articles focused on the capability of LLMs to analyze textual content for detecting suicidal ideation [54,65,70,72,78]. Most studies (10/40, 25%) used BERT and its variants as one of the primary models [50,54,57,62,65,66,68,69,75,78], while GPT models were also commonly used (8/40, 20%) [57,60,61,66,70,72,78,81]. Most training data (10/40, 25%) comprised social media posts [50,54,62,65,68,69,72,75,78,81] from platforms such as Twitter (Twitter, Inc), Reddit, and Sina Weibo (Sina corporation), covering languages such as English, Malay dialects, Chinese, and Portuguese. In addition, 5 (12%) of the 40 studies used datasets consisting of clinical transcripts and patient interviews [50,57,60,61,66], providing deeper insights into LLM applications in clinical mental health settings.

In studies focusing on early screening for depression, comparing results horizontally is challenging due to variations in datasets, training methods, and models across different investigations. Nonetheless, substantial evidence supports the significant potential of LLMs in detecting depression from text-based data. For example, Danner et al [57] conducted a comparative analysis using a convolutional neural network on the Distress Analysis Interview Corpus-Wizard of Oz dataset, achieving F_1 -scores of 0.53 and 0.59; however, their use of GPT-3.5 demonstrated superior performance, with an F_1 -score of 0.78. Another study involving the E-Distress Analysis Interview Corpus dataset (an extension of Distress Analysis Interview Corpus-Wizard of Oz) used the Robustly Optimized BERT Approach for Depression Detection to predict the Patient Health Questionnaire-8 scores from textual data. This approach identified 3 levels of depression and achieved the lowest mean absolute error of 3.65 in Patient Health Questionnaire-8 scores [66].

LLMs play an important role in sentiment analysis [75,81], which categorizes text into overall polarity classes, such as positive, neutral, negative, and occasionally mixed, and emotion classification, which assigns labels such as “joy,” “sadness,” “anger,” and “fear” [75]. These analyses enable the detection of emotional states and potential mental health issues from textual data, facilitating early intervention [133]. Stigall et al [75] demonstrated the efficacy of these models, with their study showing that Emotion-aware BERT Tiny, a fine-tuned variant of BERT, achieved an accuracy of 93.14% in sentiment analysis and 85.46% in emotion analysis. This performance surpasses that of baseline models, including BERT-Base Cased and BERTTiny-Pretrained [75], underscoring the advantages and validity of fine-tuning in enhancing model performance. LLMs have also demonstrated robust accuracy in detecting and classifying a range of mental health syndromes, including social anxiety, loneliness, and generalized anxiety. Vajre et al [69] introduced PsychBERT, developed using a diverse training dataset from both social media texts and academic literature, which achieved an F_1 -score of 0.63, outperforming traditional deep learning approaches such as convolutional neural networks and long short-term memory networks, which recorded F_1 -scores of 0.57 and 0.51, respectively [69]. In research on detecting suicidal ideation using LLMs, Diniz et al [54] showcased the high efficacy of the BERTimbau large model within a non-English (Portuguese) context, achieving an accuracy of 0.955, precision of 0.961, and an F_1 -score of 0.954. The assessment of the BERT model by Metzler et al [65] found that it correctly identified 88.5% of tweets as suicidal or off-topic, performing comparably to human analysts and other leading models. However, Levkovich et al [70] noted that while GPT-4 assessments of suicide risk closely aligned with those by mental health professionals, it overestimated suicidal ideation. These results underscore that while LLMs have the potential to identify tweets reflecting suicidal ideation with accuracy comparable to psychological professionals, extensive follow-up studies are required to establish their practical application in clinical settings.

LLMs in Mental Health CAs

In the growing field of mental health digital support, the implementation of LLMs as CAs has exhibited both promising advantages [14,84,91,96] and significant challenges [92,96]. The studies by Ma et al [14] and Heston [96] demonstrate the effectiveness of CAs powered by LLMs in providing timely, nonjudgmental mental health support. This intervention is particularly important for those who lack ready access to a therapist due to constraints such as time, distance, and work, as well as for certain populations considered socially marginalized, such as older adults who experience chronic loneliness and a lack of companionship [14,97]. The qualitative analysis of user interactions on Reddit by Ma et al [14] highlights that LLMs encourage users to speak up and boost their confidence by providing personalized and responsive interactions. In addition, VHope, a DialoGPT-enabled mental health CA, was evaluated by 3 experts who rated its responses as 67% relevant, 78% human-like, and 79% empathetic [84]. Another study found that after observing 717 evaluations by 100 participants on 239 autism-specific questions, 46.86% of evaluators preferred responses of the chief physicians, whereas 34.87% preferred the responses of GPT-4, and 18.27% favored the responses of Enhanced Representation through Knowledge Integration Bot (ERNIE Bot; version 2.2.3; Baidu, Inc). Moreover, ChatGPT (mean 3.64, 95% CI 3.57-3.71) outperformed physicians (mean 3.13, 95% CI 3.04-3.21) in terms of empathy [98], indicating that LLM-powered CAs are not only effective but also acceptable by users. These findings highlight the potential for LLMs to complement mental health intervention systems and provide valuable medical guidance.

The development and implementation of a non-English CA for emotion capture and categorization was explored in a study by Zygadlo et al [92]. Faced with a scarcity of Polish datasets, the study adapted by translating an existing database of personal conversations from English into Polish, which decreased the accuracy in tasks from 90% in English to 80% in Polish [92]. While the performance remained commendable, it highlighted the challenges posed by the lack of robust datasets in languages other than English, impacting the effectiveness of CAs across different linguistic environments. However, findings by He et al [98] suggest that the availability of language-specific datasets is not the sole determinant of CA performance. In their study, although ERNIE Bot was trained in Chinese and ChatGPT in English, ChatGPT demonstrated greater empathy for Chinese users [98]. This implies that factors beyond the training language and dataset availability, such as model architecture or training methodology, can also affect the empathetic responsiveness of LLMs, underscoring the complexity of human-AI interaction.

Meanwhile, the reliability of LLM-driven CAs in high-risk scenarios remains a concern [14,96]. An evaluation of 25 CAs found that in tests involving suicide scenarios, only 2 included suicide hotline referrals during the conversation [96]. This suggests that while these CAs can detect extreme emotions, few are equipped to take effective preventive measures. Furthermore, CAs often struggle with maintaining consistent communication due to limited memory capacity, leading to disruptions in conversation flow and negatively affecting user experience [14].

Other Applications and Evaluation of the LLMs in Mental Health

ChatGPT has gained attention for its unparalleled ability to generate human-like text and analyze large amounts of textual data, attracting the interest of many researchers and practitioners [100]. Numerous evaluations of LLMs in mental health have focused on ChatGPT, exploring its utility across various scenarios such as clinical diagnosis [100,106,111], treatment planning [106,128,131], medication guidance [105,109,129], patient management [106], psychiatry examinations [118], and psychology education [102], among others [107,110,127,130].

Research has highlighted ChatGPT's accuracy in diagnosing various psychiatric conditions [106,110,111,126]. For example, Franco D'Souza et al [100] evaluated ChatGPT's responses to 100 clinical psychiatric cases, awarding it an "A" rating in 61 cases, with no errors in the diagnoses of different psychiatric disorders and no unacceptable responses, underscoring ChatGPT's expertise and interpretative capacity in psychiatry. Further supporting this, Schubert et al [118] assessed the performance of ChatGPT 4.0 using neurology board-style examination questions, finding that it answered 85% of the questions correctly, surpassing the average human performance of 73.8%. Meanwhile, in a study of LLMs regarding the prognosis and long-term outcomes of depression, GPT-4, Claude (Anthropic), and Bard (Google AI) showed strong agreement with mental health professionals. They all recommended a combination of psychotherapy and antidepressant medication in every case [130]. This not only proves the reliability of LLMs for mental health assessment but also highlights their usefulness in providing valuable support and guidance for individuals seeking information or coping with mental illness.

However, the direct deployment of LLMs, such as ChatGPT, in clinical settings carries inherent risks. The outputs of LLMs are heavily influenced by prompt engineering, which can lead to inconsistencies that undermine clinical reliability [102,105-107,109]. For example, Farhat et al [105] conducted a critical evaluation of ChatGPT's ability to generate medication guidelines through detailed cross-questioning and noted that altering prompts substantially changed the responses. While ChatGPT typically provided helpful advice and recommended seeking expert consultation, it occasionally produced inappropriate medication suggestions. Perlis et al [129] verified this, showing that GPT-4 Turbo suggested medications that were considered less efficient choices or contraindicated by experts in 12% of the cases. Moreover, LLMs often lack the necessary clinical judgment capabilities. This issue was highlighted in the study by Grabb [109], which revealed that despite built-in safeguards, ChatGPT remains susceptible to generating extreme and potentially hazardous recommendations. A particularly alarming example was ChatGPT advising a patient with depression to engage in high-risk activities such as bungee jumping as a means of seeking pleasure [109]. These LLMs depend on prompt engineering [102,105,109], which means their responses can vary widely depending on the wording

and context of the prompts given. The system prompts, which are predefined instructions given to the model, and the prompts used by the experimental team, such as those in the study by Farhat et al [105], guide the behavior of ChatGPT and similar LLMs. These prompts are designed to accommodate a variety of user requests within legal and ethical boundaries. However, while these boundaries are intended to ensure safe and appropriate responses, they often fail to align with the nuanced sensitivities required in psychological contexts. This mismatch underscores a significant deficiency in the clinical judgment and control of LLMs within sensitive mental health settings.

Further research into other LLMs in the mental health sector has shown a range of capabilities and limitations. For example, a study by Sezgin et al [111] highlighted Language Model for Dialogue Applications' (LaMDA's) proficiency in managing complex inquiries about postpartum depression that require medical insight or nuanced understanding; however, they pointed out its challenges with straightforward, factual questions, such as "What are antidepressants?" [111]. Assessments of LLMs such as LLaMA-7B, ChatGLM-6B, and Alpaca, involving 50 interns specializing in mental illness, received favorable feedback regarding the fluency of these models in a clinical context, with scores >9.5 out of 10. However, the results also indicated that the responses of these LLMs often failed to address mental health issues adequately, demonstrated limited professionalism, and resulted in decreased usability [116]. Similarly, a study on psychiatrists' perceptions of using LLMs such as Bard and Bing AI (Microsoft Corp) in mental health care revealed mixed feelings. While 40% of physicians indicated that they would use such LLMs to assist in answering clinical questions, some expressed serious concerns about their reliability, confidentiality, and potential to damage the patient-physician relationship [130].

Discussion

Principal Findings

In the context of the wider prominence of LLMs in the literature [14,50,57,60,61,69,96,130], this study supports the assertion that interest in LLMs is growing in the field of mental health. Figure 2 indicates an increase in the number of mental health studies using LLMs, with a notable surge observed in 2023 following the introduction of ChatGPT in late 2022. Although we included articles only up to the end of April 2024, it is evident that the number of articles related to LLMs in the field of mental health continues to show a steady increase in 2024. This marks a substantial change in the discourse around LLMs, reflecting their broader acceptance and integration into various aspects of mental health research and practice. The progression from text analysis to a diverse range of applications highlights the academic community's recognition of the multifaceted uses of LLMs. LLMs are increasingly used for complex psychological assessments, including early screening, diagnosis, and therapeutic interventions.

Figure 2. Number of articles included in this literature review, grouped by year of publication and application field. The black line indicates the total number of articles in each year. CA: conversational agent.

The findings of this study demonstrate that LLMs are highly effective in analyzing textual data to assess mental states and identify suicidal ideation [50,54,57,60,61,65,66,68,69,72,78], although their categorization often tends to be binary [50,54,65,68,69,72,78]. These LLMs possess extensive knowledge in the field of mental health and are capable of generating empathic responses that closely resemble human interactions [97,98,107]. They show great potential for providing mental health interventions with improved prognoses [50,96,110,127,128,131], with the majority being recognized by psychologists for their appropriateness and accuracy [98,100,129]. The careful and rational application of LLMs can enhance mental health care efficiently and at a lower cost, which is crucial in areas with limited health care capacity. However, there are currently no studies available that provide evaluative evidence to support the clinical use of LLMs.

Limitations

Limitations of Using LLMs in Mental Health

On the basis of the works of literature, the strengths and weaknesses of applying the LLMs in mental health are summarized in [Multimedia Appendix 5](#).

LLMs have a broad range of applications in the mental health field. These models excel in user interaction, provide empathy and anonymity, and help reduce the stigma associated with mental illness [14,107], potentially encouraging more patients to participate in treatment. They also offer a convenient, personalized, and cost-effective way for individuals to access mental health services at any time and from any location, which can be particularly helpful for populations considered socially

isolated, especially older adults [60,84,97]. In addition, LLMs can help reduce the burden of care during times of severe health care resource shortages and patient overload, such as during the COVID-19 pandemic [68]. Although previous research has highlighted the potential of LLMs in mental health, it is evident that they are not yet ready for clinical use due to unresolved technical risks and ethical issues.

The use of LLMs in mental health, particularly those fine-tuned for specific tasks such as ChatGPT, reveals clear limitations. The effectiveness of these models heavily depends on the specificity of user-generated prompts. Inappropriate or imprecise prompts can disrupt the conversation's flow and diminish the model's effectiveness [75,96,105,107,109]. Even small changes in the content or tone of prompts can sometimes lead to significant variations in responses, which can be particularly problematic in health care settings where interpretability and consistency are critical [14,105,107]. Furthermore, LLMs lack clinical judgment and are not equipped to handle emergencies [95,108]. While they can generally capture extreme emotions and recognize scenarios requiring urgent action, such as suicide ideation [54,65,70,72,78], they often fail to provide direct, practical measures, typically only advising users to seek professional help [96]. In addition, the inherent bias in LLM training data [66,106] can lead to the propagation of stereotypical, discriminatory, or biased viewpoints. This bias can also give rise to hallucinations, that is, LLMs producing erroneous or misleading information [105,131]. Furthermore, hallucinations may stem from overfitting the training data or a lack of context understanding [134]. Such inaccuracies can have serious consequences, such as providing incorrect medical information, reinforcing harmful stereotypes, or failing to

recognize and appropriately respond to mental health crises [131]. For example, an LLM might reinforce a harmful belief held by a user, potentially exacerbating their mental health issues. It could also generate nonfactual, overly optimistic, or pessimistic medical advice, delaying appropriate professional intervention. These issues could undermine the integrity and fairness of social psychology [102,105,106,110].

Another critical concern is the “black box” nature of LLMs [105,107,131]. This lack of interpretability complicates the application of LLMs in mental health, where trustworthiness and clarity are important. When we talk about neural networks as black boxes, we know details such as what they were trained with, how they were trained, and what the weights are. However, with many new LLMs, such as GPT-3.5 and 4, researchers and practitioners often access the models via web interfaces or application programming interfaces without complete knowledge of the training data, methods, and model updates. This situation not only presents the traditional challenges associated with neural networks but also has all these additional problems that come from the “hidden” model.

Ethical concern is another significant challenge associated with applying LLMs in mental health. Debates are emerging around issues such as digital personhood, informed consent, the risk of manipulation, and the appropriateness of AI in mimicking human interactions [60,102,105,106,135]. A primary ethical concern is the potential alteration of the traditional therapist-patient relationship. Individuals may struggle to fully grasp the advantages and disadvantages of LLM derivatives, often choosing these options for their lower cost or greater convenience. This shift could lead to an increased reliance on the emotional support provided by AI [14], inadvertently positioning AI as the primary diagnostician and decision maker for mental health issues, thereby undermining trust in conventional health care settings. Moreover, therapists may become overly reliant on LLM-generated answers and use them in clinical decision-making, overlooking the complexities involved in clinical assessment. This reliance could compromise their professional judgment and reduce opportunities for in-depth engagement with patients [17,129,130]. Furthermore, the dehumanization and technocratic nature of mental health care has the potential to depersonalize and dehumanize patients [136], where decisions are more driven by algorithms than by human insight and empathy. This can lead to decisions becoming mechanized, lacking empathy, and detached from ethics [137]. AI systems may fail to recognize or adequately interpret the subtle and often nonverbal cues, such as the tone of voice, facial expressions, and the emotional weightage behind words, which are critical in traditional therapeutic settings [136]. These cues are essential for comprehensively understanding a patient’s condition and providing empathetic care.

In addition, the current roles and accuracy of LLMs in mental health are limited. For instance, while LLMs can categorize a patient’s mood or symptoms, most of these categorizations are binary, such as *depressed* or *not depressed* [50,65]. This oversimplification can lead to misdiagnoses. Data security and user privacy in clinical settings are also of utmost concern [14,54,60,96,130]. Although approximately 70% of psychiatrists believe that managing medical documents will be more efficient

using LLMs, many still have concerns about their reliability and privacy [97,130,131]. These concerns could have a devastating impact on patient privacy and undermine the trust between physicians and patients if confidential treatment records stored in LLM databases are compromised. Beyond the technical limitations of AI, the current lack of an industry-benchmarked ethical framework and accountability system hinders the true application of LLMs in clinical practice [131].

Limitations of the Selected Articles

Several limitations were identified in the literature review. A significant issue is the age bias present in the social media data used for depression and mental health screening. Social media platforms tend to attract younger demographics, leading to an underrepresentation of older age groups [65]. Furthermore, most studies have focused on social media platforms, such as Twitter, primarily used by English-speaking populations, which may result in a lack of insight into mental health patterns in non-English-speaking regions. Our review included studies in Polish, Chinese, Portuguese, and Malay, all of which highlighted the significant limitations of LLMs caused by the availability and size of databases [54,61,92,98,116]. For instance, due to the absence of a dedicated Polish-language mental health database, a Polish study had to rely on machine-translated English databases [92]. While the LLMs achieve 80% accuracy in categorizing emotions and moods in Polish, this is still lower than the 90% accuracy observed in the original English dataset. This discrepancy highlights that the accuracy of LLMs can be affected by the quality of the database.

Another limitation of this study is the low diversity of LLMs studied. Although we used “large language models” as keywords in our search phase, the vast majority of identified studies (39/40, 98%) focused on BERT and its variants, as well as the GPT model, as one of the models studied. Therefore, this review provides only a limited picture of the variability expected in applicability between different LLMs. In addition, the rapid development of LLM technologies presents a limitation; this study can only reflect current advancements and may not encompass future advances or the full potential of LLMs. For instance, in tests involving psychologically relevant questions and answers, GPT-3.5 achieved an accuracy of 66.8%, while GPT-4.0 reached an accuracy of 85%, compared to the average human score of 73.8% [118]. Evaluating ChatGPT at different stages separately and comparing its performance to that of humans can lead to varied conclusions. In the assessment of prognosis and treatment planning for depression using LLMs, GPT 3.5 demonstrated a distinctly pessimistic prognosis that differed significantly from those of GPT-4, Claude, Bard, and mental health professionals [128]. Therefore, continuous monitoring and evaluation are essential to fully understand and effectively use the advancements in LLM technologies.

Opportunities and Future Work

Implementing technologies involving LLMs within the health care provision of real patients demands thorough and multifaceted evaluations. It is imperative for both industry and researchers to not let rollout exceed proportional requirements for evidence on safety and efficacy. At the level of the service provider, this includes providing explicit warnings to the public

to discourage mistaking LLM functionality for clinical reliability. For example, GPT-4 introduced the ability to process and interpret image inputs within conversational contexts, leading OpenAI to issue an official warning that GPT-4 is not approved for analyzing specialized medical images such as computed tomography scans [138].

A key challenge to address in LLM research is the tendency to produce incoherent text or hallucinations. Future efforts could focus on training LLMs specifically for mental health applications, using datasets with expert labeling to reduce bias and create specialized mental health lexicons [84,102,116]. The creation of specialized datasets could take advantage of the customizable nature of LLMs, fostering the development of models that cater to the distinct needs of varied demographic groups. For instance, unlike models designed for health care professionals that assist in tasks such as data documentation, symptom analysis, medication management, and postoperative care, LLMs intended for patient interaction might be trained with an emphasis on empathy and comfortable dialogue.

Another critical concern is the problem of outdated training data in LLMs. Traditional LLMs, such as GPT-4 (with a cutoff date up to October 2023), rely on potentially outdated training data, limiting their ability to incorporate recent events or information. This can compromise the accuracy and relevance of their responses, leading to the generation of uninformative or incorrect answers, known as “hallucinations” [139]. Retrieval-augmented generation (RAG) technology offers a solution by retrieving facts from external knowledge bases, ensuring that LLMs use the most accurate and up-to-date information [140]. By searching for relevant information from numerous documents, RAG enhances the generation process with the most recent and contextually relevant content [141]. In addition, RAG includes evidence-based information, increasing the reliability and credibility of LLM responses [139].

To further enhance the reliability of LLM content and minimize hallucinations, recent studies suggest adjusting model parameters, such as the “temperature” setting [142-144]. The temperature parameter influences the randomness and predictability of outputs [145]. Lowering the temperature typically results in more deterministic outputs, enhancing coherence and reducing irrelevant content [146]. However, this adjustment can also limit the model’s creativity and adaptability, potentially making it less effective in scenarios requiring diverse or nuanced responses. In mental therapy, where nuanced and sensitive responses are essential, maintaining an optimal balance is crucial. While a lower temperature can ensure accuracy, which is important for tasks such as clinical documentation, it may not suit therapeutic dialogues where personalized engagement is key. Low temperatures can lead to repetitive and impersonal responses, reducing patient engagement and therapeutic effectiveness. To mitigate these risks, regular updates of the model incorporating the latest therapeutic practices and clinical feedback are essential. Such updates could refine the model’s understanding and response mechanisms, ensuring it remains a safe and effective tool for mental health care. Nevertheless, determining the “optimal” temperature setting is challenging, primarily due to the variability in tasks and interaction contexts, which require different levels of creativity and precision.

Data privacy is another important area of concern. Many LLMs, such as ChatGPT and Claude, involve sending data to third-party servers, which poses the risk of data leakage. Current studies have found that LLMs can be enhanced by privacy-enhancing techniques, such as zero-knowledge proofs, differential privacy, and federated learning [147]. In addition, privacy can be preserved by replacing identifying information in textual data with generic tokens. For example, when recording sensitive information (eg, names, addresses, or credit card numbers), using alternatives to mask tokens can help protect user data from unauthorized access [148]. This obfuscation technique ensures that sensitive user information is not stored directly, thereby enhancing data security.

The lack of interpretability in LLM decision-making is another crucial area for future research on health care applications. Future research should examine the models’ architecture, training, and inferential processes for clearer understanding. Detailed documentation of training datasets, sharing of model architectures, and third-party audits would ideally form part of this undertaking. Investigating techniques such as attention mechanisms and modular architectures could illuminate aspects of neural network processing. The implementation of knowledge graphs might help in outlining logical relationships and facts [149]. In addition, another promising approach involves creating a dedicated embedding space during training, guided by an LLM. This space aligns with a causal graph and aids in identifying matches that approximate counterfactuals [146].

Before deploying LLMs in mental health settings, a comprehensive assessment of their reliability, safety, fairness, abuse resistance, interpretability, compliance with social norms, robustness, performance, linguistic accuracy, and cognitive ability is essential. It is also crucial to foster collaborative relationships among mental health professionals, patients, AI researchers, and policy makers. LLMs, for instance, have demonstrated initial competence in providing medication advice; however, their responses can sometimes be inconsistent or include inappropriate suggestions. As such, LLMs require professional oversight and should not be used independently. Nevertheless, when used as decision aids, LLMs have the potential to enhance health care efficiency. This study calls on developers of LLMs to collaborate with authoritative regulators in actively developing ethical guidelines for AI research in health care. These guidelines should aim to adopt a balanced approach that considers the multifaceted nature of LLMs and ensures their responsible integration into medical practice. They are expected to become industry benchmarks, facilitating the future development of LLMs in mental health.

Conclusions

This review examines the use of LLMs in mental health applications, including text-based screening for mental health conditions, detection of suicidal ideation, CAs, clinical use, and other related applications. Despite the potential of LLMs, challenges such as the production of hallucinatory or harmful information, output inconsistency, and ethical concerns remain. Nevertheless, as technology advances and ethical guidelines improve, LLMs are expected to become increasingly integral

and valuable in mental health services, providing alternative solutions to this global health care issue.

Acknowledgments

This work was funded by the UK Research and Innovation (UKRI) Centre for Doctoral Training in artificial intelligence-enabled health care systems (grant EP/S021612/1). The funders were not involved in the study design, data collection, analysis, publication decisions, or manuscript writing. The views expressed in the text are those of the authors and not those of the funder.

Data Availability

The authors ensure that all pertinent data have been incorporated in the manuscript and the multimedia appendices. For access to the research data, interested parties may contact the corresponding author (KL) subject to a reasonable request.

Authors' Contributions

ZG and KL contributed to the conception and design of the study. ZG, KL, and AL contributed to the development of the search strategy. Database search outputs were screened by ZG, and data were extracted by ZG and KL. An assessment of the risk of bias in the included studies was performed by ZG and KL. ZG completed the literature review, collated the data, performed the data analysis, interpreted the results, and wrote the first draft of the manuscript. KL, AL, JHT, JF, and TK reviewed the manuscript and provided multiple rounds of guidance in the writing of the manuscript. All authors read and approved the final version of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: In many countries, health care professionals are legally obliged to share information from electronic health records with patients. However, concerns have been raised regarding the sharing of notes with adolescents in mental health care, and health care professionals have called for recommendations to guide this practice.

Objective: The aim was to reach a consensus among authors of scientific papers on recommendations for health care professionals' digital sharing of notes with adolescents in mental health care and to investigate whether staff at child and adolescent specialist mental health care clinics agreed with the recommendations.

Methods: A Delphi study was conducted with authors of scientific papers to reach a consensus on recommendations. The process of making the recommendations involved three steps. First, scientific papers meeting the eligibility criteria were identified through a PubMed search where the references were screened. Second, the results from the included papers were coded and transformed into recommendations in an iterative process. Third, the authors of the included papers were asked to provide feedback and consider their agreement with each of the suggested recommendations in two rounds. After the Delphi process, a cross-sectional study was conducted among staff at specialist child and adolescent mental health care clinics to assess whether they agreed with the recommendations that reached a consensus.

Results: Of the 84 invited authors, 27 responded. A consensus was reached on 17 recommendations on areas related to digital sharing of notes with adolescents in mental health care. The recommendations considered how to introduce digital access to notes, write notes, and support health care professionals, and when to withhold notes. Of the 41 staff members at child and adolescent specialist mental health care clinics, 60% or more agreed with the 17 recommendations. No consensus was reached regarding the age at which adolescents should receive digital access to their notes and the timing of digitally sharing notes with parents.

Conclusions: A total of 17 recommendations related to key aspects of health care professionals' digital sharing of notes with adolescents in mental health care achieved consensus. Health care professionals can use these recommendations to guide their practice of sharing notes with adolescents in mental health care. However, the effects and experiences of following these recommendations should be tested in clinical practice.

Introduction

In many countries, health care professionals are legally obligated to share information from electronic health records (EHRs), including clinical notes, medications, and test results with patients [1,2]. This information is often shared through patient portals and aligns with the growing focus on patient-centered

care and patient engagement to improve health care services and individual health outcomes, such as quality of life and mental health status [3,4]. However, this practice may pose challenges for health care professionals working with adolescents in mental health care, such as preventing potential harm arising from accessing mental health notes or limiting adolescents' confidentiality [5,6].

Although health care professionals' experience of sharing notes with adolescents in mental health care has not been studied, health care professionals in adult mental health care have expressed concerns about the sensitive nature of notes in mental health care and whether reading them can be harmful to the patient or damaging for the therapeutic relationship [7-9].

Moreover, it has been stated that different levels of autonomy and maturity among adolescents can pose challenges regarding the consequences of having access to notes about themselves [6,10]. Additionally, the possibility of parents or guardians accessing notes meant for the adolescent can compromise the confidentiality of what is discussed between the health care professional and the adolescent and impede the adolescent's autonomy [5,10,11]. These potential harms make it challenging for health care professionals to determine what type of information from the EHR should be shared and when [6,12].

Health care professionals have called for recommendations and support on how to handle challenges with sharing notes with adolescents in mental health care or their guardians [8,10]. The World Health Organization has proposed that recommendations should be based on formal consensus methods such as the Delphi method [13]. Over the last decade, such recommendations have been made in related areas, for example, by providing guidance on supporting self-management and the transition to adult health care for adolescents with chronic somatic diseases [14-16] and communicating with young people in mental health care about their online behavior [17]. Such recommendations for health care professionals typically include providing adolescents and young people with information about the specific topic or treatment program early on and relevant topics to cover when giving information [14-17]. While these recommendations are often either created based on or evaluated by members of medical societies and associations, the views of diverse staff members working in the specific field are not always included, potentially excluding some experiences [16,18]

To our knowledge, no recommendations are available to guide health care professionals' digital sharing of notes with adolescents in mental health care despite the specific challenges associated with this practice. Therefore, the aim was to reach a consensus among authors of scientific papers on recommendations for health care professionals' digital sharing of notes with adolescents in mental health care and to investigate

whether staff at child and adolescent specialist mental health care clinics agreed with the recommendations.

Methods

To address the aims, a Delphi study and a cross-sectional study were conducted. The CREDES (Guidance on Conducting and Reporting Delphi Studies) [19] and STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines for cross-sectional studies [20] were consulted during the planning and reporting of the study.

Delphi Study With Authors of Scientific Papers

The Delphi method [21] was used to reach a consensus on recommendations for the digital sharing of notes with adolescents in mental health care. The Delphi study involved creating suggestions for recommendations, receiving feedback on the recommendations from Delphi participants, and creating final recommendations based on consensus. A literature search was performed to develop suggestions for recommendations and to identify participants for the Delphi study.

Literature Search

The aim was to include scientific papers indexed in PubMed about the digital sharing of clinical notes with adolescents in general, somatic, and mental health care, and adults in mental health care. Moreover, relevant papers identified in the references of the papers from the PubMed search were invited to participate. The search for papers was performed in PubMed in April 2023 by searching the references of the papers meeting the eligibility criteria (Table 1).

The publication date range was selected because the field is rapidly evolving, and most research relevant to our aim has been conducted within the last couple of years. An initial review of older references showed that the digital solutions, particularly those from before 2016, differed from later publications (eg, by being prototypes made for the research project). Moreover, they were, to a greater extent, considering perceptions and expectations toward potential digital solutions. Peer review in international journals indexed in PubMed was used as a proxy for quality, and hence, authors of protocols, unpublished papers, and gray literature were excluded due to the challenge of evaluating their quality.

Table . Inclusion and exclusion criteria for identifying relevant publications.

Area	Inclusion criteria	Exclusion criteria
Criteria		
Population	<ul style="list-style-type: none"> • Adolescents (in general) • Adolescents in psychiatry/mental health care • Adolescents in somatic health care • Adults in psychiatry/mental health care 	All other study populations
Phenomenon of interest	<ul style="list-style-type: none"> • Electronic health record • Patient-accessible electronic health record • Access to clinical notes • Patient portal use 	All other phenomena
Information sources and methods		
Identifications of papers via database: database name, search string, and time period	<ul style="list-style-type: none"> • Relevant papers from PubMed search: “(((Adolescent[MeSH Terms]) OR (Mental Health[MeSH Terms])) OR (Psychiatr*[MeSH Terms])) AND (electronic health record*[MeSH Terms])” from 2021 to 2023 	Papers from the PubMed search published before 2021
Identification of papers via other methods: search method and time period	<ul style="list-style-type: none"> • Relevant references from the papers identified in the PubMed search 2016 - 2020 	Papers published before 2016
Limits and restrictions

Participants

All authors of the scientific papers identified in the literature search were invited to participate in the Delphi study if their email addresses could be identified through the publication, their institutions' web pages, or a Google search.

Together with the invitation to participate, the authors received a description of the task and the project's purpose. Additionally, they received information explaining how they had been selected, why their participation was requested, what participation involved, and details regarding the storage and use of their data.

Data Collection

The Delphi study started with screening the scientific papers included from the literature search to identify findings that could be turned into suggestions for recommendations ([Multimedia Appendix 1](#) [7-10,22-53]). This process is further reported in the Analysis and Results sections.

The authors who created the suggestions have experience from research on patient portals, adolescents, and mental health. Care was taken to ensure that the created suggestions were based on

the reviewed literature. Before sending out the suggested recommendations, they were discussed with a research group at a university that possesses expertise in research related to digital health, patient participation, and patient education. The suggestions for recommendations were sent to the Delphi participants between June and September 2023.

The Delphi participants' responses to the recommendations were collected in two rounds, referred to as round 1 and round 2. Due to the summer holiday, the Delphi participants were given 8 weeks to respond to round 1 and 6 weeks in round 2. Two reminders were sent 2 weeks apart for both rounds.

In both rounds, the Delphi participants received an email with a link to a web-based questionnaire with the suggested recommendations for the digital sharing of notes with adolescents in mental health care. Adolescence was defined as being legally old enough to access their notes digitally. The participants were asked to score their agreement with each recommendation on a Likert scale from 1 to 5 (“strongly agree,” “agree,” “don't know,” “disagree,” and “strongly disagree”). In round 1, the participants could also comment on each recommendation and give overall comments ([Multimedia Appendix 2](#)).

In round 2 of the Delphi study, participants who responded in round 1 were asked to score the recommendations supported in round 1 (in either their original or a modified form based on comments) and the recommendations generated based on comments in round 1. Moreover, the participants were informed about the proportion of participants who agreed with each of these recommendations in round 1, in accordance with recommendations for Delphi studies [19,54-56]. For both rounds, demographic data were collected on participants' gender, profession, age, and years of working experience.

Analysis

The process of making the recommendations involved three steps: identifying scientific papers, creating suggestions for recommendations, and receiving feedback from the Delphi participants. In the first step, the eligibility criteria were first used to screen the titles and the abstracts, and then the full paper of those not possible to classify based on the title or abstract. Finally, the references of the included papers were screened to identify additional relevant studies.

The second step involved creating suggestions for recommendations. The results of all scientific papers were first coded in NVivo 14 (Lumivero) by the first author, who identified codes related to experiences, effects, views, and expectations regarding access to EHRs. After this, the coded results were discussed with the other authors who read the coded results and some of the papers. The authors prepared the recommendations in an iterative process, where several discussions were held on how the coded results could be transformed into recommendations. The first author proposed suggestions, which were then discussed until there was agreement among all authors that the suggested recommendations accurately represented the coded results. Unambiguous results from the papers were used to suggest recommendations, while conflicting or hesitant results were used to propose mutually exclusive recommendations.

The third step involved receiving feedback on the recommendations from the Delphi participants, where the scoring and comments were considered. A predetermined criterion for agreement was set for both rounds; a consensus was reached if 70% of participants responded with "strongly agree" or "agree" with the recommendation [54,55]. The recommendations that did not achieve consensus were dropped unless comments suggested modifications. The authors reviewed all the free-text comments and incorporated suggestions from comments that proposed alternative formulations of recommendations or suggested new recommendations for the preparation of round 2. The authors considered the wording of the recommendations, achieving consensus and suggestions for new recommendations in several meetings and rounds of review before round 2 was sent out. Answers to round 2 from authors who were health care professionals and those who were not were compared in a subgroup analysis to determine potential differences in the proportions agreeing. The responses from round 2 were used to create the final list of recommendations.

Cross-Sectional Study With Staff

A cross-sectional study was used to investigate if staff at specialist child and adolescent mental health care clinics agreed with the recommendations for the digital sharing of notes with adolescents in mental health care. For this purpose, a survey with a web-based questionnaire was conducted in October 2023.

Participants

Participants in the cross-sectional study were staff working at child and adolescent specialist mental health care clinics geographically spread in Norway. Inclusion criteria were staff at child and adolescent specialist mental health care clinics who had contact with patients, including administrative staff. This choice was made because different types of staff can provide information about digital access to mental health notes at various times. Staff without patient contact, such as cleaning personnel, were excluded.

To recruit staff, four departments of child and adolescent mental health at university hospitals, geographically spread in Norway, were asked to distribute invitations to relevant clinics in their region. The total number of staff at their affiliated clinics was approximately 690. Eligible staff received information about the study and a link to the questionnaire.

Data Collection

The questionnaire sent to the staff at the specialist child and adolescent mental health care clinics included the recommendations that achieved consensus in the Delphi process translated to Norwegian. Moreover, questions about their gender, years of work experience in child and adolescent specialist mental health care, profession, and role at the clinic were asked. The staff were informed about the origin of the recommendations and instructed to think about adolescents as legally old enough to access their clinical notes digitally. For each recommendation, they were asked whether they "agreed" or "disagreed." The link for the questionnaire was open for 1 month.

Analysis

To investigate whether staff at child and adolescent specialist mental health care clinics agreed with the recommendations developed in the Delphi study, the frequencies of agreement and disagreement with each statement were calculated. Moreover, descriptive statistics were performed on the sociodemographic data to present the characteristics of the staff.

Ethical Considerations

This study was approved by the Norwegian Agency for Shared Services in Education and Research (717040), which ensures that the data processing is performed in accordance with national data protection legislation. All methods were carried out in accordance with the Declaration of Helsinki. Informed consent was obtained from all participants. None of the participants received any compensation for their participation.

Results

Results From the Delphi Study

From the 1199 papers identified in the PubMed search and their relevant references, 37 scientific papers published between 2016 and 2023 were identified (Figure 1). The majority of the papers were from the United States (n=21), while 10 were from Europe,

4 were from Canada, and 1 was from Australia. Most papers used a quantitative method (n=14); 11 were qualitative, 4 were systematic and scoping reviews, and 7 were other studies such as mixed methods studies and a Delphi study (Multimedia Appendix 1). The identified papers had a total of 121 authors, of which email addresses were identified for 84 authors (Figure 1).

Figure 1. Flowchart for identification of scientific papers and participants for the Delphi study.

Among the 84 invited Delphi participants (ie, the authors of the identified papers), 27 (32%) responded in round 1; of whom, 21 (78%) responded in round 2. Most participants were researchers, and approximately one-third were health care

professionals. Among the 7 health care professionals, 2 were exclusively health care professionals, while the remaining were also researchers. Most of the authors were female (Table 2).

Development and Adjustment of Recommendations

Initially, 43 suggestions for recommendations were formulated focusing on various aspects of the digital sharing of notes, including informing about digital access to notes, the forms of the notes that are being shared, training and support for professionals, and the possibility of withholding notes from the adolescents ([Multimedia Appendix 2](#)).

The responses from round 1 were analyzed for consensus (70% agreement), and the suggested recommendations that did not reach a consensus were dropped ([Figure 2](#)). Some recommendations were intentionally formulated to be mutually exclusive; thus, support for some was not anticipated. This included recommendations to abstain from any action, while others recommended specific actions. As a result, the Delphi participants were expected to support only one of these options.

Figure 2. Flow diagram illustrating the two rounds of the Delphi study.

The recommendations that did not reach a consensus in round 1 included mutually exclusive recommendations (n=9), at what age adolescents should receive digital access to their notes or be informed about their access (n=9), the timing of digitally sharing notes with parents or guardians (n=5), and some of the

points on how to inform the adolescent about their digital access to their notes (n=3). Three recommendations regarding withholding notes from adolescents did not reach a consensus in round 1, yet comments on these were used to formulate 3 new recommendations for round 2 (Table 3).

Table . Recommendations sent out in the final round (round 2), with the proportion of agreement for each recommendation in rounds 1 and 2.

Recommendations	Participants who agreed, n (%)	
	Round 1 (n=27)	Round 2 (n=21)
Information about digital access to mental health notes should be given:		
1a ...only if considered appropriate by the health care provider. ^a	19 (70)	5 (25)
1b ...between the first contact with the service and the first clinical consultation.	— ^b	17 (81)

^aStatement is reformulated or modified based on comments from round 1.

^bNew in round 2.

The Final List of Recommendations

A consensus was reached on recommendations concerning how to introduce digital access to notes, write notes, and support health care professionals, and when to withhold notes (Multimedia Appendix 3). Additionally, a consensus was reached on areas where professionals should receive support and training, and on three situations where it should be possible to withhold notes from adolescents. A subgroup analysis was also conducted comparing round 2 responses between participants who were also health care professionals and those who were not, but this did not reveal any noteworthy differences.

Results From the Cross-Sectional Study

The 17 recommendations that achieved a consensus in the Delphi study were sent to staff at 4 child and adolescent specialist mental health care clinics in Norway to assess whether they agreed with the recommendations.

A total of 41 staff members responded, 90% (n=37) of whom were female. In total, 80% (n=33) of the respondents currently worked as health care professionals, 10% (n=4) worked in management positions, and 10% (n=4) worked as administrative staff. The largest groups of health care professionals were psychologists (n=21, 51%), medical doctors (n=5, 12%), and clinical social workers (n=3, 7%). Most informants (n=29, 70%) had worked at a specialist mental health care clinic for at least 5 years.

At child and adolescent specialist mental health care clinics, 70% (n=29) or more of staff agreed on 14 recommendations, and 60% (n=25) or more agreed on all 17 (Multimedia Appendix 4). The recommendations that the fewest staff agreed on were recommendation 1b (that information about digital access to notes should be given between the first contact with the service and the first clinical consultation; n=24, 59% agreed), recommendation 1e (that it should be given if requested by the

adolescent; n=25, 61% agreed), and recommendation 3c (that notes should primarily be written to be useful for other health care professionals; n=27, 66% agreed).

Almost all staff agreed that training should be provided on how to write notes to be shared with the adolescent (n=40, 98%) and about the legal or formal regulations on digital access to notes for adolescents (n=40, 98%). Additionally, staff agreed it should be possible to withhold notes from the adolescent if it endangers their life or causes serious harm to the health of the adolescent or their next of kin (n=40, 98%).

Discussion

Principal Findings

A consensus was reached on 17 recommendations regarding central areas related to the digital sharing of notes with adolescents in mental health care who are legally old enough to access their notes digitally. The recommendations considered how to introduce digital access to notes, write notes, and support health care professionals, and when to withhold notes. At child and adolescent specialist mental health care clinics, 60% or more of the 41 staff members agreed with the 17 recommendations.

The findings of this study contribute to the knowledge about which recommendations related to the digital sharing of notes with adolescents are agreed on by both the authors of scientific papers and staff at child and adolescent specialist mental health care clinics. While similar recommendations for the digital sharing of notes with adolescents or with adults in mental health care have not been identified, the current recommendations resonate with the advice given to health care professionals regarding communicating with young people in mental health care about online behavior [17] and for adolescents' transition into adult care [14-16]. The similarities include initiating a

conversation about the specific topic during an initial meeting [17] or at an early stage [14-16]; encouraging adolescents to ask questions [15-17]; giving advice on relevant legal regulations [14]; and addressing confidentiality, parents' role, and privacy [15,16].

Most recommendations also aligned with results from prior studies on this subject identified in the literature search. For instance, several studies in adult mental health care have highlighted the significance of communicating with patients about their access to clinical notes [9,22], the importance of how clinical notes are written when they are shared [22-24,57], and consideration of situations where some information should not be shared with the patient [22]. In addition, the need to offer support and training for health care professionals in sharing notes with adolescents [12,25] and in mental health care [8,10,26,58] has been reported in previous studies. Although consistency with prior studies was anticipated since the recommendations were based on these studies, some of the recommendations also stemmed from areas characterized by contradictory research findings [8,10,26,58].

Areas where no consensus was reached may indicate opposing opinions in the field [8,10] and geographical differences in regulations and practices [1,27,28]. In this study, a consensus was not reached on when adolescents or parents should have access to notes. This is consistent with the findings of a scoping review about sharing EHR information with children, adolescents, and parents, which reported inconclusive results and complexity related to both manual adjustments for sharing and set age limits for automatic access [10]. Moreover, it aligns with the multifaceted experiences of health care professionals with experiences of sharing clinical notes with adolescents and parents [5,10,29,59-61]. Studies have reported that health care professionals appreciate how sharing clinical notes with adolescents and parents encouraged them to ask questions about what they read [59] and improved communication [10,60], but it also could pose a threat to the adolescents' autonomy and confidentiality [5,29]. Furthermore, health care professionals face ethical challenges in preventing adolescents from accessing information that their parents have shared and from reading confidential information about their adolescent [6,10,61]. Such individual aspects can challenge set age limits for access while at the same time making decisions for manual adjustments a complex and time-consuming process.

Both authors of scientific papers and staff from child and adolescent specialist mental health care clinics agreed that notes should be written in respectful language. However, they were less certain about who the main receiver of the notes should be, with three-quarters of the authors and two-thirds of the staff agreeing that notes should primarily be written to be useful for health care professionals. This is interesting considering the increased focus on writing in a language that patients can understand, with the aim of, for example, improving their understanding of and engagement with their health and treatment [30,62,63]. This may indicate that we are still in the early stages of implementing this practice, and there are some challenges associated with the multiple audiences of the notes.

A previous study reported that mental health care professionals working with adults experienced an overall improvement in the quality of their notes even though they adapted their note writing to make it more understandable to the patient [31]. However, mental health care professionals in another study were concerned about the consequences of omitting clinically relevant information that was considered inappropriate for the patient to read [7]. A study found that health care professionals in psychiatry were more likely to perform off-the-record journaling and underreporting than those in somatic health care when sharing clinical notes with adult patients [64]. Although these studies focused on mental health care professionals working with adults, their diverse results align with this study's finding that both the authors of scientific papers and the staff reported that health professionals should receive training on note writing.

Implications

The recommendations developed in this study need to be tested, and future research should be conducted to assess the consequences of following the recommendations. However, health care professionals currently do not have recommendations that can be used in clinical practice. The implementation should be accompanied by training and support.

Strengths and Limitations

To the best of our knowledge, this is the first study to create recommendations for the digital sharing of notes with adolescents in mental health care. A strength of the study was the systematic process of developing recommendations based on research in the field. Moreover, international authors in the field evaluated and agreed on these recommendations, including researchers and health care professionals. Additionally, the recommendations underwent external validation, as most recommendations were supported by staff working at child and adolescent specialist mental health care clinics.

One limitation of the study was that the response rate for the Delphi study was relatively low (32%). This means that it is unclear whether the participants in the Delphi study were a selected group or representative of the researchers in the field. A limitation might be that most of the invited participants were authors from studies in the United States and Europe. While this might reflect that the practice of digital access to notes is more developed and common in these regions, we might have missed experiences from other settings and cultures. Similarly, selection bias could be connected to staff recruitment at child and adolescent specialist mental health care clinics. The most likely consequence is that those with a special interest will reply. Still, it is not possible to know whether they have opinions regarding the recommendations that diverge from others.

Another possible limitation is the external validity of the recommendations since they were based on studies from the United States; fewer were from Europe, and no studies were from South America, Asia, or Africa. The results may not be generalizable to these areas.

Conclusions

A total of 17 recommendations related to key aspects of health care professionals' digital sharing of notes with adolescents in

mental health care achieved consensus. Health care professionals can use these recommendations to guide their practice of sharing notes with adolescents in mental health care. However, the effects and experiences of following these recommendations should be tested in clinical practice.

Acknowledgments

The authors thank the participants in the Delphi study and the staff from the specialist child and adolescent mental health care clinics for participating in this study. Moreover, we acknowledge the management of the four departments of child and adolescent mental health at university hospitals for distributing the questionnaires. This study was funded by the Faculty of Medicine and Health Sciences at the Norwegian University of Science and Technology.

Authors' Contributions

MSN, THN, and AS were responsible for designing and conceptualizing the study. MSN performed the literature search and data collection and drafted the manuscript. MSN, THN, and AS were involved in the formulation of the recommendations, the data analysis, and the writing of the manuscript. All the authors have read and approved the final manuscript.

Conflicts of Interest

Abstract

Background: While the number of digital therapeutics (DTx) has proliferated, there is little real-world research on the characteristics of providers recommending DTx, their recommendation behaviors, or the characteristics of patients receiving recommendations in the clinical setting.

Objective: The aim of this study was to characterize the clinical and demographic characteristics of patients receiving DTx recommendations and describe provider characteristics and behaviors regarding DTx.

Methods: This retrospective cohort study used electronic health record data from a large, integrated health care delivery system. Demographic and clinical characteristics of adult patients recommended versus not recommended DTx by a mental health provider between May 2020 and December 2021 were examined. A cross-sectional survey of mental health providers providing these recommendations was conducted in December 2022 to assess the characteristics of providers and recommendation behaviors related to DTx. Parametric and nonparametric tests were used to examine statistical significance between groups.

Results: Of 335,250 patients with a mental health appointment, 53,546 (16%) received a DTx recommendation. Patients recommended to DTx were younger, were of Asian or Hispanic race or ethnicity, were female, were without medical comorbidities, and had commercial insurance compared to those without a DTx recommendation ($P < .001$). More patients receiving a DTx recommendation had anxiety or adjustment disorder diagnoses, but less had depression, bipolar, or psychotic disorder diagnoses ($P < .001$) versus matched controls not recommended to DTx. Overall, depression and anxiety symptom scores were lower in patients recommended to DTx compared to matched controls not receiving a recommendation, although female patients had a higher proportion of severe depression and anxiety scores compared to male patients. Provider survey results indicated a higher proportion of nonprescribers recommended DTx to patients compared to prescribers ($P = .008$). Of all providers, 29.4% (45/153) reported using the suggested internal electronic health record–based tools (eg, smart text) to recommend DTx, and of providers recommending DTx resources to patients, 64.1% (98/153) reported they follow up with patients to inquire on DTx benefits. Only 38.4% (58/151) of respondents report recommending specific DTx modules, and of those, 58.6% (34/58) report following up on the impact of these specific modules.

Conclusions: DTx use in mental health was modest and varied by patient and provider characteristics. Providers do not appear to actively engage with these tools and integrate them into treatment plans. Providers, while expressing interest in potential benefits from DTx, may view DTx as a passive strategy to augment traditional treatment for select patients.

Introduction

The digital therapeutics (DTx) market has experienced rapid growth in recent years, with the global DTx market valued around US \$5.2 billion in 2022 and market research analysis

projecting double-digit compounded annual growth from 2023 through 2030 [1]. In the first half of 2021 alone, the DTx business sector raised US \$1.6 billion in venture capital [2]. Evidence suggests that DTx resources may be acceptable and scalable and therefore are a logical adjunct for mental health

treatment, particularly given the growing need for mental health care [3].

However, despite DTx proliferation and potential for application in the mental health care space, patient engagement has been minimal [4]. Reasons for this poor engagement may include a lack of personal support in DTx (ie, integration of the tool into treatment rather than passive deployment of digital resources), which has been shown as important for the acceptability and usability of mental health DTx [5]. Further, there is a notable evidence gap for DTx's mental health treatment effectiveness, with most evidence-based DTx having minimal market share [6], which may impact provider recommendations of DTx. Small, randomized controlled trials (RCTs) of DTx have shown small to moderate effect sizes for smartphone interventions in reducing depression and anxiety symptoms compared to controls [7,8]. A recent meta-analysis of 22 RCTs of mindfulness DTx showed small to moderate positive effects on depression and stress symptoms but not on anxiety [9]. An RCT of 88 college students using the Calm app (CALM.com, Inc) showed an improvement in perceived stress, mindfulness, and self-compassion in the users compared to controls [10]. Finally, an RCT of 146 employees with depressive symptoms using the myStrength app (Livongo Health, Inc) showed a more rapid reduction in depressive symptoms compared to controls [11]. The literature is not yet robust on which clinical populations are most appropriate for DTx, but those with mild to moderate symptoms of depression and anxiety, rather than severe, appear to benefit most [12,13]. DTx that are based on cognitive behavioral therapy may also be more effective, but much depends on the patient population as well as DTx design [13].

A mental health provider recommendation could be an influential factor for patient engagement with DTx tools. A 2016 survey of physicians found broad interest in DTx, but physicians also reported concerns over limited experience with such tools as well as lack of DTx data availability in the electronic medical record as barriers to DTx implementation [14]. Provider lack of knowledge regarding DTx, lack of investment and infrastructure, technical issues, workflow, and workload concerns have been identified as barriers to mobile health app adoption and implementation by providers [15-17]. In mental health, DTx tool adoption may vary by provider type and scope of practice, with psychiatrists reporting less bandwidth to focus on therapeutic DTx tools and therapists reporting that caseload, familiarity with DTx content and evidence, and limits on access to DTx data impact the ability to engage with patients around these tools [18]. Despite these descriptions of barriers to DTx tool adoption, there are little data on who providers recommend DTx tools to, the characteristics of providers recommending DTx tools, or their behaviors in recommending DTx tools. Understanding the characteristics of providers and their behaviors in recommending DTx tools can inform how these tools are integrated into mental health care, which is of particular importance given the increasing patient need for mental health resources and the dominant role mental health is assuming in the DTx space.

This study sought to characterize the clinical use of DTx resources within a large, integrated health care delivery system in two ways: (1) using electronic health record (EHR) data to

identify the clinical and demographic characteristics of patients receiving recommendations from mental health providers to use DTx tools and (2) using an anonymous provider survey to determine characteristics and DTx recommending behaviors of mental health providers in clinical practice. Findings can inform the integration of DTx into mental health clinical care.

Methods

Setting

Kaiser Permanente Northern California (KPNC) is a large, diverse, integrated health care delivery system with approximately 4.6 million members. The membership is largely representative of the region, with less representation at the extreme ends of the income distribution [19]. Mental health services are primarily provided internally, both individually and in group format. Services are also available by referral to external community providers as needed.

DTx Resources

KPNC offers multiple DTx tools to its members at no cost. During the study time frame, the portfolio included Calm, myStrength, Headspace (Headspace Health, Inc), SilverCloud (Amwell), Thrive (Waypoint), and Whil (RethinkFirst) [20]. Providers can recommend DTx tools to patients based on their clinical judgment using smart text elements in the EHR, which are inserted into electronic secure messages to the patients with an associated link to the DTx. This electronic secure message contact is documented in the after-visit summary if providers use these smart text elements.

Study Design and Data Sources

Overview

This study had 2 components. The first used a retrospective cohort design with KPNC EHR data to identify adult patients who were seen in the mental health department, diagnosed with a mental health disorder, and received a provider recommendation to a DTx, as well as a matched cohort of patients who were also seen in the mental health department with a diagnosed mental health disorder but did not receive a recommendation to a DTx. The second component consisted of an anonymous web-based survey of health system mental health providers. This study followed the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines for observational studies [21] and the CHERRIES (Checklist for Reporting Results of Internet E-Surveys) for web-based surveys (Checklists 1 and 2) [22].

EHR Cohort

Adult patients aged 18 years or older with a mental health department visit and mental health diagnosis between May 1, 2020, and December 31, 2021, were included (Multimedia Appendix 1). Qualifying mental health disorders based on the *International Classification of Diseases, 10th Revision (ICD-10)* diagnosis codes included generalized anxiety disorder, bipolar disorder, major depressive disorder, adjustment disorders, posttraumatic stress disorder, psychosis, and sleep disorders (Multimedia Appendix 2). The index date was the first mental health visit; subsequent visits were excluded. Patients were

excluded if they had less than 1-year health plan membership prior to their index mental health visit, in order to ensure the ability to capture baseline diagnoses assigned at patient encounters.

EHR Measures

The primary outcomes were the number and proportion of patients who received a DTx recommendation within 30 days of their index date. Within this time frame, we assumed that the primary diagnosis of their index mental health visit was the reason for a DTx recommendation. The recommendation was determined through text string searches ([Multimedia Appendix 3](#)) using relevant phrases within provider progress notes, smart data element capturing questionnaires, and secure messages from the patient's provider.

Additional EHR-based measures included patient demographic variables (sex, race, ethnicity, and age group), type of psychiatric provider seen (nurse, therapist, and physician), neighborhood deprivation index (as a proxy measure for socioeconomic status, categorized into quintiles), insurance type (commercial, Medicare, or Medicaid), Charlson Comorbidity Index [23], and KPNC medical service area. The Patient Health Questionnaire 9-Item (PHQ-9) [24] and Generalized Anxiety Disorder 7-Item (GAD-7) [25] questionnaires, which identify symptoms for depression and anxiety, respectively, were extracted from the EHR if available within 30 days of the index visit. Each item in the PHQ-9 is scored 0 to 3, providing a 0 to 27 severity total score. The total score is used to determine cut points for depression: 0 - 4 is normal, 5 - 9 is mild, 10 - 14 is moderate, 15 - 19 is moderate severe, and 20 or more is severe. The GAD-7 is a 7-item generalized anxiety disorder scale. Each item is scored 0 to 3, providing a 0 to 21 severity total score. The total score is used to determine cut points for generalized anxiety disorder: 0 - 4 is normal, 5 - 9 is mild, 10 - 14 is moderate, and 15 or more is severe.

Provider Survey

We conducted an anonymous web-based survey of a convenience sample of mental health providers throughout the KPNC region to understand the characteristics of providers recommending DTx tools and their recommendation behaviors. This survey was distributed 3 times in December 2022 to department managers and chiefs of psychiatry via an email that contained a Microsoft Forms link and a request to distribute it to clinical staff of approximately 2130 therapists and 375 psychiatrists. Participation was voluntary.

The survey included 26 multiple-choice questions and a free-text comment section ([Multimedia Appendix 4](#)). Specifically, we collected data on providers' attitudes toward DTx adoption, DTx utility and effectiveness, preference for the type of DTx, awareness of different DTx modules, patient criteria for DTx recommendation, patterns of recommendation to DTx (self-assessment regarding manner of recommendation and monthly volume), barriers to recommendation, and demographics (professional role, practice experience, service area, work hours, sex [female or male self-identified hereafter referred to as "female" or "male"], age, race or ethnicity, and

work hours). The primary outcome was the percentage of KPNC providers who reported recommending DTx.

Ethical Considerations

This study received approval from the KPNC Institutional Review Board (1899252) and was determined exempt, with a waiver of consent for the EHR-based analyses and a waiver of written consent for the anonymized provider survey, which did not gather protected health information. No compensation was provided to the providers per health system policy.

Statistical Analysis

EHR-Based Characteristics of Patients Receiving Versus Not Receiving DTx Recommendations

Demographic variables, clinical characteristics, and depression and anxiety symptom burden scores (PHQ-9 and GAD-7) were compared between patients who were and were not recommended to DTx with a series of bivariate analyses. Among those who received a DTx recommendation, we also examined the relationships of mental health symptoms by sex. To examine depression and anxiety diagnoses and symptom burden associated with DTx recommendations while accounting for potential confounding factors, we performed a frequency match to create a 1:1 matched cohort of patients without a recommendation to those recommended to DTx. Patients were matched based on a 5-year age group, sex, and geographical service area within KPNC. We then conducted bivariate analyses comparing the PHQ-9 and GAD-7 using the cases and matched patients.

Provider Survey

We performed descriptive statistics (eg, frequencies and bivariate tests) to characterize provider characteristics and DTx recommendations based on multiple-choice responses. Comparisons were done based on whether respondents were "prescribers" (eg, psychiatrists and nurse practitioners and able to prescribe medications to patients) or "nonprescribers" (eg, therapists such as psychologists and marriage and family therapists) to examine potential differences by provider role.

For both the EHR-based provider recommendation and survey analyses, the Pearson or Mantel-Haenszel chi-square test or Fisher exact test was used to calculate *P* values for categorical variables, the 2-tailed *t* test was used to calculate *P* values for continuous variables when the assumptions for a parametric test assumption were met, and the Mann-Whitney *U* test was applied to calculate ordinal data when the assumptions for a nonparametric test assumption was met. All item responses were used. All analyses were performed using SAS (version 9.4) for Windows and SAS Studio (version 3.81; SAS Institute Inc).

Results

Characteristics of Patients Recommended Versus Not Recommended DTx

Of the 335,250 adults eligible during the study time period, 16% (53,546/335,250) were recommended a DTx by a provider ([Table 1](#)). Patients recommended versus not recommended to

a DTx were more likely to be younger (age 18 - 44 years: 37,744/53,546, 70.5% vs 164,456/281,704, 58.4%; $P<.001$), Asian or Hispanic (20,360/53,546, 38% vs 88,827/281,704, 31.6%; $P<.001$), and female (38,338/53,546, 71.6% vs 193,063/281,704, 68.5%; $P<.001$). Additionally, there was a higher proportion of patients in the lowest ("0") category of the Charlson Comorbidity Index (40,261/53,546, 75.2% vs 188,414/281,704, 66.9%; $P<.001$) and a higher proportion of commercially insured patients (44,960/53,363, 84.3% vs 205,425/280,546, 73.2%; $P<.001$) among those who received recommendations versus those without a recommendation. Most DTx recommendations originated from therapy providers (48,916/53,546, 91.4%).

Matched Analyses—Mental Health Diagnoses and Symptoms of Patients Recommended Versus Not Recommended DTx

Given the significant demographic differences between patients recommended a DTx versus those not recommended, we performed a matched analysis to compare mental health diagnoses and symptoms between these 2 groups. Patients recommended to DTx versus not recommended had higher proportions of anxiety (22,247/53,545, 41.5% vs 19,039/53,545, 35.6%) and adjustment disorders (11,024/53,545, 20.6% vs 7592/53,545, 14.2%) and lower proportions of depression (13,151/53,545, 24.6% vs 16,517/53,545, 30.8%), bipolar (588/53,545, 1.1% vs 2685/53,545, 5%), or psychotic diagnoses

(173/53,545, 0.3% vs 1239/53,545, 2.3%; all $P < .001$; [Table 2](#)). Additionally, more patients recommended to DTx had PHQ-9 depressive symptom scores in the mild (5-9: 10,643/37,282, 28.5% vs 6926/25,749, 26.9%), moderate (10-14: 10,597/37,282, 28.4% vs 7104/25,749, 27.6%), and moderate severe (15-19: 7513/37,282, 20.2% vs 5115/25,749, 19.9%) ranges compared to patients not recommended to DTx ($P < .001$ for all). The distribution of GAD-7 anxiety scores was similar between patients recommended and not recommended to DTx, albeit with the distribution of recommended patients having a slightly higher proportion of mild (5-9: 4852/23,251, 20.9% vs 2579/13,080, 19.7%) and lower proportion of severe (≥ 15 : 9283/23,251, 39.9% vs 5391/13,080, 41.2%) GAD-7 scores ($P = .003$ for all).

^aProvider referred members to DTx within 1 month of index mental health visit.

^bDTx includes Calm, myStrength, Headspace, SilverCloud, Thrive, or Whil.

^cNeighborhood Deprivation Index reports quintile cut points for our specific study population.

^dSection does sum to a cohort of recommended patients because of missing item data.

^ePatient Health Questionnaire 9-Item depression scale. Each item is scored 0 to 3, providing a 0 to 27 severity total score. Using the total score to represent the cut point for depression, 0 - 4 is normal, 5 - 9 is mild, 10 - 14 is moderate, 15 - 19 is moderate severe, and 20 or more is severe.

^fGeneralized Anxiety Disorder 7-Item scale. Each item is scored 0 to 3, providing a 0 to 21 severity total score. Using the total score to represent the cut point for generalized anxiety disorder, 0 - 4 is normal, 5 - 9 is mild, 10 - 14 is moderate, and 15 or more is severe.

Mental Health Symptom Burden by Sex in DTx-Recommended Patients

Since approximately two-thirds of patients recommended to DTx were female, we conducted ad hoc analyses examining symptom burden stratified by sex among those who received a recommendation to DTx. Female patients recommended to DTx had higher proportions of PHQ-9 depressive symptom scores in the moderate (7575/26,416, 28.7% vs 3022/10,867, 27.8%), moderate severe (5414/26,416, 20.5% vs 2099/10,867, 19.3%), and severe (3246/26,416, 12.3% vs 1220/10,867, 11.2%) range

compared to male patients; and male patients had higher proportions of PHQ-9 scores in the normal (2804/26,416, 10.6% vs 1260/10,867, 11.6%) and mild (7377/26,416, 27.9% vs 3266/10,867, 30.1%) ranges ($P=.003$; Table 3). Female patients recommended to DTx had higher proportions of GAD-7 scores in the severe (6839/16,526, 41.4% vs 2444/6725, 36.3%) range compared to male patients; and male patients had more representation in the normal (516/16,526, 3.1% vs 341/6725, 5.1%) and mild (3296/16,526, 19.9% vs 1556/6725, 23.1%) ranges for GAD-7 ($P<.001$).

Table . Mental health symptoms by sex among patients recommended digital therapeutics (DTx)^{a,b}.

Characteristic	Overall cohort (N=53,546), n (%)	Female patients (n=38,337), n (%)	Male patients (n=15,208), n (%)	P value
Mental health symptom PHQ-9 ^{c, d}				.003
Normal	4064 (10.90)	2804 (10.6)	1260 (11.6)	
Mild	10,643 (28.55)	7377 (27.9)	3266 (30.1)	
Moderate	10,597 (28.42)	7575 (28.7)	3022 (27.8)	
Moderate severe	7513 (20.15)	5414 (20.5)	2099 (19.3)	
Severe	4466 (11.98)	3246 (12.3)	1220 (11.2)	
Mental health symptom GAD-7 ^{d, e}				<.001
Normal	857 (3.69)	516 (3.1)	341 (5.1)	
Mild	4852 (20.87)	3296 (19.9)	1556 (23.1)	
Moderate	8259 (35.52)	5875 (35.6)	2384 (35.4)	
Severe	9283 (39.93)	6839 (41.4)	2444 (36.3)	

^aMember recommended DTx within 1 month of index mental health visit.

^bDTx includes Calm, myStrength, Headspace, SilverCloud, Thrive, or Whil.

^cPatient Health Questionnaire 9-Item depression scale. Each item is scored 0 to 3, providing a 0 to 27 severity total score. Using the total score to represent the cut point for depression, 0 - 4 is normal, 5 - 9 is mild, 10 - 14 is moderate, 15 - 19 is moderate severe, and 20 or more is severe.

^dColumns do not sum to the respective cohort because of missing data.

^eGeneralized Anxiety Disorder 7-Item scale. Each item is scored 0 to 3, providing a 0 to 21 severity total score. Using the total score to represent the cut point for generalized anxiety disorder, 0 - 4 is normal, 5 - 9 is mild, 10 - 14 is moderate, and 15 or more is severe.

Characteristics of Providers Recommending DTx

A total of 211 individuals responded to the provider survey on DTx prescribing patterns for a participation rate of 8.4% (211/2505). Of those, 19.6% (40/204) identified as prescribers, 68.6% (140/204) as nonprescribers, and the remainder as having an administrative or managerial role in the clinic. Of respondents, 91.9% (192/209) were between the ages of 30 and 59 years, 54.1% (113/209) identified as White, 17.2% (36/209) as Asian, 12% (25/209) as Hispanic or Latino, and 6.2% (13/209) as Black. Nearly all respondents reported working at least half-time, and two-thirds of respondents reported working a full-time schedule.

Provider DTx Recommendation Behaviors

Overall, a higher proportion of nonprescribers (127/164, 77.4%) indicated they recommend DTx to patients compared to prescribers (22/39, 56.4%; $P=.008$). Of providers who recommend DTx, 83.6% (122/146) do so via an electronic secure message to patients, and only 12.3% (18/146) do so during a clinic appointment. Calm was the most commonly recommended DTx, followed by myStrength, Headspace, SilverCloud, Thrive, and Whil. Only 29.4% (45/153) of providers indicated using the suggested internal EHR-based smart text to recommend DTx. Prescribers were more likely than nonprescribers to report that they did not know how to make patient recommendations using EHR-based protocols ($P=.01$). Of providers recommending DTx to patients, 64.1% (98/153) report that they follow up with patients to inquire whether the resource was helpful. Only 38.4% (58/151) of providers recommend specific modules of DTx resources, and of those 58.6% (34/58) report following up with patients on these specific recommendations.

On a scale of 0 - 10 regarding the perceived effectiveness of DTx resources to impact symptoms (0=none and 10=extreme), both prescribers and nonprescribers rated cognitive behavioral therapy and mindfulness content between 6 and 7 or moderate to highly effective.

Discussion

Principal Findings

These are some of the first pragmatic results regarding provider recommendation patterns, characteristics, and attitudes toward mental health DTx. In this large, integrated health system with mental health DTx tools included as a benefit, a very modest percentage of patients with mental health disorders received recommendations to DTx tools. Those who did were more likely to be young, female, Asian or Hispanic, with less medical comorbidity, and to have commercial insurance compared to patients not recommended to DTx. Recommendations for DTx were more often made for anxiety or adjustment diagnoses and for patients with less severe mental health symptoms, although female patients recommended to DTx tools had a higher proportion of anxiety symptoms compared to male patients. A provider survey showed that DTx are recommended more frequently by nonprescribers and via electronic secure messages rather than during clinical appointments. Of providers recommending DTx, a modest majority follow up with the patient regarding DTx effectiveness, and few knew how to follow the recommended EHR protocols to do so.

Previous studies reporting demographic characteristics of patients using DTx have been from pilot trials or RCTs [7-9]. Using real-world data collected in the course of clinical care,

we found that patient characteristics were similar to those of DTx trials. Overall, patients who received DTx recommendations were younger with less severe mental health symptoms, suggesting that providers are likely tailoring their recommendations to those they feel are most suitable. This may also reflect the initial emphasis of the health system DTx implementation focusing on patients with mild to moderate symptoms of depression or anxiety [20]. These results highlight a gap in the evidence base regarding the effectiveness of DTx for patients with mild to severe mental health symptoms or multiple comorbidities.

Asian or Hispanic patients were more likely to receive DTx recommendations. There are many potential drivers of this finding, including provider beliefs about patient DTx uptake, patient ability to interface with DTx, if providers felt the symptom severity reported by these patients was more appropriate for DTx, or other unrecognized factors. This finding merits further investigation. Of note, the significant association for insurance type with a DTx recommendation suggests slightly more patients with commercial insurance receiving recommendations. This may reflect provider-perceived barriers to care (eg, differences in disease severity or mobile phone access) for patients with other types of insurance coverage.

The finding that a higher proportion of female patients with severe mental health symptoms were referred to DTx compared to male patients could reflect a bias to implement more tools to treat symptoms in female patients, a reporting bias of symptoms by male or female patients, refusal of the DTx recommendation by male patients, or other sex-associated biases in care [26]. These findings warrant further research.

Provider survey results indicate that a higher proportion of nonprescribers recommend DTx and reported familiarity with EHR-based protocols to recommend DTx compared to prescribers. These results could reflect uneven training by provider type during the initial rollout or a lack of awareness or interest in the DTx tools by prescribers. Nonprescribers may appreciate having another treatment option to recommend beyond their typical strategies, given the therapeutic role DTx can fill and the silos of mental health care (ie, “therapy” vs “medication management” tasks). Interestingly, a minority of providers reported using the EHR-based protocols to recommend DTx to patients, with very few recommending specific modules or follow-up on module recommendations. Providers may view DTx tools as a passive, adjunctive resource rather than part of an active mental health treatment plan. Further, only a modest

majority of providers reported asking patients if they found the DTx effective. A similar follow-up rate for a recommended or prescribed medical device, medication, or therapeutic program such as intensive outpatient or partial hospitalization would likely be regarded as very low. It is unclear why providers perceive DTx offerings in this way; it is possible that providers do not see DTx as having robust effectiveness data, which may impact their rate of follow-up. Similarly, providers may not view DTx resources as part of clinical care or within their scope of practice to monitor. This may reflect the early stage of growth and implementation of DTx in mental health and may evolve over time. If DTx are to be integrated into clinical mental health care, it may be more effective as a formalized part of the treatment plan and followed in the same way as other treatment aspects.

Limitations

This study was conducted in an integrated health care system, which limits generalizability to providers and patients in different systems of care. The survey participation rate was low, given constraints related to direct dissemination and reapproaching for response, though consistent with reported response rates in similar investigations [15]. While our integrated health system made multiple DTx available at no cost to patients during the study time period, such resources may not be as easily available to patients in other health care systems. Recommendations that were in person only or sent in messages without using the EHR protocols and smart text were not captured, nor were recommendations related to later visits, although our intent was to identify options presented earlier in the treatment course. The large sample size of EHR-based recommendation data makes it likely to detect associations that may have statistical significance but may not have meaningful clinical implications. The data we explored are observational and exploratory; future work warrants further examination into these initial findings along with an examination of patient-level outcomes associated with DTx.

Conclusions

The use of DTx is growing at a rapid pace, and health systems and patients see these as potentially valuable resources. However, the extent of provider recommendations to DTx is modest, as is provider knowledge about DTx and their follow-up with patients about DTx use, which suggests a largely passive DTx uptake by providers. Given the likely continued interest by patients, health care systems, and industry, future research on how to effectively implement these tools is critical.

Acknowledgments

This project was supported by The Permanente Medical Group Delivery Science and Applied Research initiative. The sponsors were not involved in the study design; collection, analysis, or interpretation of the data; writing of the manuscript; or decision to submit the paper for publication. The authors also gratefully acknowledge their survey respondents. The authors thank Doug Corley, MD, for his early consultation on study design. No generative artificial intelligence was used in the development of this study or writing of the manuscript.

Data Availability

The data sets used and analyzed during this study are not publicly available due to reasons of sensitivity but are available from the corresponding author on reasonable request and with appropriate data sharing agreements and institutional review board approval.

Authors' Contributions

SJR was responsible for funding acquisition and conceptualization. SJR, CIC, and TYL were responsible for developing the study design. SJR developed and fielded the survey. SJR, CIC, and TYL developed the statistical analysis plan. TYL prepared the data sets and conducted the statistical analyses. SJR wrote the initial draft of the paper. All authors participated in the review and revision process and approved the submission.

Conflicts of Interest

CIC has received support managed through their institution from the Industry PMR Consortium, a consortium of companies working together to conduct postmarketing studies required by the Food and Drug Administration that assess risks related to opioid analgesic use. The remaining authors declare no conflicts of interest.

Abstract

Background: Workplace mental health is an important global health concern.

Objectives: This unblinded, phase-III, wait-listed cluster randomized controlled trial aimed to examine the effectiveness of a mobile health (mHealth) psychoeducation program using a spaced education approach on mental health literacy (MHL) in the workplace. The main interest of this paper was the immediate and 3-month medium-term effect of the program on the MHL of workers. The purposely built mHealth platform was also evaluated as a health-related app.

Methods: The mHealth platform was designed using the principle of spaced education as a psychoeducation intervention program, with various modules of web-based and mobile materials presented to the participant in a progressive manner. Short quizzes at the end of each module ensured adequate learning, and successful completion qualified the learner to progress to the next level. The trial recruited 456 employees of specific industries with high levels of work-related stress. Participants who were nested in different offices or units were allocated into the intervention and wait-listed control groups using a block randomization process, with the office or unit as the cluster. A separate sample of 70 individual raters were used for the evaluation of the mHealth platform. The Australian National MHL and Stigma Survey and the Mobile Apps Rating Scale were completed through a web-based self-reported survey to assess MHL and evaluate the app. The trial and follow-up data were analyzed by a generalized linear latent and mixed model with adjustments for the clustering effect of work sites and repeated measures.

Results: Of the 456 participants in the trial, 236 (51.8%) responded to the follow-up survey. Most MHL outcomes obtained significant results immediately after the intervention and across time. After adjusting for the clustering effect, the postintervention weighted mean scores were significantly higher in the intervention group than the control group for correct recognition of a mental health problem, help seeking, and stigmatization by 0.2 (SE 0.1; $P=.003$), 0.9 (SE 0.2; $P<.001$), and 1.8 (SE 0.4; $P<.001$), respectively. After adjusting for the clustering effect, significant differences across time were found in help-seeking intention ($P=.01$), stigmatization ($P<.001$), and social distancing ($P<.001$). The evaluation of the mHealth program resulted in average scores of the 4 major domains ranging from 3.8 to 4.2, with engagement having the lowest score.

Conclusions: The mHealth psychoeducation intervention program using this platform had immediate and 3-month medium-term effects of retaining and improving MHL. The platform was evaluated to have satisfactory performance in terms of functionality, aesthetics, information content, and utility in enhancing MHL. It is anticipated that ongoing development in digital health will provide great benefits in improving the mental health of the global population.

Introduction

Mental ill health has long been recognized as an important global health problem [1]. The workplace has also been identified as an important venue for preventing mental health problems and for promoting mental wellness [2,3]. Preventive programs designed as a workplace strategy could provide benefits to workers in terms of early identification and intervention of mental health problems, as well as promoting mental well-being [4]. One specific approach is to enhance workers' mental health literacy (MHL). MHL was defined as "knowledge and beliefs about mental disorders which aid their recognition, management or prevention" by Jorm [5]. In this construct, there are different aspects, including the ability to recognize specific disorders, knowledge about mental health, attitudes toward help seeking and stigmatization, and social distancing from people with mental health problems.

In response to the urgent need for a well-designed workplace mental health intervention program in Hong Kong, a group of researchers developed the mobile health (mHealth) web-based and mobile Workplace Mental Health Literacy (WPMHL) project with funding support from the Hong Kong government [6]. The program consists of 2 main components: psychoeducation modules for the enhancement of workers' MHL and a work environment scan addressing more structural issues in the workplace [6].

The psychoeducation modules of the program incorporated elements of mental health first aid in the design but focused on the workplace environment, addressing common workplace mental health issues such as work-related stress and burnout [6]. The underpinning educational paradigm or approach of the proposed psychoeducation intervention program is called the spaced learning or spaced education approach. Based on the initial neuropsychological concept proposed by the internationally acclaimed neuroscientist Fields [7] and modified and advocated by Kelly [8], the spaced learning approach is a learning methodology for creating long-term memories. This concept is operationalized by presenting highly condensed learning materials repeatedly, based on a predesigned temporal pattern and a number of presentations, to allow the individual to encode the material into one's memory system. The repetition of the process will reinforce the encoding mechanism and, in turn, commit the materials into long-term memory [8]. Applying this empirically validated approach to education and training, the learning materials could be presented repeatedly in a temporally sequential manner to allow the learner to generate long-term memory. In the design of the psychoeducation component of the intervention program, the principle of spaced education was applied, with various modules of web-based and mobile materials presented to the participant in a progressive manner and some simple exercises presented at the end of each module. Successful completion of 1 module gained access to the next progressively until all modules were completed. Within each module, essential materials were presented repeatedly in a short duration with a temporal pattern of 3 times in a row for the participant to create a long-term memory. The spaced

learning or spaced education approach has been used in different fields of training and education, such as continuous medical education [9,10]. Different versions of the main interface, as a website for PCs and as a downloadable mobile app for tablets and smartphones, are presented in Figure 1.

mHealth is defined by the World Health Organization (WHO) as technology "used for medical and public health practice supported by mobile devices, such as mobile phones, patient monitoring devices, Personal Digital Assistants (PDAs), and other wireless devices" [11]. With the rapid development of mobile technologies and further advancement in telecommunication platforms in recent years, mHealth has been adopted as one of the widely used approaches in preventive medicine across different diseases [12-16]. For example, mHealth was used for the promotion of a healthy lifestyle in the prevention of cardiovascular diseases and diabetes [13,16], sexually transmittable infections [9], and cancer [8]. In the prevention of mental health problems, the mHealth approach was also adopted for alcohol and other substance abuse, suicide prevention, and other problems [17-20].

In terms of the effectiveness of the mHealth approach on mental health problems, review studies found some evidence for a positive effect on the reduction of risk factors, such as a reduction in depressive symptoms and stress and an increase in coping, but not on the actual behavior [17,18]. This might be due to the small number of studies included in the reviews since mHealth is still a relatively novel approach. There is also a concern that a number of the studies under review had methodological issues or a lack of proper evaluation that might have contributed to the nonsignificant results obtained [21]. As such, it was recommended that more methodologically robust research should be implemented to further ascertain the efficacy of intervention programs using the mHealth approach [21].

To evaluate the efficacy of the mHealth web-based and mobile WPMHL intervention program, a wait-listed cluster randomized controlled trial (CRCT) was conducted, with MHL as the primary outcome and work-related stress and burnout as the secondary outcomes. The immediate effect of the intervention program was described in a previous report, suggesting a significant result on stress and burnout in favor of the intervention [22]. In terms of MHL, the intervention group scored significantly higher than the control group in the correct recognition of mental problems, help seeking, and stigmatization by 0.2 (SE 0.1; $P=.003$), 0.9 (SE 0.2; $P<.001$), and 1.8 (SE 0.4; $P<.001$), respectively [22]. These results provided evidence for the immediate effect of the psychoeducation component of the program in improving the mental health of the participants [22].

In this study, we aim to focus on both the immediate and 3-month medium-term effects of the intervention program on the MHL of workers. We also aim to report the results obtained for the evaluation of the mHealth psychoeducation platform, particularly engagement, functionality, aesthetics, and the information provided. It is anticipated that the psychoeducation modules will be efficacious in improving MHL immediately and that the effect will remain in the medium term.

Methods

Study Design and Target Population

As aforementioned, the protocol for this phase-III, wait-listed CRCT targeting the workplace was reported previously [6]. In brief, 6 large corporations were invited to participate in the trial, and employees were recruited through their corresponding human resources departments. Voluntary participation of recruits was ensured without any influence from the companies' management. The recruited sample consisted of a wide range of work natures, ranging from manual labor to senior executives, since the business of these corporations covered a multitude of work types. The trial was conducted between March and

December 2021 with a 3-month follow-up phase in both intervention and control arms ([Checklist 1](#)).

Recruitment of Participants and Randomization

The primary unit of randomization was the different offices or units of the participating corporations, and recruited workers were clustered in each office or unit. Potential participants were screened for their eligibility at the point of recruitment. Workers who had been exposed to any similar psychoeducation training were excluded from the trial. To randomly allocate the offices and units, the human resources departments of these corporations provided a list of participating offices and units with some basic staffing information, such as the number of staff in the offices and units and their positions. A qualified statistician, who was

blinded to the process of recruitment and the subsequent operation and data collection, conducted the randomization using a block randomization process. Each cluster with participants nested in different offices or units was then allocated to either the intervention or wait-listed control groups. Once the cluster had been randomized, participants completed the baseline data collection using the built-in feature of the web-based platform. Postintervention data collection took place immediately after the completion of the psychoeducation modules and at the 3-month follow-up.

Intervention and the Platform

Details of the intervention program were described in the *Introduction* section. Regarding the mHealth platform, as aforementioned, it was specifically designed for this project by a software company. It was developed to be adaptable for multiple interfaces with web (PC) and app (tablet and smartphone) versions with identical content and functionalities. For the study, participants were provided with a unique log-in to a central server for accessing the platform upon random allocation. Participants who were allocated to the wait-listed control group could activate their log-in when the group changed from the control phase to the intervention phase. Participants could access the web-based platform directly through the server, or they could download the mobile app from the server to be used on their tablets or smartphones for both Android and iOS.

Study Outcome and Outcome Measures

For the outcome measures of this study, namely MHL and the evaluation of the mHealth platform, 2 instruments were used. For MHL, the Australian National MHL and Stigma Survey was used [23]. The instrument has been validated and widely used in many studies in different countries [24]. In this study, the full survey was not used, given that it is a lengthy instrument and comprises many different submodules, with each module adopting a validated scale that can be used separately. After considering the specific local context, some components of the instrument were selected. These included the correct identification of mental health problems, help seeking for a mental health problem, stigmatization, and social distancing. The responses of these scales were set in a positive direction such that a higher score represented a higher level of the construct. Therefore, a lower score on the stigmatization and social distancing scales reflected a lower level in both constructs. In terms of the evaluation of the mHealth platform, the Mobile App Rating Scale (MARS) was used to assess the quality of different aspects of the platform, including engagement, functionality, aesthetics, and the information provided [25]. The MARS is an instrument designed to assess the quality of mHealth apps developed for addressing health problems or improving health status [25]. As such, it includes an app-specific domain for assessing specific health literacy. It has been validated with a good internal consistency with a Cronbach α value of .90 and a moderately high interrater reliability with an intraclass correlation coefficient of 0.79 [25]. It has also been widely used for evaluating mHealth apps worldwide and translated into different languages [26,27]. Both the MARS and MHL assessments were self-reported, and data were collected through a web-based self-reported survey at different time

points. Participants' information was also collected. This included demographics; employment status; and health behaviors, such as drinking, smoking, and physical activity.

Procedures

As per the protocol of a wait-listed CRCT, participants in the control arm were offered the same intervention upon the completion of the intervention program by the intervention arm. Hence, all participants received the same intervention treatment eventually. As a result, data collection on MHL was planned to be conducted at 3 different time points: at baseline, immediately after the completion of the program, and 3 months after the completion of the program. Participants were invited to respond to the data collection survey 3 months after the completion of the intervention program with multiple waves of invitations through emails. For the evaluation of the app, a small group of raters was recruited from a different population of workers who were not involved in the trial. They were invited to use the app and then evaluate it using the web-based questionnaire that included the MARS. Training was provided to these raters prior to their exposure to the platform. The raters were invited to rate the platform from a user's perspective in order to mimic the user's experience.

Sample Size and Data Analysis

Based on the assumed effect size of an approximate 0.5 SD difference in the MHL scores between the intervention and control arms, 80% power of the study, a type I error rate of 5%, and an interclass correlation of 0.01, it was estimated that about 400 workers were required. It was also assumed that 10% of participants would drop out of the project. Data were analyzed using the statistical software program Stata BE18.0 (StataCorp LLC). Data obtained from the MARS were analyzed descriptively, with means and SDs or SEs calculated. As suggested by the authors of the scale, the rating was designed as a 5-point Likert scale with 1=inadequate, 2=poor, 3=acceptable, 4=good, and 5=excellent [25]. The mean score of each aspect of the platform was interpreted following the suggested levels of quality and specific health literacy. For MHL, the analysis focused on the efficacy of the intervention program and the changes in outcome measures across time. For investigating the efficacy of the intervention program, comparisons of the mean scores of the outcome measures between the intervention and control groups after the intervention program, adjusting for the clustering effect, and the baseline assessment of the outcome measures were conducted. Given that participants were nested in different clusters and the outcome variables were measured repeatedly, these factors were taken into consideration for the analyses. As a result, a generalized linear latent and mixed model was applied to test the time effect while adjusting for the clustering effect. To handle any loss to follow-up, the main analyses were conducted according to the intention-to-treat principle, and missing data in any variables were imputed using the multiple imputation approach with an assumption of missing at random for all missing values. Since all respondents should have received the intervention at follow-up, including those in the control group, the focus of the comparison was mainly on the change of MHL scores across time with adjustment for the

clustering effect. A type I error rate of 5% was adopted for the testing of hypotheses.

Ethical Considerations

Participation in the trial was voluntary, and no compensation was provided. Potential participants were provided with information on the trial before participation through the corporations' human resource departments. Willing participants were enrolled in the trial through direct, personal contact with the research team. Informed consent was implied when the participant logged in to the web-based platform. All participants were free to opt out at any time. Confidentiality and privacy were ensured with minimal personal information collected for enrollment purposes, and this information was stored separately on a password-protected database from the trial data. All data collected from the trial were deidentified and stored on a double-layered, password-protected database. The study obtained human ethics approval from the Human Research Ethics Committee of the Tung Wah College (approval REC2018020). Trial registration was also completed with the Australian New Zealand Clinical Trials Registry (ANZCTR; registration ACTRN12619000464167).

Results

Primary Outcome of MHL

The results obtained from the wait-listed CRCT, including the demographic and other health-related information of the full sample, had been reported previously [22]. Interested readers should refer to the results in the published paper. In brief, the

mean age of the 456 participants was 40.7 (SD 9.8) years, with 215 (47.2%) being male and the majority (n=363, 79.6%) having attained an education level of university or above. Slightly more than half (n=271, 59.4%) were married, and nearly all (n=454, 99.6%) worked full-time. In terms of their health, the majority (n=344, 76.6%) did not exercise regularly; however, very few were reported to be regular smokers (n=17, 3.6%) and drinkers (n=8, 1.8%). A total of 229 (50.2%) participants were randomized to receive the intervention program first, and the rest (n=227, 49.8%) were wait-listed controls providing data for the analyses for the immediate effect. As reported previously, comparisons of the demographics and health-related variables at baseline between groups found no significant differences at all (all $P > .05$). The results obtained on the immediate effect of the psychoeducation program on MHL are summarized in [Table 1](#). As shown, significant differences between groups were observed in all domains except social distancing. After adjusting for the clustering effect and the potential confounding factors, the postintervention weighted mean scores were significantly higher in the intervention group than the control group for correct recognition of a mental health problem, help seeking, and stigmatization by 0.2 (SE 0.1; $P = .003$), 0.9 (SE 0.2; $P < .001$), and 1.8 (SE 0.4; $P < .001$), respectively.

Of the 456 participants, 236 (51.8%) responded to the follow-up survey after multiple waves of invitations and reminders. Comparisons of the demographic variables between respondents and nonrespondents of the follow-up survey indicated no significant differences in basic demographics (all $P < .05$). The demographics and health-related variables of the respondents are summarized in [Table 2](#).

Table . Different aspects of mental health literacy (MHL) assessed immediately after the intervention by groups and the results on comparisons between groups (N=456).

MHL domains	Intervention (n=229), mean (SE)	Control (n=227), mean (SE)	P value ^a
Correct recognition	3.4 (0.1)	3.2 (0.1)	.003
Help seeking	12.9 (0.3)	11.9 (0.2)	<.001
Stigmatization	26.3 (0.5)	24.5 (0.6)	<.001
Social distancing	11.9 (0.5)	12.3 (0.6)	.16

^aAdjusted for the clustering effect, age, education level, and baseline assessment of the outcome measure.

Table . Demographics and health-related variables of respondents who responded at baseline, postintervention, and 3-month follow-up (n=236).

Characteristics	Value ^a
Demographics	
Age (years), mean (SD)	42.8 (9.7)
Male sex, n (%)	107 (45.3)
Education level (university or above), n (%)	184 (78)
Marital status (married), n (%)	155 (65.7)
Full-time employment (yes), n (%)	236 (100)
Health-related variables, n (%)	
Regular exercise (yes)	168 (71.2)
Smoker (yes)	6 (2.5)
Drinker (moderate or heavy)	4 (1.7)

^aAdjusted for the clustering effect.

The results of the changes in the MHL outcome measures and the comparisons are presented in Table 3. As shown, of the 4 main MHL outcomes, all but 1 yielded a significant time effect. After adjusting for the clustering effect, significant differences across time were found in help-seeking intention ($P=.01$),

stigmatization ($P<.001$), and social distancing ($P<.001$). As suggested from the mean values, on the whole, there was an increase in help-seeking intention scores and a reduction in stigmatization and social distancing scores over time.

Table . Different aspects of mental health literacy (MHL) at baseline, postintervention, and 3-month follow-up and the results on the time effect (n=236).

MHL domains	Baseline, mean (SD)	Postintervention, mean (SD)	3-month follow-up, mean (SD)	P value
Correct recognition	3.2 (0.6)	3.4 (0.7)	3.3 (0.7)	.20
Help seeking	12.4 (1.9)	12.7 (2.3)	12.7 (2.1)	.01
Stigmatization	24.7 (3.6)	25.8 (4.1)	25.8 (3.9)	<.001
Social distancing	12.5 (3.2)	12.1 (3.3)	11.9 (3.5)	<.001

Evaluation of the mHealth Platform

For the evaluation of the mHealth Platform, a total of 70 individuals were recruited. Of these, there were 26 (37%) male individuals with an average age of 34.2 (SD 1.6) years. None of these participants had been exposed to any similar psychoeducation materials or mHealth platforms prior to the

evaluation exercise. The results of the evaluation are summarized in Table 4. As shown, the average scores of the 4 major domains ranged from 3.8 to 4.2, with engagement having the lowest score. For the perceived impact on MHL, all items were scored higher than 4.0, suggesting a greater tendency of respondents to endorse the positive impact of the content on their MHL.

Table . Different domains of the Mobile Application Rating Scale (MARS) and the perceived impact on mental health literacy (n=70).

Variable	Value, mean (SD)
MARS domains	
Engagement	3.8 (0.6)
Functionality	4.2 (0.5)
Aesthetics	4.0 (0.5)
Information	4.2 (0.5)
Overall	4.0 (0.4)
Perceived impact on mental health literacy	
Awareness	4.4 (0.6)
Knowledge	4.4 (0.5)
Attitude	4.4 (0.6)
Intention to change	4.3 (0.6)
Help seeking	4.4 (0.6)
Behavior change	4.3 (0.6)

Discussions

Principal Findings

This study was a continuation of a wait-listed CRCT of the effect of a psychoeducation intervention program using an mHealth spaced education approach on workplace MHL. The main results of the immediate efficacy of the intervention program had been reported previously [22]. This study aimed to further report the results obtained on the evaluation of the mHealth platform and the medium-term effect of the intervention program on the MHL of participants. Based on the MARS scores of different aspects of the platform, the results have demonstrated that the mobile platform is well acceptable, with an overall score of 4.0 (SD 0.4) and individual domain scores ranging between 3.8 and 4.2. This represents a generally good reception of the platform by the respondents in terms of the functionality, aesthetics, and the information provided. The result for the engagement domain was slightly below the level of good, in accordance with the classification of the original author of the MARS [25]. These results are compatible with the results obtained from a study rating 50 mental health and well-being mobile apps using the MARS by the original authors [25]. The average domain scores of these 50 apps ranged between 2.7 to 4.0 [25]. In comparison, the mHealth platform has shown better performance than these reported results.

The immediate effect of the psychoeducation intervention program on MHL was interpreted and discussed previously [22]. The significant and positive results indicated the efficacy of the intervention program in improving workers' MHL. There were significant improvements in 3 of the 4 main domains of MHL, including correct recognition, help seeking, and stigmatization, after the intervention. In terms of the medium-term sustainability of these gained benefits, the results obtained from the follow-up phase of the study provided some evidence. As shown, these effects were sustained 3 months after the intervention, with further improvement in social distancing, as reflected in the average scores. These results suggest the

retention of the gained benefits in the enhancement of MHL in these participants. These results are consistent with those in the literature. A recent systematic review and meta-analytical study on the long-term effects of interventions for MHL in children and adolescents reported similar results [28]. In pooling data from 25 studies with an average follow-up period of 5 months, it was found that the improvement in MHL was sustained, particularly for stigmatization ($d=0.30$, 95% CI 0.24-0.36) and social distancing ($d=0.16$, 95% CI 0.03-0.29) [28]. When combining the results obtained from the evaluation exercise using the MARS, the results provide stronger evidence that the mHealth psychoeducation intervention program is effective in improving and retaining the gain in the MHL of workers in the workplace.

The *Mental Health Action Plan 2013-2020* produced by the WHO has affirmed the importance of the workplace as a venue for mental health education and advancement [2]. The results reported previously by the authors, in conjunction with those obtained from this study, provide further evidence that a well-developed and executed psychoeducation intervention program in the workplace can not only reduce burnout and stress but also enhance MHL. Moreover, the effect of MHL enhancement can be sustained and, to a certain extent, further improved over time. The results of this study have also demonstrated that a well-designed and engaging mHealth platform with good functionality and aesthetics would also be a vehicle for enhancing MHL. As aforementioned, the mHealth approach for disease treatment, management, and health promotion has been used in many different health areas [11,12]. However, it is still considered a rather recent area of development according to some scholars in the field [15]. It is anticipated that the COVID-19 pandemic could be a catalyst in stimulating and motivating health professionals to develop and adopt digital health more readily and rapidly [29]. With the latest development in the field of data science and artificial intelligence, it is also expected that greater health advancements could be achieved through personalized information provision for education and promotion [30].

The strengths and limitations of the wait-listed CRCT were discussed in the previous report and will not be reiterated [22]. In this study, the focuses were the evaluation of the mHealth platform and the medium-term effect of the intervention program. One of the strengths of the study is the use of standardized and validated assessment instruments for outcome variables. The MARS and MHL measures are widely used instruments with ample evidence for their reliability and validity. As a result, the measurement and interpretation biases can be minimized. Another strength of the study is the samples recruited for the evaluation study and the CRCT. The random sample of the CRCT consisted of employees of different large-sized industries, thus covering a wide range of work nature and seniority. Hence, it could be considered a representative sample. For the evaluation study, the sample also consisted of participants from different companies and working backgrounds, thus preserving some degree of representation of the target working population. A few limitations have been identified in this study. The design of the mHealth platform for the psychoeducation intervention program is based on the spaced education concept. However, in the evaluation of the platform, the use of the MARS could only focus on the design aspects of the app but not the effect of the approach on participants' learning. As a result, the effect of the spaced education approach

adopted in this platform could not be evaluated. Another drawback of the study on the medium-term effect of the program is the low follow-up rate, with slightly more than half (236/456, 51.8%) of the original trial sample fully completing all assessments. This may incur a response bias in the follow-up study, although it has been demonstrated that there are no significant differences in the demographic variables between the follow-up and non-follow-up groups. To evaluate the learning effect of the spaced education approach, it is suggested that a randomized controlled trial with the use of an appropriate assessment instrument should be conducted. For minimizing the loss to follow-up, as suggested by some trialists, more frequent contact and better communication could help in retaining trial participants [31].

Conclusion

In conclusion, the web-based and mobile spaced education psychoeducation intervention program (WPMHL) has immediate and 3-month medium-term effects of retaining and improving MHL. The platform performed satisfactorily in terms of functionality, aesthetics, information content, and utility in enhancing MHL. It is anticipated that ongoing development in digital health will provide great benefits in improving the mental health of the global population.

Acknowledgments

The authors would like to acknowledge the Health and Medical Research Fund, the Food and Health Bureau, the Government of the Hong Kong Special Administrative Region for providing financial support for the study (grant #02181028). We would also like to acknowledge the kind assistance provided by colleagues, particularly Mr. Vincent Wong, of the Mental Health Association Hong Kong and Macau (MAHHKM), in providing administrative support.

Authors' Contributions

LTL and MKPL designed the study, and LTL obtained the funding. LTL also designed the statistical analysis plan and will direct the data analyses. LTL masterminded the design of the psychoeducation intervention program. The data collection questionnaire was developed by LTL and MKPL, with the mental health literacy scale translated and validated by LTL with the permission of the original author. All authors read and approved the final manuscript. The allocation of authorship is in accordance with the requirements of the International Committee of Medical Journal Editors (ICMJE).

Conflicts of Interest

None declared.

Abstract

Background: Youth, aged 15 to 24 years, are more likely to experience mental health (MH) or substance use issues than other age groups. This is a critical period for intervention because MH disorders, if left unattended, may become chronic and serious and negatively affect many aspects of a young person's life. Even among those who are treated, poor outcomes will still occur for a percentage of youth. Electronic MH (eMH) tools have been implemented in traditional MH settings to reach youth requiring assistance with MH and substance use issues. However, the utility of eMH tools in school settings has yet to be investigated.

Objective: The objective of this study was to gain an understanding of the perspectives of key school staff stakeholders regarding barriers and facilitators to the implementation of the Innowell eMH platform in secondary schools across the province of Alberta, Canada.

Methods: Guided by a qualitative descriptive approach, focus groups were conducted to elicit stakeholder perspectives on the perceived implementation challenges and opportunities of embedding the Innowell eMH platform in secondary school MH services. In total, 8 focus groups were conducted with 52 key school staff stakeholders.

Results: Themes related to barriers and facilitators to youth and school MH care professional (MHCP) capacity in implementing and using eMH tools were identified. With respect to youth capacity barriers, the following themes were inductively generated: (1) concerns about some students not being suitable for eMH services, (2) minors requiring consent from parents or caregivers to use eMH services as well as confidentiality and privacy concerns, and (3) limited access to technology and internet service among youth. A second theme related to school MHCP barriers to implementation, which included (1) feeling stretched with high caseloads and change fatigue, (2) concerns with risk and liability, and (3) unmasking MH issues in the face of limited

resources. In contrast to the barriers to youth and MHCP capacity, many facilitators to implementation were discussed. Youth capacity facilitators included (1) the potential for youth to be empowered using eMH tools, (2) the platform fostering therapeutic relationships with school personnel, and (3) enhancing access to needed services and resources. MHCP capacity facilitators to implementation were (1) system transformation through flexibility and problem-solving, (2) opportunities for collaboration with youth and MHCPs and across different systems, and (3) an opportunity for the continuity of services.

Conclusions: Our findings highlight nuanced school MHCP perspectives that demonstrate critical youth and MHCP capacity concerns, with consideration for organizational factors that may impede or enhance the implementation processes for embedding eMH in a school context. The barriers and facilitators to implementation provide future researchers and decision makers with challenges and opportunities that could be addressed in the preimplementation phase.

Introduction

Background

Globally, mental health (MH) issues are on the rise among young people, particularly since the onset of the COVID-19 pandemic [1,2]. A recent meta-analysis showed that of all people with MH disorders, 62.5% had onset before the age of 25 years [3]. Furthermore, 1 in 10 youths is estimated to experience an MH disorder in their lifetime, including depression, anxiety, and eating disorders [4]. Approximately 1 in 3 youths is estimated to experience an MH disorder in their lifetime [5]. Since the onset of the COVID-19 pandemic, the rates of depression and anxiety are estimated to have doubled among youth compared with the pre-pandemic period [6]. A recent systematic review found evidence of decreases in access to preventive MH supports coupled with increases in attempted suicide, self-harm, and suicidal ideation among adolescents during the COVID-19 pandemic [2]. The increase is linked to a disruption to daily routines and family connections [4], a reduction in the availability of social support [1], and a lack of necessary coping skills to navigate challenges and stressors experienced by youth [4]. Furthermore, public health restrictions and the increasing rates of social isolation have resulted in higher rates of internet and gaming problems among youth [7,8].

Despite the concerns about the rise in MH problems among youth, many barriers to help-seeking behaviors have been noted, including stigma [9], low MH literacy, and a reluctance to seek MH services [10]. There are many systemic barriers that further interfere with youth accessing needed services when they seek support, including long waitlists and limited availability of evidence-based treatments that are youth friendly and developmentally appropriate [11]. In a recent systematic review, long wait times for MH services were linked to a deterioration in MH outcomes [12]. As a result of the pandemic, web-based care options, including the application of electronic MH (eMH) tools, were widely and rapidly implemented, demonstrating their utility in reaching youth affected by MH and substance misuse and their ability to transcend geographic distance during public health restrictions [13].

The global spike in poor youth MH calls for early detection and intervention of MH disorders using traditional and nontraditional

MH services, including eMH services [9,14]. eMH is defined as the “provision of guided mental health care where consumers navigate a rapid and more effective system experience of service entry, skilled assessment, and multidisciplinary and coordinated care, as well as ongoing outcome-based monitoring” [15]. A proliferation of eMH services has been observed using smartphone apps and electronic tools (e-tools) [16,17]. eMH services may supplement various aspects of MH service delivery, including disseminating resources and information, performing ongoing assessments, tracking changes to symptoms and behaviors, delivering psychosocial therapies, and providing peer support [16]. Randomized controlled trials have consistently demonstrated a reduction in some MH symptoms, including mild to moderate depression and anxiety [18-20]. These randomized controlled trials have especially focused on delivering treatment via smartphone interventions (those that provided in-app feedback, and those used to enhance or support face-to-face interventions) [18]. However, research on the implementation of eMH tools outside of routine clinical settings is lacking.

Research suggests the importance of the school setting as a place of first contact for youth who seek MH support [21-23], positioning teachers as the first point of contact to see MH “red flags” [24]. The use of eMH technology provides an opportunity to transform services, including improving the early detection of MH issues, better care coordination and care plans, and referrals to necessary services for youth [25]. However, there is limited research on the implementation and use of eMH tools in school systems.

Existing studies have highlighted general barriers and facilitators to the implementation of digital MH tools among both youth and MH care professionals (MHCPs). Stigma remains a daunting barrier to using eMH services, deterring individuals from seeking help owing to societal and internal biases [26,27]. The quality of the therapeutic relationship, fostered by well-designed interfaces and personalized content, serves as a facilitator, particularly in remote settings [26,27]. Systemic influences (eg, access and infrastructure) can both hinder and facilitate engagement [26]. In addition, one’s level of MH literacy significantly impacts one’s decision to engage, with greater literacy leading to the increased acceptance and use of eMH resources [26]. In summary, these intertwined factors create a

complex landscape for eMH and digital MH interventions. The available literature exploring the barriers and facilitators to implementing eMH interventions in the school setting is notably scarce, underscoring the need for a deeper exploration of this important topic. To our knowledge, this study is the first to explore the barriers and facilitators to implementing eMH interventions in the school setting.

The Innowell eMH platform is a configurable web-based tool that seeks to provide a more personalized approach using measurement-based care to complement existing MH services [25]. The platform empowers youth and young adults to actively participate in their care plan by using measurement-based MH care, including a comprehensive questionnaire consisting of psychometric tools exploring 20 biopsychosocial domains (eg, depression, anxiety, and social connectedness). Examples of health priorities and health cards on the platform’s dashboard are provided in Figure 1 [28] and Figure 2 [29]. After

completing baseline measures, platform users are immediately provided access to vetted web-based resources, including apps, e-tools, and crisis line options to use between sessions, and cues to discuss care options with their MHCPs. The platform can assist “with the assessment, feedback, management, and monitoring of their mental ill health and maintenance of well-being by collecting personal and health information from a young person, their clinician(s), and supportive others” [25]. The platform was designed using participatory design in Australia. The participatory design processes included participants with lived experience, health professionals, and service staff from diverse service populations to optimize the usability of the platform design [25,30]. It is important to note that the “platform does not provide stand-alone medical or health advice, risk assessment, clinical diagnosis, or treatment. Instead, it guides and supports (but does not direct) young people and their providers to decide what may be suitable care options” [25].

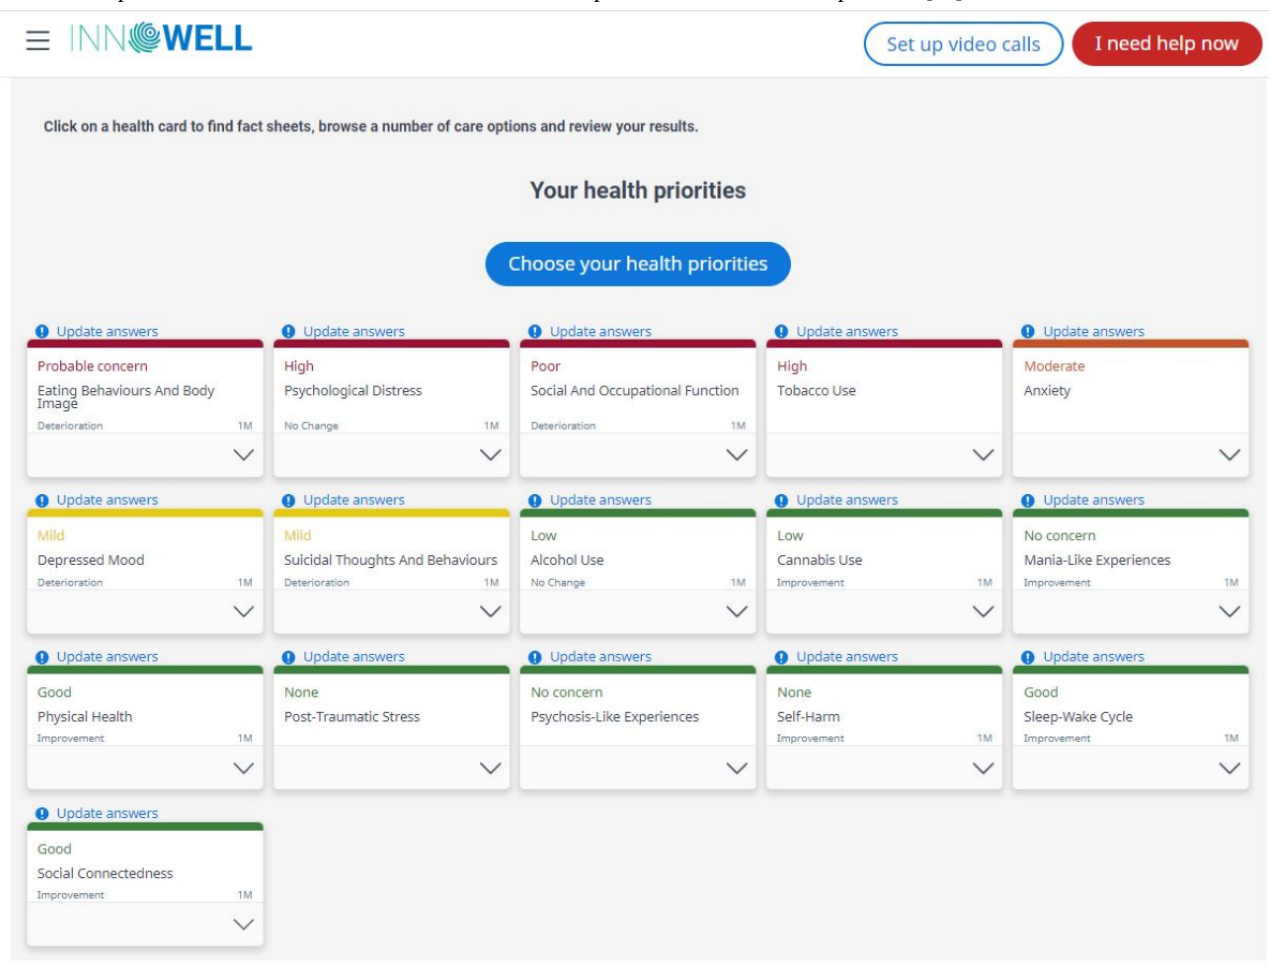

Figure 2. Participant and clinician electronic mental health Innowell platform dashboard health cards [29].

Objectives

Hence, it is critical to evaluate the implementation of an eMH tool such as the Innowell eMH platform in secondary schools to assess its acceptability, usability, and efficacy in school contexts. Furthermore, there is a need to examine how eMH tools can be customized for school-based organizations where youth often spend most of their time interacting with educators, guidance counselors, and school MHCPs. This study seeks to elicit the perspectives of key stakeholders within the school divisions regarding their perceptions of barriers and facilitators to the potential implementation of an eMH platform in schools across the province of Alberta, Canada.

Methods

This study used a qualitative thematic analysis of school stakeholder focus groups (FGs) to better understand their perceived barriers and facilitators to the implementation of an eMH platform for youth and young adults in Alberta.

Ethical Considerations

This research study received human participant research ethics approval from the University of Calgary Research Ethics Board (project name “Pre-Implementation and Implementation Phase of E-Mental Health for Youth and Young Adults in Alberta”; REB20-1137). Informed consent was completed on the web before the commencement of the FGs. The study participants’ data were deidentified to ensure privacy and confidentiality. Participants were not compensated for their participation.

Qualitative Descriptive Methodology

A qualitative descriptive methodology was used to describe barriers and facilitators to the implementation of the Innowell eMH platform through the exploration of participants’ perceptions and experiences [31]. This methodology is well suited to health research and is descriptive in nature [31,32], capturing events or conditions from the perspective of individuals and in their everyday language [33]. We sought to obtain a rich description of key stakeholder perspectives rather than researcher-provided interpretations of their preconceived views about the value of an eMH platform. We used an FG approach to obtain data from a group of key stakeholders in schools who may hold diverse concerns about the utility of the platform. In contrast to individual interviews, FGs offer participants the opportunity to share a range of thoughts and to iteratively build on ideas and considerations for integrating an eMH platform in school settings across different geographic regions and diverse student populations [34]. The sample consisted of 52 school district key stakeholders representing 8 communities across Alberta. The web-based FGs were conducted from February 1, 2021 to May 31, 2022.

A semistructured interview guide was created with input from the research and implementation teams on the project. The questions included a focus on thoughts and feelings about the platform and the implementation processes. The interview guide was structured into 3 separate but related sections and was constructed to suit the study objectives, research questions, and the theoretical domains framework (TDF). The TDF is an integrative framework that includes 14 theoretical domains derived from 33 validated health and social psychology theories

and 128 constructs that have the potential to drive and explain health-related behavior change [35]. The 14 theoretical domains are knowledge; skills; social or professional role and identity; beliefs about capabilities; optimism; beliefs about consequences; reinforcement; intentions; goals; memory, attention, and decision processes; environmental context and resources; social influences; emotions; and behavioral regulation [36]. The interview guide was designed to explore which TDF domains were relevant for the implementation of the Innowell eMH platform.

FGs were conducted to evaluate the barriers and facilitators that may affect the implementation of the Innowell eMH platform in existing school services. The interview guide covered unique factors about the service setting and organization, unique community contexts that can influence implementation, questions about the unique youth population that the school serves, and the barriers and facilitators that might influence implementation.

The study setting for recruitment included kindergarten to grade 12 schools situated in rural and urban communities across Alberta. This study used a targeted email and web-based meeting recruitment, whereby practice leads from the implementation team working with each community shared recruitment materials with senior decision makers and clinical supervisors at schools taking part in the eMH study. Key stakeholders in this area were recruited, including teachers, administrators, psychologists, school counselors, community connectors, and social workers. The site clinical lead for each community identified potential participants who would be involved in using the platform from a range of different roles, including managers, leaders, and frontline clinicians. Three members of the research team moderated all FGs.

There were 3 inclusion criteria for participants of this study. Each participant had to be employed in the school district as an MHCP, decision maker, educator, or administrator; be proficient in written and spoken English; and use web-based technologies on a laptop computer, desktop computer, tablet, or smartphone.

The FGs were conducted by the research team and included an implementation practice lead, 2 facilitators, and a notetaker who was often a youth research partner. The FGs lasted approximately 90 minutes. Of the 52 participants, 3 (6%) to 10 (19%) participated in each FG. All interviews were audio recorded and transcribed verbatim by a professional transcriber. The transcribed interviews were checked for accuracy by a member of the research team.

A total of 8 FGs were conducted with the 52 key stakeholders from 11 school divisions. The FGs collectively contained representation from 21 schools, including high schools (grades 10-12; $n=10$, 48%), an elementary school (kindergarten to grade 6; $n=1$, 5%), combined elementary to high school (kindergarten to grade 12; $n=3$, 14%), combined junior high to high school (grades 7-12; $n=3$, 14%), as well as outreach and web-based schools ($n=4$, 19%). Participants included teachers, administrators, psychologists, school counselors, community connectors, and social workers. Community connectors in the school division are members of the community who support and inform individuals about how to access support groups,

services, and information that might help improve their MH and well-being [37]. Sample size was justified at 52 key stakeholders when the research team determined that the sample provided “information power,” a concept used in qualitative methodology to denote that the sample held substantial information [38]. There was representation from public, Catholic, Francophone, and web-based and alternative outreach schools for students (also referred to as clients by some of the participants) who benefit from nontraditional learning methods. The FGs were composed of diverse school district MHCPs, from managers and administrators to teachers.

Analytic Plan: Thematic Analysis

Using a combined inductive-deductive approach, the research team used the 6 stages of thematic analysis outlined by Braun and Clarke [39]. Thematic analysis is a method of identifying and reporting on themes that emerge through the data [39]. The six-stage analytical process consists of (1) familiarization with the data, (2) coding, (3) generating themes, (4) reviewing themes, (5) defining and naming themes, and (6) producing the report [39].

As part of the project’s youth engagement strategy, a team of coders, including youth and young adults with varying research experience, reviewed the transcribed FGs independently to increase familiarization with the data. After familiarization, the coders conducted a preliminary descriptive coding of their assigned transcripts. The research team generated these codes independently using Microsoft Word and Taguette qualitative coding software. The coders then exchanged FG transcripts and conducted secondary coding. Each transcript was coded by a minimum of 2 coders, which ensured reliability because the codes depended on 2 different individuals achieving and deciding on the same code outcome [40]. The research team then worked collaboratively to group the codes into broader themes through discussion and consensus. Finally, illustrative quotes for each theme were identified. The core research team met regularly to share their impressions of patterns across and within the FG transcripts.

The team closely followed guidelines for publishing qualitative data [41]; for instance, the research team recorded decisions about the coding and the decision-making processes for establishing the themes. The coders worked independently to analyze the data and met regularly to discuss the codes established and assigned. Through consensus, the coding group members formulated their themes based on patterns across the FGs with different school settings. As a form of member checking, our team presented our findings to the broader research team consisting of researchers from different academic institutions to ensure that the data resonated with their experiences and understanding of the academic literature. The practice of reflexivity was used through memoing and group discussions, where members of the research team reflected on their biases and their positionality and questioned their own assumptions throughout the direction of the research process. The practice of keeping written memos was used to record the process and document the rationale for how the data were coded [42].

Results

Participant Demographics

Most of the participants (38/52, 73%) identified as women. Many of the participants were counselors or therapists (12/52,

23%) or social workers (11/52, 21%). Of the 52 participants, 19 (37%) were aged between 40 and 49 years, and 32 (62%) had been practicing their profession for ≥ 11 years. The majority of the participants were born in Canada (45/52, 87%) and held a graduate degree (22/52, 42%). A complete list of descriptive information about the participants is presented in [Table 1](#).

Barriers and Facilitators

In each of the following subsections, we highlight youth and MHCP capacity barriers and facilitators to the implementation of eMH tools in school settings. Youth capacity to engage in eMH services refers to their ability to effectively use digital tools and platforms, such as eMH, for addressing MH concerns. This involves not only their technical skills but also their understanding of the potential benefits and limitations of eMH services. Clinician capacity to engage in eMH services refers to their proficiency in using digital tools and platforms, such as MH assessment tools, to provide MH services to their patients. This also encompasses their ability to navigate the technical aspects of an eMH platform as well as their competence in delivering quality MH care while adhering to the regulations of their profession's governing body as well as their health care organization's ethics and regulatory guidelines in the eMH realm.

First, youth capacity barriers were identified, which included the suitability of measurement-based care for all youth with different types of MH disorders that may impact their engagement in eMH services; the role of caregivers, confidentiality, and perceived consent concerns among youth; and inadequate device and internet access. We then established a second theme relating to MHCP capacity barriers to implementation, which included MHCPs feeling stretched with high caseloads and change fatigue, concerns about liability and risk considerations, and the potential to unmask MH issues in the face of service and resource constraints.

By contrast, the final 2 themes consisted of many facilitators to implementation. The third theme—youth capacity facilitators—included the potential for an active and empowered role in care, the potential to foster and enhance therapeutic relationships, and the importance of improving access to services and resources. The fourth theme covered MHCP capacity facilitators to implementation, including the unique flexibility and natural problem-solving skills of school staff that can

contribute to system transformation, the potential for collaboration with MHCPs across the continuum and with different systems, and an opportunity to strengthen the continuity of services. Collectively, these themes highlight the potential of the school setting to create opportunities for system transformation through the implementation of eMH tools.

Barriers to the Implementation of eMH Tools in School Settings

Youth Capacity Barriers

Individual Characteristics and Implications for the Engagement of Measurement-Based Care

Participants identified numerous factors as potential barriers to youth using the measurement-based care protocol integrated within the Innowell eMH platform. Given the large and diverse youth population served by secondary schools in Alberta, participants expressed concern that some youth with certain types of MH issues and sociodemographic characteristics may be unable to use the Innowell eMH platform. Participants perceived that measurement-based care may not be suitable for youth with the following conditions: severe MH diagnoses (eg, moderate to severe depression or anorexia nervosa), disability diagnoses (eg, attention-deficit/hyperactivity disorder), low cognitive capacities, those experiencing suicidal and self-harm behaviors, and low literacy levels and new or migrating Canadians not fluent in English. Participants were concerned that measurement-based care, which includes the 20-domain assessment features on the Innowell eMH platform, might be lengthy, difficult to understand, and overwhelming:

I do wonder about say students just with their literacy levels, like their comprehension. And especially those who maybe present a specific neurotypical, they present that way but actually maybe their comprehension is really, really weak. And so, onboarding and then going through the diagnostic

tools and the self-assessment tools. Like I do wonder about the implications of that. [FG21-P02]

This quote demonstrates many participants' reflections about the implications of onboarding youth who may be unable to easily navigate certain aspects of the platform on their own.

Participants also described a concern that the extensive measurement-based care assessment protocol on the Innowell eMH platform might exacerbate symptoms for some of the youth experiencing complex MH issues:

I do worry that part of this platform, although [it] gives them the tools and the apps and all of those things, and reminds them to speak to the therapist or go see their person. We're also asking a lot of kids who are struggling...Right? So, they're not feeling very mentally well and then we're asking them to do other things to take care of their own wellness. And I worry—are they capable of that? I guess we'll see. [FG17-P03]

This quote demonstrates a perception that some youth may find it difficult to navigate the Innowell eMH platform when they are struggling with MH issues and wellness.

Role of Caregivers, Confidentiality, and Caregiver Consent

Other potential barriers identified by participants are problems that may arise in obtaining consent from caregivers and protecting the confidentiality of youth who will access the platform but do not wish to disclose their MH concerns to family members:

And if a lot of the issues surrounds the parent relationship, then that becomes a problem and that has definitely been the past barrier to them getting services sometimes is they don't want their parents having to sign consents. [FG22-P03]

Although not a pervasive issue, participants raised concerns about some youth living in unsafe family environments where it would not be acceptable to disclose an MH issue owing to stigma and fear of reprisals from family members. These factors were described as significant barriers if consent is required from caregivers for the access and use of the Innowell eMH platform. In the absence of clear confidentiality assurances, it may prevent young people from engaging in the apps and e-tools available through the platform and in MH services more broadly.

Information-sharing requirements within the school district with caregivers was also described as a potential barrier to implementation. Participants were concerned about who *owns* the assessment information completed by youth and having to navigate information-sharing requests or requirements from caregivers or other MHCPs:

I think it would need to be very clear what, if any, of the information would be getting shared with their parents, like abundantly clear. I get questions on this all the time when I meet the kids for the first time is, "What exactly is confidentiality?" And many, many questions surrounding that. [FG10-P03]

This participant builds on this concern, stating that many young people come to their first session reluctantly, which could spread

to minimal uptake of the Innowell eMH platform if information-sharing protocols about consent and parental involvement are unclear. Participants shared that being unclear about confidentiality with young people would be a barrier not only to using the platform but also to young people accessing MH services and resources more generally.

Limited Access to Technology and Internet Service Among Youth

A significant barrier described in the school context is a lack of access to technology for youth to use the Innowell eMH platform. With the shift to web-based school and MH services during the COVID-19 pandemic, many MHCPs learned of the access-related challenges with remote and web-based schooling for some youth, especially those residing in remote or rural geographic regions. Participants learned that many youth lack access to technology or devices that would be necessary to use the platform; and many youth also have unstable, or completely lack, Wi-Fi, data, or an internet connection needed to access the platform:

[O]ne of the things that has been a challenge over—specifically with the course of the pandemic, is it really has brought to light how many students—because we are in a rural, northern remote area where Wi-Fi access and device access, cell phone access, all that stuff can be really spotty if not almost impossible for some of our families which means some of the students don't have access to this kind of thing outside of typical school hours. [FG22-P03]

Participants were concerned that introducing an eMH platform, the use of which requires access to devices and a stable Wi-Fi connection, would be an unsuitable initiative for many of their youth population, especially those who cannot afford Wi-Fi access, thus not addressing existing barriers to care for youth considered disadvantaged and vulnerable.

MHCP Capacity Barriers

Feeling “Really Stretched” With High Caseloads and Change Fatigue

Participants described the school system as often the first point of contact for “a revolving door” (FG17-P02) of students experiencing diverse challenges, from interpersonal problems to the onset of MH disorders. This creates difficulty for them to envision the integration of an eMH platform that might worsen their already high caseloads. Participants described feeling “really stretched” (FG5-P08) and supporting students in the school district as “mentally taxing” (FG21-P02). A participant highlighted these concerns:

[L]ike my vested interest in this point-in-time is it not just a huge, huge source of time and energy suck for them because obviously, before this project, they were busy with their full-time work anyways. Now this is like another thing on their plate. So, that would be my sort of trepidation with this is how it will add more to their plate and potentially increase their stress. [FG21-P02]

Participants were concerned about implementing a new eMH platform that would be time consuming and potentially overwhelming to navigate, given the many conflicting demands on their schedules in an ever-changing work environment. Participants also described a reluctance to undergo the necessary organizational changes needed to integrate eMH into their routine practice:

[W]e're always given new tools constantly. "Try this, these are different assessments and mental health promotions has this going on." [FG17-P02]

Participants questioned how a new tool could be integrated into the existing organizational flow and day-to-day tasks for school staff. This includes the allocation of resources to integrate a new eMH tool, the limited contact time with youth, how this tool factors into waitlist management, and how to integrate this into current data management practices and software. Participants described other data management tools that they have been grappling with in the school system and a concern about how additional eMH tools may create work duplication, especially if there is a lack of interoperability.

Furthermore, the impact of the COVID-19 pandemic on the school system resulted in higher workloads for many school MH staff. Some of the participants noted experiencing a high volume of cases with students with severe MH acuity and a reduction in the availability of community-based MH services; for example, a participant shared how the COVID-19 pandemic has impacted the availability of other community-based MHCPs:

[L]ack of resources. We lost our child psychiatrist in the community. The contract wasn't renewed. So, that puts an extra burden on the schools for services. That affects both school jurisdictions as well as with the current COVID situation again, it's the lack of service providers being able to access the school environment. [FG22-P04]

Thus, when grappling with external factors, such as the unexpected consequences of the COVID-19 pandemic and the constant upgrading of organizational tools, participants were apprehensive about additional training requirements for another tool to integrate into their daily school routines.

MHCP Concerns About Liability

One of the key concerns among participants was the possibility of being liable for the *suicidal thoughts and behaviors* notification embedded in the Innowell eMH platform. Many of the participants shared that they were concerned that a slow response time to a notification that a student is reporting high levels of suicidal thoughts and behaviors may inadvertently prevent timely intervention and therefore contribute to a youth's suicide. This lag time in responding to a notification of acute crisis could be seen as negligence and thus render the MHCP liable. Participants described a concern that youth might erroneously assume that school professionals are immediately made aware that they are in distress or experiencing an emotional crisis after triggering the suicidal thoughts and behaviors notification:

[B]ut the consistent challenge that happens over and over again is when the school closes at 3:30 PM, our

mental health closes at 4:30 PM, what do these parents—so now we know that there's ideation and we're at high risk. What do we do in [the community] with these students? [FG22-P02]

Thus, participants were concerned about who would be responsible for responding to youth outside of school hours and during school closures, including weekends and summer holidays.

Unmasking MH Issues in the Face of Limited Services

Finally, many of the participants expressed concern that they may not have the capacity to respond to the needs of the students within their school district. Some of the participants worried that the increased assessments conducted using measurement-based care embedded within the Innowell eMH platform would unmask the degree to which MH problems impact their student population. Increased assessment would inevitably lead to increased identification of students requiring MH care within student MH services in the school environment. However, participants expressed concern that they would not be able to access needed resources, supports, and specialty services for students presenting with MH concerns owing to long wait times and the absence of evidence-based treatments:

So, to me it's no different than a lot of rural communities, just a lack of support services to address mental health needs and the negative stigma around mental health and its needs as well. [FG22-P04]

Participants were concerned about the potential for this to create a crisis in the school district where MHCPs would be inundated with students with MH problems without proper services and resources to refer them to in the community:

Like I don't want to say that as "Be careful, let's not [open the floodgates]." I think we just need to be prepared for that and how are we going to support everybody in the meantime or through that? [FG5-P07]

The knowledge of the shortage of primary care services and specialty clinics within the school and across the MH community created significant reservations among participants in considering using the Innowell eMH platform.

Facilitators to Implementation of eMH Tools in School Settings

Youth Capacity Facilitators

Creates Potential for an Empowered and Active Role in Care

Participants argued that the most important facilitator to implementation is the belief that the Innowell eMH platform may empower youth to take an active role in their care journey. Being able to access the platform independently, completing assessments that are relevant to them, and accessing apps and e-tools that reflect their needs are key facilitators to implementation. Relatedly, participants acknowledged that young people are far more comfortable using technology, and therefore their readiness to adopt the Innowell eMH platform may be high. Many young people are already using technology

to complete and upload homework assignments, schedule appointments, and, in some cases, attend appointments and classes. Thus, participants in our study asserted that there was strong potential for young people to use the platform as an extension of these existing practices.

Participants further suggested that integrating an eMH platform into the school system from primary to secondary schools would allow students to incrementally develop self-management skills and scaffold the information and resources they need for wellness and MH care. Using the Innowell eMH platform within the school context would also allow young people to monitor MH changes over time:

[A] grade 9 student could carry through this platform for the next 4 years and actually manage their own care. [FG5-P04]

Collectively, participants viewed the many advantages of eMH technology for their students, including youth empowerment and the ability to acquire self-management skills, resources, and psychoeducation information:

But also, empowering youth. I love the idea that they can access this and it's at their fingertips and they can start to really see their growth and that's exciting to me. [FG5-P01]

Participants acknowledged youth being able to see their growth over time and access apps and e-tools while in the school system as a salient facilitator to them agreeing to adopt and implement eMH technology in their school. Thus, capitalizing on the young people's receptivity to technology, embracing their desire to self-manage, and acknowledging this tool as an opportunity to empower youth are all potential implementation enablers.

Fosters Therapeutic Relationships

Many of the participants highlighted the important ways in which the Innowell eMH platform can foster a stronger therapeutic relationship between themselves and youth. Participants described several ways in which this can occur, including the potential for youth to develop greater MH literacy, which would lead to awareness and the use of terminology about MH and well-being, leading to a shared language with their MHCP and increased collaboration to explore what care is needed:

[I]t can be a great tool by the looks of it for youth to identify areas. We might know how they're feeling but not quite able to categorize. "Oh, maybe I'm struggling due to grief;" and being able to recognize, name, and have the language for that, I think, can also be an empowering tool. [FG5-P02]

Many of the participants further highlighted that the repeated use of the measures to assess MH issues might be an effective way for youth to alert their MHCP on how they are coping between sessions or how their MH symptoms are changing over time. Participants described the ease of reviewing assessment information that could be updated between sessions and identifying trends that students may not be verbally sharing with their MHCP:

I can see the benefit of it in terms of that—the narrative in between sessions. I often have encouraged the youth that I work with to use the accompanying email to sort of do exactly this piece...there's a narrative in between things that are happening between sessions, I can't answer all the time, but you can just send me little notes to say, "This is for next session." And just sort of in that hopes of creating some sort of form of accountability. [FG8-P01]

Participants also anticipated the measurement-based care of the Innowell eMH platform providing information on students' progress at different time points during the academic year. In a school setting, the platform can facilitate the sharing of information and the strengthening of the therapeutic relationship over many years. The accessibility of the baseline assessments and records of MH changes over time helps inform the students and their MHCP while also increasing the continuity of care.

Enhances Access to Services and Resources

The final youth capacity facilitator identified by participants is the opportunity to enhance access to information, resources, wellness apps and e-tools, and web-based support by using the Innowell eMH platform. Closely interconnected to the previous facilitator, participants suggested that youth can learn about, explore, and access resources, services, apps, and e-tools more easily by using the platform:

I feel like this could be beneficial to them because they can kind of access areas that is of interest or is of concern to them and they can get resources right there and then. That they can click on those apps, those different phone numbers or websites are things that I saw when I was clicking on some of those. And I think that that will be great for them. [FG10-P01]

Participants recognized that long wait times for specialty services, limited resources, and barriers to accessing MH services, especially in rural areas, might be temporarily addressed by students accessing resources via the Innowell eMH platform.

MHCP Capacity Facilitators

System Transformation Through Flexibility and Problem-Solving

Participants view the school environment as creating the conditions for them to be early adopters of the Innowell eMH platform because educators are flexible, resilient, and solution focused when faced with challenges:

Yeah. I think our program is unique just in the flexibility that we have...We have the flexibility that, you know, you meet a student, the next day they're in tears, they can stop by. Or you have a high-risk who could check in in a couple days as opposed to having to wait for 2 weeks. [FG14-P03]

Participants suggested that by using the Innowell eMH platform, youth would be monitored more carefully, which is different from what might typically occur at the MH clinics in the community. Many of the participants also brainstormed solutions

to the barriers listed in the preceding section; for example, a participant brainstormed solutions for youth who may not have access to devices that allow them to use the Innowell eMH platform and apps:

[E]ven if they don't have the media devices, there's nothing wrong with using the Chromebook [in the school] and sitting in the next room and working on it. [FG5-P05]

Despite the many barriers delineated by the school personnel regarding the implementation of the Innowell eMH platform, participants frequently brainstormed solutions to some of their unique challenges while participating in the FGs. This speaks to the flexibility and natural problem-solving ability of school personnel to contribute to creating system transformation.

Collaboration With MHCPs Across the Continuum and With Different Systems

By developing a comprehensive baseline assessment of students using measurement-based care on the Innowell eMH platform, participants believed that they would develop a better understanding of the care required to meet their students' unique needs. The information gleaned from the measurement-based care assessment protocol was further perceived as supporting a stepped and staged care approach. This was highlighted by a participant who described how the information could be used:

[F]or like, a clinician's dashboard—to be able to see those alerts right away would help us really prioritize where we need to target. [FG14-P01]

Participants further highlighted that sharing the results of the assessments and ongoing monitoring of MH symptoms with other MHCPs would allow them to share the mutual understanding and language that would enhance collaborations with other MHCPs:

I agree, collaboration and communication is so important. I think being able to get out of our silos and work as a team of professionals will only serve to benefit our young people in need of supports. [FG9-P02]

Participants were eager to highlight the potential to remove silos from the MH care system by embracing an eMH platform that could be used across MH care systems. Collectively, many of the MHCPs recognized the potential for these factors to foster a therapeutic relationship with youth, especially if there is increased collaboration among MH teams.

Opportunity for the Continuity of Services

Finally, participants shared that the Innowell eMH platform may be used to facilitate the continuity of care across services

in the community. Participants highlighted the potential for all members of the care team to share, communicate, and access similar information on the platform about a shared youth client and thus promote the continuity of care. This can help in streamlining the service process by enhancing the continuity of care among services:

'Cause we want a wraparound service for the kids and I know there's been lots of privacy issues and that's kind of been better actually for some clinicians—the more open sharing. [FG9-P04]

Some of the participants suggested that MHCPs may embrace the implementation of the Innowell eMH platform as an opportunity to create change within the health care system:

We have a beautiful opportunity here at the middle to drive what happens at the top and at the bottom from a client perspective, our students and our families that'll be impacted and our community and then our leadership. Our superintendents, our mayors, all of those people. And we right now are the driving middle force that can actually change what's happening. And we need to utilize this opportunity well. [FG5-P04]

Participants of this study strongly advocated that school staff hold a unique role within the community: they establish relationships with a majority of the youth and young adults in every community for many years, while also maintaining relationships with leaders of the school districts and with municipal and provincial levels of government as well, thus providing them with the opportunity to build stronger relationships and drive MH care change by embracing this implementation project.

Discussion

Principal Findings

This study aimed to explore perceived barriers and facilitators relating to the implementation of the Innowell eMH platform in secondary schools in Alberta. Using a descriptive qualitative methodology, we held FGs with key stakeholders in school divisions, including administrators, teachers, management staff, school counselors, psychologists, and community connectors (N=52). Our research shows interconnected barriers and facilitators to implementation as it relates to youth and school MHCP capacities, with system-level considerations. We conclude the discussion with a summary of recommendations for addressing implementation in school settings ([Textbox 1](#)).

Textbox 1. Recommendations from the qualitative focus groups with school stakeholders.

<p>Recommendation and description</p> <p>Clear policies and processes for consent (with regard to accessing mental health [MH] services)</p> <ul style="list-style-type: none"> • School-based leaders and decision makers establish policies and processes regarding consenting mature minors and obtaining and navigating parental consent • Development or tailoring of existing policies and processes in the local context and culture around the consenting process <p>Web-based training environment</p> <ul style="list-style-type: none"> • Create interactive learning activities to enhance educators' knowledge regarding the application of electronic MH (eMH) tools with diverse students <p>Level of education, knowledge, and skills</p> <ul style="list-style-type: none"> • Train school MH care professional (MHCPs) on how to support youth to identify when and how to share MH issues with caregivers, if appropriate • Establish communities of practice as an approach to provide post training education and supervisory support to ensure that school personnel can apply their knowledge and skills of measurement-based care and eMH tools <p>Level of support and supervision</p> <ul style="list-style-type: none"> • Decision makers within school settings identify how to support staff to receive adequate training and supervision to learn to use, and embrace the implementation of, eMH tools and apps • Ongoing mentorship, supervision, and support is needed to integrate eMH tools into the school settings <p>Structure of the school system and contexts of practice</p> <ul style="list-style-type: none"> • Integrated eMH tools fit into established workflows and processes, and work duplication is removed where possible to maximize implementation efforts • The process of adaption and adoption requires attention to the cultural and contextual components of assessment, formulation, and intervention, including the ways school personnel recognize, explain, and manage distress <p>Existing socioeconomic barriers to access</p> <ul style="list-style-type: none"> • Considering socioeconomic status and access in the communities of implementation is a key pillar of equity that should be addressed in the implementation of eMH tools and measurement-based care • Emphasize the inclusion and integration of local culture beliefs, practices, language, social norms, family, community, and social network for better understanding of help-seeking behaviors <p>Address liability concerns and ensure crisis response protocol</p> <ul style="list-style-type: none"> • Liability concerns among stakeholders should be heard, integrated, and rapidly addressed through training and clinical supervision to increase willingness to use eMH tools in school settings • Ensure that MHCPs have the competencies to effectively respond to a student's disclosure of suicidal thoughts and behaviors via the Innowell eMH platform • School administrators and decision makers must establish risk mitigation protocols and procedures to assure school MHCPs that clear pathways are determined and easily implemented to rapidly respond to students experiencing suicidal thoughts and behaviors • Clinical supervision and administrative support must be made available to school MHCPs requiring assistance with students' disclosures of suicidal thoughts and behaviors and need of acute care <p>Youth focus</p> <ul style="list-style-type: none"> • Keeping youth at the center of eMH implementation strategies could inspire and enliven uptake among MHCPs <p>Youth engagement</p> <ul style="list-style-type: none"> • Use eMH tools to enhance and improve the way that youth and MHCPs interact with each other and the way that MH teams from different systems communicate • Youth should be included in discussions about how to implement eMH in schools
--

The first theme highlights concern about the extensive assessments embedded within the Innowell eMH platform and youth capacity (eg, attention span and literacy skills) to complete

assessment measures. In general, there is concern about whether the literacy level of the Innowell eMH platform matches that of its intended users in the community. In line with our findings,

MH status and demographic variables are among the primary user capacity factors described in the literature that can affect eMH use [26,43]. A systematic review by Borghouts et al [43] found 59 studies that reported that the MH status of the user can play a significant role in the engagement and uptake of eMH tools. Although the severity of MH symptoms can be a barrier to some patients using eMH tools [44,45], this may also depend on the type of eMH tool; for example, individuals with more severe MH symptoms may be more likely to use eMH tools inclusive of assessment measures [43,46]. To achieve this, researchers have co-designed a game that trains clinicians to identify how and when to adopt eMH tools with their clients [47]. A similar type of learning activity can be used to enhance educators' knowledge about the application of eMH tools with diverse students. MHCPs would also benefit from evaluating digital tools through the adoption of adapted rating scales and digital navigators [48].

The results of our study also suggest that school personnel share a concern about how to obtain parental consent and maintain student confidentiality when considering using eMH tools with youth. In keeping with existing research, this finding shows that one of the most significant barriers to young people accessing school MH services is a lack of clarity about confidentiality, especially from their caregivers [10,49]. Young people may avoid accessing school-based MH services and resources if they anticipate negative consequences from their family members [50,51] or if they are required to obtain parental consent [52,53]. This concern also extends to digital MH tools: Cavazos-Rehg et al [51] found that two-thirds of underage youths displaying symptoms of eating disorders were unwilling to obtain parental consent to access a mobile MH intervention. Researchers and clinicians alike strongly advocate that MHCPs use parental consent waivers, reassure young people of their privacy and autonomy, and address adolescent stigma concerns [51] to increase the use of eMH tools. Given the pervasive concerns about confidentiality and the requirement of parental consent to use the Innowell eMH platform in schools, we strongly recommend that school-based leaders and decision makers establish clear policies and processes about consenting mature minors and navigating parental consent. School staff would benefit from informed consent policies, inclusive of teachers, social workers, and administrators that have been approved across school districts in the province or country. We also recommend training school MH personnel on how to support young people to identify when and how to share MH issues with family, if appropriate.

Related to youth capacity barriers, participants were concerned that introducing an eMH platform, the use of which requires access to devices and a stable internet connection, would be unsuitable for many of their youth population, especially for those residing in remote and rural communities. This finding reaffirms the concern about how to integrate eMH technology, given the existing barriers to service access noted in multiple studies [43,54]. Strudwick et al [54] reviewed a total of 31 mobile apps and 114 web-based applications and resources that had the potential to support the MH needs of the broader Canadian population during the COVID-19 pandemic. Key barriers of concern tended to be access, cost, and poor

connectivity [54]. Socioeconomic status and access in the communities of implementation are considered key pillars of equity that should be addressed to support the success of future implementation strategies and ensure equitable access of this opportunity [54].

This study points to specific issues and concerns about the lack of available time to build capacity and integrate the Innowell eMH platform into practice. Time constraints, burnout, and change fatigue were also identified as significant barriers to implementation. In alignment with our findings, although high-quality person-centered care is a priority for MH services [55], there are issues pertinent to school MHCPs, such as limited time, competing demands, high caseloads [56], high degrees of burnout [57], and insufficient training and administrative support [58], all of which can create barriers to providing optimal care and adopting a new eMH platform in a system. Furthermore, LaMonica et al [28] argue that if digital solutions are to be successfully used by MH professionals, decision makers must reduce the administrative burden and responsibilities placed on individuals to adopt eMH technology. Importantly, if eMH tools are introduced in an MH service setting, implementation strategies must consider what could be removed or combined to avoid increasing workloads of school MHCPs. We recommend that decision makers within school settings identify how to support staff to receive adequate training and supervision to learn to use, and embrace their curiosity about the implementation of, eMH tools and apps.

From an MHCP capacity perspective, participants expressed concern about how a new eMH platform could be integrated into the existing organizational flow and day-to-day tasks for school MHCPs. If an eMH platform is operationalized into current vision, mission, priorities, and work plans, this is reported to enable implementation and delivery [59]. Operationalization factors that increase implementation are reported to include workflow processes; leadership, including workplace culture and management; and systems, including the organization of people and resources to meet the needs of the community [59]. Greenhalgh et al [60] draw attention to the importance of integrating technological advances in MH care into the work processes and existing tools and resources used by MHCPs. When eMH tools do not fit into traditional workflows and processes, there is a risk of low engagement and poorly sustained implementation once trials end [17,60,61]. Thus, eMH initiatives must fit into the standard workflows of the health system setting [61,62] to improve youth MH outcomes [63]. Work duplication could be removed by reducing administrative burden on professionals by ensuring the interoperability of MH tools with existing management systems (removing the need to enter the same data across multiple systems) [28]. This finding is particularly meaningful for school district professionals who already use existing data management processes, as well as MH tools and resources, and are concerned about the integration of eMH tools into the established organizational workflow. Our findings support the recommendation that eMH tools must fit into established workflows and processes and work duplication removed where possible to maximize implementation efforts.

A major implementation barrier concern among participants is the potential to be held liable for a youth's suicidal thoughts and behaviors notification alerted through the platform. Although liability concerns have not been sufficiently discussed in the literature, Scott et al [64] examined telehealth policy implications and suggested that some risk should be anticipated and expected in the implementation of eMH tools. Thus, liability concerns among stakeholders should be heard and considered and rapidly addressed through training and clinical supervision to increase willingness to use eMH tools in school settings. Our research sheds light on key liability concerns among school staff that should be considered and urgently addressed during the preimplementation phase to ensure that school MHCPs have the competencies to effectively respond to a student's disclosure of suicidal thoughts and behaviors via the Innowell eMH platform. This points to a key improvement in quality care by providing young people the opportunity to assess and detect suicidality and, furthermore, empowering the young person to seek support and care pathways for suicidality [65]. Equally important, school administrators and decision makers must establish risk mitigation protocols and procedures to assure school MHCPs that clear pathways are determined and easily implemented to rapidly respond to students experiencing suicidal thoughts and behaviors. A systematic review of MH training for secondary teachers shows that most training interventions have been carried out through facilitated course trainings and workshops, such as MH first aid training, peer support, and suicide prevention and postvention, to name a few [66]. This review showed an improvement in MH knowledge and attitudes among teachers, and the interventions reviewed should be considered in training and preparing schools to implement eMH tools, especially when suicide assessments and alert systems are included in the eMH options. Finally, clinical supervision and administrative support must be made available to school MHCPs requiring assistance with students' disclosures of suicidal thoughts and behaviors and need of acute care. An area of future research is to review the legal and ethical considerations of telehealth services [64] across different systems to facilitate the successful implementation of eMH tools.

Many of the participants also expressed concern that they may not have the capacity to respond to the needs of the students within their school district owing to limited resources in their school and the broader community. These concerns regarding the availability and accessibility of resources are reported to be challenges with accessing MH services across the globe [67]. Research has shown that school MHCPs tend to have variable or insufficient training coupled with a lack of support from administration, affecting their ability to respond to the diverse needs of students in the school setting [58]. Without the resources available to meet the needs of students who are identified as requiring more MH support, there is great concern that MH symptoms and risk of suicide will worsen [68]. Our findings suggest that early assessment and intervention, including the capacity to respond to the needs of young people and potentially refer them on to additional resources, are critical to the improvement of long-term health and social outcomes [69]. Introducing an eMH platform in a school setting may inevitably lead to the identification of youth who urgently need

MH care, validating this concern. Alternatively, the Innowell eMH platform may also identify youth who are able to self-manage through the platform's apps and electronic resources, preserving current MH services for those individuals in greatest need. Furthermore, gaining an understanding of the number of youth requiring MH services provides a starting point for advocating for increased publicly funded MH services. This advocacy can be done by capitalizing on the surge of interest in digital MH tools through building awareness regarding ways to modernize access to MH services, highlighting evidence of the effectiveness of digital MH tools, and advocating for financial investment [14].

When discussing facilitators to the implementation of eMH tools, participants described the capacity among young people to use technology to access services. We learned that participants view young people as having a strong desire to direct and manage their own care. The ability of young people to take an active role in their own care journey and access resources and information at times that work for them, whether independently or with their MHCP, all highlight the importance of youth capacity as a facilitator to the implementation of the Innowell eMH platform. In line with this finding, Iorfino et al [70] suggest that health systems will see an increased push toward youth owning and managing their own health data to the benefit of both youth and MHCPs. Many studies have addressed the importance of eMH tools as empowering their users by affording more control, choice [71], and shared decision-making [72]. By contrast, MHCPs who are early adopters of digital tools tend to be those who believe that the initiatives will be beneficial to their clients [73]. The scoping review by Hawke et al [74] demonstrated that youth prefer to provide feedback on the care they receive because they have a strong desire to be involved in decision-making. Playing an active role in their care enables young people to cope better, increases their sense of empowerment, and strengthens their connections with health professionals [75]. As MHCPs expressed enthusiasm around the implementation of the Innowell eMH platform, particularly when considering its potential benefits for their students, keeping youth at the center of eMH implementation strategies could inspire and enliven uptake among school MHCPs.

The findings of our study suggest that school MHCPs may use measurement-based care through an eMH platform to identify and monitor how students' MH concerns are progressing and where new MH problems may be emerging. In fact, our study demonstrated that MHCPs view the measurement-based care protocol embedded in the Innowell eMH platform as providing critical information about a young person's MH status, a common language for talking about MH concerns, and when changes in MH symptoms are a signal for adaptations in the intensity of services required. This common language as well as the ability to communicate, understand, and interpret their problems and strengths, subjective symptoms, and preferences for care with their MHCP could be established in their collaboration with other MHCPs as well [76]. The changes or lack of changes in the MH symptoms could open collaboration through thoughtful conversations between youth and their MHCP about the direction for care moving forward [77]. To inspire uptake among MHCPs, we support stressing the

importance of eMH tools enhancing and improving the way that youth and MHCPs interact with each other and the way that MH teams from different systems communicate, where possible [78].

This study further highlighted organizational implications to the implementation of eMH tools, recognizing the potential for increased access to community-based services and resources and available apps and e-tools. In a scoping review of MH service-level factors for access and engagement for young people, Anderson et al [79] note that choices around resources, increased information, flexible treatment delivery, and person-centered care contributed to young people being engaged in MH services. These benefits also extend to MHCPs and service delivery by helping to better connect young people to the services that they need and providing options to explore when their MHCP is unavailable. Study participants highlighted the potential for all members of the school MH team to share and access similar information about a student to ensure the continuity of care. Furthermore, participants also perceived school MHCPs being involved in the implementation of eMH tools as a turning point for MH services in the community. The unique relationship of school districts with municipal and provincial levels of government was seen as an implementation facilitator that could support significant transformation of youth MH services. Davenport et al [15] demonstrate how primary MH services can be “flipped” using digital health tools. Their work highlights the potential of digital MH services when assessment, triage, and care pathways are created to ensure that young people are matched to the care they need [15]. More recently, the Innowell eMH platform has been used to compare the needs of clients among services and across geographic regions, which can be used to understand the needs of a heterogeneous population and plan services accordingly [80]. This highlights the potential of eMH tools to ensure that youth are accessing the right care at the right time and promoting the continuity of care to avoid the fragmentation of services [81]. Our findings point to the potential of the school setting to support “flipping” youth MH service experiences and outcomes. The school setting is of particular importance, given the unique community-based relationships formed with young people and the potential to participate in deciding the direction of youth MH strategies with local and provincial governments, especially through the implementation of new eMH tools.

Limitations and Strengths

This study has a few limitations and strengths. Dynamics varied and differed among the FGs, with some groups having more representation from diverse stakeholders than others despite our best efforts to encourage diversity. An open discussion was embraced with each group; therefore, some groups spoke more organically about systemic and organizational implementation challenges than others. A potential limitation is that the clinical lead was often present in the FGs, which may have prevented some people from being forthright about the barriers and enablers specific to their community context as well as their views of the implementation of eMH tools and organizational culture. FGs may also result in certain types of socially acceptable opinions emerging and certain participants dominating. Therefore, this may not be the collective voice we expected. Some strengths of this study that we would like to highlight are the intentional involvement of youth research partners in the analysis of the FG data. This study also recruited from diverse school settings with respect to size, approach, and location (both urban and rural areas in the province). An opportunity for future research would be to target more diverse individuals and ask more targeted questions about organizational and systemic barriers and facilitators experienced by MHCPs and youth, respectively. Future studies could also use multiple methods to increase validity, such as observations and interviews. In addition, this gives way to include young people with lived experiences as participants, which was done as part of this study, and these results will be published in a subsequent manuscript.

Conclusions

This study sought to explore school MHCPs’ perspectives relating to the implementation of the Innowell eMH platform. Schools are a critical setting to implement eMH tools for youth. Our findings highlight the nuanced perspectives among MHCPs with regard to implementation. Their insights demonstrate critical youth and MHCP concerns, with considerations for organizational-level factors that may impede or enhance the implementation processes for embedding eMH tools in the school context. The identified barriers and facilitators to implementation in a school setting provide future researchers and decision makers with expected (and unexpected) challenges that could be addressed in the preimplementation phase.

Acknowledgments

The authors are grateful for the contributions from their research assistants Brea McLaughlin, Simron Sidhu, Katelyn Greer, Karina Pintson, and Sarah Daniel. The authors acknowledge the contributions of the team implementing the electronic mental health tools in coordinating and delivering the focus group presentations on the Innowell electronic mental health platform and providing manuscript feedback. The authors could not have conducted this research without the support of the various stakeholders and participants of this study. Finally, the authors would like to acknowledge the Alberta Children’s Hospital Foundation and the Partnership for Research and Innovation in the Health System for funding and supporting the project.

Data Availability

The data generated and analyzed during this study are restricted because the transcripts in entirety could potentially identify participants and are confidential.

Authors' Contributions

GD, EMB, and KSB wrote the initial draft of the manuscript. All authors participated in the refinement of the draft, critically reviewed it, and provided feedback on the final version submitted for publication in accordance with the International Committee of Medical Journal Editors criteria.

Conflicts of Interest

HML is a Section Editor for JMIR Aging (at the time of this publication). All other authors declare no other conflicts of interest.

Abstract

Background: Over the past few years, online record access (ORA) has been established through secure patient portals in various countries, allowing patients to access their health data, including clinical notes (“open notes”). Previous research indicates that ORA in mental health, particularly among patients with severe mental illness (SMI), has been rarely offered. Little is known about the expectations and motivations of patients with SMI when reading what their clinicians share via ORA.

Objective: The aim of this study is to explore the reasons why patients with SMI consider or reject ORA and whether sociodemographic characteristics may influence patient decisions.

Methods: ORA was offered to randomly selected patients at 3 university outpatient clinics in Brandenburg, Germany, which exclusively treat patients with SMI. Within the framework of a mixed methods evaluation, qualitative interviews were conducted with patients who chose to participate in ORA and those who declined, aiming to explore the underlying reasons for their decisions. The interviews were transcribed and analyzed using thematic analysis. Sociodemographic characteristics of patients were examined using descriptive statistics to identify predictors of acceptance or rejection of ORA.

Results: Out of 103 included patients, 58% (n=60) wished to read their clinical notes. The reasons varied, ranging from a desire to engage more actively in their treatment to critically monitoring it and using the accessible data for third-party purposes. Conversely, 42% (n=43) chose not to use ORA, voicing concerns about possibly harming the trustful relationship with their clinicians as well as potential personal distress or uncertainty arising from reading the notes. Practical barriers such as a lack of digital literacy or suspected difficult-to-understand medical language were also named as contributing factors. Correlation analysis revealed that the majority of patients with depressive disorder desired to read the clinical notes ($P<.001$), while individuals with psychotic disorders showed a higher tendency to decline ORA ($P<.05$). No significant group differences were observed for other patient groups or characteristics.

Conclusions: The adoption of ORA is influenced by a wide range of motivational factors, while patients also present a similar variety of reasons for declining its use. The results emphasize the urgent need for knowledge and patient education regarding factors that may hinder the decision to use ORA, including its practical usage, its application possibilities, and concerns related to data privacy. Further research is needed to explore approaches for adequately preparing individuals with SMI to transition from their inherent interest to active engagement with ORA.

KEYWORDS

open notes; patient-clinician relations; electronic health record; clinical notes; visit notes; patient participation; online record access; mental illness; patient portal; mental health; qualitative interview; patient education

Introduction

In recent years, several countries have established secure patient portals to enable online record access (ORA), allowing patients to view their health data, including clinical notes (“open notes”) from their health care providers [1]. The United States, Canada, and Scandinavian countries, particularly Estonia, Sweden, and Norway, have been at the forefront, providing access to a significant number of patients across multiple regions [2,3]. More recently, the United Kingdom introduced the NHS app, offering access to primary care provider medical records since just last year [4]. In Germany, offering ORA was made mandatory for statutory health insurance providers by 2021, although the inclusion of open notes remains uncertain [5,6].

Research conducted in general health settings indicates clear benefits of patient access to clinical notes, including improved treatment satisfaction, transparency, patient engagement, patient-clinician communication, and health literacy [7-9]. Additionally, ORA enhances medication adherence and security in patients, helps patients to identify and correct treatment errors [10], increases a sense of control over the treatment, and reduces anxieties regarding the treatment process [11]. Health care providers generally view ORA as a valuable tool to promote patient engagement, even though it may be connected to an additional workload related to documentation and communication [12].

Studies conducted in mental health generally yield similar results to those in general health settings, but they also highlight distinct ethical and practical challenges [13,14]. For example, these challenges encompass navigating disagreements between patients and health care professionals (HCPs) regarding clinical notes, as well as discussing exceptions to or limitations of access for patient groups with specific diagnoses or acute conditions, such as severe mental illnesses (SMI) [15,16]. SMI is commonly characterized by conditions including (1) nonorganic psychoses, bipolar disorders, personality disorders, or severe chronic depression; (2) a prolonged psychiatric history involving multiple hospitalizations or outpatient treatments; or (3) moderate impairment in work and leisure activities alongside mild impairment in basic needs [17]. Clinicians often hold reservations about offering ORA to patients affected by SMI. Their concerns primarily revolve around the apprehension that ORA might contribute to self-harming or violent behaviors, especially in patients with whom establishing a trusting relationship is challenging [14]. Patient surveys, however, have demonstrated that individuals with SMI using ORA also exhibit an improved understanding of medication prescriptions, higher medication adherence, and a greater sense of control over their medication [18]. Nevertheless, the adoption of ORA among patients with SMI remains lower compared to those receiving treatment for somatic conditions [18,19].

Apart from assumed positive effects on the patient-clinician relationship and concerns regarding data security, little is known about the motivations and expectations of patients with SMI toward ORA [14,20]. Examining these aspects is crucial for addressing the barriers that hinder the widespread acceptance of ORA among patients with SMI. Therefore, this study aims to thoroughly explore the reasons why patients with SMI consider or reject ORA and whether sociodemographic characteristics may influence patient decisions. More specifically, the following research questions will be addressed (1) which factors influence the decision of patients with SMI, who are offered access to their clinical notes, to either embrace or reject this option? (2) Does the decision for or against ORA in the context of SMI relate to any patient characteristics?

Methods

Design

This study is part of the PEPPSY project (Piloting and Evaluation of a Participatory Patient-Accessible Electronic Health Record in Psychiatry and Somatics; 2021-2023) that focuses on piloting and evaluating a participatory patient record in psychiatry and somatic medicine [21,22]. It aims to examine the development, implementation, processes, and outcomes of the corresponding patient portal, also known as PEPPSY, from the perspectives of patients and HCPs. Based on a concurrent mixed methods design, a qualitative methodology was used to comprehensively explore the reasons for and against ORA as well as the potential benefits and challenges [23]. This was complemented by a quantitative analysis to study the possible association between the decision for or against ORA and patient characteristics. Qualitative and quantitative data were analyzed separately. The concurrent design was chosen in order to obtain a comprehensive view of the research question [23], as it simultaneously provides in-depth, qualitative insights into the reasons for acceptance or rejection of ORA and broad, quantitatively measurable data on the patient characteristics in relation to this approval or rejection.

Ethical Considerations

The ethics approval from the Ethics Committee of the Brandenburg Medical School (MHB) was obtained (E-01-20210727), and the study was registered with the German Clinical Trial Register (DRKS00030188).

PEPPSY App

The patient portal PEPPSY was developed as part of a research collaboration between the Norwegian University of Science and Technology (NTNU) and the MHB. It emerged from an iterative process of participatory design, development, application, and evaluation [21,22]. PEPPSY’s primary function is to provide patients with secure, 2-factor authenticated access to their physician’s notes, but it also includes other information such

as laboratory results and a list of prescribed medications. In the current second phase of the pilot, PEPPSY is being expanded to serve a broader patient population, offering additional features such as a messaging function to allow communication between patients and clinicians concerning the open notes.

Study Setting

The study was conducted at 3 psychiatric outpatient university clinics of psychiatry and psychotherapy at MHB, Immanuel Klinik Rüdersdorf. Located in the metropolitan region Berlin/Brandenburg, the clinics are responsible for providing mental health care services to approximately 255,000 inhabitants in the catchment area. These outpatient clinics offer specialized care for patients who require a comprehensive, multidisciplinary approach due to the nature, severity, or duration of their conditions. The eligibility for receiving treatment in these psychiatric outpatient clinics is based on specific diagnoses, including SMI and other diagnoses, as determined by the insurance providers and the hospital association.

Recruitment and Sampling

From January to June 2023, eligible patients were randomly selected from the 3 study centers by the PEPPSY research team consecutively. Participants had to meet the following inclusion criteria: age 18 years or older, diagnosed with SMI and confirmed by an external report, and currently receiving treatment in an outpatient psychiatric clinic. Exclusion criteria were previous ORA use related to mental health issues; acute psychiatric conditions or symptoms such as disorientation, severe delusions, hallucinations, katatonia, or agitation that may be associated with significant impairment of cognitive and social functioning; or acute self-harm or harm to others. Eligible patients were informed about the study and written informed consent was obtained. The former included detailed information about ORA, such as how it works, the health information it provides, and offers to participate in (1) this qualitative study and (2) the intervention part of the study, that is, to try out ORA for a period of several months in the study setting described.

Data Collection

The interviews that form the basis of the data in this study were conducted immediately after informed consent was obtained, which included a decision about whether or not participants wished to receive ORA. Sociodemographic data were collected, followed by face-to-face interviews. Information on the diagnoses of the study participants according to the International Classification of Diseases (ICD) was taken from the patient's medical records. The interviews were performed at the aforesaid outpatient clinics by the authors and psychiatrists, ST and JS, who were not the outpatient treatment providers of the participating patients. The interviewers conducted the interviews out of genuine interest in understanding why ORA is accepted or rejected. For the interviews, a semistructured approach based on an interview guide was chosen in order to ensure the comparability of the interviews. This interview guide (see [Multimedia Appendix 1](#)) was developed deductively with the participation of all researchers on the basis of a desktop study (or literary research) on the topic of acceptance of ORA among patients with psychiatric disorders using Google Scholar and

PubMed [24]. The interview guide was then tested in 2 pilot sessions with patients within the authors' institution. Since no changes to the guide were necessary, the sample interviews could be included in the analysis.

The interviews explored each patient's reasons for acceptance or rejection of ORA usage and had a mean duration of 11.3 (SD 4.5) minutes. In addition to the interviews, the researchers also took field notes, which were later included in the data analysis. Data collection continued until thematic saturation of categories was reached, which occurred when no new themes emerged from the transcripts. The saturation of categories was defined as the point at which no new codes appeared and the meaning of the category and subcategories were established [25].

Data Analysis

The interviews were transcribed verbatim and pseudonymized (JS and ST) and analyzed with thematic analysis (JS, ST, and KN) using the MAXQDA Software (Verbi Software Ltd). Thematic analysis is a flexible approach that was used to inductively ("bottom up") analyze data gathered from semistructured interviews [23]. Data analysis was initially conducted by 2 researchers on each interview individually and verified for consensus; a third person joined in when coders could not reach consensus. The analysis proceeded in six steps (1) familiarizing oneself or becoming familiar with the data, (2) generating initial codes, (3) generating initial themes, (4) reviewing themes, (5) defining and adequately naming themes related to the research questions, and (6) formulating key concepts. After all the themes were generated for each of the interviews, they were divided into 2 groups, reasons for acceptance or rejection of ORA. Subsequently, these themes were clustered within these groups and overarching categories and subcategories were formed. This was a recursive process where different categories were repeatedly tested for coherence and differentiability from the other categories and subcategories. In the final step, 2 researchers jointly selected the most relevant and succinct quotes from the subjects for each of the categories and subcategories. For the group of acceptance of ORA, 4 categories and 13 subcategories were formed. For the group of rejection of ORA, 5 categories and 13 subcategories were formed. For quality assurance purposes, the Consolidated Criteria for Reporting Qualitative research (COREQ) checklist was used (see [Multimedia Appendix 2](#)) [26].

The sociodemographic data of participants were analyzed according to their group affiliation (acceptance vs rejection ORA). Descriptive statistics were used to examine possible differences in sociodemographic characteristics between groups using R software (R Core Team) [27], which is available license-free. These between-group differences and their significance were assessed using chi-square test and *t* test [28]. No data were excluded from the data analysis.

Results

Sociodemographic Data

Out of the 124 eligible patients, 83.1% (n=103) agreed to participate in the study about reasons to use or not to use ORA. Sociodemographics are summarized in [Table 1](#). The respondents

had an average age of 46.1 (ranging from 19 to 86) years. The majority of the participants were women (n=64, 62%) with an average age of 47.2 years. Respondents who were men had an average age of 44.2 years. Among the approached patients, 58% (n=60) expressed a desire to use ORA, while 42% (n=43) declined ORA. When differentiating for gender, 56% (n=36) of the respondents who were women agreed to participate, while 44% (n=28) declined. Among respondents who were men, 62% (n=24) agreed to participate, while 38% (n=15) declined. The

willingness to participate was highest among younger respondents (aged 18 to 39 years) and among patients aged 50 to 59 years. In terms of diagnosis, a high willingness to participate was observed among individuals with affective disorders (ICD 10, F3 [mood (affective) disorders]) at 91% (n=48; $P<.001$). The lowest agreement was found among individuals with schizophrenia, schizotypal, and delusional disorders (ICD 10, F2 [schizophrenia, schizotypal, and delusional disorders]) at 35% (n=6; $P=.01$).

Table 1. Sociodemographic characteristics of the study sample (N=103).

Characteristics	All (N=103)	Do you want online record access?		P value
		Yes (n=60)	No (n=43)	
Gender, n (%)				.68
Women	64 (62.1)	36 (56.2)	28 (43.8)	N/A ^a

^aN/A: not applicable.

^bP values were calculated using *t* test, while all other values were calculated based on chi-square test.

^cF1: Mental and behavioral disorders due to psychoactive substance use.

^dF2: Schizophrenia, schizotypal, and delusional disorders.

^eF3: Mood (affective) disorders.

^fF4: Neurotic, stress-related, and somatoform disorders.

^gF6: Disorders of adult personality and behavior.

^hOthers: All mental disorders in the International Classification of Diseases-F chapter beyond those previously listed were subsumed under this category.

Reasons for Acceptance and Rejection of Participation in ORA

The categories and subcategories for the respective reasons provided by the respondents are summarized in [Table 2](#).

Subcategories and quotes in the following text are represented in italics.

Table 2. Categories and subcategories of stated reasons for acceptance and declination of ORA (N=103).

Categories and subcategories	Values ^a , n (%)
Reasons for acceptance of ORA^b	
Wish to engage in treatment	
Improved self-understanding and self-knowledge	14 (13.6)
Interest in the external perspective provided by clinicians	12 (11.7)
Continual contact and exchange	10 (9.7)
Incentive for increased engagement in treatment	6 (5.8)
Understanding the treatment process	
Reminder of content discussed in therapy sessions	27 (26.2)
Ability to track the progress of treatment over time	5 (4.9)
Interest in medical translation of own symptoms	3 (2.9)
Critically assessing clinicians	
Gaining more transparency into the perspective of health care providers on patients	6 (5.8)
Needing to verify the correctness of the notes in order to be able to trust the clinician	10 (9.7)
Avoiding and correcting misunderstandings	13 (12.6)
Sharing personal health data with third parties	
Improving communication about the illness with significant others	7 (6.8)
Ability to share own health data with public institutions	3 (2.9)
Having access to own health data	2 (1.9)
Reasons for rejection of ORA	
Feeling well supported in face-to-face interactions	
Sufficient oral “transmission” of notes	15 (14.6)
Desire to address problems and inquiries more effectively in direct conversation	10 (9.7)
Adequate satisfaction with in-person appointments	7 (6.8)
Self-uncertainty	
Feeling emotionally burdened by reading the notes	16 (15.5)
Fear of excessive confrontation with one’s own condition	3 (2.9)
Adequate satisfaction with one’s own perspective	7 (6.8)
Uncertainty in the relationship with the clinician	
Control weakens trust	2 (1.9)
Trust does not require control	19 (18.4)
Concern about technical demands for clinicians	1 (1.0)
Concerns about the misuse of health data by third parties	
Worries about data security	5 (4.9)
Concerns of unwanted control by family members	2 (1.9)
Practical barriers	
Difficulties in dealing with technology	13 (12.6)
Difficulties in reading and understanding the notes	7 (6.8)

^aThe number of patients (n, %) who mentioned each theme is indicated in parentheses.

^bORA: online record access.

Reasons for Acceptance

Overview

The stated reasons for accepting participation in ORA can be grouped into 4 main categories with a total of 13 subcategories.

Wish to Engage in Treatment

The respondents associated their agreement to participate with the wish and motivation to become more actively engaged in their treatment. They hoped that by using the portal, they could gain a better understanding of themselves and their condition, often driven by their interest in the external perspectives of their clinicians.

I am interested in knowing what they actually [think] about me here, because it's about me, my health. Maybe I can understand everything [about why I'm feeling unwell] better. [Patient 14]

In the responses, this interest was often connected to a wish for ongoing communication and interaction.

I find it quite practical because it helps me stay in touch with my doctor and keep track of documentation. This way, I can tell the doctor when I'm not feeling well. [Patient 55]

Overall, the participants viewed their participation as an incentive to become more engaged in their treatment.

Overview of the Treatment Process

Gaining a comprehensive understanding of the treatment process is another category that emerged from the participants' responses. While closely related to their willingness to engage in treatment, it primarily focused on the desire to have an overview of the treatment process. Many participants appreciated the ability to read their open notes through ORA, as it served as a reminder of therapy sessions and allowed them to track the chronological progression of their treatment.

I would like to have an overview of how my condition has changed over time, whether things have improved or worsened. Otherwise, you just live in the moment and with the things I tell you in this moment. But having it documented from appointment to appointment, and knowing that things might have gotten better without me realizing it, I would like to have that on paper. [Patient 89]

Additionally, embracing ORA was motivated by an interest in understanding how their own symptoms are translated in a medical context. This includes the use of specialized terminology to describe their symptoms and the subsequent treatment recommendations.

I would like to know how you medically process what I tell you during the treatment and what implications it has for the diagnosis. I'm just sharing things from my life, but what does it mean for the illness and what needs to be done now? I would like to see that. [Patient 84]

Critically Assessing Clinicians

Participants expressed their acceptance of ORA not only as a means to engage more actively in their treatment but also as an opportunity to critically assess the perspectives and approaches of clinicians. Participants valued the chance to gain more transparency about how clinicians view their patients by reading clinical notes and being able to provide feedback via comments.

To find out what therapists think about me behind my back and whether they even notice you in the hospital setting. [Patient 72]

Participants expressed concerns that clinicians might not accurately understand or document patients' individual needs, leading to doubts about whether they can be trusted. This led to a need to verify the correctness of the notes in order to be able to trust their clinician.

I have so much mistrust towards doctors, especially regarding my psychosis and the forced medication, and how things I've said and done have been twisted. I can see it happening with my grandma too, how she's being treated. That's why I just want to see what you actually write down. [Patient 91]

From a more constructive perspective, many participants saw the possibility of viewing open notes within ORA as a way of preventing and rectifying misunderstandings that may arise during conversations.

Sharing Personal Health Data With Third Parties

This category describes aspects that are less focused on the treatment itself and its documentation, but rather on the use of this documentation with third parties. Participants expressed the hope that sharing the clinical documentation with significant others (eg, family members and friends) and other health care providers would improve the exchange of information about their illness.

For instance, my wife would like to talk to someone about how to handle my condition. That was my first thought, that she could also read what you write. I can't remember and convey everything. This way, she could participate without me burdening her with it. [Patient 27]

Furthermore, participants viewed the ability to share their own health data with public institutions such as health insurance companies or the police through ORA as a positive aspect.

I recently had an issue with the health insurance company where they just declared me as healthy. They requested my medical records, but nobody was available at the psychiatric outpatient clinic. I could simply print out my documentation. That would be just great. [Patient 36]

Furthermore, the basic opportunity to have access to one's own health data was also mentioned as a reason for accepting ORA.

Reasons for Rejection

Overview

The reasons for declining participation in ORA can be grouped into 5 categories with 13 subcategories.

Feeling Well-Supported in Face-To-Face Interactions

This category includes topics in which participants decline ORA because they already feel adequately cared for through the current mode of contact. For instance, they perceived their in-office appointments as sufficient for their needs.

I am feeling satisfied with conversations. (...) I'm not someone who spends a lot of time on their phone. I prefer being outdoors. (...) If I don't understand something, I can simply ask for clarification. Looking at the notes would only add more information to my already busy mind. [Patient 32]

This feeling of being adequately cared for through in-office appointments was repeatedly associated with the desire of the respondents to address problems and inquiries through direct conversation. Moreover, they expressed a preference for discussing their own notes through verbal communication.

We have already discussed it [the topic of today's session]. If there's anything or if I want to know more, I can always ask. [Patient 12]

Self-Uncertainty

Another central theme in the patients' statements was the concern or fear of becoming unsettled by reading the notes. While several respondents mentioned being sufficiently satisfied with their own perspective on themselves, there was often an underlying fear of being burdened by reading the notes.

I don't need to read that; I'm already experiencing all this crap myself. I don't need to see it in black and white too. [Patient 78]

In this context, some respondents specifically expressed fear of too much confrontation with their own condition, and some of the participants wished to leave that within the scope of the therapeutic conversation and not reactivate it through reading clinical notes.

I wouldn't be up for that. Because, well, I unload all this stuff on you here that makes me sick, and afterwards, I actually feel better. But if I were to read through all that I've told you again, it would really bring me down all over again. [Patient 67]

Uncertainty in the Relationship to the Clinician

The respondents expressed concerns about not only their own self-uncertainty but also about feeling uncertain toward the health care provider and the therapeutic relationship when it comes to using ORA. Specifically, they highlighted that allowing patients to review their notes could potentially undermine the trust and rapport they have established with their clinicians.

I am a doctor myself and I know that it harms the doctor-patient relationship when patients read what doctors write about them. It is very important to me

that I trust you without constantly reviewing what you document. [Patient 92]

Contrary to the wish to critically assess the clinician as a justification for the use of ORA (as mentioned above), the respondents emphasized that satisfaction with treatment and a trusting relationship do not require such control.

I trust you that everything is accurate, right? How you write it down. I'm really satisfied with the treatment, I've even had my pension extended, and all the services I need are being provided, so everything you document and how you communicate it to others must be correct, right? Others might want to know sometimes, but I also feel that what I tell you is being understood, so I don't need to read anything extra. [Patient 73]

Here, concerns were raised about the potential increase in workload for clinicians, which could potentially strain the therapeutic relationship due to the perceived additional workload.

Concerns About the Misuse of Health Data by Third Parties

Some respondents explained their rejection based on concerns about data security, specifically regarding the potentially insecure storage of documentation for instance on mobile devices, which could result in unauthorized access by third parties. Unlike the proponents of ORA, those who expressed opposition to it also raised concerns about unwanted control by care partners through unauthorized access to the patient portal.

I have a curious girlfriend who doesn't necessarily need to read along. (...) It's not for my family members. I would feel too controlled by my partner. She already opens my mail and goes through my bank statements. [Patient 52]

Practical Barriers

Finally, some respondents mentioned technical and practical challenges as reasons for their rejection. Specifically, participants over the age of 49 years highlighted the difficulty of dealing with the technology required for ORA, such as smartphones, browser apps, and 2-factor authentication. Additionally, some expressed feeling overwhelmed by the comprehension of the notes, as they encountered challenges due to the use of medical terminology and their own difficulties in reading caused by issues with concentration.

I have really bad concentration problems, so that I can't understand anything anymore and can't fully engage in anything, [I] would only understand half of it, especially when reading. Additionally, I don't have internet access, and I don't understand how to set it up. [Patient 97]

Discussion

Principal Findings

In summary, the reasons provided by the interviewed patients with SMI for their decision to use or not use ORA are diverse.

Among those in favor, motivations range from a desire for increased engagement in treatment to critical evaluation of clinicians and using accessible health data for sharing with third parties. In contrast, those who opposed ORA perceived their therapeutic relationship as already well-established and feared that it might be jeopardized by the use of ORA. Finally, practical barriers, mostly related to digital literacy, were cited as reasons for their opposition.

Acceptance of ORA

The reasons for approval are briefly discussed as they largely align with those found in existing studies, thus providing limited implications for the further development of ORA. Those reasons include the motivation to engage more actively in treatment: by using the portal, patients hope to better understand the content of medical appointments and to obtain a clearer view of themselves, their illness, and the external perspective of their doctors [29]. Although not explicitly thematized in this study, it is reasonable to infer that this motivation also leads to increased adherence to medical treatment. This assumption is supported by another study, which found that patients with SMI when using ORA, reported an improved understanding of their medication prescriptions and described feeling more comfortable and in control throughout the therapeutic process [18,30]. However, this question requires further investigation in a follow-up study.

Moreover, many patients see ORA as a way to obtain a comprehensive overview of their treatment process. This includes accessing open notes as a reminder of therapy sessions, tracking treatment progress, and understanding how their symptoms are documented in a medical context.

Critical evaluation of clinicians is another reason for the acceptance of ORA by patients which is also reported by other studies [31]. The participants in our study reported that by reading the clinical notes, they want to evaluate the transparency and accuracy of clinicians' perceptions and documentation of their needs. This critical view is also seen as an opportunity to address and correct potential misunderstandings that may occur during the consultation. However, this need for critical monitoring of the practitioners was ultimately linked to the desire to deepen trust in the practitioner and the treatment process. This need or desire to enhance trust is also highlighted in a study by Cromer et al [32].

In addition to patients appreciating gaining access to their health data through ORA, the ability to share personal health information with third parties, such as family, friends, other health care providers and public bodies, is also viewed positively. Again, this finding is consistent with preexisting literature on the perceived benefits of ORA by health care users [33].

Rejection of ORA

When considering the rejections of ORA among patients with SMI, differences compared to patients from general health settings become apparent. For example, 1 patient acknowledges having significant comprehension difficulties during direct patient-clinician interactions due to concentration problems and suspects that reading clinical notes would exacerbate the issue.

This aligns with existing studies that suggest severe symptoms, which persist in daily life and tend to hinder participation in digital health interventions [34]. Furthermore, patients with SMI more often experience intersecting factors such as low educational attainment and language barriers [35], which was also repeatedly stated by study participants with regard to difficulties in dealing with technology and understanding the notes. Low educational attainment and language barriers can subject them to greater stress in patient-clinician interactions when trying to understand health care providers' explanations [35]. Collectively, these individual limitations can lead to concerns and experiences not being adequately articulated, misunderstood, or possibly forgotten within the limited time available at an appointment. Consequently, this may result in less interest in accessing the notes made by the clinician. On the other hand, these individual limitations could also serve as an argument in favor of ORA: ORA offers the opportunity to enhance understanding of the patient-clinician relationship [36]. It can contribute to mitigating the mentioned disadvantages of inequities by extending the therapeutic interaction beyond physical encounters into the digital space where patients may feel less pressured to conform with the HCP and may also express themselves more easily than in the physical space. However, it is crucial that the clinical notes are written in a language that is relatable to everyday life and nonjudgmental [8,37]. This allows patients to reread and better understand the content discussed during previous appointments in preparation for an upcoming one. Furthermore, a messaging or commenting feature enables patients to ask questions or gather any unresolved concerns. Nonetheless, concern about being emotionally burdened by reading the notes was a common reason for deciding against ORA. Remarkably, these fears correspond with those expectations of HCPs, even though they were rarely confirmed after adopting ORA [3,7,8,12].

These arguments raise the question of whether patients with SMI, who experience daily limitations due to their symptoms, should be informed about the potential benefits of ORA in a more specific or repeated manner, and whether such adapted and improved information could potentially modify the approval rate. On the other hand, it might be that just the opposite is the case and that providers are particularly reluctant to share notes with this population and do in fact not routinely discuss open notes or encourage their clients to read them [38,39]. Unfortunately, this issue did not emerge from our data and further research is needed to clarify this question.

Then there is a group of patients who reject ORA because they already feel well taken care of in face-to-face interactions for various reasons. Studies examining the willingness to adopt digital health services explain the preference for direct patient contact, among other factors, through personality traits [34]. Extraversion, in particular, is considered a predictor of a lower likelihood of engaging with digital health services [40]. Individuals who displayed higher extraversion preferred meeting and connecting with the doctor in person. Some of the statements made by the participants convey a certain persistence in favor of nondigital means of communication (see subcategory "Sufficient oral 'transmission' of notes" in Table 2). In line with this, other findings indicate that personality traits associated

with resistance to change and openness to new experiences result in a lower adoption of digital health services [41]. Therefore, it would be interesting for further research to explore whether these corresponding personality traits align with the thematic trends found in our study. Beyond these considerations, the attitude of rejecting ORA seems to be explained in particular by the fact of enduring SMI. On the one hand, the hope of indirectly positively influencing one's own mental health through ORA may be reduced due to the length or severity of the course of illness [34]. On the other hand, in the examined health care system for individuals with SMI, assuming they are in a phase of predominant psychological stability, treatment contacts are rare (approximately 1-2 sessions of 15 minutes each in 3 months). As a result, the opportunities for exchange and the scope of exchangeable content through ORA are limited from the perspective of the surveyed patients [42]. However, it is worth noting that precisely because appointments are short and there are potentially many topics to be discussed (current status of well-being, medications, laboratory results, medication levels, etc), ORA could provide patients with SMI with more space to exchange a wide range of information at a later time and overall enhance the therapeutic contact beyond the physical encounter.

Other participants expressed their rejection of ORA by explaining that the burden of their mental illness in their everyday lives was already substantial, leading them to decline any additional confrontation beyond their appointments at the outpatient clinic. This aspect seems to correspond with the preceding factor, suggesting that these patients are currently unable to dedicate any further (mental) capacity to engage with their chronic mental condition beyond medical appointments.

Comparison of Acceptance and Rejection of ORA

When comparing the reasons provided by patients for or against the use of ORA, several interesting contrasts become apparent. While some reasons for approval can be interpreted as a desire to deepen the therapeutic relationship, the opposition, in certain cases, stems from the apprehension that this therapeutic alliance may be undermined and jeopardized through the introduction of control (refer to subcategory "Trust does not require control" in Table 2). Conversely, patients who embraced ORA described a high need for control, which motivates their use of ORA. Accordingly, the use of ORA is perceived as an opportunity to critically review the HCP's perspective and documentation, rather than blindly trusting them (see subcategory "Needing to verify the correctness of the notes in order to be able to trust the clinician" in Table 2). The disclosure of notes, in the optimal scenario, can thus be regarded as a demonstration of trust that allows for a deepening of the therapeutic relationship [42].

Another theme that underlies both the approval and rejection of ORA is the use of health data by third parties. This issue raises concerns about data security and the potential for unwanted control by family members when sharing information with significant others, health care providers, and public institutions. It is important to note that privacy and trustworthiness are among the most common reservations regarding ORA and digital (mental) health interventions in general, given the sensitive and potentially stigmatizing nature

of the content involved [16,34,43]. A recent study conducted in Sweden provides evidence that these reservations are valid, as patients with mental illness experience significantly more attempts by unauthorized individuals to access their mental health records compared to patients in general health settings [44]. In our study, 1 patient expressed the misconception that health data are directly stored on their mobile phone. This misunderstanding highlights a knowledge gap where patients may not be aware that the data are actually securely stored remotely using 2-factor authentication, thereby aiming to prevent unauthorized access through the phone. However, the concerns expressed in our study once again emphasize the importance of data protection in the implementation of digital health platforms and the need for sufficient patient and provider education on this matter.

Differences Between Patient Groups

Generally, the proportion of patients willing to use ORA is approximately 60%, which is consistent with findings from previous studies [19,43,45]. However, the actual usage rate of ORA among patients is expected to be even lower [18]. The 2 groups, those in favor and those against ORA show little difference in terms of age, gender, distribution of diagnoses, and comorbidity, except for psychotic and depressive disorders. The higher levels of agreement and motivation among patients with depression align with findings from other studies [43,45], possibly due to a higher prevalence of socially desirable behavior in this patient group. The low approval rate among patients with schizophrenia is somewhat surprising compared to the existing literature. According to previous studies, patients with psychosis are generally very well able to use web-based interventions, exhibit positive attitudes toward them, and use the web-based more frequently to build their social networks compared to the general population [46-48]. The rejection of ORA in our study population could be attributed to reduced digital literacy, functional impairments caused by psychotic symptoms, as well as an approach to the illness characterized by internalized stigma and social withdrawal [49]. This social withdrawal has also been described as a protective mechanism against overly social and open interactions [50].

Strengths and Limitations

This is the first study that examines the reasons for the acceptance and rejection of ORA among patients with SMI in the German health care system. The investigation of these factors is crucial for advancing the implementation of ORA in the German-speaking region and can only be meaningful through a comparison with international research findings. Moreover, the study contributes to filling the research gap regarding the perspectives of individuals with SMI toward ORA.

One limitation of the study is that while a variety of reasons for rejecting ORA became apparent in the qualitative survey, raising further questions about factors such as digital literacy or the respondents' social behavior, these factors were not explored in the quantitative survey. Similarly, comprehensive sociodemographic information such as educational level, socioeconomic status, or duration of mental illness was unfortunately not available in the data corpus. A follow-up study may be useful to further validate the qualitative data and to

analyze in-depth the role of other patient characteristics that contribute to the decision for or against ORA.

Another limitation of the study is that it did not present the proportion of patients who actually used ORA after having consented to do so. Since this study is based on baseline data from the PEPPSY study [21], the analysis of usage patterns and effects of ORA is yet to be conducted. Another issue at first glance is the dichotomization of the results (see Table 2). The question arises as to how any positive attitudes of patients who reject ORA (and vice versa) were taken into account. For instance, patients who opt for ORA may still hold concerns regarding data privacy. However, this limitation was addressed by incorporating any sub-aspects of patient statements that are in opposition to their decision for or against ORA in the qualitative analysis of the data. This means that all patient statements and attitudes toward ORA were accounted for in our qualitative analysis independently from the patients' decisions for or against ORA.

Future Research

In addition to the research gaps identified above, further research is needed to address the unique needs of individuals with SMI in order to effectively facilitate maintained engagement with ORA. First, the extent to which patient characteristics and, in particular, psychiatric functional impairments, as well as concepts such as internalized stigma and social withdrawal, influence acceptance of ORA should be investigated further. Possible influences of personality traits such as extraversion or resistance to change on willingness to use ORA should also be considered.

Second, it should be investigated to a larger extent, whether the fear of possible adverse effects from reading the findings and clinical notes made available via ORA is confirmed in practice. Although studies to date tend to suggest otherwise, patients' concerns should be taken seriously. In this context, research should be conducted on how to formulate clinical notes in a way that is both understandable and empathetic to patients without overburdening the available resources of practitioners. In this respect, there are preliminary indications of promising use of generative language models [51].

Third, there is no evidence on what cues, explanations, or motivations patients with SMI need from the medical team, and especially from their clinicians, to want to use ORA more. In this context, it should be investigated whether improved patient information about the benefits of ORA increases adoption rates. At the same time, there seems to be a need to explore what skills HCPs need to acquire in order to formulate clinical notes in a way that is understood by patients and adds value, which involves adapting their communication style to align with patients' familiar vocabulary rather than relying solely on technical medical terminology. Finally, actual rates of ORA use among patients with SMI compared to adoption rates and reasons for potential discrepancies should be explored.

Conclusions

In general, patients with affective disorders (ICD 10, F3) showed high interest in ORA, whereas patients with schizophrenia, schizotypal and delusional disorders (ICD 10, F2) were less interested. It was mainly female patients of younger (18-39 years) and middle (50-59 years) age who agreed to receive ORA. Acceptance of ORA by patients with SMI stems primarily from a desire to be more actively involved in their care, to have a comprehensive view of their treatment process, and to evaluate the accuracy of physicians' perception and documentation of their needs. This critical perspective is also seen as an opportunity to address and correct any misunderstandings that may have occurred during the consultation. The value placed on access to personal health information, combined with the ability to share that information with third parties, underscores the patients' positive attitudes toward ORA.

Rejection of ORA by patients with SMI is primarily motivated by a sense of already being well supported by face-to-face interactions, as well as concerns rooted in their own insecurities. These range from fear of being unsettled by reading clinical notes to avoidance of excessive confrontation with one's condition outside of the therapeutic conversations. Patients worry that the transparency created by ORA could undermine trust in their health care providers, especially given the additional workload for clinicians. Finally, data security risks and practical barriers such as lack of digital literacy and incomprehensible medical jargon contributed to the decision not to use ORA.

Acknowledgments

This study was funded by the Brandenburg Medical School publication fund supported by the German Research Foundation and the Ministry of Science, Research and Cultural Affairs of the State of Brandenburg. ST received internal clinical scientist funding by the Brandenburg Medical School.

Authors' Contributions

JS and ST contributed to the study design and collected the data. KN, ST, and JS conducted data analysis. JS and ST wrote a first draft. EMD translated the study into the English language. Successive drafts were revised by EMD and YE. All authors critically reviewed and commented on the study.

Abstract

Background: Integrating innovative digital mental health interventions within specialist services is a promising strategy to address the shortcomings of both face-to-face and web-based mental health services. However, despite young people's preferences and calls for integration of these services, current mental health services rarely offer blended models of care.

Objective: This pilot study tested an integrated digital and face-to-face transdiagnostic intervention (eOrygen) as a blended model of care for youth psychosis and borderline personality disorder. The primary aim was to evaluate the feasibility, acceptability, and safety of eOrygen. The secondary aim was to assess pre-post changes in key clinical and psychosocial outcomes. An exploratory aim was to explore the barriers and facilitators identified by young people and clinicians in implementing a blended model of care into practice.

Methods: A total of 33 young people (aged 15-25 years) and 18 clinicians were recruited over 4 months from two youth mental health services in Melbourne, Victoria, Australia: (1) the Early Psychosis Prevention and Intervention Centre, an early intervention service for first-episode psychosis; and (2) the Helping Young People Early Clinic, an early intervention service for borderline personality disorder. The feasibility, acceptability, and safety of eOrygen were evaluated via an uncontrolled single-group study. Repeated measures 2-tailed *t* tests assessed changes in clinical and psychosocial outcomes between before and after the intervention (3 months). Eight semistructured qualitative interviews were conducted with the young people, and 3 focus groups, attended by 15 (83%) of the 18 clinicians, were conducted after the intervention.

Results: eOrygen was found to be feasible, acceptable, and safe. Feasibility was established owing to a low refusal rate of 25% (15/59) and by exceeding our goal of young people recruited to the study per clinician. Acceptability was established because 93% (22/24) of the young people reported that they would recommend eOrygen to others, and safety was established because no adverse events or unlawful entries were recorded and there were no worsening of clinical and social outcome measures. Interviews with the young people identified facilitators to engagement such as peer support and personalized therapy content, as well as barriers such as low motivation, social anxiety, and privacy concerns. The clinician focus groups identified evidence-based content as an implementation facilitator, whereas a lack of familiarity with the platform was identified as a barrier owing to clinicians' competing priorities, such as concerns related to risk and handling acute presentations, as well as the challenge of being understaffed.

Conclusions: eOrygen as a blended transdiagnostic intervention has the potential to increase therapeutic continuity, engagement, alliance, and intensity. Future research will need to establish the effectiveness of blended models of care for young people with complex mental health conditions and determine how to optimize the implementation of such models into specialized services.

Introduction

Background

The evolution of specialist early intervention services for youth represents a major global reform of mental health services [1-3]. However, there are shortcomings that remain to be addressed for these services to fully deliver on their promise; for example, 42% of young people drop out of treatment by the third therapy session [4], indicating low engagement rates with early intervention services [5]. Furthermore, those who continue treatment receive time-limited support [6], and up to 80% of young people with severe mental health conditions will incur repeated relapses, leading to long-term disability and high societal cost [7,8]. Estimates suggest that the cost associated with recurring mental ill-health is up to 5 times that of nonrelapsing presentations [9]. Even when young people receive evidence-based treatment, its effectiveness is limited [10]; for example, between one-third and two-thirds of young people do not experience symptom reduction [11], and functional impairment often remains an issue after remission [12].

Digital technologies have the potential to address these challenges and limitations by enhancing the accessibility, impact, reach, and cost-effectiveness of youth mental health (YMH) services [13,14]. Many young people, recognizing their need for help, are turning to technology, including smartphone apps, websites, and social media, to self-manage their mental well-being [15]. Research findings support the efficacy of digital mental health interventions in improving treatment outcomes in severe mental health conditions such as psychosis [16-18] and borderline personality disorder (BPD) [19]. Web-based treatment programs have also demonstrated efficacy comparable to that of face-to-face psychotherapy [20-22], and self-guided smartphone-based mental health interventions are proving to be promising self-management tools for depression and anxiety symptoms [23].

However, despite the evidence for the effectiveness of digital interventions, limitations have also been reported, such as high attrition rates [24,25], a focus on mild to moderate mental health conditions [26-28], a focus on single disorders ignoring potential comorbidity [29], and a lack of integration within clinical settings [30,31]. Factors affecting attrition and dropout from digital interventions have been identified, such as a lack of personalization within digital interventions and severe mental disorders hampering engagement with interventions [32]. Most of the first generation of digital interventions have also been deployed and evaluated without face-to-face care, generating a divide between face-to-face and digital supports [33]. Furthermore, clinical trials of digital interventions often recruit

highly motivated early adopters from the community, resulting in poor generalizability of the findings in clinical settings [33,34].

Blended care refers to treatment that includes face-to-face and digital elements, both of which contribute to the treatment process and can be integrated or offered sequentially [35,36]. Blended models of care offer an innovative approach to address the limitations of both face-to-face and digital therapy for young people with serious mental illness, while maintaining the strengths of both modalities [36,37]. This integrated approach is in line with World Health Organization recommendations [38] and young people's preferences, as well as national and international calls for the integration of web-based and in-person mental health services [39]. Young people have indicated that blended models of care could enhance clinical care by increasing accessibility and continuity of care, providing access to posttherapy support, and strengthening the relationship with their clinician [40]. However, despite young people's preferences and calls for the integration of face-to-face and web-based services [16,41], current mental health services rarely provide this type of integrated web-based support [42]. Barriers to implementing digital interventions in clinical settings have also been identified, such as a lack of time for clinicians and skepticism toward digital interventions [43], and these need to be taken into account when developing blended interventions. Furthermore, there is limited research testing blended models of care as a treatment approach [37,44], despite the demonstrated efficacy of stand-alone digital interventions [45-47].

Furthermore, transdiagnostic interventions that target underlying mechanisms or symptoms that are common across multiple mental disorders have the potential to provide more effective, personalized, and engaging treatment, addressing comorbidity and being applicable to a wider range of young people [48,49]. Evidence also suggests that transdiagnostic interventions may be at least as effective, more engaging, and easier to scale up in real-world clinical settings compared with single-disorder interventions [50,51].

As blended transdiagnostic interventions for first-episode psychosis and BPD have not yet been evaluated, a 3-month pilot evaluation of a blended transdiagnostic digital intervention (eOrygen) designed to enhance the accessibility, responsiveness, and impact of face-to-face specialized YMH clinical services for youth psychosis and BPD was carried out. Pilot studies are an important first step before running a full-powered clinical trial because they focus on whether an intervention can be carried out, whether it would be worth proceeding with it, and how to proceed before focusing on evaluating the effectiveness of the intervention [52].

Objectives

The primary objective of the eOrygen pilot was to evaluate the feasibility, acceptability, and safety of an integrated web-based clinic that blends moderated online social therapy (MOST) support with face-to-face specialized YMH clinical services for youth psychosis and BPD. A secondary aim of the pilot was to assess changes in key clinical and psychosocial outcomes for young people from the point of enrollment in eOrygen to after the intervention. Furthermore, the failure to integrate digital technologies into routine practice is well documented [53], and, therefore, an additional objective of this study was to understand young people's and clinicians' experiences of barriers and facilitators to using a blended model of care in clinical practice.

Methods

Study Design

This was a 3-month multisite pre-post single-group pilot study conducted at the Early Psychosis Prevention and Intervention Centre (EPPIC) and the Helping Young People Early (HYPE) Clinic at Orygen Youth Health in Melbourne, Victoria, Australia. EPPIC provides services for young people aged 15 to 25 years experiencing their first episode of psychosis, and admission to the service is based on a clinical assessment determining the presence of full-threshold first-episode psychosis, including full-threshold psychotic symptoms such as hallucinations, delusions, or formal thought disorder [54]. The HYPE Clinic offers an early intervention program for young people aged 15 to 25 years with BPD, and intake to the service is based on meeting ≥ 3 BPD criteria according to the *DSM-5 (Diagnostic and Statistical Manual of Mental Disorders [Fifth Edition])* Text Revision [55]. These services deliver specialized early interventions, with treatment offered from 6 months to a maximum of 2 years. Each young person at Orygen Youth Health receives case management by a dedicated mental health clinician, with additional assessment and treatment support provided by a psychiatrist. Each year, approximately 155 young people access HYPE Clinic services, and approximately 250 young people access EPPIC services.

Sample Size

It is recommended that the sample size of a pilot study be approximately 10% of the sample size projected for the larger parent study [56]. At present, there is little definitive research available to determine the sample size of the larger parent randomized controlled trial for a transdiagnostic blended model of care, hence the importance of conducting this pilot feasibility study. In a recent study using the same technology, a total sample of 140 participants was determined to detect changes in social functioning at 90% power, accounting for attrition of 20% [57]. Given this, we proposed to recruit 25 clinicians and 1 to 2 young people per clinician, resulting in an anticipated 25 to 50 young people in the study.

Ethics Approval

Ethics approval was obtained from the Melbourne Health Human Research Ethics Committee (HREC/49492/MH-2019).

Participants and Procedure

The participants were 18 mental health clinicians and 33 young people recruited by participating clinicians and the Orygen research team across HYPE Clinic and EPPIC clinical services. Clinician recruitment took place over a 2-month period, and the recruitment of young people took place over a 4-month period from May 15 to September 25, 2020.

Young People

Inclusion and Exclusion Criteria

Young people were recruited via their clinician and the research team. Clinicians within each service were invited to identify potentially eligible young people based on the following criteria: (1) aged 15 to 25 years (inclusive), (2) currently receiving treatment at the HYPE Clinic or EPPIC, (3) engaged with treatment as judged by the treating clinician and not approaching discharge from service, (4) willing to nominate an emergency contact person, (5) have regular and ongoing internet and telephone access, and (6) able to give informed consent and comply with study procedures. The exclusion criteria were as follows: (1) young people with an intellectual disability who were unable to meet the cognitive demands of the web-based intervention, interfering with the likelihood of benefiting from the intervention as judged by their treating clinician; and (2) young people with an inability to converse in, or read, English. There were no specific exclusion criteria related to level of suicide risk or interpersonal hostility (ie, a consideration for harm to self or others while engaging within a web-based social network). However, clinicians were consulted on a case-by-case basis regarding participant suitability, and clinician judgment regarding suitability could be reassessed at any time. The exclusion criteria for the pilot study were kept to a minimum both to facilitate the recruitment process and to ensure that the intervention was tested and adequately mirrored the real-world characteristics of the broad population of young people accessing specialist YMH services. Furthermore, to mirror the intended real-world implementation of eOrygen, these exclusion criteria were assessed and monitored by the participating clinicians.

Recruitment Process

Once eligibility was determined, eligible young people were invited to participate in the study by the research team. Among the HYPE Clinic clients, of the 106 young people who were assessed for eligibility for this study, 42 (39.6%) met the inclusion criteria; however, 23 (55%) of these 42 young people could not be approached because of their involvement with another research study. Thus, 19 young people were approached to participate, and 15 (79%) agreed to participate and enrolled in the study, whereas 4 (21%) declined. Of the 106 young people assessed for eligibility, 64 (60.4%) were ineligible to participate in this study owing to clinical risk, poor engagement with treatment, a lack of access to technology, age, or because they were approaching discharge.

Among the EPPIC clients, of the 59 young people who were assessed for eligibility, 43 (73%) met the inclusion criteria; however, 3 (7%) of these 43 young people were already participating in another research study. Thus, 40 young people

were approached to participate, and 20 (50%) agreed to participate, whereas 11 (28%) declined, and 9 (23%) could not be contacted by the research team. Of the 20 young people who agreed to participate, 2 (10%) could not be contacted to complete their baseline assessments and did not enroll in the study; the remaining 18 (90%) enrolled in the study. However, of these 18 young people, 7 (39%) were lost to follow-up during the study period ($n=3$, 43% before onboarding to the eOrygen platform and $n=4$, 57% before completing the 3-month follow-up assessments). The young people lost to follow-up were unresponsive to telephone calls and messages from the research team but were still engaged with face-to-face treatment with their clinicians. Of the 59 young people assessed for eligibility, 16 (27%) were ineligible to participate in this study for the same aforementioned reasons.

Participant consent was obtained from those interested in participating and parental or guardian consent was also obtained for young people aged <18 years.

Assessments

The consenting young people were contacted at baseline via email and telephone to complete baseline measures before setting up their eOrygen user account. The young people then continued treatment with their clinician while having access to the eOrygen platform for 3 months. They were contacted again at the end of the 3-month intervention to complete the postintervention assessments.

During postintervention follow-up telephone call assessments, the young people were asked whether they were willing to be contacted for a subsequent qualitative interview, and 19 (58%) of the 33 young people agreed to be followed up. After the intervention phase, a randomly selected subgroup comprising 12 (63%) of the 19 young people who agreed to be contacted were invited via SMS text messaging to participate. These semistructured qualitative interviews were designed to explore their experiences with the eOrygen platform. The primary goal of these interviews was to identify both barriers and facilitators to their engagement with the intervention.

Of the 12 young people approached after the intervention, 1 (8%) declined to participate (no reason provided), and 2 (17%) agreed to participate but did not attend the scheduled interviews and were not able to be contacted; thus, 9 (75%) participants successfully completed the interview process. However, a technical issue resulted in a recording failure during 1 (11%) of the 9 interviews, and it could not be included in the subsequent analysis.

The interviews were all conducted via Zoom (Zoom Video Communications, Inc), and interview times ranged from 22 to 38 minutes. Participants were recruited and interviewed by a study research assistant and author EC. Interview questions were underpinned by a user-centered design approach [24] and focused on the following aspects: what initially interested participants about using the eOrygen platform; the experience of onboarding; hopes and expectations; barriers and facilitators; and the overall experience of the therapy journeys, clinical and peer support, and community features of the platform.

Clinicians

All mental health clinicians employed at the HYPE Clinic and EPPIC were eligible for inclusion in this study. Clinicians attended a workshop focused on learning about the background of the intervention, including previous empirical findings using the same technology and how to use the eOrygen platform. The latter aspect concerned how to use the intervention functions and set up an account, with suggestions provided on how to integrate this into the clinicians' work with young people, with the possibility of using it within and between face-to-face sessions as they felt appropriate. This included clinical case studies that applied to the populations of both HYPE Clinic and EPPIC services and were coauthored by clinicians at these services. Clinicians were also provided a training manual that was used to help them navigate the platform during the workshop and also to keep and reuse as necessary when navigating the intervention platform independently. As the workshop was held before recruiting young people to the study, clinicians were provided with a training video at a later date describing once again how to use the intervention platform features.

Eligible clinicians were then invited to identify eligible young people who met the aforementioned inclusion criteria. All participating clinicians had at least 1 young person using the eOrygen platform. The clinicians were contacted via email at baseline to complete the clinician-rated measures. They were then invited to use the eOrygen platform with their clients for 3 months. At the end of the intervention, they were contacted again via email to complete the postintervention clinician-rated measures.

After the postintervention phase, an invitation was extended to all 18 clinicians to participate in a structured focus group session. The aim of this session was to delve into the obstructive and conducive factors influencing the effective implementation of the eOrygen platform into routine clinical practice. This evaluative process was grounded in the Consolidated Framework for Implementation Research (CFIR), a recognized and widely used framework for assessing the determinants influencing implementation in health care settings [58]. The interview schedule was designed by author LV and based on the CFIR constructs that were identified via both formal and informal consultation with the specialist service settings throughout the intervention period. Among the notable constructs under consideration were those related to evidence, adaptability, complexity, needs and resources, and self-efficacy.

Clinicians were invited via email and supported by their line managers to attend. Of the 18 clinicians, 15 (83%) were available to participate in the focus groups that were conducted over Zoom. Because of the number of clinicians available to participate, the focus groups were divided into 3 distinct sessions to facilitate more extensive discussions and allow individual clinicians ample opportunity to share their insights and experiences. Authors LV, DC, and EK each conducted 1 of the 3 parallel sessions.

Intervention: eOrygen

The eOrygen intervention was based on Orygen Digital’s MOST model, which was the first digital solution to offer continuous integrated face-to-face and digital care to young people across the mental health diagnostic and severity spectrum and stages of treatment [59-61]. In partnership with young people, the MOST model was iteratively developed by a multidisciplinary team of researchers, clinical psychologists, programmers, creative writers, graphic artists, and experts in human-computer interaction [61-63]. A recent clinical trial with young people with psychosis demonstrated that an intervention based on the MOST model was effective in improving vocational and educational outcomes as well as reducing the use of emergency services; in addition, it was cost-effective, with evidence of a dose-response effect [60,64,65].

The eOrygen intervention was a purpose-built web-based platform designed to integrate face-to-face and web-based support for young people experiencing mental ill-health (Figure 1). This was achieved through the use of both clinician and young person user accounts, making it possible for young people and their treating clinician to use the platform throughout the treatment process, during their face-to-face sessions or between sessions. Young people could also use the platform in a self-directed way, but no automated prompts or reminders were provided for young people to use eOrygen between sessions, unless clinicians made suggestions to their young clients using the platform.

The platform was designed to enhance, not replace, recommended treatments for mental health conditions (eg, clinician-administered cognitive behavioral therapy). eOrygen comprised interactive user-directed psychosocial interventions (*therapy journeys*), a social network, clinical moderation, and peer support.

Therapy journeys comprised collections of *therapy activities* relating to different themes. Themes related to the treatment of

mental ill-health, such as managing social anxiety, anxiety, and depression, as well as social functioning. Users were assigned a suggested *therapy journey* based on their responses to a questionnaire they completed after being onboarded to the eOrygen platform, providing personalized content specific to their individual mental health concerns (Figure 2). Users could complete multiple *therapy journeys*, and clinicians or young people could change the assigned journey.

Therapy activities could be accessed as part of a *therapy journey* or as stand-alone activities via the *explore* function. The *explore* function enabled young people to use a search bar to locate therapy content of interest, and eOrygen clinicians could also recommend personalized content to young people using this function. *Therapy activities* included *activities*, *comics*, *talking points*, and *actions*. *Activities* comprised written content, and *comics* comprised storyboard panels focusing on a particular therapeutic theme and target related to the treatment of mental ill-health challenges. *Talking points* enabled participants to propose a solution to identified problems (eg, how to incorporate mindfulness into everyday activities), which encouraged social problem-solving and effective peer modeling. *Actions* were behavioral prompts that young people could complete to translate learning on a mental health topic into behavior change.

The eOrygen *social network* was moderated by trained peer workers, who were young people who had a lived experience of mental illness. The *social network* included a community newsfeed and individual profile pages where participants and peer workers could create *posts* to share thoughts, information, pictures, and videos (Figure 3). They could also respond to other users’ posts through *comments* or *reactions*. *Reactions* were designed to facilitate social support (eg, “I get you” and “Thinking of you”). Likewise, *talking points* were designed as collaborative spaces to discuss specific topics by leaving *comments*. Young people were also able to receive direct support from peer workers and clinicians on the platform via private *messages*.

Figure 1. eOrygen as a blended model of care.

Figure 2. eOxygen therapy journey.

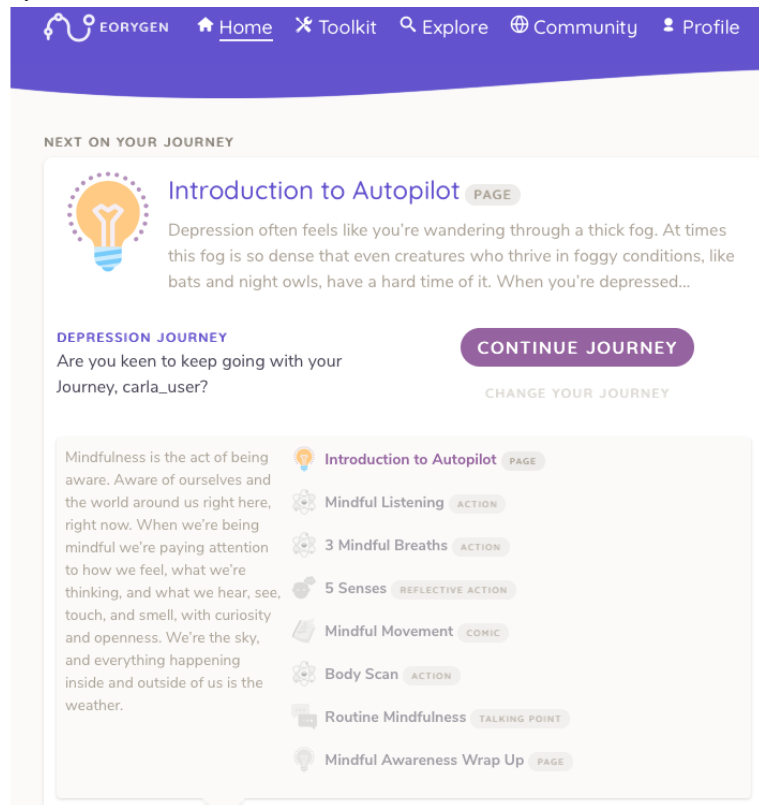

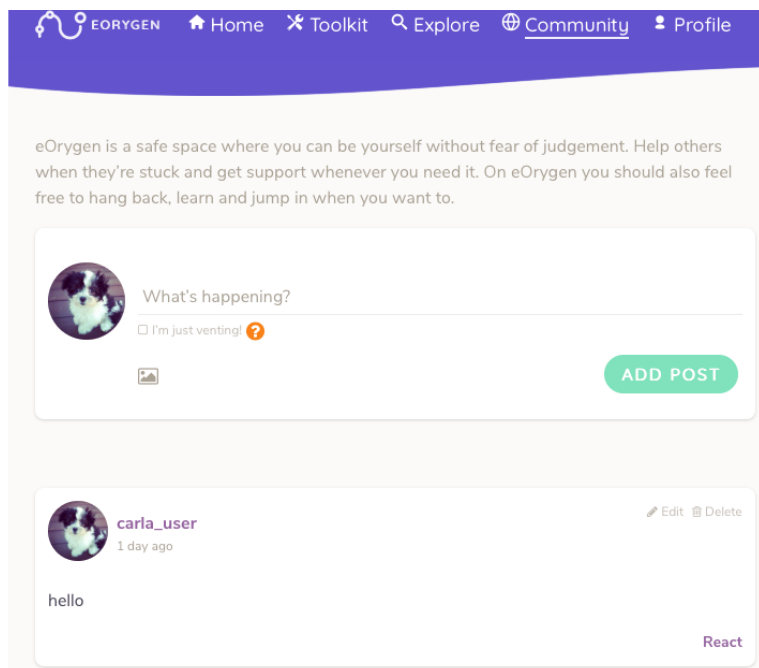

Figure 3. eOxygen social network.

Outcome Measures

Feasibility

The feasibility of eOxygen was measured by tracking recruitment to the study, which is in line with other studies testing the feasibility of digital interventions [66]. Although no a priori minimum or maximum number of participants per clinician or per clinic was specified, to accurately assess feasibility, we anticipated recruiting approximately 15 clinicians from EPPIC

and 1 to 2 young people per each participating clinician as well as 10 clinicians from the HYPE Clinic and 1 to 2 young people per clinician.

Feasibility was indicated if (1) the recruitment goal was met and (2) the participant refusal rate was <50%. If the recruitment goal was not met after 2 months of recruitment, barriers to recruitment were to be identified.

Acceptability

Intervention acceptability was measured via responses to a feedback questionnaire. The pilot was considered to indicate acceptability of the eOrygen intervention if at least 90% of the young people reported that they would recommend it to others, which is in line with a previous pilot study testing the acceptability of a digital mental health intervention [59].

Safety

Intervention safety was measured by analyzing reports of any adverse events, tracking the security of the web-based system, and analyzing responses to a feedback questionnaire, following a similar protocol for a previous study [7,67]. An adverse event was defined as any unfavorable or unintended sign, symptom, or disease temporally associated with the use of the intervention, whether or not it was related to the intervention. A serious adverse event was defined as any untoward medical occurrence that could be life threatening, result in death, require inpatient hospitalization, or result in persistent or significant disability. All participants were closely monitored by clinical moderators for adverse events and serious adverse events. The research team members were trained in study procedures, including adverse event assessments, and attended good clinical practice training. In addition, treating clinicians were asked to report any adverse events, including suicide attempts and serious self-harm, to the research team.

The pilot was considered to indicate the safety of eOrygen if (1) there were no unlawful entries recorded in the eOrygen system during the pilot, (2) no young people experienced a serious adverse event as a result of their engagement with the system during the 3-month intervention period, (3) at least 95% of the young people reported it to be safe via the feedback questionnaire, and (4) clinical and social measures did not show a worsening pattern over the course of the study.

Safety was also reported by assessing pre-post changes in BPD symptomatology for HYPE Clinic participants as measured by the 23-item version of the Borderline Symptom List [68], and pre-post changes in psychotic symptoms for EPPIC participants as measured by 3 items of the expanded Brief Psychiatric Rating Scale (version 4.0), including suspiciousness, hallucinations, and unusual thought content [69].

Potential Clinical Effects

Potential clinical effects were assessed by measuring pre- to postintervention changes in clinical and psychosocial outcomes at baseline and at 3 months. Clinician-rated measures included social and occupational functioning as measured by the Social and Occupational Functioning Assessment Scale [70] and therapeutic alliance (TA) as measured by the Working Alliance Inventory–Short Revised (therapist version) [71].

Young people self-report measures included depression as measured by the Patient Health Questionnaire-9 [72]; TA with their face-to-face clinician as measured by the Working Alliance Inventory–Short Revised (client version) [73]; psychological well-being as measured by the Flourishing Scale [74]; self-determination as measured by the Basic Psychological Needs Satisfaction Questionnaire [75]; loneliness as measured

by the University of California, Los Angeles Loneliness Scale (version 3) [76]; social isolation as measured by the Friendship Scale [77]; social anxiety as measured by the Social Interaction Anxiety Scale [78]; stress as measured by the Perceived Stress Scale [79]; and psychological distress as measured by the 10-item Kessler Psychological Distress Scale [80]. These measures have been validated in a youth population and were chosen for their demonstrated reliability. All baseline measures were completed before onboarding participants to the eOrygen platform, and all assessments were completed via Qualtrics (Qualtrics International Inc) where possible or otherwise administered by a research assistant over the telephone.

Satisfaction Survey Feedback

Purpose-designed questionnaires administered via Qualtrics were used to assess user satisfaction and user feedback.

Statistical Analyses

Overview

This study used a mixed methods design involving both quantitative and qualitative data, which allowed for a more robust analysis [81]. Quantitative data assessing the feasibility, acceptability, safety, and potential clinical effects of the intervention were measured at baseline and at 3-month follow-up. Qualitative data were used to assess young people's and clinicians' barriers and facilitators to implementing eOrygen within clinical services, which enhanced our understanding of the feasibility and acceptability aspects of the intervention and provided valuable information for designing a full-powered trial that would have not been achieved through quantitative data strands alone.

Quantitative Analyses

Chi-square tests showed no differences between the clinical sites in baseline demographic and clinical and psychosocial outcomes. Therefore, data were pooled, repeated measures 2-tailed *t* tests were conducted, and within-group effect sizes (Cohen *d*) were reported for changes in pre- to postintervention scores on effectiveness outcome measures. Parametric and nonparametric correlations were conducted to explore the association between the use of eOrygen and the degree of change between before and after the intervention on effectiveness outcome measures, but no relationships between use and effectiveness outcomes were found.

Aggregated data from the user satisfaction questionnaire and descriptive statistics from insights into using eOrygen were reported as exploratory findings. The data for the acceptability criterion of whether young people would recommend eOrygen to others were derived from insights into eOrygen descriptive statistics. The data for 1 of the safety criteria regarding whether young people felt safe using eOrygen were derived from the user satisfaction questionnaire. Statistical analyses were performed using SPSS (version 27.0; IBM Corp).

Qualitative Analyses

Young People

Given the user-centered design approach, thematic analysis was considered the most appropriate method of data analysis [82].

The data analysis was conducted by author EC under the supervision of author LV.

The analysis process used an inductive approach in which EC explored young people's experiences for factors relating to barriers and facilitators to young people's engagement with the blended model of care. To gain familiarity with the data set, the interview transcripts were read and reread. Subsequently, initial codes were applied to the transcripts to identify relevant factors to engagement. Any recurring codes, both within and across different transcripts, were identified and recorded.

Following the principles of thematic analysis, these codes were then grouped into preliminary themes and subjected to thorough review in relation to all other identified themes. Some themes were identified as superordinate, representing broader categories of experience, whereas others assumed subordinate positions, delineating into subthemes.

Clinicians

Three focus groups were conducted by authors DC, EK, and LV with 15 service clinicians overall. Focus groups comprised a mix of both HYPE Clinic and EPPIC clinicians and lasted between 31 and 44 minutes. Interview questions were underpinned by the CFIR [58], which is one of the most widely used frameworks for identifying factors impacting implementation outcomes [83]. The CFIR comprises 39 constructs across 5 domains. The domains identified as most relevant to this implementation setting in the preimplementation phase were *inner and outer settings*, *individual characteristics*, and *innovation characteristics*. The clinician focus groups underwent deductive coding by authors JN and LV in accordance with the CFIR. JN and LV then engaged in a rigorous discussion to examine how the attributes within the identified domains acted as either obstacles or enablers to the implementation of eOrygen in this clinical setting.

Use Metrics

Use metrics were used to measure engagement with eOrygen. *Number of active days* was used as an overall metric for platform

use and referred to the number of days a young person accessed eOrygen after completing onboarding until the end of the 3-month intervention period.

Therapy views comprised the number of times a young person opened *therapy activities* via a *therapy journey* or via a search function. Users were encouraged to revisit activities, and repeat views were counted within the number of *therapy views*. *Journey components completed* was a count of the number of unique *therapy activities* a user completed within a *therapy journey*.

Engagement with the social networking component of eOrygen was measured by the *number of posts, comments, and reactions made* by young people on the social network. This included *posts made* on the newsfeed and on individual users' profiles. *Comments made* could be in response to *posts made* by other users or peer workers or *talking point* therapy activities. *Reactions made* could be in response to any post or comment on the social network.

There was also a chat function where young people could communicate with eOrygen staff (clinicians and peer workers) through private direct messages on the platform. Engagement with clinicians and peer workers was measured by the *number of messages sent* (by young people) and the *number of messages received* (from clinicians or peer workers).

Results

Demographics

Participants were aged between 15 and 24 (mean 19.48, SD 2.84) years, and the majority were female individuals (21/33, 64%). Of the 33 participants, 27 (82%) were born in Australia, 7 (21%) spoke languages other than English at home, 3 (9%) identified as Aboriginal or Torres Strait Islander, 9 (27%) were engaged in paid work, and 22 (66%) were studying part time or full time (Table 1).

Table 1. Participants' descriptive statistics (total and by each clinical site).

	Total sample (n=33)	Clinical sites

^cn=29.

^dn=15.

^en=14.

Feasibility

We sought to recruit 25 clinicians; the final number of clinicians enrolled in the study was 18 (78%). The final number of young people recruited was 33 (which exceeded our goal of 1 young person per clinician). We also anticipated that the refusal rate would be <50%, which it was at 25% (15/59).

Acceptability

We exceeded our acceptability goal, with 92% (22/24) of the young people reporting that they would recommend eOrygen to others ([Multimedia Appendix 1](#)).

Safety

There were no unlawful entries recorded on the eOrygen platform during the study, there were no serious adverse events experienced by participants, there was no worsening of clinical and social outcome measures, and 96% (24/25) of the young people stated that they felt safe using the platform ([Multimedia Appendix 2](#)).

In terms of symptom monitoring, the mean score for BPD symptomatology for HYPE Clinic participants reduced from 2.65 (SD 0.75) at baseline to 1.99 (SD 0.83) after the intervention. For the assessment of psychotic symptoms in EPPIC participants, the mean score for suspiciousness reduced from 2.72 (SD 1.64) at baseline to 0.94 (SD 3.78) after the intervention. In addition, the mean score for hallucinations reduced from 2.89 (SD 1.97) at baseline to 1.22 (SD 4.11) after the intervention, and the mean score for unusual thought content reduced from 1.72 (SD 1.13) at baseline to 0.67 (SD 3.74) after the intervention.

Potential Clinical Effects

Significant pre- to postintervention improvements were observed for 9 (82%) of the 11 clinical outcome measures, including social and occupational functioning, depression, psychological distress, social anxiety, social isolation, stress, borderline symptoms, and loneliness, as well as all aspects of therapist-rated working alliance, including goal, task, and bond, with effect sizes ranging from 0.56 to 0.89 ([Table 2](#)).

Table 2. Inferential statistics exploring the differences between before and after the intervention in well-being and mental health symptomology.

	Participants, n	Before the intervention, mean (SD)	After the intervention, mean (SD)	Mean difference (95% CI)	Repeated measures <i>t</i> test (<i>df</i>)	<i>P</i> value	Cohen <i>d</i>

Young People's Satisfaction Survey Feedback

In terms of client feedback, 88% (21/24) of the young people reported that they would use eOrygen again. The top initial reasons of interest in using eOrygen included (1) practicing well-being skills (22/24, 92%), (2) contributing to research (22/24, 92%), (3) receiving support from clinicians (17/24, 71%), (4) connecting with others with similar mental health experiences (17/24, 71%), and (5) learning and well-being

(17/24, 71%). [Multimedia Appendix 1](#) presents a full list of reasons for the young people's use of eOrygen.

In terms of the young people's satisfaction with eOrygen, 96% (23/24) rated it as a positive experience, 88% (22/25) rated it as easy to use, and 83% (20/25) rated it as helpful ([Multimedia Appendix 2](#)).

Engagement

A total of 30 young people were onboarded to eOrygen (n=15, 50% from the HYPE Clinic and n=15, 50% from EPPIC). The mean number of active days on eOrygen was 8.4 (SD 7.5) days; 50% (15/30) of the young people had between 6 and 30 active days, 43% (13/30) had between 2 and 5 active days, and 7% (2/30) had 1 active day (Table 3). Of the 30 young people, 12 (40%) used the platform at least once per fortnight during the initial 6 weeks of the intervention, and 6 (20%) maintained fortnightly access across the entire 12 weeks.

In terms of therapy engagement specifically, 40% (12/30) of the young people viewed ≥ 3 therapy activities, 23% (7/30) viewed 1 to 2 therapy activities, and 37% (11/30) did not view any therapy activities. Half of the onboarded young people (15/30, 50%) began a therapy journey, whereas 40% (12/30) of the participants completed at least 1 journey component (ie, therapy activity within a therapy journey), 20% (6/30) completed 2 to 7 journey components, and 20% (6/30) completed ≥ 10 journey components (refer to Table 3 for a summary of all therapy engagement metrics).

In terms of social network engagement, it was mandatory for the young people to make an introductory post to the community as part of the onboarding process. However, almost half (14/30, 47%) of the young people made at least 1 additional post or comment, whereas 10% (3/30) of them made 2 additional posts or comments, 20% (6/30) of them made 3 to 5 additional posts or comments, and 17% (5/30) of them made >6 additional posts or comments. Furthermore, 47% (14/30) of the young people reacted to at least 1 post or comment on the social network, whereas 27% (8/30) of them reacted to >1 post or comment (refer to Table 3 for a summary of all therapy engagement metrics).

In relation to exchanging private messages with eOrygen staff using the chat function, 47% (14/30) of the young people sent at least 1 message, whereas 13% (4/30) of them sent 1 to 2 messages, 13% (4/30) of them sent 3 to 6 messages, and 20% (6/30) of them sent ≥ 10 messages. By contrast, 97% (29/30) of the young people received at least 1 private chat message from a clinician or peer worker, whereas 37% (11/30) of them received 1 to 3 messages, 37% (11/30) of them received 4 to 9 messages, and 23% (7/30) of them received ≥ 14 messages (refer to Table 3 for a summary of these metrics).

Table 3. User engagement with eOrygen.

Variables, n	All sites (n=30), mean (SD; range)	EPPIC ^a (n=15), mean (SD; range)	HYPE ^b Clinic (n=15), mean (SD; range)
Active days	8.4 (7.5; 1-30)	10.4 (8.6; 1-30)	6.3 (5.7; 1-23)
Therapy views	9.1 (21.5; 0-115)	12.9 (29.2; 0-115)	5.3 (8.5; 0-29)
Journey components completed	6.0 (18.3; 0-100)	9.3 (25.4; 0-100)	2.7 (5.2; 0-18)
Posts and comments made	3.3 (4.3; 1-22)	4.1 (5.4; 1-22)	2.6 (2.9; 1-11)
Reactions made	2.2 (4.3; 0-16)	3.3 (5.1; 0-16)	1.1 (3.1; 0-12)
Messages sent	4.6 (11.6; 0-62)	8.0 (15.8; 0-62)	1.1 (1.8; 0-6)
Messages received	8.1 (11.3; 0-60)	11.1 (15.3; 0-60)	5.2 (3.6; 1-15)

Qualitative Findings

Young People

A thematic analysis of the interviews with the young people was conducted, regarding their experiences with eOrygen, with the aim of identifying facilitators and barriers to their engagement with the platform (Table 4). Facilitators included clinician endorsement, which increased trust in the platform; the presence of peer support workers, fostering a sense of safety and support; a sense of community and connection with other

users; personalized therapy content recommended by clinicians; the use of eOrygen for between-sessions work, supported by follow-up discussions; and an easy-to-use interface. Conversely, barriers to engagement included general low motivation, social anxiety hindering social interactions, privacy concerns, inflexible progression in modules, and periods of limited content and interactions on the platform. Addressing these barriers and leveraging the facilitators can enhance the platform's appeal and effectiveness for a broader range of users seeking mental health support.

Table 4. Facilitators and barriers to young people's engagement with eOrygen as a blended model of care integrated into specialized services.

	Description
Facilitators	
Clinician endorsement	Clinician endorsement of eOrygen seemed to increase young people's trust in the platform. Several participants mentioned that their clinician's recommendation to use eOrygen was central to their signing up to use the platform.
Professional peer support workers	The presence of professional peer support workers on the platform was engaging and increased young people's sense of safety in the community space.
Community, connection, and belonging	Participants appreciated interacting with other young people or sharing space on the platform, even if they did not post much themselves. The sense of community and connection was a facilitator for engagement.
Personalized therapy content	Young people found it helpful when clinicians recommended specific content aligned with their therapeutic work in face-to-face sessions. Therapeutic modules and resources within the platform were seen as valuable, trustworthy, and informative.
Blended care	Young people commonly reported that eOrygen was used for between-sessions work. Follow-up discussions in sessions regarding the <i>homework</i> were described as helpful and valuable for consolidating learning and providing accountability to support homework completion.
Ease of use	When participants found the platform easy to navigate and understand, it positively impacted their engagement.
Barriers	
Low motivation	Several participants mentioned a general lack of motivation as a barrier to engagement.
Social anxiety	Some participants experienced anxiety or insecurity related to social interactions on the platform. This social anxiety acted as a barrier, and participants reported feeling too anxious to post or reply to other young people's posts. Several young people felt anxiety about the perceived lack of clarity regarding the rules of the online community.
Privacy concerns	Privacy and confidentiality concerns were mentioned by some participants, impacting their willingness to engage fully with the platform. Some young people reported that uncertainty about who could see their posts or information raised anxiety. Several young people expressed discomfort at the thought of their face-to-face clinician viewing personal content that they may post on the platform's social network.
Inflexible module progression	One interviewee identified the inability to skip sections or activities within a therapy module as a barrier and requested more autonomy when engaging with therapy modules. Some participants described desiring more flexibility with how they engaged with content, such as wanting to change therapy journeys (eg, from depression to anxiety) but not being able to.
Limited content and interactions	Periods of low activity or limited content being posted by other young people on the platform could lead to reduced engagement. Participants mentioned that the lack of new posts or interactions could be discouraging. More young people and greater interaction was requested by several young people.

Clinicians

The analysis of the clinician focus group grounded in the CFIR identified various barriers and facilitators to the successful implementation and use of the eOrygen intervention (Table 5). Among the notable barriers were the length of the onboarding process for young people, a need for increased confidence in using the platform, and a perceived lack of practical knowledge regarding its features and how these features are related to benefits for young people; in addition, competing priorities,

such as addressing risk and acute presentations amid understaffing, consistently disrupted platform use. Conversely, the platform's positive reputation and alignment with evidence-based frameworks emerged as facilitators. In addition, the ability to access trustworthy content was highlighted as advantageous for clinicians. These findings underscore the multifaceted nature of implementing digital mental health resources and the importance of addressing both barriers and facilitators to optimize their effectiveness.

Table 5. Summary of factors impacting clinician implementation of eOrygen using the Consolidated Framework for Implementation Research (CFIR).

CFIR domain	CFIR construct	Description	Illustrative quote	Implementation impact
Characteristics of individuals	Self-efficacy	Clinicians expressed varying levels of confidence when it came to implementing the intervention. This variance in confidence had a notable influence on their motivation and capacity to use the platform as part of their clinical practice.	"[H]ard when I didn't know exactly what I was prompting them to do sometimes." (Focus group 1)	Barrier
Inner setting	Implementation climate: relative priority	Clinicians frequently cited competing priorities, including concerns related to young people's risk, handling acute presentations, and the challenge of being understaffed, as significant barriers that impeded their ability to engage with, and become familiar with, the eOrygen platform.	"Might've been a little bit me as well of not feeling like I had the time or just forgetting sometimes to just the other priorities I have." (Focus group 3)	Barrier
Outer setting	Young people's needs and resources	Clinicians demonstrated a strong understanding of young people's needs, including the complexities associated with addressing these needs effectively. This encompassed underaddressed comorbid conditions, clinical complexity, and barriers related to motivation and the specific age group within the cohort.	"All the comorbidities...we don't always get to do the, you know, anxiety management stuff or like skills-based stuff as much as, um, I feel like as much as I did in other clinics." (Focus group 3)	Facilitator
Intervention characteristics	Complexity	Clinicians considered the process for connecting and onboarding young people to the eOrygen platform to be lengthier and more in-depth than what young people typically expect when engaging with technology.	"Cause young people want, unfortunately, they want everything now and right there and then. So, if they click and it doesn't work, they'll be like, 'now there's nothing, it's not working.'" (Focus group 3)	Barrier
Characteristics of individuals	Knowledge and beliefs about intervention	Clinicians had positive regard for the eOrygen platform overall. However, their implementation was hindered by a lack of comprehensive knowledge about how the platform practically worked.	"We're all probably a bit limited in thinking about how we're using it." (Focus group 2)	Facilitator and barrier
Intervention characteristics	Evidence strength and quality	Clinicians had the perception that the intervention had a strong evidence base and provided quality information to support young people. However, they also had a limited understanding of which components of the intervention led to effective outcomes.	"I didn't have to go and do my own homework or ensure that I was using like, up-to-date and relevant information." (Focus group 3)	Facilitator and barrier

Discussion

Principal Findings

To the best of our knowledge, this was the first study to test an integrated blended model of care for youth psychosis and BPD in young people aged 15 to 25 years. The results of this study showed that eOrygen was feasible, acceptable, and safe. In terms of feasibility, we anticipated recruiting approximately 25 clinicians and 1 to 2 young people per clinician to the intervention and expected that the refusal rate would be <50%. Our refusal rate was 25% (15/59), which indicated 1 element of feasibility. We sought to recruit 25 clinicians; the final number of clinicians enrolled in the study was 18 (78%). In addition, we recruited 33 young people (which exceeded our goal) to the study over a 4-month period. Although we did not meet our clinician goal, our recruitment took place at the beginning of the COVID-19 pandemic, which proved a difficult period to introduce a new digital intervention to YMH services

and to train clinicians in the use of a new digital platform. Despite these challenges, we still recruited a relatively high percentage of clinicians to the study and exceeded our goal in recruiting young people.

In terms of acceptability, 92% (22/24) of the young people onboarded reported that they would recommend eOrygen to others, exceeding our goal of 90%. Furthermore, 40% (12/30) of the participants used the platform at least once per fortnight during the initial 6 weeks of the intervention period, although only 20% (6/30) maintained fortnightly access across the entire 12 weeks. These findings compare well with another study reporting decreased engagement over time, with retention rates of only 3.9% over 15 days and 3.3% over 30 days for the use of mental health apps in the general population [84]. Although engagement was strong during the first 6 weeks, more strategies are needed to sustain engagement over longer periods. We did not use any strategies in this pilot to promote young people's or clinicians' engagement and left this to the discretion of the

participating clinicians because it was purely an ecological study. Therefore, future studies should implement scalable strategies to sustain engagement for clinicians and young people, such as external support, coaching, and automated prompts or reminders.

Higher engagement rates with eOrygen were also observed for young people attending EPPIC (mean 10.4, SD 8.6 active days) versus those attending the HYPE Clinic (mean 6.3, SD 5.7 active days). To the best of our knowledge, this was the first blended model tested for young people with BPD. The MOST model was originally developed and optimized for young people with first-episode psychosis [57,60,85]. Therefore, lower engagement rates for young people attending the HYPE Clinic could be because the therapeutic model used by clinicians in face-to-face care was slightly different than the content in eOrygen, and the MOST model may need further refinement and optimization for young people with BPD. Research has indicated that young people with BPD are difficult to engage in face-to-face treatment [86-88], and it is possible that this extends to digital mental health care.

In terms of safety, there were no unlawful entries recorded on the web-based platform, no serious adverse events were experienced by participants, and there was no worsening of clinical or social outcome measures during the intervention. We also anticipated that at least 95% of young people would report feeling safe using the platform, and this goal was exceeded with 96% of the participants reporting feeling safe. Our primary findings are also in line with a previous pilot study testing Orygen Digital's MOST platform with real-time clinician-delivered web chat counseling, which found that all acceptability and safety indicators exceeded their a priori established criteria [59].

The secondary outcome variables showed significant pre-post improvements in 9 (75%) of the 12 outcomes assessed. These included borderline symptoms, depression, loneliness, social isolation, social anxiety, stress, psychological distress, social and occupational functioning, and the therapist-reported working alliance. It is important to note that although our study included 2 clinical sites treating young people with complex mental health disorders (eg, psychotic disorders and BPD), there were no significant differences between the sites on outcome variables at baseline. Therefore, improvements in clinical outcomes relate to all participants in the study. The findings also support a previous pilot study (MOST+) that integrated MOST with real-time clinician-delivered web chat counseling [59]. MOST+ also found statistically significant improvements in psychological distress, depression, and stress. However, both studies are single-group pilot studies, and we cannot make causal inferences from the findings because it cannot be determined from uncontrolled studies whether the observed effects are related to the intervention or to external factors such as individual or in-person treatment characteristics. Future research should confirm these findings by conducting controlled studies with larger sample sizes and greater power.

Findings from a recent qualitative study also suggested that blended care has the potential to enhance the therapeutic relationship [40]. The study suggested that the TA developed

through blended care can enhance engagement with both face-to-face and web-based treatment modalities by offering treatment continuity and personalization as well as enhancing therapeutic intensity, which are key areas of concern in the field [24,40]. In our study, we observed statistically significant improvements for therapist-reported TA but no improvements in client-reported TA. Research has also indicated that TA has moderate but reliable correlations with mental health outcomes [89-91]. Although we observed improvements in therapist-rated TA, they did not correlate with improvements in clinical outcomes; therefore, future research should further explore this, along with the importance of client-rated TA in relation to outcomes.

By contrast, qualitative feedback from participants in our study indicated that eOrygen was beneficial when used in a blended way; for example, young people found it helpful when their clinician recommended content to them that aligned with their in-session work, and they also found the homework to be completed on the eOrygen platform to be helpful for between-sessions work. These findings are in line with other research indicating that blended care is beneficial when it is integrated and intensifies treatment [92]. However, research has indicated that blended care may not be effective if perceived as burdensome or time consuming by clinicians, but this may be related to trial-related factors, such as reporting to a research team if using the intervention during a clinical trial or inflexible intervention structure [93]. One way to overcome this could be for developers to work with clinicians to ensure suitable content and for features to be provided within the intervention, which would enable clinicians to use the intervention with young people in a way that is meaningful, relevant, and related to the face-to-face treatment they provide [94].

Limitations

A number of limitations should be noted. The single-group design was chosen to enhance external validity by maximizing real-world uptake of the intervention. Therefore, it was important to expose as many young people and clinicians to the intervention as possible to determine real-world uptake with eOrygen, and the inclusion of a control group may have negatively impacted the number of clinicians and young people who signed up to the intervention, potentially limiting our understanding of feasibility in this context. However, this study design limited our ability to determine a cause-and-effect relationship between the intervention and outcomes [95]. Furthermore, a 3-month time frame was chosen because this is an acceptable time frame that is comparable to the time frames of other pilot studies testing the feasibility, safety, and acceptability of digital interventions [59,66,96].

Although this study tested an integrated blended model of care, we did not collect data on how young people engaged with face-to-face treatment or how participating clinicians used the eOrygen platform, and future studies should consider this when evaluating blended models of care. Furthermore, our goal to provide flexibility and autonomy to clinicians may have negatively impacted competence in the use of the platform; for example, clinicians attended a 1-day workshop and received a printed user manual and training videos on how to use the

eOrygen platform. However, as noted in the clinician-identified barriers to implementation, attending 1 workshop may be inadequate to gain competence, and there was also a substantial gap in time between clinician training and the implementation of eOrygen owing to the COVID-19 pandemic. Therefore, the training may have been forgotten, and a lack of time to review training materials may have also been an issue. Future studies should consider providing ongoing clinician support in this regard, while also remaining flexible to the needs of clinicians. Furthermore, although the recruitment goal was met for this study, it must be noted that the sample of male participants in the study was small at only 21% (7/33) of the total sample, limiting the generalizability of these findings and highlighting that significant barriers may still exist for young men to access mental health treatment [97] and that difficulties may also exist in tailoring interventions to young men [98].

Conclusions

In conclusion, our pilot study was an important first step in testing a transdiagnostic blended model of care for youth psychosis and BPD in young people aged 15 to 25 years. We found that eOrygen was feasible, acceptable, and safe; there

were indications that eOrygen may improve treatment outcomes if tested in a full-powered trial; and the majority of participants and clinicians reported positive experiences of using eOrygen as a blended model of care. However, some participants misunderstood the meaning of blended care, and future research should ensure that this is clearly outlined before integrating a digital tool into clinical practice. Furthermore, some clinicians reported a lack of knowledge and confidence in their ability to implement the intervention, and future research should aim to understand the possible barriers and address them to ensure clinician competence and confidence with the intervention itself. Overall, this pilot study provides promise for integrating blended models of care into specialized services for young people with complex mental health conditions, but a full-scale trial will be needed to test the effectiveness of such an intervention. This study also reaffirms prior findings indicating that blended models of care have the potential to increase therapeutic intensity, continuity, engagement, and effectiveness. Future research needs to focus on the development of tools to integrate blended care into practice specifically [36], as well as strategies to support both clinicians and young people in continuous use of the platform.

Acknowledgments

The authors would like to thank the young people who participated in the eOrygen pilot study and agreed to share their data for research purposes. The study was funded by generous support from the Telstra Foundation. MA-J was supported by an investigator grant (APP1177235) from the National Health and Medical Research Council and a Dame Kate Campbell Fellowship from The University of Melbourne. JN was supported by a National Health and Medical Research Council Emerging Leader Fellowship (ID 2009782).

Conflicts of Interest

None declared.

Abstract

Background: Compromised well-being and mental health problems pose a significant threat to individuals and societies worldwide. Resource-intensive psychological treatments alone cannot alleviate this burden. There is a need for low-cost, evidence-based interventions aimed at preventing illness and promoting well-being. Five activity domains appear to be linked with well-being promotion across populations: connecting with others, being active, taking notice, learning, and being generous/giving. The activities mentioned are part of the Five Ways to Wellbeing framework and the web-based intervention Five Ways to Wellbeing for All (5waysA).

Objective: This randomized controlled trial aims to test the effects of the 5waysA intervention, a web-based, low-cost, well-being-promoting measure targeting the general population. To date, the Five Ways to Wellbeing framework has not been tested in this specific format. The 5waysA intervention comprises 2 webinars and SMS text message reminders delivered over a 10-week period.

Methods: In 2021, a total of 969 study participants from various regions across Norway were openly recruited through a web page. They were then randomly assigned to either an intervention group or 1 of 2 waiting list control groups, namely, active or passive. Self-reported life satisfaction (Satisfaction With Life Scale [SWLS]), flourishing (Flourishing Scale [FS]), positive emotions, anxiety, and depression symptoms (Hopkins Symptom Checklist-8 [HSCL-8]) were assessed before the intervention, at 4 weeks into the intervention, and 1-2 weeks after the intervention (over 10 weeks). Data analysis was conducted using linear mixed (multilevel) models.

Results: After 10 weeks, 453 participants (171 in the intervention group and 282 in the waiting list control group) were assessed on outcome variables, with a dropout rate of 53.2% (516/969). Results revealed a significantly greater increase in the intervention group compared with the controls for SWLS ($b=0.13$, 95% CI 0.03-0.23; $P=.001$), FS ($b=0.19$, 95% CI 0.08-0.30; $P=.001$), positive emotions ($b=0.43$, 95% CI 0.27-0.60; $P<.001$), and these factors combined into a global well-being measure ($b=0.28$, CI 0.16-0.39; $P<.001$). Effect sizes (Cohen d) for the well-being outcomes ranged from 0.30 to 0.49. In addition, a significant decrease in anxiety and depressive symptoms was observed ($b=-0.17$, 95% CI -0.30 to -0.04 ; $P=.001$) with an effect size (Cohen d) of -0.20 .

Conclusions: The findings suggest that the web-based 5waysA intervention could serve as an effective approach for enhancing well-being and mental health within the general population. This study offers individuals, policy makers, and local stakeholders an accessible and potentially cost-effective well-being intervention that could be easily implemented.

Introduction

Background

The burden on society is significant due to compromised well-being and a sharp increase in mental health issues [1]. Longitudinal studies indicate that more than 80% of the population could meet the diagnostic criteria for a mental disorder at some point in their lifetime [2,3]. The early onset, widespread prevalence, presence of multiple health issues, and prolonged work absences as a result of associated disabilities significantly contribute to the substantial burden of mental health problems and low well-being [4]. Well-being is not simply the absence of mental illness [5]; rather, it encompasses positive elements such as joy and life satisfaction. However, the notably high negative correlation between well-being and mental illness implies a significant connection between them. Thus, gains in levels of well-being can possibly decrease the risk of future mental illness, and vice versa [6,7]. Remarkably, mental illness and compromised well-being can also impact our physical health [8], influencing cardiovascular and immune system functioning [9,10], hastening physical aging [11], and raising mortality rates [12]. Therefore, promoting well-being may enhance not only mental health [1] but also physical health. Evidence-based interventions aimed at promoting well-being, with wide-reaching accessibility and implemented before the onset of mental illness, have been shown to be cost-effective [13,14] and are strongly recommended. In this regard, internet-based interventions emerge as a promising and scalable approach for both treating [15] and preventing [16] mental disorders, as well as enhancing well-being [15,17-19].

Strategies for promoting well-being should target different societal levels and address various risk factors [20]. Poverty and social exclusion are notable risk factors for both compromised well-being and mental health issues, highlighting the necessity of adopting a public health approach and implementing universal interventions, such as political and structural measures [20]. However, the significance of structural strategies aimed at the general population is still not adequately recognized [21], and their implementation within the population is surprisingly limited [22]. In addition to universal interventions, there is a critical need for more targeted interventions that are easily accessible and can be seamlessly integrated into individuals' daily lives. Recent years have demonstrated that pandemics and related crises can profoundly impact health and well-being on a widespread scale. As a result, the significance of scalable interventions using adaptable

delivery methods through technology has become increasingly apparent [23,24].

Well-Being and Mental Health

Numerous studies using various research designs have consistently demonstrated a close and often prospective association between well-being, mental health, and overall health outcomes, including longevity [8,12,25,26]. The concept and components of well-being have been extensively deliberated upon since ancient times [27]. Contemporary conceptualizations frequently incorporate 3 dimensions of well-being, encompassing how individuals (1) emotionally experience life, (2) cognitively evaluate life, and (3) find meaning and fulfillment in life (eudaimonia) [28,29]. Therefore, well-being entails both feeling good and functioning effectively, including the ability to cope with negative or distressing emotions. In summary, well-being and its components are multidimensional and closely intertwined with mental health, as defined by the World Health Organization (WHO) as “a state of well-being in which individuals realize their own abilities, can cope with the normal stresses of life, can work productively and fruitfully, and are able to make contributions to their communities” [30]. In addition, well-being is closely associated with fundamental psychological needs [31,32].

Well-being is frequently compromised when individuals endure prolonged periods of elevated negative emotions [33]. Similarly, psychopathology is acknowledged as a risk factor for diminished well-being. However, a dual model of mental health underscores that well-being and mental health are distinct, partially independent dimensions. Hence, experiencing high levels of well-being (such as flourishing) does not necessarily imply the absence of mental illness, and conversely, having a mental illness does not mean that joy, meaning, and positive emotions are absent from life [5]. However, the significant correlations between psychopathological symptoms (eg, depression and anxiety) and well-being [6,7] underscore the importance of addressing both well-being and mental health in interventions.

The connections between well-being and both physical and mental health appear to, at least partially, stem from the beneficial and protective effects of positive emotions on health and healthy behaviors [26,34]. Consequently, interventions aimed at promoting well-being and related psychological interventions frequently incorporate the enhancement of positive affect as a target outcome among others.

The Effectiveness of Interventions

Numerous meta-analyses indicate that various types of psychological interventions can enhance various aspects of well-being while concurrently reducing psychological symptoms, with average Cohen d effect sizes ranging between 0.29 and 0.62 [35-38]. Furthermore, lifestyle-oriented interventions that prioritize health behaviors such as physical activity and maintaining a balanced diet have shown promise in promoting well-being and positive mental health [39-41].

Psychological interventions can be costly and resource-intensive, particularly when they require individual face-to-face follow-up. In a health care system under economic strain, there is a need for more efficient solutions. Numerous studies and meta-analyses have shown that web-based interventions are effective alternatives [16,19,24,42-45]. In a recent meta-analysis focusing on positive psychology interventions in nonclinical populations, comparisons were made between interventions using technology-assisted and traditional (ie, face-to-face) methods. The findings indicated that face-to-face interventions were somewhat more effective in enhancing well-being compared with technology-assisted ones (Cohen $d=0.32$ vs 0.17, respectively) [23]. Indeed, research corroborates the effectiveness of stand-alone (ie, without human support) internet and mobile-based psychological interventions in treating various types of psychological issues and improving mental health [16,19,24]. Moreover, web-based psychological interventions have the potential to reach a larger number of individuals in need and are frequently less resource-intensive and costly [15,18]. The ongoing research on the web-based intervention Five Ways to Wellbeing for All (5waysA) seeks to evaluate the effectiveness of a stand-alone, cost-effective, internet-based intervention aimed at promoting well-being with a wide reach.

The Five Ways to Wellbeing Framework and The Five Ways to All Intervention

Overview

The Five Ways to Wellbeing (5ways) originated from a UK government initiative aimed at identifying 5 action domains crucial for promoting well-being and mental health. These action domains were to be evidence based and applicable to individuals of all ages [46]. The resulting 5 action domains are connecting (emphasizing the need for social relations, belongingness, and inclusion), being active (highlighting movement), taking notice (focusing on awareness), keep learning (emphasizing growth, development, and mastery), and giving (encouraging prosocial behavior and adding value). The following sections elaborate on the 5 action domains of the Five ways framework.

Connecting

Decades of psychological research have underscored the fundamental human need for attachment [47] and belonging [31,48,49], demonstrating that social relations are indispensable for well-being [50-52]. In a recent study, researchers used network analysis to investigate the connection between well-being and various environmental factors in a sample of 31,000 Norwegian adults. A strong association was observed between perceiving social relations as supportive and rewarding and higher levels of well-being, as well as fewer symptoms of

depression and anxiety [53]. In addition, social relations appear to serve as a protective factor against stressors and are linked to mental resilience, even after accounting for genetic factors [54].

Be Active

Studies have demonstrated that activity and movement play a crucial role in well-being and can be enhanced through regular practice [41,55,56]. Physical activity has been shown to be effective in alleviating symptoms of depression, anxiety, and psychological distress, both in the general population and in groups with compromised health [57]. Indeed, a recent study using Mendelian randomization provides further evidence supporting a causal relationship between physical activity and the preventative effect on depression [39].

Taking Notice

Meta-analyses indicate that engaging in mindfulness practices, which involve being present and aware in the moment, is linked to various benefits for well-being [58-60]. These benefits include changes in brain regions associated with mood modulation [61], suggesting that mindfulness may have a positive impact on mental health. Furthermore, research suggests that awareness, as a skill, can be cultivated and strengthened through practice [32]. In a systematic review and meta-analysis examining the impact of various psychological interventions on well-being, mental, and physical health, mindfulness training and other psychological interventions had the most significant effect on both clinical and nonclinical populations [38].

Learning

Humans possess an inherent drive to develop competence, foster curiosity, strive for mastery in diverse life skills, and seek autonomy [62]. Learning and exposure to novelty are linked to the anticipation and sustained engagement of reward circuits in the brain, which typically have positive effects on well-being and serve as a buffer against stress [63,64]. Moreover, introducing novelty into familiar experiences in life appears to be an effective method for enhancing well-being [65,66].

Giving

Engaging in acts of kindness typically leads to increased happiness among individuals [67]. Furthermore, being generous and participating in informal giving are associated with various eudaimonic well-being benefits [68] and are considered essential for fulfilling our basic need for relatedness [31]. In addition, the need for mattering, which involves feeling valued and adding value, is emphasized as crucial for a fulfilling life [69]. A recent review of 15 preregistered studies on prosocial spending concluded that such acts not only benefit others but also increase one's own happiness [70].

Since its launch in 2008, the Five Ways to Wellbeing concept has gained traction in both policy and practice. It has been incorporated into national well-being surveys, school curricula, and local procurement decisions [71]. In 2011, the National Mental Health Development Unit and the National Association of Health Authorities and Trusts Confederation (UK) conducted a survey to assess the extent to which the Five Ways to Wellbeing had been used since its inception. The survey

identified 76 instances of the Five Ways to Wellbeing framework being applied across various settings, organizations, and initiatives. However, it also underscored the necessity for rigorous evaluations [71]. Despite the evidence-based nature and widespread adoption of the 5 activity domains, there is a noticeable absence of high-quality preregistered studies demonstrating the effectiveness of these activities when combined. Furthermore, to the best of our knowledge, no one has empirically examined the Five Ways to Wellbeing as a web-based intervention. Research on the Five Ways to Wellbeing framework appears to be limited to a few studies. One previous well-powered cross-sectional study conducted in New Zealand reported positive associations between the 5 ways activities and well-being [72]. Similarly, other cross-sectional surveys across different nations have documented a positive relationship [73]. In addition, 2 experimental studies have incorporated the 5 ways concept into their research, albeit focusing on different angles [74] and targeting different groups (ie, in-patients) [75] compared with our study.

The web-based 5waysA intervention tested in this study is a multicomponent approach aimed at the nonclinical population. It offers individuals knowledge (well-being literacy), exercises, activities, and experiences tailored to build resources and fulfill basic psychological needs, thereby enhancing well-being. This 10-week intervention is resource effective and delivered via the web, incorporating 2 webinars and subsequent SMS text message reminders to support participants. Adopting a high-quality research design, we used a randomized controlled trial with waitlist controls, encompassing both an active and a passive control group.

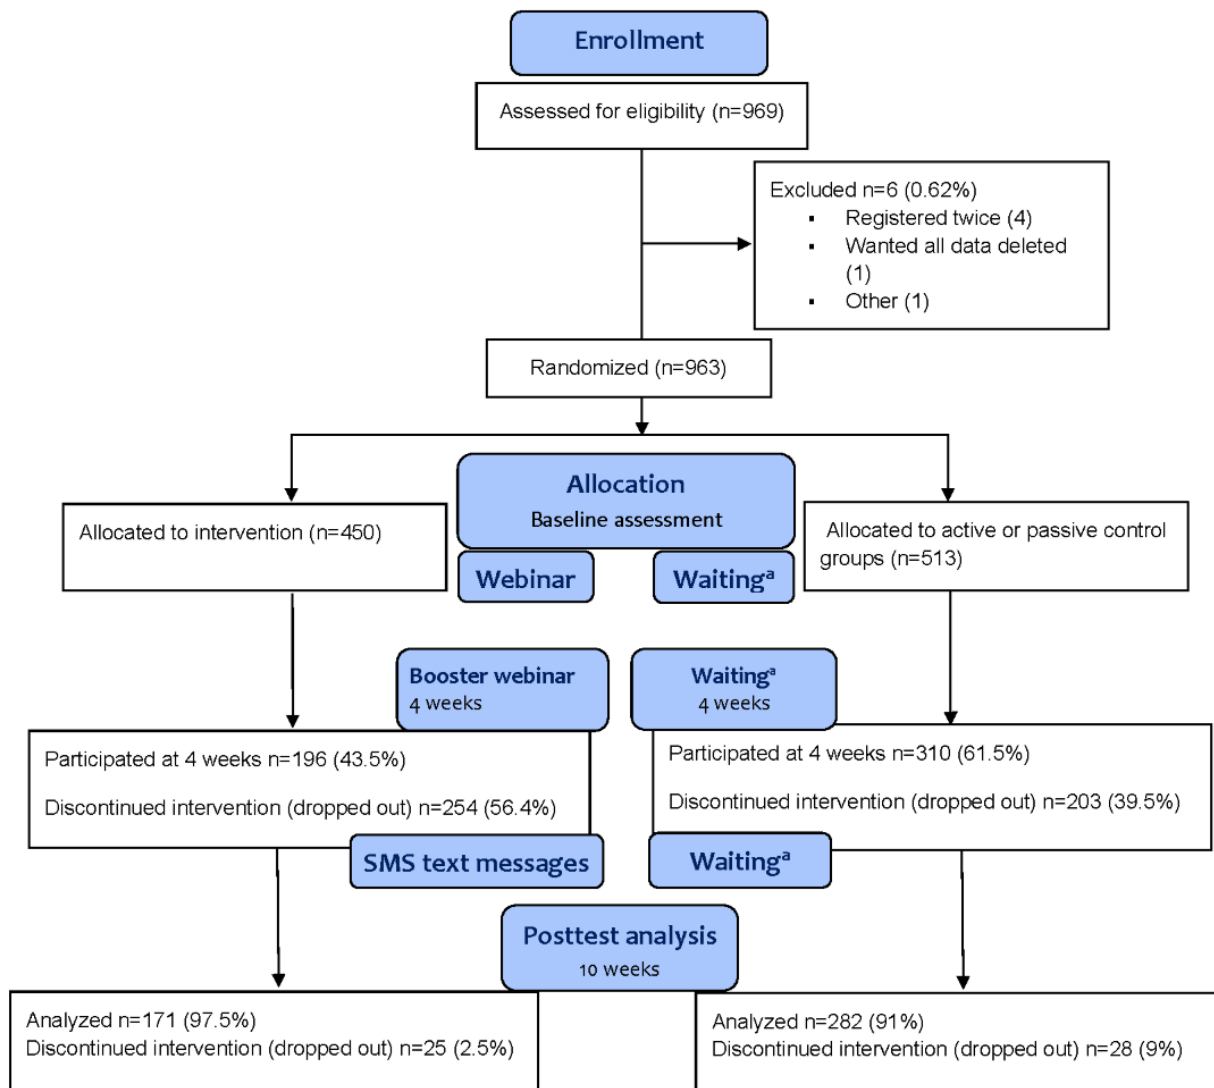

Methods

Design

This study adheres to a 2-armed randomized controlled trial design and follows the CONSORT (Consolidated Standards of Reporting Trials) guidelines and checklist ([Multimedia Appendix 1](#) [76]) for transparent reporting of clinical trials [77,78]. Initially intending to recruit 1500 participants, recruitment was halted upon reaching a total of 969 participants to align with the project's time frame. Inclusion criteria were broad, with the only requirement being participants to be 18

years or older, while there were no specific exclusion criteria. All participants were recruited in 3 rounds from across Norway between February 2021 and November 2021. Our primary recruiting channels were the official social media platforms (ie, Facebook and Instagram) of local municipalities, the Norwegian Institute of Public Health, the Norwegian unit of the WHO European Healthy Cities Network, and a women's magazine (Kamille). The overall recruitment message invited individuals to participate in a study entitled "Hverdagsglede for alle" (Everyday Joy for All) aimed at learning about a health-promoting concept and related exercises to enhance well-being, health, and joy in their everyday lives. Participants were provided with information about the study and the randomization process. We explicitly outlined that 2 groups (the "active" group and the "passive control" group) would have to wait 3-5 months for the intervention, while 1 group (the intervention group) would receive the intervention promptly. Moreover, we openly communicated that 1 of the waiting list groups would receive a small registration exercise while awaiting the intervention. All participants were informed that they were automatically entered into a lottery for 5 gift cards (each worth €50 [US \$54]). Data collection was conducted using "Nettskjema," a Norwegian standard tool for designing and administering online surveys developed by the University Information Technology Center (USIT) at the University of Oslo, Norway. This software is specifically designed for collecting highly sensitive research data, is integrated with the Services for Sensitive Data (TSD), and is known for its user-friendly interface [79].

The randomization was computer generated within the "Nettskjema" solution. As shown in [Figure 1](#), 2 control conditions, namely, the "passive" and "active" control groups, were included to investigate potential differences across control conditions [80] and mitigate the risk of artificially inflating effect sizes [81,82]. The "passive" control group received no recommendations or exercises while waiting. The "active" control group was instructed to use an activity log containing a list of 10 everyday activities. They were asked to indicate whether they had completed these activities or not during the previous week. Participants in the active control group repeated this process for 10 weeks while waiting for the intervention.

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) flow diagram. ^aHalf of the control group wrote an activity log while waiting.

Power

The a priori power analysis was conducted using G*Power3 (The G*Power Team), assuming a small effect size ($f=0.10$) for the intervention, with an α level of .05. Even with a high dropout rate of 50%, our power of 0.999 would still be sufficient to detect a group \times time interaction.

Participant Eligibility

All participants received an online letter of information about the study, which also outlined the requirements of The Regional Committees for Health Research Ethics (REK). Written consent was obtained from all participants in all groups through "Nettskjema," along with 2-factor authentication (Multimedia Appendix 2). All sensitive personal information was managed in compliance with General Data Protection Regulation (GDPR) requirements. Data were stored and analyzed using the TSD at the University of Oslo.

Ethics Approval

The trial obtained ethical approval (reference number: 62155) from The Regional Committees for Health Research Ethics (REK).

The 5waysA Intervention

The 5waysA program is structured as a 10-week intervention comprising a 2-hour webinar, a 1-hour booster webinar (4 weeks later), and 10 SMS text message reminders (Table 1). In summary, the webinars offer a thorough introduction to how stressors in life impact well-being and health. In addition, participants are educated on how the 5ways activities can serve as a remedy for unhealthy stress, elevate positive emotions, and improve overall well-being. Following the 2 webinars, participants receive 2 SMS text messages weekly for 5 weeks. Each SMS text message contains a brief review text, a reminder of the 5ways activities, and a list of example exercises for practicing the activities. Moreover, they provide a time schedule, allowing participants to select a suitable time for practicing the activities (eg, "On my way to work," "during the weekends when I'm at home").

Procedure

The webinars were delivered as live lectures and facilitated by a medical doctor. Participants who were unable to attend received a recorded version of the webinars. Web-based questionnaires were distributed by the project manager, and participants were assessed at 3 time points: (1) baseline measurement at the time of enrollment, (2) measurement after the booster webinar 4 weeks later, and (3) measurement after completing the full 10-week intervention. The control groups were assessed at the same time points as the intervention group. While most participants completed the baseline assessment at least 5 weeks before the intervention and within 2 weeks of the end of the intervention (posttest), a small subset experienced delays or misunderstandings, resulting in completion outside this time frame. Nonetheless, they were still included in the study. On average, it took participants 10 minutes to complete the questionnaires.

Outcome Measures

To capture key aspects of well-being and mental health problems, we used various measures. Life satisfaction was assessed using the Satisfaction With Life Scale (SWLS), a well-established 5-item scale designed to gauge overall satisfaction with life [83]. The SWLS includes statements such as “I am satisfied with my life,” with responses provided on a 7-point scale ranging from 1 (strongly disagree) to 7 (strongly agree). In our sample, Cronbach α for the SWLS was .90, indicating high internal consistency. Besides, we used the 8-item Flourishing Scale (FS), which measures eudaimonic aspects of well-being [84]. This scale has excellent psychometric properties and includes statements such as “I lead a purposeful and meaningful life,” scored on the same 7-point scale as the SWLS. The estimated Cronbach α for the FS was .87, demonstrating strong internal reliability. In addition to the SWLS and FS, we used a set of questions from the National Quality of Life Survey to assess basic positive emotions (ie, happiness, engagement,

calmness, and curiosity/interest) experienced over the past week. Participants rated each emotion on an 11-point scale ranging from 0 (not at all) to 10 (very much) [85]. The Cronbach α for the 4 positive emotions in our sample was .79, indicating good internal consistency. Notably, this set of emotional items is included in several large-scale national and regional surveys in Norway from 2019, with a total sample size exceeding 400,000. In addition to the individual scales, we aggregated the SWLS, FS, and positive emotion measures into a global well-being measure, which encompasses 3 crucial factors (cognitive, eudaimonic, and positive affect) in subjective well-being [86]. Furthermore, mental health was assessed using the Hopkins Symptom Checklist-8 (HSCL-8), an 8-item scale commonly used to gauge anxiety and depressive symptoms. The HSCL-8 includes questions such as whether participants feel “nervousness and shakiness inside” or “down or blue”. We used a 5-point response scale ranging from 1 (not being bothered at all) to 5 (bothering me a lot) [87]. To ensure consistency across measures, 1 item concerning hopelessness about the future was excluded from the HSCL-8 scale, as it was partially covered by other measures. The Cronbach α for the resulting 7-item HSCL (HSCL-7) was calculated to be .90, indicating high internal consistency. Before analysis, each of the 5 outcome measures (SWLS, FS, positive emotion, global well-being, and HSCL-8) was standardized with respect to the first measurement point. Specifically, we subtracted the mean at baseline and divided by the SD at baseline.

Analytic Strategy

We used linear mixed (multilevel) models to investigate changes during the intervention period, using data from all assessments. Mixed modeling offers flexibility in handling missingness resulting from nonparticipation and dropout, as well as accounting for clustering caused by observations nested within individuals [88]. The time variable was coded as 0.0, 0.5, and 1.0 for baseline, booster, and posttest, respectively. The intervention group exhibited a greater increase in well-being

and a decrease in mental health problems over time, as evidenced by a significant group \times time interaction in the mixed models ($\alpha < .05$). This interaction was interpreted as evidence for an intervention effect. Effect sizes were reported using Cohen d for all measures. In the primary analysis, we used an intention-to-treat approach, which included all participants who had completed more than 1 questionnaire within the intervention period. To assess the robustness of the results, we conducted additional analyses using only complete cases, which included participants who responded at all 3 time points (Multimedia Appendix 3). Furthermore, to explore the association between baseline levels and subsequent development, we fitted a model with a 3-way interaction between baseline level, time, and group (Multimedia Appendix 4).

Results

Characteristics of Participants

Table 2 presents the self-reported characteristics of the study participants at baseline. The majority of participants identified themselves as women (287/450, 63.8%), with a smaller proportion identifying as men (3 participants identified themselves as nonbinary). In addition, 393/450 (87.3%) participants reported having higher education (>high school). Chi-square analyses indicated no significant differences in age ($P = .30$), gender ($P = .19$), or education levels ($P = .28$) between the intervention and control groups. Across all groups, there was a moderate tendency for participants who dropped out at the posttest assessment to have lower SWLS scores at baseline.

Table 2. Participants characteristics (N=963).

Characteristics	Intervention group (n=450), n (%)	Control group (n=513), n (%)
Age (years)		
18-39	161 (35.8)	175 (34.1)
40-59	246 (54.7)	281 (54.8)
≥ 60	43 (9.6)	57 (11.1)
Gender		
Female	287 (63.8)	328 (63.9)
Male	160 (35.6)	185 (36.1)
Nonbinary	3 (0.7)	0 (0)
Education		
Primary school	6 (1.3)	6 (1.2)
High school	51 (11.3)	54 (10.5)
≤ 4 years of college or university	93 (20.7)	131 (25.5)
> 4 years of college or university	300 (66.7)	322 (62.7)

Outcomes

While there was a small trend toward more positive development in the active control group compared with the passive control group, these differences were not statistically significant for any of the outcome variables (SWLS, $P = .97$; flourishing, $P = .44$; positive emotions, $P = .76$; global well-being, $P = .70$; and HSCL, $P = .15$). Therefore, in the main analysis, the 2 control conditions were combined to increase statistical power and simplify interpretation. As reported in Table 3, multilevel analysis revealed a significantly greater increase from baseline to posttest in the intervention group compared with the control group for various outcome measures. Specifically, for the SWLS, the increase was significant ($b = 0.13$, 95% CI 0.03-0.23; $P = .001$). Similarly, for the FS, positive emotions, and global well-being, the increases were also significant (FS: $b = 0.19$, 95% CI 0.08-0.30; $P = .001$; positive emotions: $b = 0.43$, 95% CI 0.27-0.60; $P < .001$; and global well-being: $b = 0.28$, 95% CI 0.16-0.39; $P < .001$). The effect sizes for the intervention effect, calculated as Cohen d , were as follows: 0.30 (95% CI 0.11-0.49) for the SWLS, 0.32 (95% CI 0.12-0.51) for the FS, 0.49 (95% CI 0.29-0.68) for positive emotions, and 0.48 (95% CI 0.29-0.68) for global well-being. All of these effect sizes were

statistically significant at $P < .05$. Furthermore, the multilevel analysis for HSCL-7 revealed a greater decrease from baseline to posttest in the intervention group compared with the control group ($b = -0.17$, 95% CI -0.30 to -0.04). This finding underscores the effectiveness of the intervention in reducing mental health problems. The significance level for the decrease in the HSCL-7 score from baseline to posttest was $P = .001$, with a Cohen d of -0.20 (95% CI -0.40 to -0.01). The results for all the outcomes are graphically presented in Figure 2. The attrition rate from baseline to posttest was 53.2% (516/969). Across all groups, there was a moderate tendency for participants who dropped out at the posttest assessment to have lower SWLS scores at baseline. To further investigate the robustness of the data, we reran the analyses with only the participants who had completed all 3 measurements (baseline, 4 weeks, and posttest). The results from the complete case analysis remained significant for all outcome measures, indicating the robustness of the findings (see Tables S6-S10 in Multimedia Appendix 3 for more details). Although we found no significant 3-way interaction between baseline levels, time, and group for any of the well-being outcomes, a significant interaction was observed for symptoms of depression and anxiety. This suggests that individuals with higher symptoms at baseline experienced a

greater decrease in symptoms following the intervention [Appendix 4](#) for more details). compared with those with low symptom levels (see [Multimedia](#)

Table 3. Results from the multilevel regression model of the 5 outcome measures with the effect size Cohen *d* for the intervention effect ($P < .05$).

Outcome measure	Intervention group		Control group		Intervention effect	
	n	Mean (SD)	n	Mean (SD)	Estimates (95% CI) ^a	Cohen <i>d</i> (95% CI) ^b
Life satisfaction					0.13 (0.03 to 0.23)	0.30 (0.11 to 0.50)
Baseline	450	4.23 (1.28)	513	4.27 (1.27)		
Booster	196	4.36 (1.37)	310	4.38 (1.31)		
Posttest	171	4.69 (1.34)	282	4.46 (1.35)		
Flourishing					0.19 (0.08 to 0.30)	0.32 (0.12 to 0.51)
Baseline	450	5.38 (1.16)	513	5.44 (1.12)		
Booster	196	5.58 (1.22)	310	5.56 (1.11)		
Posttest	171	5.79 (1.17)	282	5.6 (1.13)

Booster	196	0.15 (1.06)	310	0.12 (1.01)		
Posttest	171	0.42 (1.01)	282	0.17 (1.03)		
Anxiety/depression symptoms					-0.17 (-0.30 to -0.04)	-0.20 (-0.40 to -0.01)
Baseline	450	2.22 (0.89)	513	2.17 (0.85)		
Booster	196	2.14 (0.92)	310	2.13 (0.86)		
Posttest	171	1.97 (0.80)	282	2.02 (0.85)		

^aEstimates for the intervention effect from baseline to posttest

^bCohen *d* for the intervention effect from baseline to posttest.

Figure 2. Mean scores for the intervention group and the control group for life satisfaction, flourishing, positive emotions, the 3 well-being outcomes combined (global well-being), and depression and anxiety symptoms at baseline, 4 weeks into the intervention (booster), and at posttest 10 weeks after baseline. The bars indicate SEs.

Adherence

To assess adherence, participants were asked whether they watched the webinars in their entirety or partially, either live or recorded. Moreover, they were asked whether they engaged in the exercises sent to them via SMS text messages. Of the 171 participants in the intervention group, adherence was assessed in 134 participants, while 37 participants were not asked about

this because of a delay in incorporating the relevant questions in the questionnaires. As we could not identify attendees or register them through the webinar platform, nor could we directly measure whether they received the SMS text messages, self-reporting became the sole method for assessing adherence. This realization emerged after the initial 37 participants had provided their responses, which is why they were excluded from

this assessment. At the posttest, 117/134 (87.3%) of the participants reported having watched the entire main webinar, or parts of it, either live or recorded. In addition, 105/134 (78.3%) reported having watched the entire or parts of the booster webinar, either live or recorded. Furthermore, 126/134 (94.0%) reported engaging in some or all of the exercises sent to them in the weekly SMS text messages.

Discussion

Principal Findings

The findings from this study suggest that 5waysA is an effective web-based intervention for promoting well-being and mental health. This aligns with previous research indicating the effectiveness of internet-based interventions [16,19,24]. While the effect sizes may be small classified according to Cohen's *d*, they are still noteworthy and comparable to psychological intervention studies that detect small to moderate effects [35,38]. Moreover, the effect sizes observed in this study are comparable to those reported for psychotherapy or antidepressant medication in treating depression [89-91]. Indeed, meta-analyses have highlighted the importance of control conditions in intervention studies [81,82]. However, in this study, the distinction between passive and active control conditions did not significantly impact the observed effects of the 5waysA intervention. This underscores the effectiveness of the intervention itself rather than the specific type of control condition used. These positive outcomes align with existing research demonstrating that psychological interventions, regardless of their theoretical framework or delivery method, can effectively improve well-being and reduce symptoms of anxiety and depression [35-38]. This study provides additional support for the effectiveness of the Five Ways to Wellbeing framework in enhancing well-being and mental health among the general population. Previous examinations of the framework have primarily occurred in nonintervention settings [74] or with hospitalized patients [75], rather than as a web-based intervention aimed at the broader population.

The significance of our study lies in its ability to demonstrate effects across all core dimensions of subjective well-being—cognitive evaluations, emotional experiences, and eudaimonic aspects. This breadth of impact suggests relevance for individuals facing various struggles or experiencing a state of languishing within the multidimensional construct of well-being. Moreover, our findings indicate that participants with a higher number of symptoms associated with depression and anxiety were more responsive to the intervention than those with few symptoms, suggesting that the 5waysA intervention may also be beneficial for clinical or subclinical populations. The alignment between the 5 action domains in the Five Ways to Wellbeing framework and the basic psychological needs in self-determination theory, such as autonomy, relatedness, and competence, as well as the core dimensions of the training-based framework by Dahl et al [32], including awareness, connection, insight, and purpose, is noteworthy. These perspectives share the common goal of guiding individuals toward actions that yield observable and meaningful positive consequences for their overall well-being, health, and capacity to thrive and flourish.

The potential to guide individuals toward actions and promote cognitive and behavioral coping strategies is often considered a common mechanism of change across psychological interventions. In web-based interventions, this can be facilitated through reminders sent via emails, apps, or SMS text messages, promoting user self-reliance in a cost-effective and easily implemented manner. The strong emphasis on self-management and self-empowerment may be one of several mechanisms that contribute to making internet-based interventions comparable to on-site treatments and interventions. However, the active mechanisms of change in web-based interventions are still not fully understood.

Web-based interventions show promise in their ability to reach a broad audience. A recent review and meta-analysis [15] suggested that internet-based interventions for treating mental health problems are likely cost-effective, although the heterogeneity of studies makes generalizability challenging. In addition, prevention is known to be more cost-effective than treatment. The paradox of prevention [13] suggests that universal, broad health and well-being-promoting interventions aimed at the general population can be highly beneficial. Even modest improvements in many individuals can have a powerful impact at the population level. The 5waysA intervention, with its web-based delivery mode, has the potential to reach many people efficiently. It can be implemented through primary care, workplaces, municipal websites, high schools, universities, and other institutions.

Enhanced well-being can potentially impact both mental and physical health. The 5waysA intervention, as a transdiagnostic, multidimensional intervention, may represent a cost-effective measure capable of promoting overall well-being and mental health. Its low administration costs and web-based format make it suitable for an economically pressured health care service. This solution is also suitable for individuals who live in remote areas without easy access to health care services, are physically disabled, have busy schedules, or simply prefer web-based options (eg, young people). In addition, because this study was conducted during the COVID-19 outbreak, which had a significant impact on well-being, we anticipate that the intervention could also prove effective in future pandemics and lockdowns.

Strengths and Limitations

This study possesses several strengths, including its relatively large sample size, utilization of various control conditions, incorporation of validated outcome measures, and the use of items/scales enabling comparison with national surveys conducted concurrently. However, it also exhibits some limitations. As anticipated with web-based interventions [92], the attrition rate was relatively high (516/969, 53.2%). In terms of demographic variables, there were no systematic differences observed regarding the participants lost between groups. However, between the baseline and booster webinar, there was a higher dropout rate observed in the intervention group compared with the control group. The reason behind the increased dropout rate in the intervention group during this period remains unclear to us. The higher dropout rate in the intervention group during this period may be attributed to

elevated expectations, such as potential disappointment following the webinar attendance, or reluctance to engage with the intervention if the webinar was missed, while the control group remained expectant. Future studies should delve deeper into strategies for preventing attrition in web-based interventions, exploring the intricate interplay among technological challenges, levels of support, and reminders, alongside individual user demographics [93,94].

The control condition in this study comprises both an active and a passive group, thus demonstrating a high-quality design. However, future studies should contemplate comparing the 5waysA with other web-based interventions within the multicomponent positive psychology interventions spectrum (eg, Chilver and Gatt [42]) to mitigate uncertainties surrounding its true effectiveness.

In addition, an important limitation of this study pertains to the short follow-up time. Future research should also explore potential mediating mechanisms. The representativeness of the sample is suboptimal, with 393/450 (87.3%) participants reporting a higher level of education, whereas the population mean is 36.9% [95]. However, the participants' mean baseline SWLS (sum) score of 21.25 was notably lower than the population mean of 25.21 [53], suggesting that our sample population might be at risk of transitioning toward compromised mental health or a state of languishing. Moreover, our results

appear to indicate that they constitute a subset of the population that responds positively to well-being-promoting interventions. Their improved well-being may subsequently enhance their ability to manage work-life balance and caregiving responsibilities and shield them from detrimental stress. Indeed, future studies should evaluate the effectiveness of the 5waysA intervention in a more diverse sample, encompassing marginalized populations and specific illness groups. It might also be suitable to incorporate the Five Ways to Wellbeing concept into a population health approach, where interventions are less focused on individual behavior change and more integrated into local structures as societal measures and initiatives. This approach could ensure equal accessibility of the concept to various societal groups. Future research should assess the effectiveness of these types of Five Ways to Wellbeing measures.

Conclusions

Our results indicate that the web-based 5waysA intervention is an effective and promising intervention for promoting well-being among the general population. This study offers policy makers and local stakeholders a scalable, potentially cost-effective, and efficacious health promotion intervention with the potential for widespread impact. The 5waysA intervention targets the individual level, but its benefits can have meaning for individuals, groups, and societies as well.

Acknowledgments

First and foremost, we thank all the participants in this project. We also thank the user group who gave us feedback all the way from creating the intervention to the process of disseminating the results. In addition, we thank all the municipalities that helped us with the recruitment process, and especially the municipality of Bærum for letting us run a pilot study in 2020. Finally, we express our gratitude to the Norwegian Council of Mental Health for their support and collaboration throughout the entirety of the project. This project is funded by the Foundation Dam of Norway (grant 2021/FO347431). The University of Oslo applied for the funding through The Norwegian Council of Mental Health. The Dam Foundation of Norway has no role in designing the study, collecting data, analysis or interpretation of data, writing, or deciding to submit it for publication. This likewise applies to the Norwegian Council of Mental Health, except for its assistance in the recruitment of participants.

Abstract

Background: The field of mental health technology presently has significant gaps that need addressing, particularly in the domain of daily monitoring and personalized assessments. Current noninvasive devices such as wristbands and smartphones are capable of collecting a wide range of data, which has not yet been fully used for mental health monitoring.

Objective: This study aims to introduce a novel dataset for personalized daily mental health monitoring and a new macro-micro framework. This framework is designed to use multimodal and multitask learning strategies for improved personalization and prediction of emotional states in individuals.

Methods: Data were collected from 298 individuals using wristbands and smartphones, capturing physiological signals, speech data, and self-annotated emotional states. The proposed framework combines macro-level emotion transformer embeddings with micro-level personalization layers specific to each user. It also introduces a Dynamic Restrained Uncertainty Weighting method to effectively integrate various data types for a balanced representation of emotional states. Several fusion techniques, personalization strategies, and multitask learning approaches were explored.

Results: The proposed framework was evaluated using the concordance correlation coefficient, resulting in a score of 0.503. This result demonstrates the framework's efficacy in predicting emotional states.

Conclusions: The study concludes that the proposed multimodal and multitask learning framework, which leverages transformer-based techniques and dynamic task weighting strategies, is superior for the personalized monitoring of mental health. The study indicates the potential of transforming daily mental health monitoring into a more personalized app, opening up new avenues for technology-based mental health interventions.

Introduction

Background

Mental health, recognized as a critical component of overall well-being, has garnered increasing attention and concern. The World Health Organization [1] defines mental health as a state of well-being where individuals realize their potential, cope with normal life stresses, work productively, and contribute to their community. However, mental health issues continue to present a significant burden globally, affecting individuals' quality of life and posing challenges. In response to these challenges, the concept of "daily mental health monitoring" has emerged as a critical area of research and application [2,3]. This concept refers to the regular, continuous observation and assessment of an individual's emotional states, using a variety of methods and tools to capture data in real time [4]. Such monitoring aims to provide a comprehensive understanding of an individual's mental health, facilitating early detection of patterns, changes, or emerging issues. Consequently, accurate monitoring and understanding of daily mental health have become imperative for timely interventions and sustained mental well-being.

However, the field of daily mental health monitoring remains surprisingly underdeveloped, particularly regarding real-life applications [4]. The challenges faced by existing datasets and methods are not merely academic concerns but represent significant barriers to the effective and widespread adoption of mental health monitoring in everyday life. These challenges include the following.

- Real-world representation where a significant portion of existing datasets lack data derived from real-world settings, instead relying on artificial or laboratory conditions.
- Lack of self-annotation. many datasets do not use self-annotation [5-8], relying instead on experts' observation or clinical interpretation. This approach often fails to capture the subjective experience of the individual, crucial for a person-centered understanding and monitoring of mental health [4,9]. In addition, clinical assessments typically occur at discrete time points, potentially missing the dynamic, moment-to-moment fluctuations in mental states that individuals experience in their daily lives [10].
- Challenges in accessibility of monitoring data. Many studies use electroencephalography (EEG) [11,12] while providing valuable insights into brain activity and emotional states, requiring specialized equipment and expertise, making it impractical for daily monitoring. Similarly, facial expression data [13,14] capture often necessitates continuous video monitoring, posing substantial privacy and practicality challenges for everyday use.
- Limited modalities and single-model approach. Most available research focuses on a single modality [15,16], this overlooks the inherently multimodal nature of human

emotional expression and mental states, reducing the systems' reliability.

To address the aforementioned challenges, our study adopts an innovative methodology aimed at forging more accurate, and efficacious tools for mental health monitoring. The contributions of our research are manifold, highlighted by the following key developments.

- Introducing a novel dataset collected from 298 individuals using noninvasive, everyday devices including wristband-type devices and smartphones, our dataset captures physiological signals: zero crossing mode (ZCM), proportional integration mode (PIM), and speech data. Participants provided self-annotated emotional states over 2 weeks, creating a rich, multimodal resource for understanding daily mental health dynamics.
- Developing a macro-micro framework for personalized daily mental health. Our framework develops a multimodal and multitask learning (MTL) strategy, innovatively built global emotion embeddings with individual personalization embedding.

In our research, the decision to focus on physiological signals and speech data, while excluding modalities such as facial expressions and EEG, was driven by several key considerations: Physiological signals have been shown to have a significant association with mental health and well-being. These signals, such as heart rate, skin conductance, and activity levels, can provide valuable insights into an individual's emotional and psychological state [17]. The relationship between physiological signals and mental health is complex and multifaceted. For example, changes in heart rate variability (HRV) have been linked to stress, anxiety, and depression [18]. Reduced HRV has been observed in individuals with mental health disorders, suggesting that it may serve as a potential biomarker for mental well-being [19].

In our research, we apply the wrist-worn device used in our study which is equipped with a highly sensitive piezoelectric accelerometer that can detect even the most subtle wrist movements, with a resolution as fine as 0.01 G/rad/s. This allows for the capture of a wide range of daily activities and movements that may be relevant to mental health assessment [20]. The device uses 2 key modes for processing the accelerometer data: ZCM and PIM [21].

In addition to physiological signals, our study also incorporates speech data as a key modality for assessing mental health. Speech provides a rich source of information about an individual's emotional state, cognitive functioning, and overall well-being [22]. There are several reasons why speech is a valuable tool for mental health assessment. First, speech carries emotional information through various features such as tone, pitch, and intonation. Changes in these features can reflect an individual's emotional state, such as increased monotonicity in speech being associated with depression [23]. Second, speech

patterns and characteristics can provide insights into an individual's cognitive processes. For example, changes in speech fluency, coherence, and word choice have been linked to cognitive impairments and mental health conditions [24]. In addition, speech data can be collected noninvasively using readily available devices such as smartphones or voice recorders. This makes it a convenient and accessible modality for mental health assessment, especially in remote or telehealth settings [25].

Ecological momentary assessment (EMA) is a key methodological approach used in our study. EMA involves the repeated sampling of individuals' current behaviors and experiences in real time, in their natural environments [26]. While EMA offers several advantages, such as reducing recall bias and capturing the dynamics of mental states in real-world contexts [10], it also has limitations. These include potential reactivity (ie, the act of self-reporting influencing the very experiences being reported) and compliance issues [27]. In this study, we aim to mitigate these limitations through careful design and participant training, which will be discussed in the Methods section.

Furthermore, our study introduces the Dynamic Restrained Uncertainty Weighting (DRUW) fusion method, a novel approach for integrating multimodal data in the context of mental health monitoring. The DRUW fusion method adaptively weights the contribution of each modality based on its uncertainty and distinct characteristics, ensuring a balanced representation of the fused data. This method builds upon the principles of uncertainty weighting [28] and extends them to the multimodal fusion context. The key novelty of the DRUW fusion method lies in its ability to dynamically adjust the weighting of each modality based on the inherent uncertainty and complementary nature of the physiological signals and speech data [29].

By collecting and analyzing data on emotional states, speech characteristics, and physiological patterns, our study aims to contribute to the development of more effective, personalized, and accessible mental health interventions. The data collected in our study can contribute to better mental health outcomes in several ways.

Early Detection and Intervention

By correlating objective measures with subjective emotional states, we can develop tools for early detection of mental health issues, enabling timely interventions [30].

Personalized Treatment and Monitoring

Insights from our study can inform personalized treatment plans and monitoring strategies, tailoring interventions to individual needs [31].

Remote Monitoring and Telemedicine

Our use of wearable devices and speech analysis can contribute to remote monitoring tools, crucial for mental health support, especially in light of recent global events [32].

Reducing Stigma and Increasing Access

By demonstrating objective measures for mental health assessment, we can potentially reduce stigma and increase access to care, particularly for underserved populations [33].

Related Work

This section delves into various aspects of mental health monitoring research domain, including mental health data, EMA, personalization, and their real-world implications.

Recent research efforts, particularly in mental health detection and monitoring, have gained significant momentum. Key studies like the systematic review by Hickey et al [34] and Long et al [35] have critically evaluated the use of smart devices and wearable technologies. These investigations underline the capability of these devices in detecting stress, anxiety, and depression through physiological measures such as HRV, electrodermal activity, and EEG data. However, they also identify a notable gap in the availability of commercial depression-detecting devices, emphasizing the need for integrating multimodal data to enhance both accuracy and predictive power.

Recent advancements in multimodal data analysis have shown promising results in mental health diagnosis [36]. For instance, a study by Xu et al [36] proposed a measurement method for mental health based on dynamic multimodal feature recognition. This approach integrates various data sources, including physiological signals, speech patterns, and behavioral indicators, to provide a more comprehensive assessment of an individual's mental state. Similarly, Huckins et al [37] developed a multimodal machine learning approach that combines smartphone sensing data with self-reported mental health scores to predict changes in depression and anxiety among college students.

Building on this, the role of mental health datasets becomes crucial in understanding the complex and varied nature of mental health conditions across different populations. The comprehensive analysis of datasets, such as those examined during the COVID-19 pandemic [38], offers deep insights into the mental health effects of global crises on specific demographics, like the Bangladeshi population. These datasets are instrumental not only in assessing the prevalence and severity of mental health conditions across various groups but also in supporting longitudinal studies vital for tracking changes over time.

Recent studies have also focused on improving data collection methods for mental health monitoring. For example, Morshed et al [39] introduced a novel approach using passive sensing and machine learning to predict mood instability in bipolar disorder. This method leverages smartphone usage patterns and environmental data to provide continuous, unobtrusive monitoring of mental health states.

In this study, we apply EMA [40], which represents a method for recording participants' behavior, psychological state, and physical symptoms in real-time and at multiple time points. The primary advantage of EMA lies in its ability to minimize the biases often associated with retrospective recall in self-report

data. Traditional self-report measures, which ask participants to remember and report past feelings, behaviors, or symptoms, can be influenced by memory distortions and subjective interpretations of past events. Thus, it reduces the likelihood of recall errors and increases the accuracy and reliability of the data collected.

Further, personalization in mental health monitoring systems is increasingly important [4]. Innovations in digital phenotyping [41] exemplify this trend. This is further advanced by groundbreaking approaches like those proposed by Gerczuk et al [42], using zero-shot personalization strategies for large speech foundation models in mood recognition.

The application of artificial intelligence and deep learning techniques in mental health monitoring has seen significant growth. A comprehensive review by Su et al [43] highlights the potential of deep learning models in analyzing multimodal data for mental health assessment. These advanced techniques allow for more nuanced interpretation of complex, high-dimensional data, potentially leading to more accurate and personalized mental health interventions.

In summary, the related work shows the dynamic nature of mental health detection and monitoring. However, bridging the gap between technological capabilities and personalized mental health care presents numerous challenges. The integration of

multimodal data, advancements in data collection methods, and the application of sophisticated artificial intelligence techniques represent promising avenues for overcoming these challenges and improving mental health monitoring and diagnosis.

Methods

Methodology and Data Collection

Overview

The study followed a 2-week data collection protocol, during which participants wore wrist-worn devices and used a smartphone app to record their speech and self-report their emotional states. The collected data included physiological signals from the wrist-worn devices and speech recordings from the smartphone app. To collect data, we developed a platform called Mental Healthcare Internet of Things (MHIT) system.

The MHIT System

The MHIT system, as shown in Figure 1, is a cloud-based platform specifically crafted to gather and analyze data from Internet of Things devices. This state-of-the-art system combines the collection of physical activity signals with speech data. The MHIT system is comprised of 2 key components: a cloud server (MHIT server) and a smartphone app (MHIT app).

Figure 1. The MHIT system designed for data collection. MHIT: Mental Healthcare Internet of Things.

Participants

A convenience sample of 298 Japanese office workers participated in our study. They were recruited by sending digital flyers. Those who agreed to participate in the study were asked to open a URL link on the flyer and complete a web-based registration form. Subsequently, the in-house wrist-worn device (ScienceNet device; ScienceNet Inc), survey progression guide, and informed consent form were mailed to them. Participants were instructed on the aim and procedure of the study through the survey progression guide. In addition, by scanning a QR code on the guide, they were able to watch a tutorial video to learn the use of the device and the MHIT app. After completing the informed consent form, they commenced the study. This recruitment process was conducted fully on the web, which

contribute to achieve data collection from workers in different residential locations.

Annotation and EMA

This study used an EMA paradigm to capture participants' emotional states in real time, thus avoiding potential distortions of retrospective recall in self-report data. The EMA protocol involved the following.

Sampling Scheme

Participants were prompted to report their emotional states by using the MHIT app at randomly selected times within -10 minutes to +10 minutes of predetermined times (11 AM, 3 PM, and 7 PM). In addition, they were instructed to voluntarily complete the same EMA questionnaires when they woke up and went to bed.

Data Collection

At each EMA, participants self-reported the intensity of 9 different expressed emotions on a (0:100) visual-analogue scale (slider) displayed on the MHIT app. These 9 emotions correspond to the items of the Depression and Anxiety Mood Scale (DAMS) [44]. To prevent response bias and predetermination, the order of the DAMS items was randomized for each evaluation.

Speech Data

Before the mental state evaluation, participants recorded their voices by speaking, for example, “the current date and time are September 5, 2022, at 10:23 PM” on the MHIT app. The reasoning behind this is to keep the content emotionally neutral. Participants also recorded activities, and the actual time was recorded by the system.

Physiological Signals

The instrument is fitted with a sensitive piezoelectric accelerometer that detects minute wrist accelerations (as fine as 0.01 G/rad/s), capturing even the most subtle daily movements. The ZCM within the device tallies the instances the accelerometer’s signal traverses the 0 mark over a predefined duration, known as the epoch time. Conversely, the PIM assesses the integral of the root-mean-square for the triaxial accelerometer signals. For the purposes of this investigation, we have configured the epoch interval at 1 minute, aggregating 60 data points (representing 1 hour) prior to each participant’s DAMS entry within their routine activities. To ensure the integrity of our dataset, we have meticulously curated instances that comprise both ZCM and PIM recordings, each consisting of 60 data points.

Annotation Scheme

The DAMS serves as a self-reported measure of an individual’s emotional state, providing a subjective assessment of their mental well-being. This scale, which encompasses nine distinct emotions—vigorous, gloomy, concerned, happy, unpleasant, anxious, cheerful, depressed, and worried—is used for comprehensively assessing mental health experiences pertinent to depression and anxiety. DAMS’s effectiveness in measuring depressive and anxious moods is particularly notable, as it uses a variety of descriptors, including adjectives, adjectival verbs, and phrases, to delineate depressive, anxious, and positive moods with high discriminant validity [44]. Moreover, its psychometric soundness has been established through methods such as parallel testing and test-retest evaluations [44], confirming its high convergent, discriminant validity, and reliability. The scale’s sensitivity to mood fluctuations is evidenced by the variance in scores observed between normal and stressful periods, underscoring its use in detecting mood changes. These features of DAMS, combined with its thorough statistical analysis across 9 emotional labels, confirmed it is a comprehensive choice for our study.

Previous research has shown that speech characteristics and patterns can reflect an individual’s emotional state. For example, depression has been associated with changes in prosody, such as reduced pitch variability and slower speaking rate [22]. Similarly, anxiety has been linked to increased vocal tension

and higher fundamental frequency [45]. By analyzing speech features such as pitch, intonation, and speaking rate, we can potentially identify objective markers that correlate with the subjective emotional states reported through DAMS.

Physiological data, collected through wrist-worn accelerometers, can also provide an indirect measure of an individual’s emotional state. Studies have demonstrated that mood disorders, such as depression and anxiety, can influence an individual’s activity levels and patterns [46]. Depression, for instance, has been associated with reduced physical activity and increased sedentary behavior [47]. By examining the activity data captured by the accelerometers, we can explore potential correlations between the objective measures of physical activity and the subjective emotional states assessed by DAMS.

While speech and physical activity data do not directly measure the emotional states captured by DAMS, they can offer complementary and objective insights into an individual’s mental well-being. By combining these different modalities—self-reported mood, objective speech characteristics, and objective physiological signal patterns—we aim to develop a more comprehensive understanding of an individual’s mental health status.

Self-Annotation

Self-annotation is a cornerstone in daily mental health monitoring for important reasons such as capturing subjective emotional experience and ecological validity. Using the MHIT app, participants self-reported their emotional states 5 times daily over 2 weeks, using the 9 emotional states outlined in DAMS.

Capturing Subjective Emotional Experiences

Emotions are inherently subjective, and self-annotation allows individuals to express their emotional states based on personal experiences. This method ensures an authentic portrayal of their mental state, which is crucial for accurate mental health assessment.

Ecological Validity

By self-reporting in real-time within their usual environments, participants provide data that more accurately reflect their day-to-day emotional experiences, enhancing the ecological validity of our study.

Data Preprocessing

In our research, the preprocessing of collected data was a critical step for both speech and physical activity. This process involved several stages, each tailored to the specific nature of the data being processed.

Preprocessing of Speech Data

For speech data, audio files were standardized in terms of their sampling rate and format for subsequent analysis.

Data Cleansing

Any recordings that were unsuccessful or contained data anomalies were removed. This step was crucial to ensure the integrity and quality of the speech dataset.

Voice Activity Detection

We used algorithms to detect and eliminate silences in voice recordings. This focus on active speech segments helped in isolating meaningful data.

Denoising

Background noise within the recordings was reduced using digital signal processing techniques. While the specific method may vary depending on the characteristics of the noise and the recording environment, common approaches include spectral subtraction, Wiener filtering, or more advanced techniques such as deep learning-based noise suppression algorithms [48].

Preprocessing of Physical Activity Data

The preprocessing of physical activity data includes the following approaches.

Signal Cleaning

Similar to speech data, physical activity data were cleaned to remove any erroneous signals.

Signal Standardization

The raw data from the physical activity sensors were standardized to ensure consistency across different participants.

Normalization Process

The intensity ratings of the emotional states reported by participants were normalized to a uniform scale ranging from 0 to 1.

Multimodal Multitask Analysis

In transitioning from data collection to the analysis of daily mental health in our study, we shift our focus toward developing a robust multimodal multitask analysis framework. The initial step involves defining the analytical task, which in our case is predicting various mental health indicators as outlined by DAMS. To effectively achieve our goals in daily mental health monitoring, we need to address three pivotal questions.

- How to fuse different modalities: specifically, how do we integrate physical activities and speech data?
- How to achieve personalization: what strategies can we use to tailor the analysis to individual participants?
- How to balance different emotional states: how can we ensure that our analysis provides a balanced view of various emotional states?

To respond to these questions, our approach involves the introduction of a comprehensive framework architecture. We plan to detail each component of this framework, starting with multimodal fusion, then moving on to personalization, and concluding with multitask balancing. This sequence is carefully chosen by allowing multimodal fusion to initially integrate and align different data types (physiological signals and speech) after feature extraction, creating a whole picture of data for further analysis. Personalization subsequently adapts this integrated data to individual differences, ensuring the model accurately represents each participant's unique mental health profile. The final stage, multitask balancing, refines the network to efficiently manage multiple analytical tasks.

Framework

The proposed framework commences with a robust feature extraction phase. For physiological signals, PIM and ZCM are input into individual 2-layer feed-forward neural networks (FFNNs). Concurrently, speech signals are preprocessed through a specialized *wav2vec-l-emo* model [49], which is a pretrained model. These speech features are then similarly processed by a 2-layer FFNN. This standardization of feature dimensions across modalities primes the data for integration.

The fusion of these data streams is executed through a DRUW fusion block, effectively merging the standardized features from physiological signals and speech. This fusion process not only integrates the data but also applies DRUW fusion.

Upon fusion, the data advances into a specific emotional FFNN and a transformer layer, means, the combined features into a global emotional space. This space is not user-specific; rather, it serves as a shared domain, namely, macro space.

Personalization is introduced at the micro stage. Here, the framework uses additional FFNN layers tailored to individual users, enabling the selection of embedding elements pertinent to their unique emotional profiles. This adaptation leverages DRUW loss.

DRUW Multimodal Fusion

A fundamental question in our study of mental health monitoring is “how to fuse different modalities,” specifically the integration of physical activity and speech data. To answer this, we have developed the DRUW fusion method.

The DRUW fusion formula can be represented as follows.

$$\frac{1}{\alpha + \beta} \left(\alpha \cdot \text{Physical Activity Data} + \beta \cdot \text{Speech Data} \right)$$

where α and β are the uncertainty parameters for the physical activity data $\text{Physical Activity Data}$ and the speech data Speech Data , respectively. The term $\frac{1}{\alpha + \beta}$ acts as a constraint, similar to $\frac{1}{\alpha + \beta}$ in the DRUW loss, the weighting of each modality in the fusion process is regulated, ensuring that neither modality is disproportionately represented in the fused data and maintaining a balanced integration. This adjustment, based on the uncertainty and distinct characteristics, ensures that each modality contributes appropriately to the combined dataset. Meanwhile, the complementary nature of these data types is capitalized upon by the DRUW fusion method. Physical activity data provides objective, quantifiable measures of movement and physiological responses, while speech data offers subjective insights into emotional states and mental well-being. Furthermore, a key advantage of the DRUW fusion method is its straightforward implementation.

Macro-Micro Personalization

A key aspect of our multimodal analysis framework is the implementation of macro-micro personalization.

To quantitatively define the macro-micro personalization approach, we can formulate the integration of the macro emotional space with the micro personalization layer. This can be represented as follows.

where α_i represents the personalized output for the i participant, \mathbf{E}_m denotes the embeddings or features extracted from the macro emotional space, \mathbf{E}_i represents the embeddings or features specific to the i participant, and w is a weighting factor that determines the balance between the influence of the macro and micro layers. It can be a fixed value or adaptively determined based on factors such as the diversity of the dataset or the specificity of the micro data.

Macro Emotional Space

Initially, we establish a macro emotional space that serves as a common ground for all participants. This space is built using FFNN-transformer embeddings, capturing generalized emotional patterns and trends observed across the entire participant pool. It reflects the shared aspects of emotional experiences and is crucial for understanding the broader context of mental health states.

Micro Personalization Space

After macro space, a micro layer is designed for each participant. This layer allows for the customization of the model based on microspecific data. It adapts the general insights from the macro space to the nuances of each participant's emotional profile.

DRUW Loss for Multitask

MTL is a crucial component in our study, particularly relevant to the diverse nature of mental health monitoring. MTL is a form of learning that involves training a model on several related tasks simultaneously. This approach is underpinned by the principle that “transfer should always be useful”; essentially,

Table 1. Data partitioning.

Set	Data (%)	Samples
Training	70	4340
Development	15	931
Test	15	929

Evaluation Metrics

In this study, the concordance correlation coefficient (CCC) is used as a key evaluation metric. CCC considers both the scale and location shifts between the predicted and actual data, providing a comprehensive measure of the model's predictive performance. In our context, this metric is crucial for assessing the accuracy of our model in reflecting the true emotional experiences of participants.

The CCC is defined as follows.

Where r represents the Pearson correlation coefficient between the predicted and actual values, $\sigma_{\hat{y}}$ and σ_y are the SDs of the

any pair of tasks should share some commonalities in their underlying distributions [50].

In addressing the critical challenge of “how to balance different emotional states” in our study, we use the DRUW loss [29], a solution developed in our previous work. This approach is particularly crucial in the context of multitask learning, where balancing the contribution of each task—especially when dealing with a spectrum of emotional states—is key to the overall model's performance. This method allows for the adaptive balancing of tasks, taking into account the varying degrees of complexity and uncertainty inherent in each task. The equation of the DRUW loss function is as follows.

Where α_i and β_i are uncertainty parameters corresponding to different tasks in our model, with α_i and β_i representing the respective task-specific loss functions. The inclusion of γ serves as a constraint, regulating the sum of these weights to prevent trivial solutions and maintain the balance among tasks.

Evaluation

Experimental Setup

To construct a reliable evaluation scheme, the dataset is partitioned into training, development, and test sets based on time-dependent criteria, as outlined in Table 1. Given that the dataset is collected over a 2-week period, we allocate the first 70% of the data from each participant to the training set. The subsequent 15% forms the development set, and the remaining 15% constitutes the test set. This partitioning strategy ensures that the evaluation is robust and reflects the temporal dynamics of the data.

predicted and actual values, respectively, and $\mu_{\hat{y}}$ and μ_y are their means.

Benchmark Model

To effectively evaluate our macro-micro framework, it is crucial to establish a benchmark for comparison. This benchmark model consists of the following key components: pure concatenation for modality fusion, 2-layer FFNN for presentation, and equal weight strategy for MTL. This benchmark model, with its straightforward concatenation, basic personalization, and uniform task weighting, provides a solid foundation for comparison.

Pure Concatenation for Modality Fusion

This approach linearly combines features from both physical activity and speech data without weighting or transformation.

2-Layer FFNN for Personalization

We designed FFNN to adapt the concatenated features to get personalized embeddings.

Equal Weight Strategy for MTL

In handling multiple tasks, we applied an equal weight strategy across all tasks.

Comparison Methods

Multimodal Fusion Techniques

In our exploration of multimodal fusion techniques, we first investigated the use of separate transformer embeddings for each modality. This approach aimed to capture unique features within physical activity and speech data independently before combining them. The results indicate that while this method was effective in isolating modality-specific characteristics, it also necessitated sophisticated alignment strategies during the fusion stage.

We also applied attention mechanisms, including solo attention [51] and postconcatenation attention. These techniques allowed the model to dynamically focus on the most informative features from each modality. The solo attention mechanism, applied before concatenation, proved particularly effective in enhancing the model’s sensitivity to contextually relevant multimodal cues.

A more straightforward approach, the pure weighted method, involved assigning fixed weights to each modality during fusion. Despite its simplicity, this method displayed limitations in adaptability, especially in scenarios where the relative importance of each modality varied.

Besides, max fusion [52] was used to capture the most significant features across modalities by taking the maximum value across feature dimensions. This method was found to be particularly useful in scenarios where the dominant features in the data were more predictive of the outcome.

We tested gated fusion [53], which was designed for dynamic control over the contribution of each modality based on the data’s contextual information. This adaptability resulted in improved performance, especially in complex scenarios where the relevance of each modality changed.

Personalization Strategies

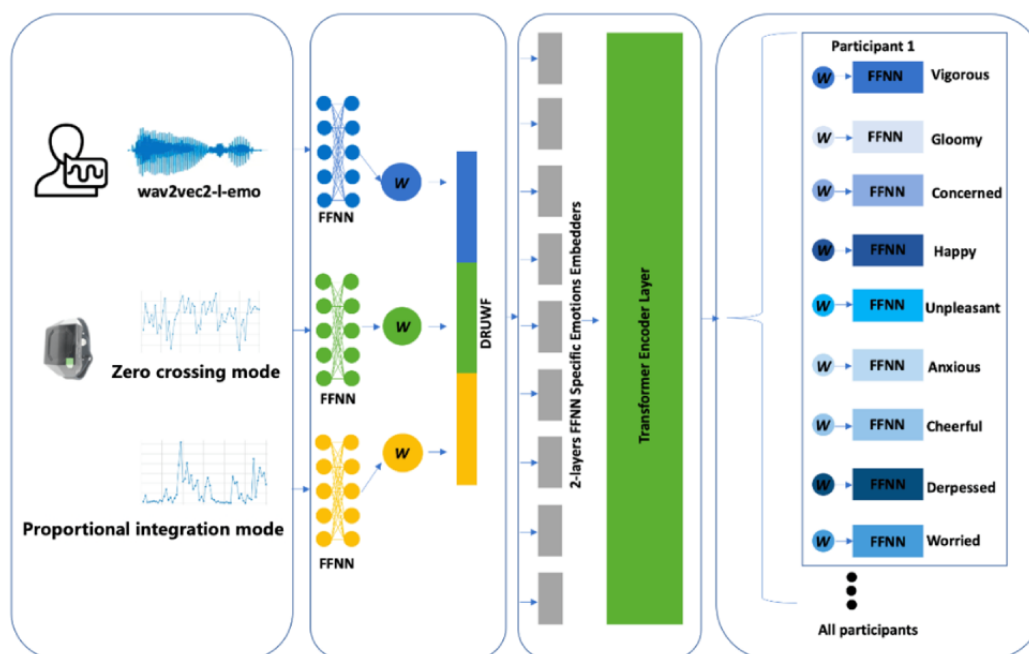

The FFNN was used as a baseline for personalization, adapting concatenated multimodal features to individual profiles. Comparatively, we used a transformer model without separate emotional FFNN for personalization.

We also applied an adapter [54] to compare. The adapter method involved integrating small, trainable modules into a pretrained model. This approach facilitated efficient and effective personalization without the need for extensive retraining.

MTL Approaches

Using a single embedding to produce outputs for multiple tasks with equal weighting provided a baseline for multitask performance. We also compared the pure weighted approach, assigning fixed weights to each task, which showed some improvements over the equal weight strategy but still lacked the dynamic adaptability required for more complex multitask scenarios. The architecture of the proposed model is given in Figure 2.

Figure 2. Macro-micro personalization framework for multimodal-multitask learning in mental health monitoring. W: weight; DRUW: Dynamic Restrained Uncertainty Weighting; DRUWF: Dynamic Restrained Uncertainty Weighting Fusion; FFNN: feed-forward neural network. The framework integrates physiological signals and speech data through feature extraction, DRUWF, macro layers with transformer encoder, and micro personalized layers.

Model Training Procedure

All models in our study were trained over 100 epochs using stochastic gradient descent with an initial learning rate set at 0.001, using a Nesterov momentum of 0.9 to enhance convergence. The learning rate was adaptively reduced by a factor of 0.9 if no improvement was observed on the development set after 5 consecutive epochs, ensuring efficient optimization. The training was conducted with a batch size of 16, balancing computational resources and model performance. Additionally, a weight decay of 0.0001 was applied to prevent overfitting. The final model configuration selected for evaluation on the test set was the one yielding the best performance on the development set, ensuring the reliability and robustness of our results. Before producing the final output, we used a sigmoid function to ensure that the predicted values ranged from 0 to 1. This adjustment was necessary because our labels had been normalized to a scale of 0 to 1.

Ethical Considerations

This study was approved by the Ethics Committee of the University of Tokyo (21-353). The study participants provided written informed consent.

Results

Overview

Our results first show CCC for various emotional dimensions using different single-modal data types (physical activity and audio), with and without personalization in [Table 2](#). Our analysis also investigated the efficacy of various multimodal fusion techniques and their capacity for personalization in assessing different emotional dimensions in [Table 3](#). The multimodal fusion approaches examined included basic, max fusion, gated fusion, attention fusion, solo-attention fusion, cross-modal attention, and a number of proposed methods. Each of these

techniques was also analyzed in conjunction with various multitasking frameworks such as basic, transformer, adapter, equal, multioutputs, and our proposed method. In comparison between the 2 tables, multimodal results generally outperform single-modal ones.

The results indicate a differential impact on the CCC across emotional states and fusion methods. For instance, the max fusion approach yielded a CCC of 0.451 for vigorous, which was a notable improvement over the basic approach's 0.415. However, this method seemed less effective for gloomy, with a CCC of 0.356. In contrast, the gated fusion technique exhibited a more consistent performance across different emotional states, with CCCs ranging from 0.277 for anxious to 0.537 for worried.

Of particular interest were the results from the proposed methods, which showed promising CCC values across several emotional states. The highest recorded CCC of the proposed methods was for worried, with a value of 0.581. Conversely, gloomy showed the lowest CCC at 0.377 using the same proposed methods.

Overall, the mean CCC values across all emotional states suggested that the proposed methods combined with our proposed multitasking framework outperformed the other techniques, achieving a mean CCC of 0.503. This mean value was computed by averaging CCCs across all the emotional states for each method. Notably, the proposed methods consistently yielded CCC values above the overall mean, underscoring their potential for enhancing emotion recognition tasks in multimodal settings.

In conclusion, our results underscore the importance of choosing the appropriate fusion and multitasking methods to maximize the agreement between predicted and actual emotional states. The proposed methods, when tailored for individual emotional dimensions, demonstrate significant promise for personalization, which is a critical aspect of effective emotional state prediction.

^bThe "Mean" column represents the average CCC across the emotional dimensions.

Statistical Validation

We also conducted a statistical analysis to complement the CCC results from our deep learning model, crucial for validating the model's reliability and generalizability across different datasets and conditions. Our mixed linear model analysis [55], presented in Table 4, reveals 2 critical insights. First, the highly significant within-individual associations (Q) across 9 emotional scales underscore the model's capability to capture nuanced emotional responses, indicating its robust predictive power. Second, the

observation of group and residual variances highlights the variability that the model does not account for, signaling areas that require further refinement. This unexplained variability invites a deeper investigation into potential factors, such as the model's sensitivity to specific data characteristics or the necessity for incorporating a more diverse range of training data. Understanding these elements can guide targeted improvements in the model's architecture and training process, ultimately enhancing its accuracy and applicability in personalized mental health monitoring.

Table 4. Mixed linear model regression results for emotional dimensions^a.

Emotional dimension	Intercept	Regression coefficient	SE	z score	P value> z	95% CI	Group variance	Residual variance
Vigorous	0.155	0.549	0.076	7.176	<.001	0.399-0.698	0.039	0.057
Gloomy	0.087	0.607	0.064	9.512	<.001	0.482-0.733	0.023	0.067

^aThe table summarizes the intercept, regression coefficients, standard errors, z scores, P values, CIs, group variances, and residual variances for each emotion studied. The emotional dimensions covered are vigorous, gloomy, concerned, happy, unpleasant, anxious, cheerful, depressed, and worried.

Discussion

Overview

This study introduces a novel dataset and a macro-micro framework for personalized daily mental health monitoring, leveraging multimodal and MTL strategies. The results demonstrate the efficacy of our approach in predicting emotional states, with a mean CCC of 0.503 across 9 emotional dimensions.

The proposed macro-micro framework, which combines macro-level emotion transformer embeddings with micro-level personalization layers, shows superior performance compared to traditional approaches. This suggests that incorporating both general emotional patterns and individual-specific adaptations is crucial for accurate mental health monitoring. The effectiveness of our DRUW fusion method in integrating multimodal data further underscores the importance of adaptive weighting strategies in handling diverse data types.

Our findings align with previous studies highlighting the potential of multimodal approaches in mental health monitoring. However, our work extends beyond existing research by incorporating personalization at both macro and micro levels, addressing a critical gap in current mental health technology.

The high significance of within-individual associations across emotional scales, as revealed by our mixed linear model analysis, validates the model's capability to capture nuanced emotional responses. This has important implications for the development of personalized mental health interventions, as it suggests that our model can detect subtle changes in an individual's emotional state over time.

However, the observed group and residual variances in our statistical analysis indicate that there is still unexplained variability in emotional states. This highlights a limitation of our model and suggests that additional factors, not captured in our framework, may influence daily emotional states. These could include external stressors, social interactions, or physiological factors not measured in our study.

Another limitation is the reliance on self-reported emotional states, which, while valuable for capturing subjective experiences, may be subject to reporting biases. Future research could explore the integration of objective measures of emotional state, such as facial expression analysis or additional physiological markers, to complement self-reports.

Looking ahead, several avenues for future research emerge from our findings. First, expanding the dataset to include a more diverse range of participants and longer monitoring periods could enhance the generalizability of our model. Second, investigating the incorporation of additional modalities, such as sleep patterns or social media activity, could provide a more comprehensive picture of mental health. Finally, exploring the application of our framework in clinical settings could help bridge the gap between research and practical mental health interventions.

Conclusions

In conclusion, this study introduces a groundbreaking dataset and a macro-micro framework that significantly advances personalized daily mental health monitoring. By leveraging multimodal and MTL strategies, we have demonstrated a robust model capable of predicting emotional states. The statistical analysis further validates the model's reliability, highlighting its potential for wider application in the mental health domain.

Moving forward, our focus will be on expanding the dataset, incorporating additional modalities, and refining our model to address these variances, with the ultimate goal of making daily mental health monitoring a more accessible, nonintrusive, and personalized practice.

Abstract

Background: Sharing mental health notes through patient accessible electronic health records (PAEHRs) is controversial. Many psychiatric organizations and regions in Sweden have resisted the implementation, as clinicians worry about possible harms when patients are reading their notes. Despite the documented benefits of PAEHRs, there is still a lack of knowledge regarding whether patients with mental health issues could reap similar benefits of reading their notes as other patient groups.

Objective: The aim of the study is to examine the use, attitudes, and experiences of patients with mental health issues by reading their notes in the PAEHR and, moreover, whether their experiences differ from other patient groups, and if so, how.

Methods: A national patient survey was conducted with answers from 2587 patients from different patient groups. In total, 504 respondents (19.5%) indicated that they experienced a mental health disease. Answers from this patient group were compared to the answers from all other respondents. Survey questions related to attitudes, information usage, and effects on contacts with care were selected for analysis. Mann-Whitney *U* tests were used to detect groupwise differences.

Results: Patients with mental health issues use PAEHRs for checking that they have received the right care (mean_mental health 2.83, SD_mental health 1.39; mean_others 2.62, SD_others 1.37; $P=.002$) or suspected inaccuracies (mean_mental health 2.55, SD_mental health 1.34; mean_others 2.31, SD_others 1.30; $P=.001$), blocking access for professionals in other specialties (mean_mental health 3.43, SD_mental health 1.46; mean_others 3.04, SD_others 1.42; $P<.001$), and checking which care professionals have accessed their record (mean_mental health 4.28, SD_mental health 1.14; mean_others 4.05, SD_others 1.25; $P<.001$) to a significantly higher degree than other patients. On the other hand, the results show that a significantly lower proportion of patients with mental health issues (mean_mental health 3.38, SD_mental health 1.21; mean_others 3.52, SD_others 1.18; $P=.02$) believe that PAEHRs help them in shared decision-making compared to other patient groups.

Conclusions: Patients with mental health issues who took part in the survey, as a group, express some minor differences in both the use of the PAEHR and their experiences regarding its usefulness, as compared to other patients, as a group. This patient group shows a slightly higher interest in 2 types of use: checking for accuracy of care in the record and blocking access to mental health notes for professionals from other parts of the health care system. Compared to other patient groups, these patients are less likely to experience that the PAEHR is a support in shared decision-making. The study indicates that the benefits of PAEHR on a general level are the same for this patient group as for other patients. The study does not support clinicians' worry about possible harm to this patient group. Further research is however needed.

Introduction

Patient accessible electronic health records (PAEHRs) aim to promote patients' engagement with their care by giving patients direct access to their electronic health records (EHRs) through a national patient portal. Patients in around 20 countries worldwide, including Estonia, the Nordic countries, Australia, the United States, Canada, and England, are now offered web-based access to at least some of their EHRs. In Sweden, the PAEHR called "Journalen" was launched in 2012, when the region of Uppsala offered all citizens 18 years and older of age access to their EHRs through the national patient portal 1177 Vårdguiden. In 2015, Journalen was launched as the national system in Sweden for web-based access to clinical notes, and at the end of 2018, all regions had implemented Journalen. The PAEHR offers the patient access to his or her medical notes, prescribed medications, laboratory results, diagnosis, maternity care records, referrals, and vaccinations. Since health care in Sweden is governed by 21 autonomous regions with their own regulations, there are some regional differences concerning what type of information a patient can access and how soon (immediately or after 2 weeks). All regions offer patients access to visit notes from somatic care and test results.

Despite the documented benefits of PAEHRs [1-3], clinicians have raised concerns that patients could become confused or anxious by what they read [4]. The web-based access to mental health notes is especially controversial. The clinicians' main argument is that in mental health, the information concerns sensitive topics that can have negative consequences for patients when they access their notes. In the study by Peck et al [5], several clinicians approved of the possibility to exclude patients from access, when they were considered too vulnerable. Different survey studies related to PAEHR and mental health suggest that clinicians worry about possible harms, and many health care professionals anticipate that patients will become confused, get angry, or decompensate when reading their notes [6,7]. Other studies report that patients with mental health can benefit from accessing their notes. Some reported benefits are increased feelings of engagement [8-10], feeling of control over their health, trusting their providers, taking better care of themselves, remembering their care plan, understanding better the rationale for medications, and being more likely to take their medications as prescribed [11,12]. A small number of studies have however found negative consequences for patients with mental health issues because of reading the mental health notes, such as feeling judged, worried, or offended [5,12-14]. A majority of studies [5,9,15] suggest that outpatient patients with mental health issues value reading their notes, that psychiatrists do not experience increased work burden or perceive negative outcomes, and that respectful, accurate mental health notes may enhance patient trust.

In Sweden, region Skåne made mental health notes accessible to adult patients from 2015. Since then, more regions have followed, and as of today, 17 of 21 regions share mental health

notes through the PAEHR Journalen [16]. There are no other differences between patients with mental health issues and other patient groups regarding what information types you have access to and when. Thus, patients with mental health issues have the same access to notes from somatic care, test results, and other information types accessible in their region as all other patients. Attitudes among physicians were studied (along with other professional affiliations) before and after the implementation of PAEHR in region Skåne [7]. That study reported that some physicians were more careful with what they documented in the record, as a result of not knowing how the patient might interpret and use the information. Similar results were reported by Dobscha et al [6] and Denneson et al [17], who found that clinicians were less detailed and changed their tone of the notes when they knew that the patient might choose to read the notes. Respondents in the study by Petersson and Erlingsdóttir [7] also indicated a fear of increasing tension between clinicians and the patient, which could manifest itself in threats and acts of violence. In their follow-up study, the professionals rather expressed that there were no changes in patient involvement after the implementation of PAEHRs [18].

Additionally, Denneson et al [17] reported that clinicians expressed concern that access to mental health notes "could damage the therapeutic relationship by exposing a disconnect between the patients' in-person experience with their clinicians and the documentation they read in their notes." Mental health notes can, they argue, reveal aspects of the therapeutic process—such as clinical formulations and subjective impressions—which clinicians frequently do not communicate to their patients. Thus, a patient reading his or her notes could cause the patient to misinterpret the clinician's notation, which could have negative effects on the patient, such as having feelings of being judged or stigmatized [17]. Moreover, patients with mental health issues are also generally considered a vulnerable patient group, which begs the question whether patients with mental health conditions can reap similar benefits of accessing their PAEHRs as other patient groups [19]. This review shows the topic to be controversial, and in practice, many psychiatric organizations resist implementation.

Empirical research is scarce, especially in Sweden. To our knowledge, there is no comparative research on how PAEHRs are perceived among patients with mental health issues as compared to other patient groups. Moreover, Petersson and Erlingsdóttir [18] make a call for empirical research regarding the perspectives of patients with mental health issues toward PAEHRs. The aim of this paper is to examine the use, attitudes, and experiences of patients with mental health issues by reading their notes in the PAEHR and if their experiences differ from other patient groups. More practical knowledge is needed in this area as input to the ongoing debate regarding the possible benefits for patients in accessing their mental health notes through PAEHRs.

Methods

Ethical Considerations

The survey, which focused on attitudes toward and experiences of using Journalen, was approved by the regional ethical review board in Uppsala, Sweden (EPN 2017/045). The respondents were informed about the voluntary participation and the aim of the study as well as presented with standard consent that needed to be accepted before the survey could be started. No data were stored unless the respondent chose to submit the answers at the end of the survey. The data were anonymized by representing each respondent with a number. No incentives were offered for participation.

Study Design

This paper is based on data from an open anonymous self-completion digital national patient survey distributed to users of the Swedish PAEHR system, Journalen, through a link on the login page. Thus, all citizens who logged in to the service during the period that the questionnaire was accessible (June to October 2016) were potential respondents to the voluntary survey.

The survey included 24 questions with a combination of Likert-scale items, multiple-choice items, and free-text alternatives. The questions covered the following themes: attitudes and reactions, access to and usage of information, effects on contact with health care, information content, security and privacy, personal health information, and demographics.

The theme “personal health information” included a question about which diagnosis group the respondents identified himself or herself to belong to. The respondents could choose between the alternatives of cancer, mental health, diabetes, high blood pressure, and others. The diagnoses of cancer, diabetes, and high blood pressure were specified as survey alternatives as they are the most common chronic conditions in Sweden. The alternative to mental health was included in order to address the ongoing debate in Sweden regarding whether psychiatric records should be made available and whether this patient group can benefit from accessing their medical record. Of the respondents, 504 people chose to identify themselves as belonging to the group of patients with mental health issues. This constitutes 19.5% (n=504) of the respondents who answered the survey. Globally, about 1 in every 8 people live with a mental disorder—most commonly, an anxiety or depressive disorder [20]. In Sweden, an official national health survey reported that 16% of respondents experienced severe mental difficulties, but that as many as 71% of respondents experienced feelings of anxiety or worry [21]. It is thus not remarkable or questionable that as many as 19.5% (n=504) of respondents in this study identified themselves to belong to this group of patients.

The full national survey was analyzed and presented by Moll et al [22]. In this study, 7 Likert-scale questions, including several items, related to attitudes, information usage, and contacts with care were selected for further analysis in relation to patients with mental health issues. Questions related to general attitudes and information usage were also picked out

in order to shed light on any differences regarding how patients view and use the possibilities that Journalen gives. Finally, questions related to information accuracy, contact with care, and involvement in the care process were selected, since they reflect issues that mental health professionals have raised, as reported by previous studies. This set of selected questions is motivated by the need to develop knowledge that addresses the controversial question regarding access of patients with mental health issues to their records, and the set of questions relate closely to the concerns that were raised by health care professionals. The paper focuses on the answers of patients with mental health issues as a group and compares those to the answers from the other respondents as constituting another group.

During the time that the survey was distributed on the login page of Journalen, only 2 regions (Skåne and Kronoberg) had opened up web-based access to mental health notes. One consequence of this is that some of the patients with mental health issues who answered the survey could not yet access the mental health notes, while others could. Patients who lived in other Swedish regions could still access other types of health information (eg, test results and notes from primary care visits). During the survey period, 154 patients (30.6% of the mental health respondents) belonged to Skåne or Kronoberg and could thus access their mental health notes.

Analysis

Apart from descriptive analysis, Mann-Whitney *U* tests were used for detecting groupwise differences in answers on the 5-point Likert-scale questions between the group of patients with mental health issues and the group of all other respondents. The same test was used for detecting groupwise differences between mental health respondents from the regions Skåne and Kronoberg, who could read the mental health notes at the time the survey was open, and all other mental health respondents. This extra comparison was performed to investigate if the survey answers were affected by the fact that some of the mental health respondents could not actually access their mental health information but only information related to somatic care. Prior to the analysis, the Likert-scale options strongly agree, agree, neutral, disagree, and strongly disagree were converted to a numerical scale (1=strongly disagree and 5=strongly agree). No free-text questions were analyzed in this study. The SPSS software (version 25; IBM Corp) was used for all calculations.

Results

Result Presentation

In the tables in the following subsections, the response options “strongly agree” and “agree” have been combined for readability. For the same reason, “strongly disagree” and “disagree” were also combined. In [Multimedia Appendix 1](#), the results for all response options are provided for completeness. As mentioned, some patients with mental health issues could access their mental health notes in Journalen at the time of the study, while others could not. Mann-Whitney *U* tests were used to check if there were any significant differences between patients with mental health issues who could and could not access their mental health notes. Significant differences were

only found for 2 of the survey questions in the study (regarding access to all types of record entries and access to log list). Hence, the vast majority of the results presented here were not affected by the respondents being able to access their mental health notes.

Demographic Information

Demographic information about the respondents is provided in [Table 1](#) together with a comparison against demographic data

from the other group of respondents. Chi-square tests were used to check for significant associations between the compared variables. The group of patients with mental health issues was a bit younger, which was expected based on current statistics [23]. Moreover, there was a female dominance that was however a bit stronger than the statistics would suggest. Additionally, the level of education is lower for the mental health group. No differences were found regarding previous work experience in health care.

^bPatients with mental health issues: n=494; other patients: n=1943.

^cPatients with mental health issues: n=498; other patients: n=1943.

^dPatients with mental health issues: n=497; other patients: n=1954.

General Attitudes

Both patients with mental health issues and all other patients are generally positive toward the Swedish PAEHR system, Journalen ([Table 2](#)). The vast majority of the respondents, no matter which of the 2 groups they belong to, believe that access to Journalen is good for them (Q3b), and that web-based access to medical records is generally a good reform (Q3a). The Mann-Whitney *U* tests showed significant differences between the 2 groups for questions Q3a (mean_mental health 4.73,

SD_mental health 0.68; mean_others 4.80, SD_others 0.60; *P*=.01) and Q3b (mean_mental health 4.78, SD_mental health 0.64; mean_others 4.86, SD_others 0.51; *P*=.005), indicating a slightly less positive attitude among patients with mental health issues. The difference between the 2 groups is, however, very small, pointing to that the results are not that significant.

Regarding the content within the PAEHR Journalen, the respondents were asked to rate how accurate they believe the content is. This question was split into 2 aspects: whether the

information that is found in the record is correct (Q15a) and whether sufficient information was recorded (Q15b; [Table 3](#)). Both groups, patients with mental health issues and all other patients, gave a fairly high rating regarding the correctness of information (mean_mental health 3.98, SD_mental health 0.99; mean_others 4.22, SD_others 0.91; $P<.001$) and a lower score regarding the completeness of information (mean_mental health 3.32, SD_mental health 1.34; mean_others 2.85, SD_others 1.40; $P<.001$). The differences between the groups were

statistically significant in both cases, indicating that patients with mental health issues were more inclined to think that information was complete but less convinced that the information was correct, as compared to all other patients. This being said, the average rating among patients with mental health issues for the question about completeness was fairly low (close to neutral), while it was higher (close to “agree”) for the question about correctness.

Table 2. The results regarding general attitudes toward Journalen from patients with mental health issues and all other patients.

Question	Mean_mental health (SD)	Mean_others (SD)	P value
I believe that access to medical records online is generally a good reform	4.73 (0.68)	4.80 (0.60)	.01
I believe that access to “Journalen” is good for me	4.78 (0.64)	4.86 (0.51)	.005

Table 3. The results regarding information accuracy in Journalen from patients with mental health issues and all other patients.

Question	Mean_mental health (SD)	Mean_others (SD)	P value
The content in the record reflects the information I think that health care has about me	3.98 (0.99)	4.22 (0.91)	<.001
There is information about me that is missing in the record which I think should be there and that the staff should know	3.32 (1.34)	2.85 (1.40)	<.001

Accessing Patient Information

Regarding the respondents’ answers to why a patient uses Journalen (Q4a-h), the results show that the most common reasons for accessing Journalen, among patients with mental health issues, are to get an overview of the medical history and treatment (Q4b), to follow-up what has been said during a health care visit (Q4e), and to become more involved in the care (Q4h). The same holds true for all other survey respondents. The least common reason for access, for both groups, was to get an overview of relatives’ medical history and treatment (Q4c). Results for all these questions are presented in [Table 4](#).

There were 4 reasons for access, where the analysis showed significant differences between patients with mental health issues and the other respondents (Q4a,b,d, and f; also in [Table 4](#); detailed results for all items related to this question (Q4) are presented in [Multimedia Appendix 1](#)). Of these 4, to get an overview of medical history and treatment, Q4b got the highest mean score, where patients with mental health issues gave slightly lower ratings (mean_mental health 4.58, SD_mental health 0.78) than other patients (mean_others 4.65, SD_others 0.80; $P=.001$). Still, the results show that patients with mental health issues see this as one of the most important reasons for accessing the PAEHR. On the other hand, compared to the other

respondents, patients with mental health issues gave slightly higher, significant, ratings for the following reasons to use: general interest (mean_mental health 3.86, SD_mental health 1.19; mean_others 3.66, SD_others 1.29; $P=.002$), insecurity of whether the care is right (mean_mental health 2.83, SD_mental health 1.39; mean_others 2.62, SD_others 1.37; $P=.002$), and suspicion of inaccuracies (mean_mental health 2.55, SD_mental health 1.34; mean_others 2.31, SD_others 1.30; $P<.001$). The differences are, however, not very large, and none of these 3 were marked as one of the most common reasons for access by any of the groups.

Respondents were also asked to rate items of their importance, in connection to being able to access Journalen (Q5). The respondents in the mental health group rated the following benefits of being able to access Journalen the highest: it makes me feel informed (Q5e), it makes me feel safe (Q5d), and it improves communication between medical staff and me (Q5a). The other respondents’ ratings gave similar results aside from that they rated Q5c (it improves the understanding of the condition) as one of the top 3 benefits instead of Q5d. It is also of interest to note that both groups of respondents gave a very low rating to the item it has no relevance (Q5j), indicating that the respondents generally see clear benefits from accessing Journalen. See [Table 5](#) for detailed results.

Table 4. Respondents' answers to the question "Why do you use Journalen?" by patients with mental health issues and all other patients^a.

Question	Mean_mental health (SD)	Mean_others (SD)	P value
Mostly general interest	3.86 (1.19)	3.66 (1.29)	.002 ^b
To get an overview of my medical history and treatment	4.58 (0.78) ^c	4.65 (0.80) ^c	.001 ^b
To get an overview of my relatives' medical history and treatment	2.06 (1.45)	2.21 (1.52)	.05
Because I am not sure if I got the right care	2.83 (1.39)	2.62 (1.37)	.002 ^b
To follow up what has been said during a health care visit	4.47 (0.91) ^c	4.39 (0.99) ^c	.10
Because I suspect inaccuracies	2.55 (1.34)	2.31 (1.30)	<.001 ^b
To prepare for my health care visit	3.40 (1.35)	3.51 (1.33)	.11
To become more involved in my care	4.21 (1.10) ^c	4.28 (1.02) ^c	.39

^aThe Mann-Whitney *U* test was used for statistical analysis.

^bSignificant *P* values.

^cThe most highly ranked options by mental health respondents and other respondents.

Table 5. Respondents' answers to the question "How important is it for you to be able to access patient information?" by patients with mental health issues and all other patients. Some items related to Q5 are only shown in [Multimedia Appendix 1](#)^a.

Question	Mean_mental health (SD)	Mean_others (SD)	P value
It improves communication between medical staff and me	4.21 (0.96) ^b	4.36 (0.92) ^b	<.001 ^c
It improves the understanding of the condition	4.18 (1.02)	4.26 (0.98) ^b	.12
It makes me feel safe	4.24 (0.99) ^b	4.22 (0.97)	.44
It makes me feel informed	4.59 (0.76) ^b	4.62 (0.72) ^b	.42
It leads to that I can take care of my health better	3.40 (1.16)	3.54 (1.13)	.02 ^c
It leads to that I can take care of my relatives health better	2.39 (1.38)	2.52 (1.36)	.04 ^c
It is essential that I am able to actively participate in decisions about my or my relatives' health	3.31 (1.44)	3.47 (1.41)	.03 ^c
It has no relevance	1.49 (0.96)	1.50 (0.93)	.52

^aThe Mann-Whitney *U* test was used for statistical analysis.

^bThe most highly ranked options by mental health respondents and other respondents.

^cSignificant *P* values.

Some significant differences were however found between the groups (also in [Table 5](#)). Patients with mental health issues rated the following benefits of Journalen as of lower importance than did the other patients: improves communication with health care ($P<.001$), enables better self-care ($P=.02$), improves the possibility to take better care of relatives ($P=.04$), and enables the essential possibility to participate in health decisions ($P=.03$). None of the stated items in Q5 were rated of higher importance by patients with mental health issues compared to other patients, with a significant difference between the groups. Among the items where significant differences could be identified, only item Q5a about improved communication was one of the most highly rated benefits of accessing Journalen.

Moreover, respondents were asked how important different information types and functions in Journalen are to them (Q17a-r). The 3 functions or information types that the group of patients with mental health issues rated to be of highest

importance to have access to were results of tests (Q17d), being able to read all types of record entries (Q17g), and overview of all health care contacts (Q17e). This rating corresponds well to the ratings from the group of other patients. Both respondent groups gave the lowest ratings to the importance of being able to communicate electronically with other patients (Q17o).

There were 18 items included in this survey question. For most of the items, no significant difference could be found between the 2 groups of respondents. The 6 items for which significant differences *could* be identified are presented in [Table 6](#). Patients with mental health issues gave higher ratings to the importance of the following information types or functions: psychiatry records ($P<.001$), all types of medical notes or record entries ($P=.02$), blocking professionals from access to certain information ($P<.001$), and access to the log list ($P<.001$). Of these, the differences were largest regarding the importance of having access to the psychiatry record (mean_mental health

4.47, SD_mental health 1.09 and mean_others 3.65, SD_others 1.38) and the possibility to block other professionals from having access to all patient information (mean_mental health 3.43, SD_mental health 1.46 and mean_others 3.04, SD_others 1.42), which was expected due to the special needs of this group. Furthermore, patients with mental health issues gave slightly lower ratings regarding the importance of the following information types or functions: referral tracking ($P=.02$) and test results ($P=.01$). It is also noticeable that both studied groups of patients gave generally high ratings to most of the information types and functions included in question Q17.

For 2 of the information types or functions listed in the survey (access to all record entries and access to the log list), the responses from patients with mental health issues who could or could not access their mental health records differed significantly. In the case of access to all types of record entries, those who could access their mental health notes gave significantly higher ratings ($P=.049$), and in the case of the log list, this group of respondents gave significantly lower ratings ($P<.001$).

Table 6. Respondents' answers to the question "How important is it for you to have access to the following information which is wholly or partly based on information contained in "Journalen"?" by patients with mental health issues and all other patients. Some items related to Q17 are only shown in [Multimedia Appendix 1](#)^a.

Question	Mean_mental health (SD)	Mean_others (SD)	P value
Referral (content and how it is handled in care)	4.50 (0.88)	4.62 (0.74) ^b	.02 ^c
Results of tests	4.69 (0.76) ^b	4.78 (0.61) ^b	.01 ^c
Overview of all health care contacts	4.59 (0.79) ^b	4.61 (0.77)	.60
Being able to read record entries from psychiatry	4.47 (1.09)	3.65 (1.38)	<.001 ^c
Being able to read all types of record entries	4.68 (0.83) ^b	4.64 (0.79) ^b	.02 ^c

Relationship With Health Care and Patient Involvement

Two of the questions in the survey (Q7 and Q16) covered aspects of the patient's relationship with health care and his or her involvement in the care process. Regarding possible changes in the patient's relationship to health care (in general) after using Journalen (Q7a) and to health care professionals (more specific) due to communication about Journalen (Q7b and c) and its content (Q7d), no significant differences could be found between respondents in the 2 groups (Table 7). Here, it is again important to remember that not all of the respondents who answered in the role of patients with mental health issues, as of the date of the survey, had access to his or her psychiatry record. The results however show that all patients, regardless of group, experience at least a moderate positive effect on the relationship with health

care. Furthermore, patients (regardless of group) and health care professionals generally do not talk about the possibility for the patient to use Journalen nor do they discuss its content.

Regarding patient involvement in the care process, some significant differences were found between the 2 groups (Table 8). Patients with mental health issues gave significantly lower ratings when it came to Journalen's potential to support communication with medical staff ($P=.02$) and its potential to enable shared decision-making ($P=.02$). No significant differences were found regarding support for following prescription of treatment ($P=.053$) or support for self-care ($P=.69$). Overall, the results indicate that Journalen had at least a moderate positive effect in the involvement in the care process for patients with mental health issues, and the same holds true for the other respondents as well.

Table 7. Respondents' answers to the question "To what extent do you agree with the following statements regarding your relationship with health care?" by patients with mental health issues and all other patients^a.

Question	Mean_mental health (SD)	Mean_others (SD)	P value
To take part of the patient information via "Journalen" has affected the relationship with health care system positively	3.80 (1.11)	3.88 (1.07)	.13
Medical staff has informed me about the possibility to read "Journalen"	1.82 (1.29)	1.87 (1.24)	.17
Medical staff has encouraged me to use the "Journalen"	1.70 (1.12)	1.72 (1.09)	.40
I discuss the content of "Journalen" with medical staff	2.53 (1.49)	2.52 (1.41)	.95

^aThe Mann-Whitney *U* test was used for statistical analysis.

Table 8. Respondents' answers to the question "How important is "Journalen" to make you feel that you are involved in your own care?" by patients with mental health issues and all other patients^a.

Question	Mean_mental health (SD)	Mean_others (SD)	P value
Information in "Journalen" has helped me in communication with medical staff	3.57 (1.19)	3.71 (1.13)	.02
Information in "Journalen" had a positive impact on the ability to work together with medical staff making decisions about care and treatment	3.38 (1.21)	3.52 (1.18)	.02
Information in "Journalen" had a positive impact on the ability to follow the prescription of treatment	3.71 (1.22)	3.83 (1.16)	.05
Information in "Journalen" had a positive impact on the ability to take own steps to improve health	3.56 (1.22)	3.60 (1.18)	.69

^aThe Mann-Whitney *U* test was used for statistical analysis.

Discussion

Principal Findings

The aim of this study was to, through a national patient survey, investigate the experiences of patients with mental health issues with the Swedish PAEHR Journalen, as well as possible differences between patients with mental health issues and other patients, related to experiences with and attitudes toward the eHealth service. The paper contributes most and foremost to a much-needed knowledge about the effects of Journalen for a specific patient group—patients with mental health issues—several years after the launch of the service. Several important conclusions about aspects that patients with mental health issues value with regard to Journalen were identified in this study, and some interesting differences between the groups of patients with mental health issues and all other patients were brought to light in the comparative analysis. The results also reveal that, in most cases, patients with mental health issues see the same values in Journalen as other patients.

First, and on an overall level, it is clear from the results of the survey that respondents in the mental health group, as well as all other respondents, were positive toward being able to access personal health information in Journalen, and that there are no big differences between patients with mental health issues and other patients. These results are in accordance with earlier research [9,12]. These results are important, as health care professionals have raised concerns that patients with mental health issues in particular would become confused and agitated from reading their PAEHR [6,7]. Moreover, the results reveal that the group of patients with mental health issues is somewhat more critical toward the accuracy of the content compared to

other respondents. A possible explanation for why more patients with mental health issues find inaccuracies could be that mental health conditions are more subjective and difficult to quantify and therefore may give rise to disagreements in how they should be described and documented. Since patients with mental health issues find more inaccuracies in the record, and since current research [6,17] has reported that some clinicians change the way they document as a result of patients reading their notes, it is of utmost importance that we open up a discussion regarding how notes could or should be written, and if, how, and when the patients should be involved.

Second, regarding the reasons for using the service as well as what information types were considered to be important to patients, there were no big differences between the 2 respondent groups. The reasons for use that were rated highest among mental health respondents are using Journalen for receiving an overview of one's treatments, following up on what was said during a health care visit, and becoming more involved in the care process. This should be seen as an important result, since it shows that the reasons for implementing Journalen in the first place are as relevant for patients with mental health issues as they are for all other patient groups represented in the survey. Nevertheless, this patient group has been treated differently during the implementation process in that, for example, mental health notes were excluded in all regions during the first 3 years and were only accessible in 2 regions 6 years after launch. Results from the comparison between mental health respondents who could access their mental health notes and those who could not, show, interestingly enough, that there are no significant differences for any of the results related to the reasons for using Journalen. Hence, this study does not show any indication that access to these particular notes makes a difference in the reasons

for using Journalen or the attitudes that patients with mental health issues have toward it.

There were some significant differences indicating specific needs that are related to patients with mental health issues, but most of these differences are still small. Hence, even though there were statistically significant differences between the groups, most of the results do not support that there, in practice, would be any big differences between patients with mental health issues and other patients. Patients with mental health issues gave a somewhat higher rating for possibilities of reviewing which of the health care professionals have read the content in the EHR (access to the log list) and for blocking professionals from other health specialties from accessing all information. They also reported somewhat higher feelings of insecurity regarding having received the right care.

The results showed that some patients might use Journalen because of insecurity about receiving the right care. This can be related to some of the concerns raised by mental health professionals. Both Petersson and Erlingsdóttir [7], from the Swedish perspective, and Dobscha et al [6], from the US perspective, reported the general concern that patients would request changes in the health record both due to found inaccuracies and notes that can be considered sensitive and that the patient might not agree with. These studies, from the perspective of health care professionals, report on health care concerns regarding the consequences of patients' access to mental health notes. This survey's results show that patients from this group indeed use Journalen to check whether they have received the right care. The perceived importance of the blocking feature in the system as well as the log list of who has accessed the record points toward an insecurity in who can access the information. This could possibly be due to the sensitive nature of the information related to mental health.

Third, when it comes to communication with health care, no big differences between patients with mental health issues and all other patients could be observed. Respondents with mental health conditions, as well as all other respondents, were generally positive regarding the effects on communication with health care, which is in line with existing research [22], but they gave lower ratings when it comes to communicating with health care professionals about the existence of Journalen. The fact that health care professionals generally do not inform patients about Journalen or encourage them to use the service has also been reported in earlier research but then concerning patients with cancer [24]. A reasonable interpretation of this neglect is that the earlier-mentioned concerns raised by health care professionals function as an obstacle.

Finally, with regard to effects on involvement in care, the results were also similar between the 2 groups. However, patients with mental health issues gave significantly lower ratings to actual effects on the relationship with health care and regarding shared decision-making. These results could possibly be related to the concerns on the effects of the therapeutic alliance that mental health professionals have raised [17]. In contrast to these results, a previous study showed that patients with cancer gave significantly higher ratings than all other patient groups and on all items regarding the effects of involvement in care [24].

Earlier studies, not focusing on specific patient groups [25], have shown that patients' web-based access to medical records has improved the possibility for patients to engage in shared decision-making, something that Rexhepi et al [24] also showed for patients with cancer in Sweden. Similar studies of patients with mental health issues are very few to date. Petersson and Erlingsdóttir [18] showed that most of their answering professionals did *not* experience a higher patient involvement. This survey indicates that patients with mental health issues, regarding participation in decisions related to their care, do not experience the same positive effect as other patient groups. This conclusion is thus in line with the health professionals' view [18]. This issue is clearly worthy of additional exploration.

Limitations

As already mentioned, at the time of the survey, only patients from the regions Skåne and Kronoberg could access mental health notes, since the introduction in 2013. Consequently, some of the patients with mental health issues who answered the survey could not yet access the mental health notes, while others in fact could. All patients with mental health issues could, however, access information on somatic care. An additional Mann-Whitney *U* test was used to compare answers between patients with mental health issues who could and could not access mental health notes. For most of the areas covered in this paper, no significant differences could be found between these 2 groups. In light of this study limitation, when it comes to actual experiences, the study is focusing more on experiences of the PAEHR among patients with mental health issues in general than mental health notes in particular. However, regarding attitudes, the study captures the ideas of patients with mental health issues regarding access to his or her mental health notes. It is also important to recognize that answers were gathered through self-report. A unique patient might have had contact with health care for numerous reasons. We cannot be sure whether there are patients with mental health issues in the "others" group who did not disclose their mental health status in the survey. Moreover, one could discuss how homogenous the mental health group is, given the diversity in both type of diagnosis and severity in symptoms that might be visible within the group. The survey did not capture this diversity.

Conclusions

The study was based on a national patient survey where 19.5% (n=504) of respondents indicated that they experienced a mental health disease. The objectives of the paper were to examine the use, attitudes, and experiences of patients with mental health issues by reading their notes in the PAEHR and, moreover, whether their experiences differ from other patient groups, and if so, how.

A first conclusion, on an overall level, is that patients with mental health issues are as positive in their attitudes toward the access of personal health information in Journalen as other patient groups. This conclusion agrees with previous research. A second conclusion is that patients with mental health issues use Journalen differently in 2 manners, as compared to other patient groups: they check the record for inaccuracies regarding care and information content and they tend to block access to mental health notes for professionals from other parts of the

health care system. These differences in usage were not known from previous research. A third conclusion is that patients with mental health issues have somewhat other experiences from Journalen than other patient groups, in that they are less likely to find it supportive of shared decision-making between themselves and their doctor. This was not known from previous research. A final conclusion is that the clinicians' worry about possible harm to this patient group does not find support by the current empirical evidence. Patients with mental health issues with access to their mental health notes reported the same positive attitudes toward Journalen as did patients with mental health issues with only access to their somatic health notes.

There are many previous studies on how patients access PAEHR and their attitudes to the introduction of such eHealth services. This study contributes with knowledge, through its comparative research design, on how PAEHRs are perceived by patients with mental health issues as compared to other patients. Further research is however needed in this area. For example, the study contributed with insights regarding different usage patterns. It would be valuable with empirical insights and explanations of why patients with mental health issues are somewhat more critical regarding the accuracy of the information content. From the perspective of professionals, previous research has predicted that patient access to mental health notes will have consequences

on what and how the professionals write the notes. This study indicates interesting paths for further investigation of that issue. A practical implication is, however, that professionals do not need to be overly concerned about potential harm to the patients. Patients with mental health issues use Journalen and its information by the same reasons as other patient groups. Patients with mental health issues are as positive to the effects on communication with health care as other patient groups, which is in line with previous research.

Patients with mental health issues are a vulnerable group, where professionals anticipate that patients may get confused, judged, worried, or angry when reading their notes. This study did not find support for that. Other studies have reported benefits from accessing the mental health notes, such as feelings of increased engagement, control over their health, and trust toward the professionals. Finally, this study contributes with the insight that the group of patients with mental health issues finds it less possible to engage in shared decision-making as compared to other patient groups. Further research could help us better understand why we need to know more about the obstacles to patient participation and how Journalen can be used to better address practical issues related to feelings of engagement, control, and trust.

Acknowledgments

The authors would like to thank the colleagues in the national Development of Online Medical Records and E-Health Services consortium who participated in the data collection. The authors would also like to thank INERA and Evry for distributing the survey through the national patient portal.

Authors' Contributions

JM led the work and analyzed all the data. JM and GM did most of the study design, and all authors contributed equally in writing and editing the paper.

Conflicts of Interest

None declared.

Abstract

Background: Digital exclusion, characterized by a lack of access to digital technology, connectivity, or digital skills, disproportionately affects marginalized groups. An important domain impacted by digital exclusion is access to health care. During COVID-19, health care services had to restrict face-to-face contact to limit the spread of the virus. The subsequent shift toward remote delivery of mental health care exacerbated the digital divide, with limited access to remote mental health care delivery. In response, Camden and Islington National Health Service Foundation Trust launched the innovative Digital Inclusion Scheme (DIS).

Objective: This study aimed to examine the impact of facilitating digital inclusion in mental health access. Camden and Islington National Health Service Foundation Trust implemented the trust-wide DIS for service users who were digitally excluded, that is, were without devices or connectivity or reported poor digital skills. The scheme provided access to a loan digital device (a tablet), internet connectivity devices, and mobile data, as well as personalized digital skills support.

Methods: The DIS went live in October 2021 and received 106 referrals by June 2022. Semistructured interviews were conducted with 12 service users to ask about their experience of accessing the DIS. A thematic analysis identified themes and subthemes relating to the extent of their digital exclusion before engaging with the scheme and the impact of accessing a scheme on their ability to engage with digital technology and well-being.

Results: There were 10 major themes. A total of 6 themes were related to factors impacting the engagement with the scheme, including digital exclusion, relationship to the trust, the importance of personalized digital support, partnership working, device usability and accessibility, and personal circumstances. The remaining 4 themes spoke to the impact of accessing the scheme, including improved access to services, impact on well-being, financial implications, and a greater sense of empowerment.

Conclusions: Participants reported an increased reliance on technology driving the need for digital inclusion; however, differences in motivation for engaging with the scheme were noted, as well as potential barriers, including lack of awareness, disability, and age. Overall, the experience of accessing the DIS was reported as positive, with participants feeling supported to access the digital world. The consequences of engaging with the scheme included greater perceived access to and control of physical and mental health care, improved well-being, and a greater sense of empowerment. An overview of the lessons learned are provided along with suggestions for other health care settings that are looking to implement similar schemes.

Introduction

Background

The emergence of COVID-19 in the United Kingdom led to a rapid transformation in the provision of health services, as it became necessary to reduce face-to-face contact to limit the spread of the virus [1]. As the general population experienced a marked and a prolonged deterioration in mental health, remote care and telehealth practices were rapidly adopted by health care systems to ensure continuity of care [2-4]. Disruption to community and third-sector services further proved detrimental to already at-risk populations, including those with preexisting mental health conditions and severe mental illness or those affected by financial destitution and homelessness [5,6]. As such, the integration of digital solutions into health care became inevitable, with advocates noting greater flexibility to meet individual needs and digital transformation as key to implementing the National Health Service (NHS) long-term transformation strategy [7-9].

However, concerns were raised by practitioners and service users as to the feasibility of engaging in telehealth interventions or other forms of digital health care delivery. These included the ability of staff and service users to navigate devices and platforms, the lack of physical or financial resources to obtain technology, poor connectivity, concerns around cybersecurity, and physical privacy when providing or receiving telehealth care in a home environment [1,8,10,11]. Digital exclusion, characterized by lack of access, connectivity, or digital skills, is another domain that presents a challenge to the remote delivery of health care with marginalized groups particularly affected [12]. This includes older adults [3], homeless people [13], immigrants [14], people with disabilities [12], and individuals with severe mental illness (eg, psychosis) [15].

The term *digital divide* conceptualizes this inequality, differentiating between those who have access and those who do not [16]. It consists of 3 levels [17]: *lack of access* to information and communications technology (ICT), for example, computer, tablet or mobile phone devices, or data; *lack of digital skills or confidence*; and *lack of awareness, or interest*, in the opportunities digital technology can provide [18]. The 3 strands of the digital divide are not linear, but rather they are interactional and reciprocal; one may have a high level of digital ability; however, without an ICT device, one cannot use these skills, while the likelihood of being digitally excluded is exacerbated by societal inequities, and the lack of access can itself perpetuate marginalization [19-21]. The relationship between digital exclusion and preexisting inequalities thus limits individuals' ability to participate in the digital world; can lead to greater social isolation [20]; and prohibit access to education, training, and employment opportunities [22] or, critically, access to mental and physical health services [13].

With the shift toward remote delivery of mental health services exacerbating the digital divide in the wake of COVID-19, the Camden and Islington NHS Foundation Trust (C&I NHS FT) launched the innovative Digital Inclusion Scheme (DIS) to support digitally excluded service users accessing community mental health services. The scheme provided access to a loan

ICT device (a tablet), internet connectivity devices, and mobile data, as well as personalized digital skills support to enhance literacy and confidence. This scheme aimed to build on lessons learned from previous initiatives, which had predominantly focused on increasing digital skills and competency to bridge the digital divide [3,11,21,23,24]. However, the lack of physical access to resources remained an immediate concern for those affected by digital exclusion [25]. Similarly, interventions restricted in time (eg, NAViGO) [12] or limited in reach, for example, only available for a small number of inpatients [4]. Interventions also tended to support organizations rather than individuals (eg, Digital Communities Wales) [26] or link together various community organizations rather than providing holistic support, for example, 100% Digital Leeds [27]. Pertinent was also the marked absence of robust evaluation regarding the impact of such schemes.

Objective

Following its launch in October 2021, this evaluation therefore aimed to understand the impact of the DIS on service users, as well as to identify the barriers and facilitators to implementing such schemes in future. Specifically, it aimed to (1) summarize the project and communicate the lessons learned to date, (2) understand the barriers and facilitators to accessing digital technology within a DIS within a population of mental health service users, and (3) explore the impact on service users who used the scheme and any impact it had on their well-being.

It is anticipated this evaluation will inform clinicians, service planners, and commissioners as to whether this type of scheme is feasible and acceptable in the context of an NHS trust and provide an example design to those both within the NHS and wider community groups.

Methods

Design

This evaluation used an intervention mixed methods framework, combining quantitative and demographic data from the referral form and baseline questionnaire (part 1) and semistructured qualitative interviews to understand the impact of the scheme (part 2). This evaluation encompasses referrals received between October 2021 and June 2022.

Setting

C&I NHS FT is a large inner-city NHS trust, which provides mental health and substance misuse services. Due to the COVID-19 pandemic and social distancing requirements, most NHS services transitioned to delivering treatment remotely, leaving many service users without continued access to care. In response, C&I NHS FT established a DIS to support service users at risk of digital exclusion. The scheme went live in October 2021 and received 106 referrals by June 2022.

Initiative

The DIS provided a response to the 3 key areas of digital exclusion: provision of devices; connectivity; and support to build skills, confidence, and motivation to engage with digital technology. To this end, the trust purchased 185 Samsung Galaxy Tablets, of which 25 supported 4G connectivity in

addition to being Wi-Fi enabled. Additionally, 100 SIM cards, each with 20 GBs of free data for 6 months, were obtained from Vodafone as part of the “charities.connected” initiative [28].

The project also extended preexisting partnerships with the UK-based not-for-profit Jangala [29] and AbilityNet, a UK charity [30]. Jangala loaned C&I NHS FT 30 Get Boxes, which is a mobile router that operated using a SIM card and provided simultaneous connectivity for up to 10 devices. AbilityNet used their web-based resources and network of community-based volunteers to provide 1:1 tailored digital support. The trust also invested in 185 protective cases and 20 Bluetooth keyboards to support accessibility needs.

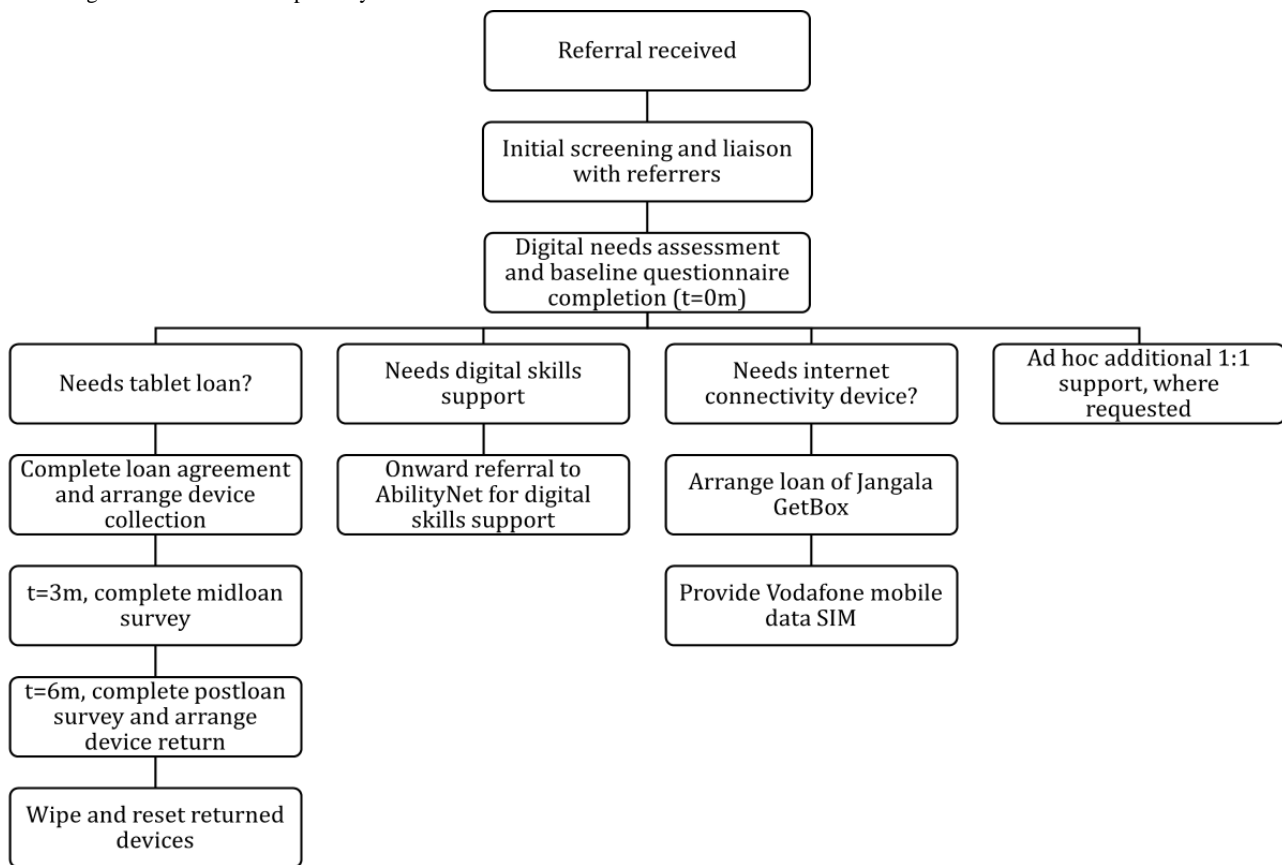

A digital inclusion officer (DIO) was employed by the trust on a 0.4 full time equivalent basis to facilitate the scheme. The DIO was embedded within a clinical team and line managed by a clinical psychologist who could provide risk and safeguarding

advice where needed. A digital workspace was developed on ServiceNow (ServiceNow, Inc) [31], which was integrated into the wider IT infrastructure. This was used by the DIO to administer the scheme, operating as both a stock inventory and log of all loans, as well as providing a digital workflow to track the loan process.

Pathway of Support

Service users were referred via a web-based form by the C&I staff members and screened by the DIO for eligibility and suitability (see Figure 1 for referral pathway). To be eligible for the scheme, service users had to be (1) currently accessing mental health services within C&I NHS Foundation Trust and (2) referred by a mental health professional or key worker who worked within the trust. In addition, they had to be at risk of digital exclusion, experiencing (1) lack of access to digital devices, (2) lack of internet connectivity, and (3) lack of skills or confidence in accessing digital technology.

Figure 1. Digital inclusion referral pathway.

Following the receipt of the referral, the DIO would screen the referral for any risk information and liaise with the referrer before contacting the service user to complete an initial telephone or in-person digital needs assessment. The digital needs assessment involved completing a baseline questionnaire (Multimedia Appendix 1) to understand individuals’ digital skills and confidence in accessing digital technology. The DIO would also clarify service users’ current digital needs and confirm eligibility for the scheme. Once service users opted into engaging with the scheme, including the receipt of a tablet loan, the DIO would discuss the practicalities of the loan, as well as the terms of the loan agreement, which detailed that

service users were able and encouraged to use the devices for personal use under the conditions of the loan agreement.

The DIO then provided the service user with a tablet loan, a connectivity device, or free mobile data SIMs and facilitated an onward referral to the partner organization AbilityNet for digital skills support. The DIO would also provide further ad hoc support around digital skills training or other digital resources. The DIO would meet service users within a familiar environment (ie, home visits) or within the trust premises, considering risk and safeguarding concerns, where identified.

Over the course of the loan, service users were contacted by telephone or email on 2 occasions to complete a midloan survey after 3 months and a postloan survey after 6 months, unless referrers or service users requested a loan extension. At the end of the loan period, the DIO would liaise with the service user and referrer to arrange the return of the device and assess further needs. Throughout their engagement with the scheme, service users were also encouraged to bring any concerns or questions about their devices to the DIO for ad hoc support. The DIO could also facilitate a referral for additional digital skills training through the partnership with AbilityNet at any point throughout the loan period. Once the device had been returned, the DIO would liaise with trust IT services to wipe and reset the device for a new loan cycle.

Participants

Part 1

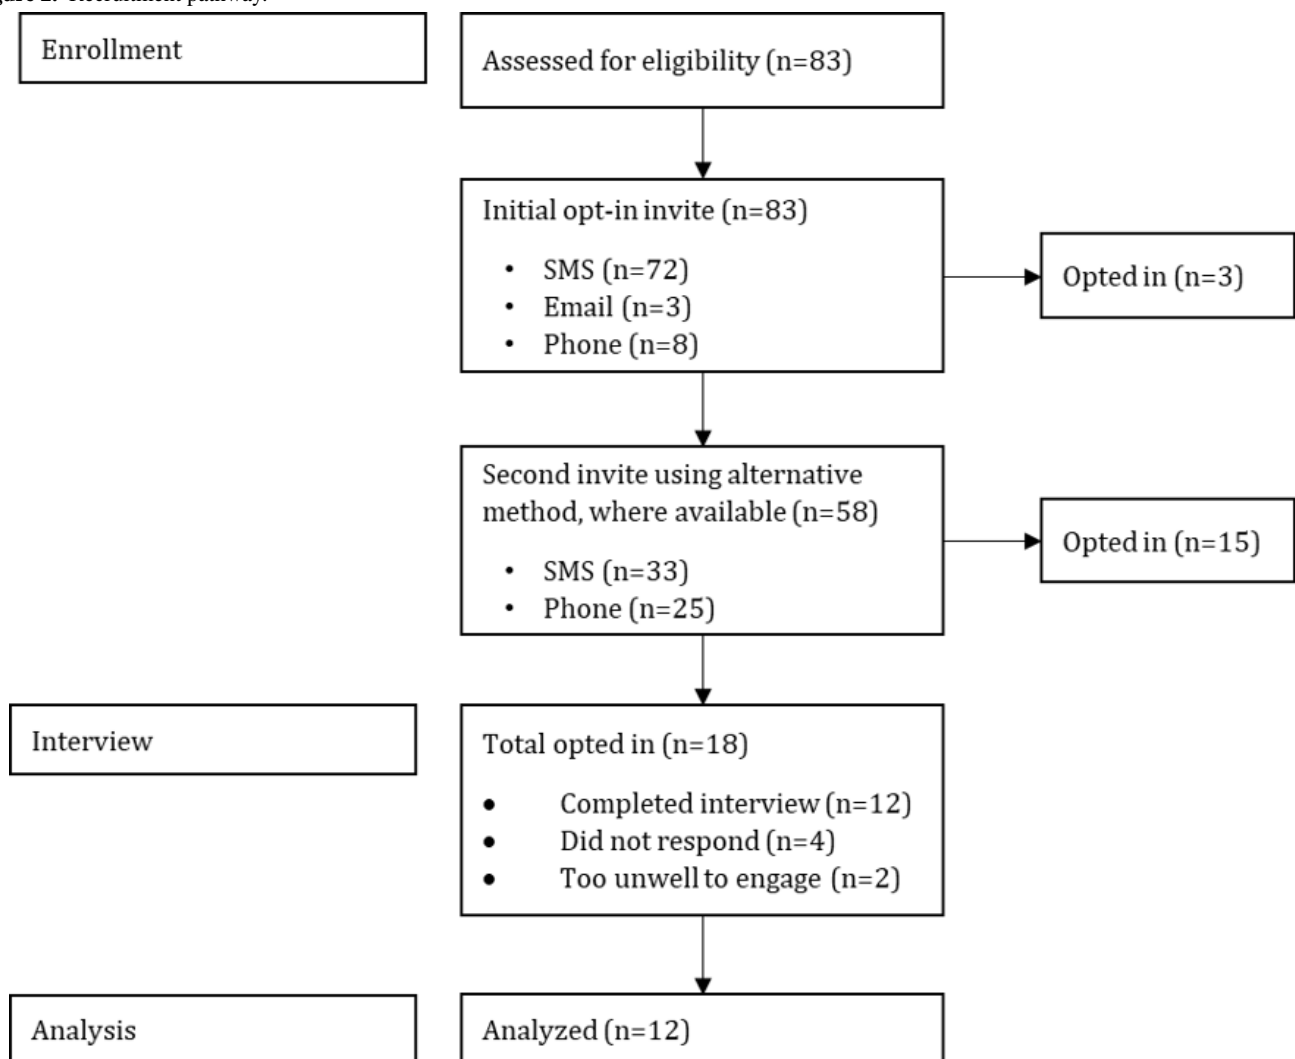

In total, 106 service users were referred to the scheme between October 2021 and June 2022. Service users were considered to have engaged with the scheme if they had completed a baseline questionnaire (Multimedia Appendix 1) following the referral.

Of the 106 service users referred, 83 (78.3%) completed the baseline questionnaire, and the remainder 23 (21.7%) either did not wish to take part in the scheme or did not engage, for example, not responding to phone calls or SMS text messages. The inclusion criteria were being a current user of mental health services within C&I NHS Foundation Trust, over the age of 18 years, and at risk of digital exclusion.

Part 2

The study used convenience sampling of individuals who had prior engagement with the DIS by completing, at minimum, the baseline questionnaire during the initial digital needs assessment. As such, 83 service users were eligible to take part in the formative service evaluation and were invited. A total of 12 participants were recruited via SMS text message, email, or telephone and were subsequently interviewed (Figure 2). Recruitment ceased once data saturation had been reached. Efforts were made to invite service users who chose not to engage with the scheme, and all the participants were informed that their contribution to the service evaluation would have no bearing on their current or future engagement with the scheme, which aimed to reduce the risk of bias.

Figure 2. Recruitment pathway.

Measures

Part 1: Baseline Questionnaire

The baseline questionnaire was derived from *The Digital Inclusion Evaluation Toolkit: Bank of Outcomes, Indicators and Survey Questions* [32] and consisted of 10 items, including questions such as “Do you consider your digital skills to be good, average, or poor?” “How confident are you in using digital technology?” and “Is there anything that limits you from using the internet at the present moment?” ([Multimedia Appendix 1](#)).

The questionnaire aimed to ascertain service users’ self-reported level of digital skills and confidence in accessing and using digital technology, as well as their frequency and type of use. It also provided insight into what factors led to service users being digitally excluded by reporting what limited their use of the internet and whether COVID-19 had made accessing the internet and using digital technology more important. It also established what resources they required from the scheme to meet their digital needs. Service users were able to indicate whether they needed assistance with acquiring equipment, accessing data connectivity, and support with using digital technology and digital resources on the internet.

Part 2: Interview Schedule

A semistructured interview schedule ([Multimedia Appendix 2](#)) was created to obtain qualitative data to understand the impact of the DIS. Each interview lasted between 30 and 40 minutes and was conducted by the same researcher (AO) to minimize interrater variability [33]. The questions were based on the initial aims and perceived outcomes of the DIS and preexisting literature [34] while also following guidance on good practice for service evaluations [35] and ensuring any potential ethical issues were considered [36]. Interview topics covered factors contributing to digital exclusion, questions relating to primary outcomes, including eliciting the perceived barriers and facilitators to engagement with the scheme (eg, “What helped or hindered you in engaging with the support offered by the scheme?” and “What changes would you make to improve the scheme?”), as well as questions relating to their experience of engaging with partner organizations, such as AbilityNet or Jangala. The interviews also attempted to elicit potential secondary outcomes, including but not limited to the impact of engagement on well-being, social interactions, ability to access C&I NHS FT or other health services, leisure, finances, education, and employment opportunities. Where applicable, participants were also asked about their experience of accessing the partnership support available, such as that offered by AbilityNet.

Procedure

Part 1

Baseline demographic, digital needs, and digital literacy information was obtained through the referral form and baseline questionnaire, which was carried out by the DIO with the service users’ consent, upon referral to the scheme.

The Initiative section provides further details on the baseline digital needs assessment.

Part 2

A link to an evaluation opt in form was sent to all eligible service users if a mobile number had been provided in the initial referral. An email was sent to those who did not provide a telephone contact and for those with only a landline number, and the invitation to those who chose to participate were contacted by their preferred method, whereby the project was explained, and interviews were scheduled.

Before the interview, participants were provided an information sheet ([Multimedia Appendix 3](#)). Further demographic information was obtained after the main interview, and participants were given opportunities to ask any questions. The information sheet also included guidance on further support available should any questions or concerns arise after the session.

The interviews were recorded using the Microsoft Word voice recorder. Interviews were automatically transcribed verbatim by Microsoft Word and anonymized by removing personally identifiable content. The final transcription was checked against the original audio recording for errors and corrected manually by the first author (AO).

Statistical Data Analysis

Part 1

The baseline questionnaire contained self-reported data of participants’ digital skills, confidence, and literacy, as well as current engagement with digital technology. Quantitative data from the referral form and baseline questionnaire was analyzed using SPSS Statistics (version 28.0.0.0; IBM Corp) and JASP (version 0.16.3; JASP Team, 2022) using descriptive statistics.

Part 2

Thematic analysis [37] was chosen to explore the qualitative experience of service users accessing the DIS from a realist approach [38]. Each interview was transcribed by the main researcher and checked by another (JAG). Each transcript was reviewed before coding the data using a combination of inductive and deductive approaches [37], deriving codes from the data within the primary areas of interest. Transcripts were repeatedly checked against the emergent themes before a list of themes and subthemes were collated through discussion between 2 authors (AO and JAG). The analysis was conducted using NVivo 12.7.0 software (QSR International) before the results were synthesized into a thematic analysis.

Ethical Considerations

Ethical approval was obtained from the Anglia Ruskin University School Research Ethics Panel (ETH2122-0635; July 29, 2022) and the C&I NHS FT Clinical and Information Governance Department (July 12, 2022). Informed consent was obtained from the participants before the interview ([Multimedia Appendix 4](#))

Results

Part 1: Baseline Digital Needs and Demographics

Of the 83 service users who completed the baseline questionnaire, 52% (n=43) were female, and 48% (n=40) were male, with a mean age of 52.42 (SD 13.47) years.

Almost all reported requiring a device (n=78, 94%), with approximately half reporting a need for internet connectivity (n=45, 54%) or digital skills support (n=57, 69%). One-third of referrals (n=31, 37%) indicated requiring support across all domains of need.

Of those reporting a lack of devices, 77 (93%) were provided with a loan tablet; 40 (48%) were provided with a Vodafone SIM card to access mobile data; and a further 15 (18%) were given SIM-enabled Jangala Get Boxes, which acted as a stand-alone internet connectivity device. A total of 29 (35%)

service users requiring extra digital skills support were referred to AbilityNet by the DIO. While the scheme could provide additional 1:1 support with the DIO, some service users were also signposted to a Recovery College [39] course focused on improving digital skills, cofacilitated by the DIO or other digital support delivered by services across the C&I NHS FT or in the wider community.

At baseline, service users reported various factors that limited their ability to access the internet (Table 1), with the lack of devices and lack of knowledge and skills in using devices representing the most common barriers to accessing the internet. Those who did access the internet did so for a variety of purposes (Table 1), with more than half of respondents (n=43, 52%) indicating entertainment as a primary driver. Overall, 70% (n=57) of service users reported that access to digital technology and the internet had become more important as a result of the COVID-19 pandemic (Table 1).

Part 2: Semistructured Interview Results

Overview

A total of 12 semistructured interviews were conducted between July 6, 2022, and July 14, 2022, either over the phone (n=11) or via Microsoft Teams (n=1). This obtained the qualitative data focusing on the service users' experience of the DIS as well as basic demographic information (Table 2).

The results from the semistructured interviews are presented in subsequent sections. There were 10 major themes in total. These

10 themes could be clustered into two superordinate themes: (1) factors impacting participant's engagement and (2) the impact of accessing the scheme. For the former (1), the 6 major themes that were shared among participants included digital exclusion, relationship to trust, the importance of personalized digital support, partnership working, device usability and accessibility, and personal circumstances. In the latter superordinate theme (2), we identified 4 major themes: improved access to services, impact on well-being, financial implications, and a greater sense of empowerment.

Table 2. Demographics of participants (n=12).

Engagement With Scheme

Digital Exclusion

Of the 12 participants, 3 (25%) participants reflected on how COVID-19 had made digital technology more important, with 7 (58%) participants reporting that they felt “forced” to learn how to use technology. They noted that before accessing the scheme, the increasing reliance on digital technology had resulted in them feeling isolated and excluded:

It's really important, especially since COVID.... Everything has moved online. [P1]

I got people bothering me...she said you gotta learn how to do emails and stuff like that. [P2]

It's just something we, we never could do before. [We felt] isolated, left behind. [P10]

I remember using the clunky old computers with the floppy disks and all of that. Very dim memories. I didn't use [new technology] particularly well...I kind...of felt excluded in the sense that [these were] things I couldn't possibly buy over the years. I didn't have the capacity to keep up to speed with it because I let it slip for so many years. [P11]

A total of 5 (42%) participants reported that the sudden digital transformation in the wake of COVID-19 left them unable to access crucial mental or physical health support, information (eg, pertaining to health care or local services), and government and banking services, as well as being unable to pay bills:

I have to transfer onto the Universal Credit scheme. That was another reason for really having to get to grips with the IT because you can only access that Universal Credit thing via IT, you can't do it postally anymore. So that was kind of a worry in the back of my mind, I knew it was coming up at some point, and some point this year I'll have to fill out one of these multi page online forms which I'm not looking forward to. [P11]

Anything to do with art I am kind of interested in, and yoga. And I said, well I can't...because my camera

doesn't work...an external camera or...external mic, none of that worked. [P6]

Moreover, participants reported that their digital exclusion before accessing the scheme was driven by a lack of suitable devices or internet access, as well as defective or unsuitable equipment. One-third (4/12, 33%) of the participants reported that their device did not work or was not fit for purpose when needing to engage in education, employment, or therapy. It was noted that, as a result, they were unable to engage with web-based mental health appointments offered, with some participants opting for telephone consultations instead:

Before I saw my therapist, I was being assessed, but because of COVID, I couldn't go out. My computer didn't work. So...in the end it was all done on the phone with another therapist. [P6]

A major impact I was finding it difficult to study. I'm a student, so it makes a big impact. I had a mobile phone, but I wasn't able to use anything like for typing and submitting assessments and assignments and things like that. [P1]

In addition, the level of self-reported competency was low before accessing the scheme. One-third (4/12, 33%) of participants reported never having used digital technology, whereas 7 (58%) struggled despite having some experience with technology though limited to laptops or computers. Only 1 (8%) participant reported being proficient, but that they were unable to afford their own device. Digital confidence was also low, with 10 (83%) participants reflecting on the challenges they faced using devices, even those who professed to have had some experience:

I would say familiar. But I wouldn't say expert, you know what I mean? I still get lost sometimes. [P6]

I never used anything like that [loan tablet] before in my life. I used to have a landline. So that's the most...we used as communication. [P12]

Relationship to the Trust

The relationship with trust staff was key in facilitating or encouraging the service users' engagement with the scheme.

All 12 participants were unaware of the existence of the scheme before being referred by staff members; however, there were differences in the motivation to engage with the scheme. One participant found that accessing the scheme helped to foster their own agency and independence:

I knew [about the DIS], from my key worker, 'cause I didn't know about you guys. [I engaged because] I couldn't keep on going to my key worker with every problem I had. [P4]

A total of 5 (42%) participants acknowledged they felt more inclined to engage with the scheme due to it being recommended by their health professional:

It was through my care worker... I remember her phoning me up and saying I've got you a tablet...so I said, well all that sounds great. I'll, I'll proceed with, with this thing, you know, and it's turned out pretty decent for me to have one, you know. [P9]

I think without being pushed into it [by the referrer], we might never have actually...ever thought we would possibly even attempt to use [a device], you know. [P7]

However, for one participant, being referred by their health professional led to them feeling obliged to accept the help, despite the benefits:

I mean, all these things have a kind of psychological element, so when you're...offered something by your...long-term nurse or therapist, you're more psychological inclined to please them and say yes, I'll try that, it's a good idea. [P11]

Nonetheless, 2 (17%) participants reported feeling more positive toward the scheme, as it was a service provided by the NHS, rather than a "corporation" (P9), with another participant reporting that they "would feel more vulnerable if Barclays had given it [the device] to me." Similarly, another participant felt that accessing NHS support and resources through the technology by the scheme was safer in general:

I also like the fact that it [is an NHS scheme], 'cause I doubt very much that Joe Public can get access to what I'm getting access to through [the NHS]. So, it's helping [the NHS] to help me, you know? [P6]

Personalized Digital Support

All participants were positive about the role of the DIO, explaining that they felt "safe" (P2) and that the process was "easy" and the DIO "supportive" (P3) and, overall, worked "extremely well" (P7). Participants appreciated that the DIO was always "available to be contacted" (P11) if there were any problems:

I liked [the DIO]. [They were] very friendly and approachable, and made it very easy because, as I said I've got agoraphobia and mental health and stuff, so when I'm accessing services or things, I find it quite difficult, although I'm quite chatty on the, outwardly but, I do like self-judge and stuff quite a lot so, yeah, [they are] just, like, [they are] friendly,

[they] made me feel at ease, so it wasn't a traumatic experience... [P8]

Similarly, P8 felt that the support offered was relevant and tailored to their needs:

I think it was quite thorough really, because [they] offered an extension of help and stuff if I needed it...and there were extra apps and stuff on the tablet that were, I felt like they were tailored towards what I had said, like the PTSD [posttraumatic stress disorder] thing, so and I think you mentioned that, that possibly your IT department would put apps on there so...so actually, I think you've done that quite well actually. [P8]

However, 7 (58%) participants reported needing further digital support to use the device, with 1 participant finding the amount of web-based content "daunting" (P11). In total, 5 (42%) participants identified needing additional support from the DIO, with 6 (50%) receiving digital skills support from external partners, such as AbilityNet or community groups. Despite this, 10 (83%) reported still feeling unsure or uncertain; for example, P7 worried that they "might press the wrong buttons" and resorted to trial and error instead of asking for help. One participant reported feeling uncomfortable asking for further support:

I guess I didn't want to be too pushy about it. I didn't know what the boundaries were. [P11]

P11 also described feeling that the scheme assumed a higher level of digital competency, which they perceived as impacting on the level of support provided:

That's a criticism that should be levelled at lots of IT schemes, sometimes they assume too much at the beginning. It was even true of the IT skills course at [the C&I NHS FT service], just a lot was assumed at the earliest stage. [P11]

The service received by the participants was also at times delayed by the staffing arrangements of the scheme, with one participant's ability to join a web-based course affected by the sole DIO being on leave:

I'm still waiting for the next art class to start because I did one session, and they were all very happy and then I got an email saying they're not happy. The other participants. And I did start quite late, but I mean that wasn't quite my fault as I couldn't get hold of the...tablet for ages. [P6]

Partnership Working

A further essential component of the scheme organization was the partnerships established with external organizations, including AbilityNet for personalized digital support, Jangala for connectivity devices, and Vodafone for SIM cards with free data.

While 1 (8%) participant described the partnership support as "invaluable" and the connectivity device provided by Jangala as "simple" to use, participants were nonetheless more inclined to seek additional support from the DIO (5/12, 42%), as opposed to the designated partner organization (2/12, 17%). For example,

while P7 reported that the telephone support provided by the AbilityNet volunteer was “helpful,” they also noted limitations:

I don't know what I could say about [external support] really, because...I just think that it was very short and quite brief...it's really not enough time to get things to sink in..., we just need that bit more help like that...just if it could have continued for even for four or five weeks, once a week or once a fortnight, or just something like, that would have been would have been very helpful. [P7]

It was just...so basic, I couldn't say if it was brilliant or not brilliant. It worked. What they said was correct...[But] well you know me with this phone, it's often turned off...So, it just never matched up. [P11]

Device Usability and Accessibility

The tablets were described as “easy to set up” (P3) and “helpful” (P1). The physical flexibility of a tablet was also cited as a positive (eg, as it allowed the tablet to be used outdoors or facilitate engagement with therapeutic services from the safety of their home environment). For example, P3 explained how accessing a portable device, such as the loan device, enabled them to participate privately in group therapy:

I didn't feel as comfortable, I would say, to participate in group therapy without it, without having that privacy element [physically being able to move the tablet to a private space] in it. And so, when I did join via video link it did...I felt more inclusive, and you know able to participate properly in the group. [P3]

The additional items available to loan (eg, a keyboard and case) were also reported to be “a massive help” (P8). However, 2 (17%) participants raised concerns about the restrictions placed on the loan device by C&I NHS FT for security purposes. As one participant explained:

I just didn't like the fact that I couldn't access some of the services... due to it being sort of owned by the trust. With Google and Google services and things like that. [P1]

Other negatives of using a tablet included it being “quite heavy in weight” (P9) and not as practical, or familiar, as a computer:

I think it can be difficult to edit PDF's, especially on tablets, it's not quite as straightforward as a computer. [P4]

Concerns around the safety or implications of use were also cited as barriers to fully using the loan device. In total, 2 participants did not engage with the loan device once it had been loaned to them, with one instead opting to use an older device provided by their daughter in case they would damage the equipment in any way:

We were quite nervous about getting [a tablet] because we were worried that we might press the wrong buttons, we might do something wrong. [P7]

I was afraid to, you know, in case I'd mess it all up. So, my daughter said just use mine and if you if you

mess it up, you know what I mean, 'cause it's old. [P5]

One participant also reported misunderstanding the terms of the tablet loan, limiting their use, believing that the tablet was “not something you use for personal use” (P3).

A total of 5 (42%) participants expressed being worried that in accessing digital technology, they may become more vulnerable to fraud, cyberattacks, or hackers accessing their personal or private information. Consequently, some participants limited their use of the loan device due to concerns around web-based security and privacy, for example:

I'd be very nervous of putting in a debit card number and buying something online, I'm thinking somebody is going to scam me here, something's going to go wrong. I'm still nervous of that. [P11]

I just don't want anything personal or private on that because it's not actually mine. [P6]

Personal Circumstances

In general, disability and poor mental health affected the participants' ability to engage with the scheme and the digital world more generally. A total of 10 (83%) participants reported having a disability, and nearly half (5/12, 42%) reported mental health difficulties that affected their daily lives and impacted their ability to engage with the scheme:

It's me, personally, not the service available.... I just lost confidence in everything. [P5]

In total, 2 (17%) participants reported difficulties with reading and writing, which hindered their ability to access the scheme or loan device, despite acknowledging its potential benefits:

It would help an awful lot of people; you know what I mean. But not in the situation I am in.... It's my spelling ability [that hindered me in engaging with the tablet]...You've got to kinda spell things. [P12]

Beliefs that older age negatively affect technology use were noted by a third of participants (4/12, 33%), both as a causal and maintaining factor for digital exclusion. In total, 2 participants stated a preference for not engaging with technology due to their age:

I grew up without, before that technology came out. So, I'm in my 50s now and I'd prefer to stay in my old school world. [P9]

At my age, what do I want a computer for? [P12]

A total of 3 (25%) participants expressed feeling motivated to access the digital world despite this. However, the need for additional support to overcome the perceived age-related difficulties in learning to use technology was also highlighted:

You know as you get older, obviously it's a bit more difficult to pick things up, and you know you need a little bit more than a couple of, sort of, half an hour or even an hour session. I know you can learn by just using it, but you really do need a bit more help in actually using it, you know. [P7]

I do find tablets a little bit difficult because I think it might be my age.... I find I'm a little bit disconnected with like iPad and things like that. I find it easier to use computers. [P8]

Impact of Accessing Scheme

Access to Services

The scheme provided “access to the digital world” (P8), with 4 (33%) participants reporting that they had accessed C&I NHS FT services as a direct result of the scheme. For example, P6, had previously struggled to manage their posttraumatic stress disorder symptoms during lockdown and described the benefits of being able to attend web-based yoga classes using their loaned tablet, rather than attending in person:

Communicating with people is becoming increasingly difficult for me. But I feel very comfortable at home, and this has nothing to do with COVID. This is just me shutting down, basically. So being able to stay within my own home environment, safe environment, nobody knows where I live. But I have access to yoga...because of who I am...the very idea of going to a place, in a room with a lot of strangers and try and do yoga or tai chi in a mask is just “no, I'm sorry.” [P6]

Improved access to education and employment was noted, with 5 (42%) participants attending web-based courses or using their device to facilitate their studies following engagement with the scheme:

It has given me a sense of, you know, of other possibilities and things like that. It's kind of, you know, got me out of the house and all that [to attend a course]. [P11]

A total of 10 (83%) participants also acknowledged the necessity of digital technology and the access it provided. For example, P1 reported the tablet to be an “essential item,” and P7 found they frequently relied upon it:

The first thing I, I would look for if I wanted help, or wanted to look for an organisation, I would look on [the tablet] straight away, you know, and ask them what I wanted and up comes an awful lot of options, you know. [P7]

Impact on Well-Being

A total of 10 (83%) participants reported that the scheme had a positive effect on their well-being. Accessing the scheme had improved participants' mood, built confidence and self-esteem, relieved stress, aided sleep, provided “comfort” (P9), and proved to be a distraction from anxiety. A total of 9 (75%) participants also reported feeling included, more connected, and less isolated; no longer the “odd ones out” (P7) and being able to “re-access parts of my old life via things like social media” (P8):

In my general well-being, it's actually good for me. I'll give you 100%, I'll tell you that much. Like literally I go home now when I finish my course at 4, I just go down there and then put music on and start cleaning the house. [P2]

It also provided opportunities for entertainment (eg, browsing the internet, playing chess, or listening to music); staying up-to-date (eg, watching the news); and social interactions (eg, video calling friends or using Facebook to keep in touch with others):

Well, maybe I listen to music. Maybe I listen to something educational, you know depends on what mood I'm in, you know. [P4]

One participant felt that accessing the tablet had “open[ed] up the world to me” (P6), as they did not feel comfortable interacting with people outside of their home:

Communicating with people is becoming increasingly difficult for me. But I feel very comfortable at home, and this has nothing to do with COVID. This is just me shutting down, basically. So being able to stay within my own home environment, safe environment, nobody knows where I live. [P6]

However, 3 (25%) participants also expressed potential negative impacts on well-being. For example, P11 expressed concern around using the tablet “too much” and described how having access to a tablet and the digital world also led to feelings of disconnection and isolation, noting that it can be “antisocial...sitting alone with a screen” where “you become wrapped up in [an]...internal and isolated world”:

I get a call from someone to come on up a coffee or something and say no I'm do[ing] this online...because I wasn't, you know, really au fait with all the IT skills, I thought no no no, I don't wanna lose my thread and lose what I'm on here...So, there is an addictive aspect. It's really kind of... ensnare you in a kind of isolating mental practice. [P11]

One participant was conscious of limiting their reliance on technology when accessing mental health support to challenge avoidance behaviors linked to their mental health difficulty:

So, for me, I prefer physical appointments even though I hate the agoraphobia..., but it's important for me to still do that otherwise I won't go out. [P8]

Financial Implications

Before engaging with the scheme, 7 (58%) participants cited the unaffordability of technology as a reason for being digitally excluded. While participants did not have to pay to access the scheme, P7 noted that they had decided to invest in Wi-Fi when they knew they were going to be loaning a tablet. P6 noted that if there had been any extra cost involved, it would have led them to reconsider their involvement. A total of 2 (17%) participants reported that the scheme had potentially saved them money:

Yes, I'm, I have listened to certain pieces of music, in the past I would have you know, saved up for a few weeks and then bought a couple of CDs, for example, yeah. [P11]

I guess that aspect of it has saved money. So, and like sending letters and replying and tracking stuff like using my phone or my travel money. [P8]

However, accessing the scheme provided other financial advantages; for example, it enabled P8 to manage their money on the web:

I use the internet banking, so it's been paramount and stuff so. ...As well, my bank is Co-Op, so they're very few and far between. That's not even one close to me, so when it comes down to banking, internet is vital. [P8]

Meanwhile, P1 and P2 reported that the scheme was a stopgap, enabling them to access a device, while they saved to purchase their own:

I couldn't afford to purchase a new, a new device.... It's given me that time to sort of bridge that gap and so I can afford to buy myself something when the loan finishes. [P1]

P2 noted that after their involvement in the scheme was over, they hoped to purchase a device themselves or obtain one via a charity or other means:

I put away like £5 away each week. Just to think, maybe I can get a tablet as well, you know...I would like to have one. [P2]

Empowerment

For most participants, the scheme provided a sense of empowerment. More than half of the participants (7/12, 58%) reported that using a tablet and having access to the digital world was either a new experience or one that broadened their world. One participant described the amount of content on the web described as a "revelation" (P11). This led participants to feel like the scheme had enabled them to learn new skills, whether it was how to access music on the web, how to use a tablet (ie, rather than a computer or laptop), or how to access the internet more generally. As a result, a quarter of participants (3/12, 25%) described that access to a tablet, connectivity, and skills now allowed them to have more control over their health, for example, by looking up information about medications, tests, and health issues or by organizing physical health appointments at the hospital, general practitioner, or dentist:

[I was] writing my appointments down on pieces of paper and things like that, so yeah. It's a lot to manage. Like I've had at least 4 appointments each week for the past three months. And that's like other-dentist, doctors, psychiatry and hospital tests...I've been able to manage myself a little bit better [using the tablet]. [P8]

Participants also felt empowered by being able to independently manage their finances (eg, web-based banking [P8]), access information (eg, health care [P7] and government services and benefits [P11]), or practical support (eg, web-based shopping [P1] or transport apps [P11]):

[What] we have done though is look up things like pensions, changes to universal credits, whether we qualify for all these new things that are coming up. So, information might change on the government websites. [P10]

Participants were unanimous in reporting that the scheme was of high value and that other trusts should look to implement similar schemes:

Well, I think, I think it's, well it's the best thing...I don't think that we've ever really had anything like this happen to us before and it has made our lives very different and a lot more interesting for both of us. And I do think that if other trusts did it, I think it's a wonderful idea. [P7]

P6 also reflected on their concern that the scheme was only available as a result of COVID-19, with digital exclusion predating COVID-19:

I don't know if I'd have been given [a tablet], if COVID had never happened. So, I guess that's a factor. And it might be a factor in the future for you lot. I mean the Government love to make excuses as to why they can't find money.... Yeah, it's hypothetical for me to kind of, put in a negative, I mean it's a hypothetical negative, right? I wonder what my life would have been like without it. And was COVID instrumental in me having it? That's the question I would ask. [P6]

One participant highlighted how it gave service users the opportunity to engage with novel technology and build their confidence:

To me [the loaned device] was just a better option than us going to a shop and getting one and not having the first idea even how to switch it on [...] Without just having a little bit of help which we got, we wouldn't really have much idea...perhaps you're a bit shy about getting into new technology...and I think without being pushed into it, we might never have actually, you know, ever thought we, we would possibly even attempt to use one. [P7]

Discussion

Principal Findings

This study highlighted the experience of digitally excluded service users engaging in an innovative tablet loan scheme. The scheme aimed to mitigate the detrimental impact of digital exclusion on service users who lacked the necessary equipment, skills, or confidence to access mental health services or effectively engage with digital ways of working at a societal level.

Findings align with prior research on the 3-level digital divide, emphasizing the negative consequences of COVID-19-related restrictions on health service access and well-being of individuals with preexisting mental health difficulties [18]. Semistructured interviews revealed 10 major themes describing the facilitators and barriers to engagement with the scheme and subsequent impact on well-being. Factors limiting engagement included disability; poor mental health; financial constraints; and concerns around web-based safety and conditions of the loan device use, linked to lower skills and confidence. This aligns with prior research on the limited uptake of digital inclusion initiatives [12,40]. While some participants

additionally reported a belief that older age influenced support needs, it was not within the scope and nature of this study to specifically assess whether age determined technological ability. However, the expressed views highlight the importance of tackling stereotypes and providing enhanced digital support for older adults, where required [41,42].

Factors facilitating engagement with the scheme included the relationship to referrers and the wider organization, as well as the personalized approach to providing digital support. Staff played a crucial role facilitating access to the scheme, but motivation varied among participants. Most expressed a desire to learn and understand technology, while others wanted to use the device to access basic functions. Some felt obligated to accept the help due to their relationship with their health care professionals, others explicitly chose not to engage with digital technology or the scheme, challenging the assumption of digital inclusion initiatives providing a desired solution. Moreover, most participants described lacking awareness of the scheme before being referred, which may be attributed to communication being limited to trust staff initially to manage limited capacity and resources before advertising the scheme more widely through posters and trust-wide communications. Regardless of their own level of engagement or participation in the scheme, participants unanimously emphasized the importance of the DIO. Participants also praised the overall value of the scheme and suggested that other NHS trusts would be well-served in implementing similar schemes. All participants described the wide-ranging impact the DIS had on their lives; facilitating the provision of mental health and other services; enabling participants to take control of their health care and finances; and providing access to social, educational, and entertainment opportunities. Participants also reported an improvement in well-being and gaining a sense of empowerment, without incurring additional costs. However, limited resources and the time-limited nature of the loan constrained the support offered by the DIS, a concern also seen in other initiatives limited in time or reach [4,12,42].

Lessons Learned

Understanding service user motivation and needs is crucial for tailored support, ensuring it is relevant and not presumptive. Future initiatives should prioritize individual consultation before implementation of schemes, even if time-consuming, to ensure full engagement and use of the support offered [43].

A dedicated DIO is a vital resource, both in administering the scheme and safeguarding service user needs. It was necessary to ensure that there was a thorough risk assessment as well as to facilitate a person-centered approach. Given the complexity of mental health needs, the DIO in turn benefited from ad hoc clinical supervision to manage risk and ensure that service user needs were met sensitively and appropriately.

Several participants noted reluctance or concern around using the loan device fully as it was not their own. Gifting devices may allow for greater engagement or use; however, finite resources were a major limitation in the scheme. Evaluations such as this highlighting the benefits of digital inclusion projects across health care services are vital to demonstrate the value of investment [44].

Considering the specific use and accessibility of loan devices is critical. It may increase engagement if the service users' specific needs were considered to determine which equipment to provide (eg, laptop rather than tablet) and the duration and type of support required to prevent the subsequent reexclusion.

Schemes should be tailored to those who need and want it most. Service users who are digitally excluded will not have access to web-based promotion or lack in understanding the value of digital technology, thus not feeling compelled to ask for support. It may be helpful to be creative in increasing awareness through physical means (eg, posters or leaflets) and workshops and by advertising support offers across community services [42]. It is also helpful to connect with staff, for example, by attending team meetings, to highlight the value of the scheme and thus facilitate the access for service users under their care.

Limitations and Future Considerations

Challenges in evaluating patient-centered programs include biased sampling or unreliable self-report data [18,43]. In addition, the method of contacting participants exposed digital divides, as those unable to opt in on the web had fewer opportunities to share their views, while the influence of health factors may have impacted others' ability to participate [11]. Moreover, by using a convenience sample drawn only from the service users who had previously engaged in the scheme, there was a risk of social desirability bias, with participants providing more positive evaluations, while insights from service users who were unable to or did not want to engage with the scheme were not captured. To address these limitations, the interviewer ensured that all the participants were aware that both positive and negative evaluations were welcome and would not negatively impact their current or future access to the scheme. In addition, the qualitative nature of the study did not allow for an investigation into the causal relationship between specific factors and digital exclusion. Nevertheless, understanding the demographics, motivations, and challenges experienced by those who participated in the scheme provided valuable insights into the populations that require support and those who may need more targeted interventions [42].

Finally, one might query whether the need for digital inclusion initiatives is still required, given the lessened immediate impact of COVID-19-related disruption on services. However, while this scheme was introduced in the height of COVID-19, the NHS long-term plan had long recommended a continued expansion of digital transformation initiatives across the United Kingdom [9]. Mounting evidence compiled before, during, and after COVID-19 suggests that web-based therapeutic interventions are at least equivalent to in-person alternatives [7] and are increasingly being trialed and evaluated in specialist health care services, such as prisons [45]. Outside of the NHS, many essential public services have also moved on the web, with the UK government committing to increased spending and investment to further improve efficiency and ease of access [46].

But despite the wider financial benefits of implementing web-based services [47], many still express a desire for in-person availability of support [47]. Furthermore, nearly a quarter of working-age adults report living with a disability that

impacts their day-to-day functioning [48], alongside greater prevalence of mental health conditions and lower employment rates [49]. Given the disproportionate impact on these groups [50], it will be necessary to consider the impact of digital transformation initiatives on access to health care, public services, and wider society for those who are not digitally enabled.

The debate around who should bear the responsibility of digital inclusion initiatives continues, with community organizations and libraries often serving as popular suggestions [44,51]. Others have argued for interventions on a macrolevel through policy change [24,25]. However, in this paper, we present the notion that when presented with disrupted access to health care,

providing support at source, that is, by the health care provider itself, can have a profound impact on uptake and response.

Conclusions

This evaluation aimed to demonstrate the potential of a digital inclusion initiative to enable NHS mental health service users to access the digital world. By examining engaged service users and their experiences within the scheme, valuable insights have been gained, addressing a previously existing knowledge gap. The study offers recommendations for future digital inclusion efforts while also highlighting the importance of providing equitable access to digital technology and support within health care contexts, especially given the rise in remotely delivered health care services.

Acknowledgments

This paper represents a service evaluation supported by Camden and Islington National Health Service (NHS) Foundation Trust and Anglia Ruskin University. The views expressed are those of the authors and not necessarily those of the NHS, Camden and Islington NHS Foundation Trust, or the Department of Health and Social Care.

Authors' Contributions

This project was designed by JAG and AO. AO recruited participants with the support of EC. AO conducted and transcribed the interviews, as well as extracted key themes, alongside JAG. The manuscript was prepared by AO, EC, and JAG.

Abstract

Background: Mental health problems are common among university students, yet many students do not seek professional help. Digital mental health interventions can increase students' access to support and have been shown to be effective in preventing and treating mental health problems. However, little is known about the extent to which students implement therapeutic skills from these programs in everyday life (ie, skill enactment) or about the impact of skill enactment on outcomes.

Objective: This study aims to assess the effects of a low-intensity video-based intervention, Uni Virtual Clinic Lite (UVC-Lite), in improving skill enactment relative to an attention-control program (primary aim) and examine whether skill enactment influences symptoms of depression and anxiety (secondary aim). The study also qualitatively explored participants' experiences of, and motivations for, engaging with the therapeutic techniques.

Methods: We analyzed data from a randomized controlled trial testing the effectiveness of UVC-Lite for symptoms of depression and anxiety among university students with mild to moderate levels of psychological distress. Participants were recruited from universities across Australia and randomly assigned to 6 weeks of self-guided use of UVC-Lite (243/487, 49.9%) or an attention-control program (244/487, 50.1%). Quantitative data on skill enactment, depression, and anxiety were collected through baseline, postintervention, and 3- and 6-month follow-up surveys. Qualitative data were obtained from 29 intervention-group participants through open-ended questions during postintervention surveys (n=17, 59%) and semistructured interviews (n=12, 41%) after the intervention period concluded.

Results: Mixed model repeated measures ANOVA demonstrated that the intervention did not significantly improve skill enactment ($F_{3,215.36}=0.50$; $P=.68$). Skill enactment was also not found to influence change in symptoms of depression ($F_{3,241.10}=1.69$; $P=.17$) or anxiety ($F_{3,233.71}=1.11$; $P=.35$). However, higher levels of skill enactment were associated with lower symptom levels among both intervention and control group participants across time points (depression: $F_{1,541.87}=134.61$; $P<.001$; anxiety: $F_{1,535.11}=73.08$; $P<.001$). Inductive content analysis confirmed low levels of skill enactment among intervention group participants. Participants were motivated to use techniques and skills that were perceived to be personally relevant, easily integrated into daily life, and that were novel or had worked for them in the past.

Conclusions: The intervention did not improve skill enactment or mental health among students with mild to moderate psychological distress. Low adherence impacted our ability to draw robust conclusions regarding the intervention's impact on outcomes. Factors influencing skill enactment differed across individuals, suggesting that it may be necessary to tailor therapeutic

skills and engagement strategies to the individual user. Theoretically informed research involving collaboration with end users is needed to understand the processes underlying skill enactment in digital mental health interventions.

Introduction

Background

University students are a population in need of mental health support. Before the COVID-19 pandemic, findings from the World Health Organization World Mental Health International College Student initiative indicated that approximately one-third of students met the criteria for a mental disorder each year [1,2]. Mood and anxiety disorders are the most common diagnoses [1]. Research conducted since the beginning of the pandemic has generally indicated an increase in the prevalence of mental health problems among university students [3,4]. It is estimated that 30% to 40% of students experienced elevated levels of depression and anxiety symptoms during the first 2 years of the pandemic alone [5,6], with the highest rates reported for students in low- and middle-income countries [4]. Mental health problems among students have been associated with a range of negative outcomes, including reduced academic performance, lower engagement in campus life, poorer interpersonal relationships, and higher dropout rates [2,7-9]. However, evidence from upper-middle and high-income countries suggests that only 25% of students with a mental disorder receive treatment in a given year [2]. Common barriers to accessing mental health services include lack of time, stigma, high treatment costs, and insufficient capacity of university counseling centers to meet student demand [10,11]. Some of these barriers may be addressed through the provision of evidence-based digital mental health interventions (DMHIs) [2,12].

University students from various countries and regions have indicated a willingness to use digital tools for mental health-related information and support, highlighting benefits in improved access, privacy, confidentiality, and reduced costs [13]. Moreover, several systematic reviews have indicated that DMHIs targeting tertiary students can be effective for symptoms of depression and anxiety when delivered under trial conditions [12,14,15], with the most robust support for programs based on cognitive behavioral therapy (CBT) [12]. However, there is also evidence to suggest that the benefits of DMHIs are diminished in real-world settings [16,17], with high rates of dropout and a lack of sustained engagement frequently reported as key challenges to program effectiveness and successful implementation in both the general and student populations [15,18]. Although strategies such as the use of reminders, coaching, and engagement facilitation interventions offer the potential to redress suboptimal levels of engagement [19-21], their effectiveness has so far been variable, and a recent systematic review concluded that more research is needed to

ensure that engagement strategies are effective and acceptable for end users [22].

Efforts to improve engagement with DMHIs are further complicated by a lack of consensus regarding how to define and measure engagement [22]. Most previous studies have focused on program use indicators of engagement (eg, number of logins or modules accessed) [23,24], reflecting the extent to which users are exposed to or interact with intervention materials. These indicators provide relatively objective information on use patterns and have been associated with small to moderate improvements in mental health outcomes in some instances [25,26]. However, they may not account for other factors that might be more closely related to positive outcomes, such as the degree to which users integrate and apply the therapeutic techniques from an intervention into their daily lives (ie, skill enactment) [27]. Recent recommendations, such as those provided by Li et al [24], Beintner et al [23], and Baumel [27], underscore the importance of investigating skill enactment as a distinct aspect of engagement that goes beyond the technology used to capture the cognitive and behavioral changes a user makes in their everyday life because of intervention [27-30]. Evaluating the strategies and techniques individuals implement from digital interventions is likely to be important both as a stand-alone outcome following intervention and because of its potential role as a mediator of treatment outcomes [31,32]. Skill enactment is likely to be an important outcome to consider in itself given suggestions that adopting healthy actions and routines may help maintain mental health or prevent future problems by improving the individual's ability to cope with stressors [31,32]. This may be especially relevant in interventions targeting relatively mild distress or symptoms where improvements in mental health outcomes may be small. Moreover, skill enactment has also been argued to be critical to understanding the impact of an intervention on symptom reduction [27,33]. This is because most therapeutic programs are predicated on the theoretical understanding that positive change occurs by facilitating the uptake of adaptive cognitive and behavioral skills [27].

The proposed importance of skill enactment has some support from recent studies that have demonstrated that DMHIs can effectively increase levels of skill enactment among adults with at least clinically mild symptoms of depression or anxiety at mid or postintervention assessments [34-36]. These studies also tend to indicate that improvements in skill enactment (ie, increase in the use of cognitive or behavioral skills, such as cognitive reframing and behavioral activation) are associated with small to moderate improvements in depression and anxiety [35-38]. However, a recent systematic review of digital CBT

programs targeting depression and anxiety identified a gap in the literature on skill enactment among young people [30], and none of the included studies explored changes in skill enactment among a university student sample. Furthermore, qualitative or mixed methods investigations of skill enactment in digital interventions are rare [39], and we are not aware of any studies specifically exploring experiences of skill enactment among university students. As little is known about skill enactment in this population, there is a need for research examining skill enactment, its potential implications for mental health outcomes, and experiences among university students participating in DMHIs.

This Study

This mixed methods study investigated skill enactment among university students with mild to moderate distress who participated in a randomized controlled trial (RCT) of the Uni Virtual Clinic Lite (UVC-Lite), a low-intensity internet-based program designed to address depression, anxiety, and other mental health problems that commonly affect university students. The results from the trial have been submitted for publication [40] and indicated no differences between the UVC-Lite intervention and an attention-control program on any of the primary (symptoms of depression and generalized anxiety disorder) or secondary outcomes at postintervention measurement, 3-month, or 6-month follow-ups. Despite these nonsignificant results, understanding patterns and experiences related to skill enactment remains pertinent due to its potential relevance in maintaining mental health and improving future interventions. The primary aim of this study was to investigate whether the UVC-Lite intervention led to improvements in skill enactment. As per the study protocol, we also intended to investigate whether improvements in skill enactment mediated change in mental health outcomes (secondary aim). Although the intervention was not shown to be effective, we retained statistical analyses to explore the association between skill enactment and mental health outcomes. As there was a significant reduction in symptoms of depression and anxiety at posttest assessment across both conditions, there remained the potential to observe whether change in mental health outcomes was associated with skill enactment. We restricted our analysis to investigate the primary outcomes of depression and anxiety symptoms. We supplemented the quantitative component with partial data set analysis of semistructured interviews and free-text response data from participants who received access to UVC-Lite to examine patterns of skill enactment and explore participants' motivations for using the techniques delivered in the program. By collecting feedback from participants, it may be possible to refine the content and features of the intervention to enhance engagement and skill enactment.

We hypothesized that skill enactment would be higher in the UVC-Lite intervention condition than the attention-control condition at postintervention, 3-month, and 6-month follow-up assessments.

Methods

Overview

The CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) is presented in [Multimedia Appendix 1](#) [41]. Data for this study were collected as part of an RCT that examined the effectiveness of UVC-Lite in reducing depression and anxiety symptoms among university students with mild to moderate levels of psychological distress. Participants were randomly assigned to either the UVC-Lite intervention or an attention-control program for a period of 6 weeks. A full description of the trial methods and primary outcomes, including information on allocation concealment, randomization procedures, and blinding, is provided in the main trial paper [40].

Participants

RCT Data

Trial participants were 487 undergraduate and postgraduate students, recruited and randomized into the trial between August 2021, and May 2022. Follow-up data were collected by January 2023. Students from all universities in Australia were invited to participate in the trial using a range of recruitment methods. These included targeted social media advertising, posts in university-related social media groups, and advertisements in university newsletters. In addition, assistance was sought from student associations and advocacy departments, student housing services, university marketing teams, survey management departments, university counseling and well-being clinics, and academic course coordinators to disseminate information about the trial to students via email and flyers. A total of 2865 students clicked on the study invitation and were screened for eligibility. Of these, 523 (18.25%) participants were initially screened into the trial, completed baseline measures, and were randomized to the UVC-Lite intervention (n=261, 49.9%) or attention-control group (n=262, 50.1%). A further 6.9% (36/523) of the participants were excluded after randomization due to being older than the eligible age range. Respondents were eligible for inclusion if they were (1) enrolled at an Australian university and resided in Australia, (2) aged between 18 and 25 years, and (3) scored between 8 and 17 on the Distress Questionnaire-5, indicating mild to moderate levels of psychological distress [42]. Students diagnosed with bipolar disorder, schizophrenia, posttraumatic stress disorder, or a personality disorder could participate if they met eligibility criteria and were receiving support or treatment for their disorder. Students who were ineligible due to high levels of psychological distress were provided with help-seeking resources.

Follow-Up Interviews

Purposive sampling was used to recruit participants for interview. All participants (131/243, 53.9%) randomized to the intervention condition who completed the postintervention survey were invited to provide additional feedback by telephone or videoconference about their experience with the modules. Of these, 38.9% (51/131) of the respondents indicated a

willingness to provide their feedback. From this group, 33% (17/51) of the participants responded to the subsequent email invitation and 24% (12/51) participated in an interview. Reasons for not participating included loss of contact (3/51, 6%) and being overseas (2/51, 4%). In addition, 1 follow-up email was sent to participants if there was no response to the initial email. No incentives were offered for participation in the interview.

Intervention and Attention-Control Conditions

Intervention Condition: UVC-Lite

The UVC-Lite is a low-intensity internet-based intervention comprising 12 modules that target the common mechanisms underlying mental health problems in university students. Content for the intervention was drawn from the Uni Virtual Clinic, an web-based mental health intervention for university students that was shown to be effective in reducing symptoms of social anxiety and improving academic self-efficacy compared to a waitlist control group in a previous trial [43,44]. Each UVC-Lite module comprises a 3- to 6-minute video presenting psychoeducation about a mental health problem and a therapeutic technique designed to address the problem. The videos provide practical examples and guidance on how to apply the techniques in daily life. The modules also include optional exercises designed to encourage the practice of therapeutic techniques, self-monitoring quizzes (included in modules 1, 3, 4, 5, 7, and 11), and links to help-seeking resources provided at their university or in the community if necessary. The twelve modules include (1) dealing with depression and low mood (behavioral activation), (2) tackling negative and anxious thoughts (cognitive reframing), (3) dealing with anxiety (cognitive reframing, breathing, and grounding techniques), (4) managing study issues: procrastination and time management (practical strategies for time management), (5) perfectionism (challenging perfectionistic thoughts and behaviors), (6) coping with stress (mindfulness practice), (7) managing sleep issues (sleep hygiene), (8) social anxiety and shyness (behavioral experiments and exposure techniques), (9) relationships and loneliness (communication skills and social support), (10) social media use (practical strategies for reducing social media use), (11) body image (body functionality appreciation), and (12) thoughts of suicide (safety planning). Modules were delivered twice weekly over the 6-week intervention period.

Attention-Control Condition: General Health Information

Participants assigned to the attention-control condition received 2 emails per week containing a web link to a PDF document providing information on topics related to general health rather than mental health, approximately matched for completion time with the active intervention. A total of 12 topics were covered, including bone health, sun exposure, food hygiene, dietary supplements, kidney health, microbes, household burns, respiratory viruses, heart health, allergens, posture, and pancreas health. A similar program has previously been shown to be associated with no therapeutic reductions in depression [45].

Data Collection

Overview

At baseline, the following demographic data were collected: age, gender, ethnicity, living situation, employment status, study discipline and year of degree, study load, and international or domestic student status. Quantitative data on skill enactment, depression symptoms, and generalized anxiety symptoms were obtained using web-based self-report questionnaires at baseline, postintervention assessment (emailed to participants 6 weeks after completion of the baseline survey), and 3- and 6-month follow-ups (emailed to participants 3 and 6 months after receiving the postintervention survey). Participants received 2 email reminders to finish the postintervention and follow-up surveys. Qualitative data were collected at postintervention assessments (free-text responses) and through interviews conducted with participants following the completion of postintervention assessments between April and August 2022.

Skill Enactment

We assessed skill enactment using a list of 14 items developed to assess the frequency of enacting therapeutic techniques from the UVC-Lite program (eg, “I made time for activities that make me feel better” and “I challenged my thinking to be more realistic and helpful”). At each time point, participants rated how often they used each of the skills over the past 2 weeks on a 5-point scale using the following response options: 0 (never), 1 (rarely), 2 (sometimes), 3 (often), and 4 (very often). Item development was informed by existing CBT skills use questionnaires [46,47]. Exploratory factor analysis was conducted on the skill enactment items before computing total scores. The results of this analysis indicated that the scale could be treated as a single factor. One item was dropped from the measure due to a low factor loading, resulting in a 13-item measure (Multimedia Appendix 2 [48-50]). The internal consistency of the scale was acceptable (Cronbach $\alpha=0.84$). The 13 items yielded a summed total score ranging from 0 to 52. Higher scores indicate more frequent skill enactment.

Mental Health Outcomes

Primary mental health outcomes were symptoms of depression, measured by the Patient Health Questionnaire-9 (PHQ-9) [51], and generalized anxiety disorder, measured by the Generalized Anxiety Disorder-7 (GAD-7) scale [52]. The PHQ-9 comprises 9 items rated on a 4-point scale, ranging from 0 (not at all) to 3 (nearly every day). Item scores are summed to produce an overall severity score ranging from 0 to 27, with higher scores indicating greater symptom severity (0-4: no symptoms, 5-9: mild symptoms, 10-14: moderate symptoms, and 15-27: severe symptoms). The GAD-7 comprises 7 items rated on the same 4-point scale as the PHQ-9. Summed scores produce an overall severity score ranging from 0 to 21 (0-4: no symptoms, 5-9: mild symptoms, 10-14: moderate symptoms, and 15-21: severe symptoms). Higher scores indicate greater symptom severity. Both scales have demonstrated robust psychometric properties in general population and university student samples [53-56]. In the current sample, internal consistency was acceptable at baseline (PHQ-9: Cronbach $\alpha=0.80$; GAD-7: Cronbach $\alpha=0.84$).

Program Use

JavaScript code was used to track intervention group participants' uptake and use behaviors. We report specific indicators in this study to provide an indication of exposure to the therapeutic content, including the number of modules accessed (ie, whether participants clicked to open each module), number of videos started (ie, >0% of the video watched), and number of therapeutic activities accessed (based on whether participants clicked through to access the exercise). For the control group, we tracked the number of modules accessed.

Qualitative Data

Semistructured interviews were conducted by the first author (HMJ), with ongoing supervision provided by the senior author (LMF). Overall, 7 interviews were conducted via Zoom (Zoom Video Communications), a web-based teleconferencing platform, and the remaining 5 interviews were conducted via telephone. The interview guide was developed by the researchers to investigate participants' thoughts about and use of the video modules and exercises, their suggestions for implementation in universities, and any barriers to the modules being used by university students. The full list of interview questions is provided in [Multimedia Appendix 3](#), although only a subset of questions was the focus of investigation in this paper. Interviews were audio-recorded and transcribed verbatim using a speech-to-text transcription application (Otter.ai; Otter.ai, Inc). Transcripts were corrected by the first author while listening to the audio-recorded interviews.

Participants' satisfaction with and views of the intervention were also assessed during postintervention surveys by asking participants open-ended questions regarding whether there was anything they liked about the program, whether there was anything they disliked about the program, and whether they would change anything about the program.

Data Analysis

Quantitative Data

Quantitative data were analyzed using SPSS for Windows (version 28.0; IBM Corp), and significance was set at $P < .05$. Primary analyses were undertaken on an intention-to-treat basis. Mixed model repeated measures (MMRM) ANOVA was conducted to compare mean scores on skill enactment between the intervention and control groups, with measurement occasion as a within-groups factor and condition as a between-groups factor. MMRM techniques incorporate all available data under the assumption that data are missing at random [57]. Within-person variation was modeled using unstructured covariance matrices, and df was estimated using Satterthwaite correction. Subgroup analyses of intervention group participants who started ≥ 1 videos versus all of the control group were conducted to estimate the effectiveness of UVC-Lite among participants who accessed at least some of the therapeutic content. We opted to use this indicator of program use in the analyses as use of the videos was considered sufficient to promote acquisition and enactment of the therapeutic skills in this intervention and because the module exercises were optional. The influence of skill enactment on primary outcomes (PHQ-9 and GAD-7) was explored using MMRM ANOVA,

including 3-way interaction terms for time \times condition \times skill enactment, as well as all main effects and 2-way interactions. Time-varying skill enactment, measured simultaneously with mental health outcomes, was used in the models. The 3-way interaction tested whether changes in outcome over time differed more for those in the intervention group with greater skill enactment, relative to the control group. The time \times skill enactment interaction tested how a change in skill enactment was related to symptoms across different time points.

Qualitative Data

Qualitative data were analyzed using inductive content analysis [58,59], as per the analytic steps outlined by Vears and Gillam [60]. This approach is well suited to answering applied research questions [60]. After reading each of the interviews and free-text responses, the first author extracted all data potentially relevant to the research question to develop a working data set (ie, extracts referring to any aspects of in-program exercises or skill enactment) [61]. Data extracts were drawn from all (12/12, 100%) interview participants and 16.5% (17/103) of the participants who provided free-text responses during the postintervention survey, resulting in the analysis of data from 11.9% (29/243) of intervention group participants. The data then went through several iterations of inductive coding and similar codes were clustered together into content categories. Reporting was structured around the categories, drawing on illustrative quotes from interview transcripts and open-ended responses. Data extracts are presented verbatim, though some words (eg, "like" and "um") were removed to improve readability. Participants are identified by their gender, a coded number, and the type of data provided (eg, M1, interview=male, interview participant 1). Quirkos (offline version; Quirkos Software) was used to analyze qualitative data.

Ethical Considerations

The trial was registered at the Australian New Zealand Clinical Trials Registry (ACTRN12621000375853) and the ethical aspects of the research were approved by the Australian National University Human Research Ethics Committee (protocol #2020/412). All participants provided informed consent by ticking a checkbox on the web after viewing an information sheet containing key details about the study. To protect participant privacy, all data were deidentified. Participants who completed all 4 surveys were entered into a prize draw to win 1 of 10 Aus \$100 (US \$66.7) gift vouchers.

Results

Sample Characteristics and Participation Rates

The flow of participants through the study is presented in [Figure 1](#) [40,62]. Of the 487 students who were eligible, randomized, and completed baseline measures, 265 (54.4%) completed postintervention surveys, 105 (21.6%) completed 3-month follow-up surveys, and 172 (35.3%) completed 6-month follow-up surveys. [Table 1](#) presents the demographic data for the full sample by trial condition. Students from 40 academic institutions across Australia participated. Most participants were female (355/487, 72.9%), with an average age of 20.62 (SD 2.12) years. Participants were predominantly domestic students

(411/487, 84.4%) living either with family (209/487, 42.9%) or in on-campus accommodation (152/487, 31.2%). Most (328/487, 67.4%) participants were in some form of paid employment. Most students were studying full time (449/487, 92.2%) for an undergraduate degree (416/487, 85.4%); *t* tests (2-tailed) and chi square analyses demonstrated that there were no significant differences between the intervention and control conditions on any of the baseline demographic variables.

Similarly, we found no significant differences between conditions on each of the outcomes of interest at baseline: skill enactment ($t_{483}=-1.06$; $P=.29$), depression ($t_{471.98}=1.59$; $P=.11$), and anxiety ($t_{485}=1.41$; $P=.16$). At preintervention, skill enactment was negatively correlated with both depression ($r=-0.35$; $P<.001$) and generalized anxiety ($r=-0.21$; $P<.001$) symptoms.

Figure 1. Flow of participants through the study. This figure is an abbreviated version of the flow diagram presented in the main trial paper by Farrer et al [40], which is published under Creative Commons Attribution 4.0 International License [62]. The figure has been adapted to include numbers on interview participation. DQ5: Distress Questionnaire-5; UVC-Lite: Uni Virtual Clinic Lite.

Program Use

The use of the UVC-Lite intervention among intervention group participants was low. Although 69.1% (168/243) of the participants accessed ≥ 1 (mean 5.10, SD 5.08) modules, more than half (129/243, 53.1%; mean 2.48, SD 3.89) of the participants did not start any of the videos, 28.8% (70/243) started 1 to 5 videos, 12.3% (30/243) started 6 to 11 videos, and only 5.8% (14/243) started all 12 videos. Engagement with the therapeutic activities was lower than engagement with the videos. Most participants (157/243, 64.6%; mean 1.31, SD 2.66) did not access any of the therapeutic activities; 27.2% (66/243) accessed 1 to 5 activities, and only 8.2% (20/243) of participants accessed ≥ 6 activities. Participants who received access to the attention-control program accessed a mean of 4.78 (SD 5.05) modules. More information on patterns of program use is provided in the study by Farrer et al [40].

Change in Skill Enactment

Table 2 presents the observed means and SDs for the outcomes of interest at each measurement occasion across the 2 conditions, and Table 3 provides the estimates of fixed effects from the MMRM ANOVA models. There was no significant overall interaction effect between measurement occasion and condition for skill enactment ($F_{3,215.36}=0.50$; $P=.68$) based on MMRM analyses. Planned contrasts demonstrated no significant interactions between time and condition on skill enactment scores at postintervention, 3-month, or 6-month follow-up

assessments, indicating no differences in skill enactment between conditions. When subgroup analyses among those who started ≥ 1 videos (vs. the control group) were conducted, the overall effect of the intervention on skill enactment scores remained nonsignificant ($F_{3,179.78}=2.08$; $P=.11$). However, exploratory post hoc contrasts demonstrated that intervention group participants who accessed ≥ 1 videos had higher levels of skill enactment than participants in the control condition at postintervention ($t_{231.96}=1.99$; $P=.048$; 95% CI 0.02-4.01) and 6-month follow-up assessment ($t_{186.84}=2.09$; $P=.04$; 95% CI 0.13-4.64), though not at 3-month follow-up ($t_{132.85}=0.58$; $P=.57$; 95% CI -2.07 to 3.77). We also explored whether a change in skill enactment over time was modified by reliable improvement (reliable improvement vs no reliable improvement. Reliable improvement was defined as a decrease of ≥ 4 points on either the PHQ-9 or GAD-7 scales from pre to postintervention). The interaction between time, condition, and improvement was not significant ($F_{3,207.14}=1.13$; $P=.34$), but there was a significant 2-way interaction between time and improvement ($F_{3,207.14}=8.78$; $P<.001$). Post hoc contrasts indicated that, regardless of condition, participants demonstrating reliable improvement reported greater skill enactment at postintervention assessment ($t_{282.72}=3.97$; $P<.001$; 95% CI 2.53-7.52) and 3 months ($t_{133.09}=2.02$; $P=.045$; 95% CI 0.09-8.23) than those who did not. This was not significant at the 6-month follow-up ($t_{216.90}=1.81$; $P=.07$; 95% CI -0.23 to 5.39).

Table 2. Observed means for skill enactment, depression, and anxiety scores at baseline, postintervention, and at 3- and 6-month follow-up.

^aPHQ-9: Patient Health Questionnaire-9.

^bGAD-7: Generalized Anxiety Disorder Scale-7.

Influence of Skill Enactment on Primary Outcomes

In MMRM models testing the effect of skill enactment on mental health outcomes, the 3-way interaction between time, condition, and skill enactment was not significant (PHQ-9: $F_{3,241.10}=1.69$; $P=.17$; GAD-7: $F_{3,233.71}=1.11$; $P=.35$), indicating no differential effects of the intervention for those with greater skill enactment. The 2-way interactions between time and skill enactment were also nonsignificant (PHQ-9: $F_{3,241.10}=1.19$; $P=.32$; GAD-7: $F_{3,233.71}=1.16$; $P=.32$). Planned contrasts confirmed these null results. However, a significant main effect of skill enactment was demonstrated on both depression ($F_{1,541.87}=134.61$; $P<.001$) and anxiety ($F_{1,535.11}=73.08$; $P<.001$) scores, indicating that higher levels of skill enactment were associated with lower symptom levels among both intervention and control group participants across time points. We also examined the influence of skill enactment among intervention group participants who started ≥ 1 videos (compared against all of the control group). While the main effect of skill enactment remained significant (PHQ-9: $F_{1,492.97}=130.47$; $P<.001$; GAD-7: $F_{1,501.66}=071.95$; $P<.001$), the 3-way interaction (PHQ-9: $F_{3,211.95}=1.47$; $P=.23$;

GAD-7: $F_{3,204.92}=0.9$; $P=.44$) and the 2-way interaction effects between time and skill enactment (PHQ-9: $F_{3,211.95}=1.28$; $P=.28$; GAD-7: $F_{3,204.92}=0.9$; $P=.44$) was not significant.

Qualitative Analysis

Description of Participants

Students from 18 academic institutions were represented in the qualitative analysis, 79% (23/29) of whom were female. The mean age of participants who provided qualitative data was 20.97 (SD 2.23) years. Most participants were domestic students (26/29, 90%) studying at the undergraduate level (21/29, 72%) across a range of disciplines (eg, Health and Medicine and Arts and Social Sciences). Unlike most participants randomized to the intervention, engagement among this group was very high; participants accessed a mean of 10.86 (SD 2.37) modules, started a mean of 8.28 (SD 4.33) videos, and accessed a mean of 4.14 (SD 3.62) exercises.

Qualitative Categories

One category was identified from the interviews and open-ended survey responses regarding patterns of skill enactment among

participants: (1) limited initial and ongoing skill enactment. Three categories were identified regarding the factors that influenced participants' use of the program techniques: (1) relevance and perceived fit, (2) practicality and ease of implementation, and (3) exploring novel approaches and reinforcing familiar ones.

Limited Initial and Ongoing Skill Enactment

Overall, participants' initial engagement with the exercises designed to facilitate the practice of the therapeutic techniques was limited. Where participants did engage, most stated that they tried only some of the exercises, and several participants described a pattern of engagement that lacked depth in terms of the time, effort, or attention they gave to the exercises. For some, this involved reading through the exercises without any or limited further engagement:

Like the exercises and things like that, like I read through them. I didn't really, I didn't do any of the exercises myself, but I did...I did read through them and look at them and they seemed pretty, pretty good. [M1, interview]

Others described completing the exercises, but not in a "fully focused" way [M3, interview], and some commented that their engagement did not go beyond their initial interaction with the exercise in the web-based platform, especially if the exercise included a writing component:

For ones that required actually writing things down, if I had something in the moment that I wanted to...that I thought of as I was, like, reading through the exercises then I put them down. But I didn't, like you know, take it as homework and adopt it within my lifestyle. [F2, interview, writing exercises]

In general, participants did not describe continuing to enact skills from the program after initially interacting with the web-based exercises, and one student noted that they were not "consistent" in their use of skills (F5, interview). At the same time, participants described finding the techniques they did try, which included a mixture of thought records, pleasant events schedules, behavioral experiments for social anxiety, procrastination strategies, body functionality appreciation, or mindfulness exercises, to be practical and useful, and several stated that they would use them in the future if needed:

But I can probably look back at that. So, I've downloaded all of them though, for like later reference if I need them. [F6, interview, behavioral experiments for social anxiety]

Relevance and Perceived Fit

Several participants described the relevance of certain strategies or techniques to their specific symptoms or challenges as a key influence on their decisions to initially engage with the exercises. Techniques that were not seen to be relevant to students' symptoms were less likely to be used, whereas those that were more relevant were more likely to be used:

I think at the time, it probably applied to me a bit more. I think that I was probably feeling a bit low in

the social skills area of life. Yeah. [F8, interview, behavioral experiment for social anxiety]

Perceived compatibility between an individual's personal characteristics, their goals, and the techniques taught in the intervention was also mentioned by some participants as positively or negatively influencing their use of specific techniques. For example, one participant commented on the fit between a cognitive exercise (a thought record) and their personal characteristics:

And it...it kind of...I am a very logical and, like, a person who likes to process things. So, like, I liked the layout of it, that you could fill in a table and see...work it out. [F1, interview, thought record exercise]

Although mentioned less often, another participant stated that their use of the techniques was motivated by their preexisting mental health goals:

Okay, so pretty much like I'd already been wanting to meditate. And I feel like the videos just like reinforced it. [M4, interview, mindfulness exercise]

To address issues of relevance and fit, participants recommended tailoring or personalizing program content, for example, by modifying content according to the needs of the student or by highlighting that users can work through the exercises based on their needs and preferences. One participant suggested that "the exercises might be improved by having a few variations by which one might manage their issues" within each module [M5, free-text response].

Practicality and Ease of Implementation

The degree to which participants perceived the strategies to be practical and easy to implement in everyday life also affected their initial willingness to engage with and enact techniques. For example, techniques that were seen as enjoyable, rewarding, and having a tangible impact on mood (such as the pleasant events schedule) were easier to implement for some participants:

So then incorporating, I think it was like one achievable task that will give you a sense of achievement and one task for fun. And I'm not used to like scheduling in things just for fun. So that felt really rewarding. [F4, interview, pleasant events schedule]

Conversely, some participants stated that they were less likely to use exercises that had a significant web-based writing component or that involved multiple steps (such as the thought records):

Yeah, there were...there was a lot to like write down and it was maybe if it was like a thought exercise like with just like a couple of steps to do I maybe would have done it more but just because I'm not at my laptop all day. [F3, interview, thought record exercise]

Other factors that made it challenging to implement the exercises, in general, and in terms of particular topics, included forgetting and lack of time due to other demands:

Ah, time, I suppose...But I've had a very kind of busy schedule, which means I probably should have prioritized it, but I didn't as much as I should have. [F6, interview, body functionality appreciation exercise]

...I did download them, but I just forgot about them. [F13, free-text response]

Participants indicated that changing the presentation of the thought records to be less cognitively demanding (such as by breaking down the exercise into smaller steps) and providing calls to action (eg, using weekly reminders) could facilitate engagement. Several participants also suggested that the exercises should be more interactive:

Possibly make them a bit more interactive—maybe add a challenge for the week or something (to help with motivation for these exercises/activities). [F19, free-text response]

Exploring Novel Approaches and Reinforcing Familiar Ones

Participants also stated that their use of certain strategies or techniques was shaped by previous exposure. Several participants commented that they used strategies that were new to them because the concepts sparked curiosity and motivated them to try out new ways of coping or relating to themselves:

And I don't know why I practiced that one in particular, because I'm happy with my body image. But it was just a really interesting notion of 'don't think about, like how your body looks, think about how it performs,' and things like that. [F5, interview, body functionality appreciation exercise]

In contrast, some participants indicated that they used strategies with which they were already familiar because this reinforced previous knowledge and behaviors:

There was like, there was one of them...that is like, you know, I think I've heard it before. I think it's like a common thing. But it was just good to reinforce it. I guess. [M2, interview, behavioral experiments for social anxiety]

Improving sleep...yeah, yeah so, I already kind of try and do some of that but it's helpful to kind of have a refresher. [F6, interview, sleep hygiene exercise]

Discussion

Principal Findings

This mixed methods study aimed to examine skill enactment among university students participating in an RCT of a low-intensity video-based intervention (UVC-Lite). The intervention was not found to be effective in improving self-reported skill enactment. There was also no evidence to indicate that participants who reported greater skill enactment experienced greater improvement in symptoms. This finding is not surprising given that skill enactment remained relatively stable over time and because we did not observe an overall effect of the intervention on primary mental health outcomes in the main trial [40]. These results raise the possibility that it

may be difficult to facilitate changes in skill enactment via the unguided use of brief transdiagnostic modules in a sample of university students with mild to moderate levels of distress. Several previous studies have demonstrated that DMHIs can lead to improvements in skill enactment, with some evidence indicating that these improvements mediate improvements in symptoms of depression and anxiety [35,36,38,63]. These factors may provide users with more opportunities to consolidate, practice, and benefit from program skills through increased repetition and reinforcement.

Use of the materials was also low in this trial (ie, approximately half of the participants either did not start any of the videos or accessed any of the activities). These results are comparable to previous studies of DMHIs for students and young people [64-66], including a recent study by Bolinski et al [67], which found that although most students started at least 1 session of an automated transdiagnostic intervention, they completed an average of only 2 (25%) out of the 8 mandatory modules. The low rates of program use in this study suggest that a key explanation for our null results may be insufficient exposure to the therapeutic content. Our subgroup analyses lent some support to this explanation, as contrasts indicated that the program may be effective in improving skill enactment at postintervention and 6-month follow-up for participants who accessed at least some of the intervention materials. However, this result should be interpreted with caution given that the analyses were post hoc and represented small effects, the overall model was not significant, and an effect was not observed at 3-month follow-up. Furthermore, improvements in skill enactment among this group also did not translate to improvements in depression or anxiety, perhaps because the analysis was not sufficiently powered to detect small effects that have been observed in other studies [36].

It is also possible that relatively high baseline levels of self-reported skill enactment (49.1%-83.6% of participants indicated that they used each of the skills, at least sometimes; median 70.8%, IQR 62.4%-78.5%) and low baseline severity of depression and anxiety symptoms affected our ability to detect change. We did find partial support for this idea in our post hoc analysis comparing skill enactment among participants who reported reliable improvement against those who did not. Higher skill enactment was reported at postintervention and 3-month follow-up among those who demonstrated reliable improvement in symptoms. However, there was no evidence to suggest that the intervention led to greater improvements in skill enactment in this group. Further investigation is needed to examine the conditions under which this intervention may be effective and to explore the relationship between skill enactment and outcomes in a larger sample of students with a higher need or more severe symptoms (ie, those with greater potential to experience reliable or clinically significant change).

The results of our qualitative analysis help to further elucidate the processes underlying skill enactment. Participants who provided qualitative data constituted a unique subset of users, as most had high levels of program use. However, even among this group, skill enactment was limited and often did not extend beyond students' initial interactions with the web-based exercises. Instead, participants tended to highlight that they

planned to use the skills if they experienced a worsening of symptoms. Similar experiences were expressed by participants in 2 previous studies of adolescent and adult users of DMHIs, wherein the authors observed that some users adopt a passive and reactive approach to applying treatment principles [39,68]. Both in these previous studies and our study, this approach appeared to be underpinned by participants' judgments concerning their current and potential future need for strategies to address various mental health concerns, suggesting that tailoring intervention content and activities based on an initial assessment of symptoms may improve skill enactment. However, other studies have reported that students are not more likely to choose content matched to their symptoms based on clinical assessment [69,70], and some research has linked choice to improved outcome [71], which suggests that tailoring approaches may need to strike a balance between student-identified concerns and clinical recommendations.

In addition, participants also highlighted that they were motivated to use skills that were easily integrated into daily routines rather than those that involved a significant writing component (eg, thought record exercises). These findings are consistent with past research on the co-design and evaluation of DMHIs among young people, which found that this group has a preference for practical and easy to use information and an aversion to text-heavy content [72-74]. This might suggest that behavioral activities (eg, pleasant events scheduling) may be more useful among students with mild to moderate distress than cognition-focused exercises, consistent with the suggestions offered by Titov et al [32] that different actions may be important at different levels of mental health. Yet individual differences also appeared to have a substantial influence on participants' decisions to enact certain skills, for example, some participants highlighted that their engagement decisions were underpinned by judgments regarding whether the approach was consistent with their personal characteristics (eg, approach to problem-solving and preexisting goals), and others pointed to the newness or, conversely, the familiarity of the strategy as positively influencing skill enactment.

Suggestions offered by participants to improve engagement with the therapeutic activities included changing the presentation of writing-based activities to be less cognitively demanding (eg, using tunneling features), providing reminders, and enhancing interactivity (eg, using weekly challenges). These results align broadly with the recommendations for persuasive system design provided by Baumel et al [27], who suggested that calls to action (eg, reminding and inspiring users to use a technique) and load reduction (eg, gradual presentation of information to reduce cognitive load) may help encourage users of digital interventions to integrate therapeutic activities in everyday life. Gamification elements, such as the use of points and reward systems or leaderboards, might also be used to enhance interactivity and support motivation among students who face barriers to skill enactment, with a previous RCT of an internet-based intervention finding that adult participants who received concurrent access to a smartphone app encouraging the completion of small challenges in daily life had greater skill enactment than those who did not have concurrent access to the app [75].

Implications

This study was motivated by calls for research to measure and report indicators of meaningful and active engagement such as skill enactment in digital interventions [23,24,27]. However, low rates of program use made it challenging to draw meaningful conclusions regarding whether low-intensity interventions such as the UVC-Lite have the capacity to improve skill enactment among students, or about the potential effects of skill enactment on outcomes. Our results related to low program use and high dropout are common in several trials of digital CBT interventions for young people with relatively mild symptoms [18,76]. They suggest that a low perceived need for intervention among students with mild to moderate symptoms may undermine their motivation to fully engage with CBT-based programs. Lack of perceived need can reduce program uptake and participation [77], but it may also result in a lack of active engagement with therapeutic skills and limited ongoing behavior changes among those who do participate. This suggests that an important priority for future research would be to establish whether low-intensity programs can effectively improve levels of skill enactment and mental health outcomes among students with more severe symptoms. In addition, the potential for the large-scale implementation of unguided interventions in university settings suggests that another direction for future research would be to ascertain the most effective approaches for prevention and early intervention among students. Alternative approaches such as those that focus on preparation for difficult times or establishing healthy routines may be needed with this population. This might include not only mental health education to promote appropriate support seeking, but also well-being interventions (eg, mindfulness-based and positive psychological interventions), stress management programs, strength-based planning, lifestyle interventions, and CBT-based programs targeting less stigmatized challenges such as sleep disturbance.

The study also points to potential pathways for improving intervention design to promote skill enactment. Our qualitative findings related to individual differences in skill enactment suggest that 1 promising approach may be to tailor therapeutic content to the needs and preferences of individual users. For instance, real-time analysis of user behaviors could be used to dynamically tailor therapeutic recommendations and feedback [27], continuous engagement with certain activities might trigger recommendations for more complex activities, while a lack of engagement could trigger recommendations for alternative activities or feedback to address barriers. Tailoring therapeutic recommendations based on other user characteristics is also likely to be beneficial (eg, through assessment of user-identified concerns, goals, or existing mental health knowledge). However, this will require a better understanding of the processes underlying skill enactment among users of DMHIs, including factors that influence initial and ongoing cognitive and behavioral change in everyday life, as well as factors that affect the enactment of different types of skills, especially among different student groups. Qualitative methods involving consultation with end users and the application of structured frameworks of behavior change during data collection and

interpretation (eg, theoretical domains framework [78]) may help address these aims.

Strengths and Limitations

Strengths of the study include the large sample relative to other trials testing web-based interventions in tertiary student populations [79-81], recruitment of participants from universities across Australia rather than a single institution, and a focus on maximizing ecological validity. However, high ecological validity was also a limitation due to high rates of attrition and low adherence. This may have led to inaccurate estimates of the treatment effect, although we used rigorous MMRM models to account for all available data. Our use of qualitative data to supplement the quantitative analysis represents an additional strength. However, we relied on a self-selected sample of students to provide these data, nearly all of whom were highly engaged. This may have resulted in a sample skewed toward those who had predominantly positive experiences of the intervention, and our findings may not apply to students who did not use or only minimally used the intervention. Questions regarding skill enactment were also asked as part of a larger qualitative study designed to examine students' views on implementing the program within universities, and thus we may not have captured other experiences related to skill enactment. Furthermore, we did not ask participants about potential factors other than the program that may have influenced skill enactment during the measurement period.

In addition, participation among males, gender-diverse students, and international students was low, which may limit the generalizability of the results to other populations. Although this reflects differences in the help-seeking and participation in mental health research more generally [82-84], ongoing efforts to improve participation are important to ensure DMHIs are acceptable and effective for these groups. Given the high number of international students attending university in Australia [85], future studies might also consider the utility of offering interventions in multiple languages to maximize accessibility for international and culturally and linguistically diverse

students. We also relied on brief self-report scales to measure outcomes. Although assessments included validated measures of depression and anxiety, a bespoke scale was used to assess skill enactment as none of the standardized measures available at the time of trial design adequately captured the range of techniques covered in the UVC-Lite intervention [46,47,86]. Titov et al [32] have since developed and evaluated a comprehensive self-report questionnaire of mentally healthy actions that is not tied to a specific therapeutic approach and which may assist other researchers to evaluate skill enactment using a standardized approach. However, it will also be important for future studies to assess the fidelity of skill enactment (ie, the extent to which individuals enact skills in line with how they are taught), for example, through evaluations of homework or therapist ratings [30]. Moreover, delivery of the 3-month follow-up assessments was delayed by approximately 1 month for a proportion of participants due to an administrative error.

Conclusions

This study indicated that a transdiagnostic low-intensity video-based program was not effective in improving skill enactment among university students with mild to moderate levels of psychological distress. Our null results may be due to several factors, including characteristics of the intervention, low program use, low baseline severity of participants' symptoms, and high levels of baseline skill enactment. The results of our qualitative analysis suggested that initial and ongoing skill enactment was limited even among participants with high program use, and individual differences appeared to have a substantial influence on decisions to enact skills. Ongoing research with university students is needed to determine who can benefit from low-intensity digital interventions, what types of digital interventions may be most effective, and how we can improve engagement, both in terms of program use and skill enactment, to ensure that the potential benefits of DMHIs are realized. Qualitative and theory-informed research may lead to a better understanding of the mechanisms underlying skill enactment.

Acknowledgments

The authors would like to thank Dr Amelia Gulliver, Dr Liana Lench, and Dr Penelope Hasking who were involved as coinvestigators in the main trial. The authors would also like to thank Natasha Katruss for the assistance with developing the intervention materials and data collection. Funding for this project was provided by Australian Rotary Health. HMJ is supported by an Australian Government Research Training Program Scholarship and the Grace Groom Memorial Scholarship (2021). LMF is supported by an Australian Research Council Discovery Early Career Researcher Award (ARC DECRA; DE190101382). ALC is supported by a National Health and Medical Research Council (NHMRC Fellowship 1173146). The funders were not involved in the writing, reviewing, or approval of the manuscript, nor were they involved in the decision to submit the manuscript for publication.

Authors' Contributions

LMF, PJB, and ALC obtained project funding and designed the trial. HMJ developed the research goals and aims and designed the skill enactment measure in consultation with all other authors. LMF and HMJ implemented the study. HMJ analyzed the data. HMJ drafted the manuscript. All authors provided critical revisions to and approved the final manuscript.

Conflicts of Interest

PJB, ALC, and LMF are codvelopers of the Uni Virtual Clinic Lite (UVC-Lite) intervention. LMF was involved in the development of the original UVC-Lite intervention. The other authors declare no conflicts of interest.

Abstract

Background: The application of artificial intelligence (AI) to health and health care is rapidly increasing. Several studies have assessed the attitudes of health professionals, but far fewer studies have explored the perspectives of patients or the general public. Studies investigating patient perspectives have focused on somatic issues, including those related to radiology, perinatal health, and general applications. Patient feedback has been elicited in the development of specific mental health care solutions, but broader perspectives toward AI for mental health care have been underexplored.

Objective: This study aims to understand public perceptions regarding potential benefits of AI, concerns about AI, comfort with AI accomplishing various tasks, and values related to AI, all pertaining to mental health care.

Methods: We conducted a 1-time cross-sectional survey with a nationally representative sample of 500 US-based adults. Participants provided structured responses on their perceived benefits, concerns, comfort, and values regarding AI for mental health care. They could also add free-text responses to elaborate on their concerns and values.

Results: A plurality of participants (245/497, 49.3%) believed AI may be beneficial for mental health care, but this perspective differed based on sociodemographic variables (all $P < .05$). Specifically, Black participants (odds ratio [OR] 1.76, 95% CI 1.03-3.05) and those with lower health literacy (OR 2.16, 95% CI 1.29-3.78) perceived AI to be more beneficial, and women (OR 0.68, 95% CI 0.46-0.99) perceived AI to be less beneficial. Participants endorsed concerns about accuracy, possible unintended consequences such as misdiagnosis, the confidentiality of their information, and the loss of connection with their health professional when AI is used for mental health care. A majority of participants (80.4%, 402/500) valued being able to understand individual factors driving their risk, confidentiality, and autonomy as it pertained to the use of AI for their mental health. When asked who was responsible for the misdiagnosis of mental health conditions using AI, 81.6% (408/500) of participants found the health professional to be responsible. Qualitative results revealed similar concerns related to the accuracy of AI and how its use may impact the confidentiality of patients' information.

Conclusions: Future work involving the use of AI for mental health care should investigate strategies for conveying the level of AI's accuracy, factors that drive patients' mental health risks, and how data are used confidentially so that patients can determine

with their health professionals when AI may be beneficial. It will also be important in a mental health care context to ensure the patient–health professional relationship is preserved when AI is used.

Introduction

Background

The potential of artificial intelligence (AI) to transform health care has been touted since the early 2010s [1-4]. In health care applications, practitioners commonly operationalize AI by training machine learning algorithms using large retrospective data sets to perform human reasoning tasks, such as identifying issues (eg, anomalies in medical images), predicting events (eg, disease incidence), recommending treatments (eg, pharmacogenomics), detecting patterns (eg, finding symptom clusters), and generating text (eg, for clinical decision support rules).

AI has already made significant strides in the field of medical imaging, aiding health professionals at various stages, including improving image quality [5], guiding image acquisition [6], risk-stratifying images to be reviewed by a specialist (ie, a radiologist) [7,8], and interpreting images [9,10]. More recently, predictive AI has been leveraged to detect mental health–related issues, including major depressive disorders [11,12], stress, anxiety [13], bipolar disorder [14], and even suicide [15,16]. AI has also commonly been used for treatment selection in fields such as oncology and mental health [17,18]. Despite the demonstrated predictive accuracy of AI, relatively few of the predictive AI tools created are implemented in everyday clinical care [19], and even fewer tools have demonstrated a positive clinical impact compared to current standards of care [20-22]. Furthermore, of the 89 unique articles in 2 systematic reviews of clinical trials evaluating predictive AI, none focused on mental health–related conditions [20,21].

Due to the gap between the predictive AI's accuracy and its lack of observed impact on health outcomes, many researchers in many countries have studied health professionals' perceptions of AI-based tools and related implementation challenges [16,23-28]. However, patients' perspectives of AI have been understudied [29-31]. While some predictive AI developers may not intend for patients to view the AI's output on their own, it has become more likely that patients have access to predictive AI output due to recent advances in patient data ownership and access. The US 21st Century Cures Act, for example, prevents blocking information from patients, requiring health organizations and insurance providers to give patients access to their eHealth information without delay or expense [32]. This may result in a patient seeing a predictive AI risk score before a discussion with their health care team. In a 2020 predictive AI preimplementation study, health professionals stressed the importance of keeping the patient in the information loop when the AI predicts a risk or recommends a treatment to justify to

the patient why they may require further support [24]. In addition to practical considerations, there is an ethical imperative to ensure patients understand how their data are being used, what predictive AI may reveal, and what the insight means, especially for sensitive issues, such as mental health care concerns [33]. Before we design solutions for communicating AI information to patients, it is important to understand the public's perceived benefits, comfort, concerns, and values related to AI use, particularly for mental health care [34].

To address the deficit in knowledge regarding patient perspectives on AI, Khullar et al [35] conducted a survey of a nationally representative panel of the US-based population. While most respondents reported a perceived benefit of using AI in health care, comfort with AI unsurprisingly varied based on the accuracy, transparency, and clinical application of AI (eg, reading a chest x-ray vs making a cancer diagnosis) [35]. The survey conducted by Khullar et al [35] focused on somatic applications of AI, leaving questions regarding public perceptions of AI for mental health care applications unanswered. However, others have explored narrower issues related to feedback on specific mental health care apps and specific prediction tasks (eg, the prediction of suicide) [36,37].

Objectives

AI applications for mental health are rapidly increasing as patients gain greater access and ownership of their data. Given the ethical concerns regarding the creation and use of AI and the stigmas surrounding mental health care, understanding patients' perceptions of whether and how AI may be appropriately used for mental health care is critical [38,39]. This study adapts and extends the survey conducted by Khullar et al [35] to evaluate patient perspectives on the use of AI for mental health care applications. We specifically surveyed members of the public to gain patient perspectives on AI applications for mental health. Khullar et al [35] did not explore values regarding AI use, that is, what patients' priorities for effective, appropriate AI use for mental health care are. We also explored these values in this study using a bioethics-informed framework. The specific research questions (RQs) guiding our work were as follows:

- RQ 1: Do the public perceive AI to be beneficial for mental health care? RQ 1 Equity: Do perceived benefits differ by sociodemographic factors?
- RQ 2: How concerned is the public about common issues related to AI use in mental health care?
- RQ 3: What types of predictive tasks are the public comfortable with AI executing in mental health care applications?

- RQ 4: What are the public's values related to AI use for mental health care?

We also elicited open-ended responses from participants to add to their quantitative feedback.

Methods

Study Design

In our study, we conducted a 1-time, cross-sectional survey of US-based adults in September 2022. We sampled a general US adult population to elicit the public's perspectives on AI for mental health. We partnered with Prolific (Prolific Academic Ltd), a web-based survey sampling platform, to recruit participants. Prolific provides access to an international sample of verified users (>100,000 users residing in the United States) who are willing to be involved in survey research studies. Prolific matches eligible participants with research studies, streamlining the recruitment, data collection, and compensation processes. Prospective participants had to be verified Prolific users aged ≥ 18 years who were fluent in written and spoken English to be eligible.

Ethical Considerations

This study was approved by the BRANY Institutional Review Board (protocol 22-01024358). Before answering the questionnaire, participants read an information sheet and consented to participate in this specific study. Participants who completed the full questionnaire were compensated at an hourly rate of US \$13.60 based on Prolific's policies.

Questionnaire Design

We designed our questionnaire such that it mimicked items asked in a previous study by Khullar et al [35] but applied to perspectives specifically related to AI for mental health, instead of AI for health care broadly. Question categories related to AI for mental health care were as follows: (1) perceived benefits of AI, (2) concerns about AI, and (3) comfort with using AI for specific predictive tasks. Adapting questions related to perceived benefits and concerns predominantly involved updating the terms "health" or "health care" to "mental health" or "mental health care," respectively. In the questionnaire developed by Khullar et al [35], questions regarding predictive tasks included those on reading a screening tool (ie, a chest x-ray); making a diagnosis for 2 different conditions, with 1 being more severe (pneumonia and cancer); and telling a patient they had either of the 2 aforementioned conditions and making a treatment recommendation. Our team worked with a trained psychiatrist to construct tasks following similar patterns but pertaining to mental health care, adding 2 more tasks (resulting in a total of 7 tasks) to explore more sensitive concepts relating to mental health. [Multimedia Appendix 1](#) presents the questions in each of the aforementioned categories along with the question from which they were adapted as applicable.

We also extended the questionnaire to understand participant's values pertaining to AI design and implementation for mental health care to facilitate a more patient-centered design of future AI applications for mental health. This section asked patients to rate their level of importance regarding various statements

pertaining to AI for mental health care, as informed by the constructs of MITRE's bioethical framework. [Multimedia Appendix 1](#) displays the value statements presented to participants based on the relevant bioethics constructs.

In addition to the questions on perspectives and values, participants also answered questions on sociodemographic characteristics, including personal characteristics, health literacy, subjective numeracy, previous mental health care experience, and pregnancy history (results reported in a separate manuscript). The full battery of sociodemographic questions is presented in [Multimedia Appendix 1](#).

Finally, following the sections regarding concerns and values, the survey contained open-ended questions to allow people to provide free-text responses with additional concerns or values.

We designed the battery of questions with input from experts in AI, human-centered design, and psychiatry and the author of the original survey from which the questions were adapted. The survey questions underwent 2 rounds of pilot testing to improve their comprehensibility and understand the amount of time needed to complete the questionnaire. The question-and-answer design was optimized and pilot tested for completion on both desktops and mobiles (ie, smartphones) to ensure those with different devices or preferences could participate in the study.

Participants

All participants were recruited from Prolific's survey sampling panel and were verified users who agreed to participate in research studies via the Prolific website. Our sample included those aged ≥ 18 years, residing in the United States, and with the ability to speak and read English. We recruited a sample representative of the adult US population in terms of age, race, and gender, according to the US Census. We initially recruited 530 survey respondents, of whom 30 (5.7%) did not begin the survey after reading the informed consent document, resulting in a total of 500 (94.3%) respondents. All 500 respondents finished the survey (0 incomplete responses) over a median time of 15 minutes and 24 seconds.

Data Collection

Our team designed and programmed the questionnaire using the Qualtrics XM (Qualtrics) platform. Participants received an invitation to complete the questionnaire through Prolific and then proceeded by clicking on a secure, anonymous link to Qualtrics. Participants could complete the survey using any smartphone, tablet, or computer, provided they had an internet connection. Participants then completed the questionnaire. There was no time limit for completing the questionnaire, and participants had the option to pause and resume completing the questionnaire at a later time. Participants also had the option to discontinue the survey at any time.

Data Analysis

Quantitative Analysis

The first level of analysis involved assessing descriptive statistics to understand trends in participant perceptions and values. We also selected an outcome of interest (perceived benefit of AI for mental health) and created a logistic regression

model to better understand whether perceived benefits may differ by sociodemographic factors, specifically age, gender, race, education, financial resources, mental health history, and self-rated health literacy [40]. The α value for all analyses was set at .05, and the R software (version 4.2.1; The R Foundation) was used. An analysis of a subset of this data (only those of participants reporting female sex at birth) related to differences in perspectives based on pregnancy history has been reported in a separate manuscript [41].

Qualitative Analysis

We analyzed free-text responses through an inductive thematic analysis and a constant comparative process. One analyst initially reviewed the codes and created a draft codebook. Free-text responses to the 2 open-ended questions were analyzed using a singular coding scheme. A second analyst then used the

coding scheme to independently dual code each free-text response. The analysts met with a third team member to resolve discrepancies, coding via consensus and updating the codebook throughout the discussion. Once detailed codes had been developed and 50% of the initial coding was completed, the team completed axial coding, coming up with higher-level summary themes to describe patterns in the detailed codes.

Results

Participant Characteristics

Table 1 describes the demographic makeup of the 500 adult, US-based survey respondents sampled using the Prolific platform [42]. Respondents were nationally representative based on race, age, and gender.

Table 1. Participant demographics (N=500).

Participant characteristics	Values
Age (y)	
Median (IQR)	46 (31-59)
Mean (SD; range)	46 (16; 18-93)
Gender, n (%)	
Women	249 (49.8)
Men	238 (47.6)
Transgender	1 (0.2)
Something else	9 (1.8)
Prefer not to answer	3 (0.6)
Race, n (%)	
Asian	25 (5)
Black or African American	66 (13.2)
White	388 (77.6)
Other or prefer not to answer ^a	21 (4.2)
Perceived financial resources, n (%)	
More than enough	65 (13)
Enough	271 (54.2)
Not enough	156 (31.2)
Prefer not to answer	8 (1.6)
Mental health history^b, n (%)	
Yes	215 (43)
No	271 (54.2)
Prefer not to answer	14 (2.8)
Health literacy^c, n (%)	
Adequate	369 (73.8)
Inadequate	131 (26.2)

^aAnswer options included American Indian or Alaskan Native, Native Hawaiian or Pacific Islander, and prefer not to answer, and multiple options could be selected.

^bThe question asked was "Have you ever been told that you have mental illness?"

^cMeasured using the Brief Health Literacy Screener developed by Chew et al [40].

RQ 1: Perceived Benefits of AI for Mental Health

Participants were first asked, “Overall, in the next 5 years, do you think AI will make mental health care in the United States...” Answer options included “much better,” “somewhat better,” “minimal change,” “somewhat worse,” “much worse,” and “don’t know.” We computed a logistic regression model such that “much better” and “somewhat better” were classified as 1, and the other responses were classified as 0, excluding the 3 (0.6) participants, among the total 500 participants, answering,

“don’t know.” Among 497 included respondents, 245 (49.3%) respondents believed that AI would make mental health care better or much better. Table 2 reveals that participants of Black or African American race ($P=.04$; odds ratio [OR] 1.76, 95% CI 1.03-3.05) and those with lower health literacy ($P=.004$; OR 2.19, 95% CI 1.29-3.78) were significantly more likely to endorse that AI would make mental health care somewhat or much better. Women, by contrast, were significantly less likely to endorse this statement ($P=.046$; OR 0.68, 95% CI 0.46-0.99).

Table 2. Logistic regression results: impact of sociodemographic variables on the perceived benefit of artificial intelligence (AI) for mental health.

Variable	β estimate	Odds ratio (95% CI)	<i>P</i> value
Intercept	0.378	— ^a	.37
Age (y)	-0.006	0.99 (0.98-1.01)	.36
Gender (woman)	-0.388	0.68 (0.46-0.99)	.046 ^b
Race (Black or African American)	0.567	1.76 (1.03-3.05)	.04 ^b
Perceived financial resources (not enough)	0.003	1.00 (0.66-1.51)	.99
Mental illness history (yes)	-0.044	0.96 (0.65-1.42)	.83
Health literacy (inadequate)	0.782	2.19 (1.29-3.78)	.004 ^b

^aNot available.

^bStatistically significant based on $\alpha<.05$.

Concerns, Comfort With Predictive Tasks, and Values (Quantitative)

RQ 2: Concerns Regarding AI for Mental Health Care

On the basis of the survey conducted by Khullar et al [35], we asked participants their level of concern (very concerned, somewhat concerned, not concerned, and don’t know) related to 6 potential challenges of using AI for mental health care

(Figure 1). Participants reported being somewhat or very concerned about AI making the wrong diagnosis (402/500, 80.4%), leading to inappropriate treatment (435/500, 87%), or leading to them not knowing their mental health care provider well (409/500, 81.8%). Participants reported being very or somewhat concerned regarding spending less time with their mental health care professional (346/500, 69.2%) and their confidentiality (302/500, 60.4%) but expressed relatively less concern regarding increased costs (217/500, 43.4%).

Figure 1. Reported levels of perceived concerns regarding artificial intelligence (AI) use for mental health.

RQ 3: Comfort With AI Accomplishing Mental Health Care Tasks

Next, we asked patients their level of comfort with AI performing various tasks instead of their mental health care professional. We assessed a range of tasks (ie, assessment, diagnosis, diagnosis delivery, and treatment recommendation) and mental health issues of varied levels of perceived severity (ie, depression, bipolar disorder, and suicide), as shown in Figure 2. Participants were the most comfortable (reporting being very or somewhat comfortable) with recommendations of nonpharmacological interventions, including general wellness management strategies (357/500, 71.4%) and talk therapy (328/500, 65.6%). Participants expressed moderate comfort with AI performing a mental health care assessment but were less comfortable (with only 20% to 32% selecting very or somewhat comfortable) with various prediction, diagnosis, and diagnosis delivery tasks, as well as a medication

recommendation task. Participants were the least comfortable with diagnosis delivery tasks (ie, telling someone directly they have a mental health condition), including for clinical depression (123/500, 24.6%) and bipolar disorder (103/500, 20.6%).

We also asked participants their level of comfort sharing mental health information with a (human) mental health care professional, an AI chatbot, or an AI program that treats disease to improve it. We chose these categories to understand perspectives of common uses of patient data for AI, such as the use of patient data to build models that make predictions or help treat diseases as compared to the use of patient information directly for patient support (eg, an AI chatbot). Patients were the most comfortable (very or somewhat) sharing information with a mental health care professional (389/500, 77.8%), followed by sharing with an AI program that treats disease (300/500, 60%) and then sharing with an AI chatbot (238/500, 47.6%).

Figure 2. Reported level of comfort with artificial intelligence (AI), instead of a mental health professional, conducting various tasks.

RQ 4: Values Related to AI for Mental Health

Overview

We replicated a series of questions from Khullar et al [35] assessing patient values of various aspects of AI, including

transparency, explainability and performance, responsibility, and the effect of AI on trust in health professionals (Table 3).

Table 3. Summary of questions regarding values related to artificial intelligence (AI) for mental health (N=500).

Value, question, and answer choice	Respondents, n (%)
Transparency of AI use	
How important do you think it is that you are told when an AI program has played a big role in your mental health diagnosis or treatment?	
Not important	13 (2.6)
Somewhat important	111 (22.2)
Very important	364 (72.8)
Don't know	12 (2.4)
How important do you think it is that you are told when an AI program has played a small role in your mental health diagnosis or treatment?	
Not important	39 (7.8)
Somewhat important	128 (25.6)
Very important	253 (50.6)
Don't know	10 (2)
[Clinical scenario]^a How important is it that your doctor tells you that the computer program helped make this decision?	
Not important	25 (5)
Somewhat important	66 (13.2)
Very important	388 (77.6)
Don't know	21 (4.2)
Explainability and performance	
How comfortable would you be receiving a mental health diagnosis from a computer program that made the right diagnosis 90% of the time but could not explain why it made the diagnosis?	
Very comfortable	15 (3)
Somewhat comfortable	94 (18.8)
Somewhat uncomfortable	184 (36.8)
Very uncomfortable	199 (39.8)
Don't know	8 (1.6)
How comfortable would you be receiving a mental health diagnosis from a computer program that made the right diagnosis 98% of the time but could not explain why it made the diagnosis?	
Very comfortable	63 (12.6)
Somewhat comfortable	138 (27.6)
Somewhat uncomfortable	172 (34.4)
Very uncomfortable	117 (23.4)
Very comfortable	10 (2)
Don't know	63 (12.6)
Responsibility and AI	
Imagine that your mental health professional and a computer program work together to treat your mental illness and a medical error occurs. An example of a medical error is getting a diagnosis that was wrong, or a treatment that was not needed. Who is responsible? (Select all that apply.)^b	
The mental health professional	412 (82.4)
The company that made the computer program	30 (6)
The hospital or clinic that bought the computer program	20 (4)
The government agency that approved the computer program	6 (1.2)
Someone else	12 (2.4)
No one	1 (0.2)

Value, question, and answer choice	Respondents, n (%)
Don't know	19 (3.8)
Imagine that you have a sleeping disorder that might be due to a mental health issue. You have a test done. Your doctor uses a computer program that says the sleeping disorder might be mental health-related, so you start medication to treat it. The medication leads to bad side effects. After another doctor evaluates your sleeping disorder, it turns out it was NOT mental health related. Who, if anyone, is to blame? (Select all that apply.)^b	
The mental health professional	408 (81.6)
The company that made the computer program	35 (7)
The hospital or clinic that bought the computer program	14 (2.8)
The government agency that approved the computer program	5 (1)
Someone else	6 (1.2)
No one	19 (3.8)
Don't know	13 (2.6)
Imagine that your hospital recently started using a computer program to help diagnose mental health problems. Who do you think has checked to make sure the computer program is safe before it is rolled out? (Select all that apply.)^b	
The mental health professional	135 (27)
The company that made the computer program	229 (45.8)
The hospital or clinic that bought the computer program	73 (14.6)
The government agency that approved the computer program	31 (6.2)
Someone else	4 (0.8)
No one	16 (3.2)
Don't know	12 (2.4)
Effect of AI on trust in mental health professionals	
Imagine that you have some symptoms that have been bothering you for a while, such as difficulty sleeping, eating, and focusing on work. You visit a doctor who runs some tests and he says he does NOT think you have any mental health issue. He also puts your symptoms into a computer program that can make the right diagnosis about 80% of the time, but can't say why it chose the diagnoses. It says you DO have mental health issue. How does the computer program affect your view?	
It would not affect my trust of the mental health professional's assessment	85 (17)
It would make me question the mental health professional's assessment	265 (53)
I do not know if it would change my view of the mental health professional's assessment.	137 (27.4)
Don't know	13 (2.6)

^aScenario wording: "Imagine that you have been told that you have been diagnosed with depression, a common mental illness that affects your mood, thoughts, and behavior. In the past, your doctor would have decided whether to prescribe a medication or refer you for psychotherapy depending on the type of symptoms you have and how severe they are. //Your doctor now has a computer program that uses many other factors. This computer program says you should start an antidepressant."

^bMultiple selections were allowed, so the sum of proportions can be >100%.

Transparency of AI Use

Participants were first asked how important it was to know when AI played a (1) small or (2) big role in their mental health treatment or diagnosis. Most participants found it somewhat or very important to know whether AI played a small (450/500, 90%) or big (474/500, 94.8%) role in their mental health treatment or diagnosis, although participants tended to report it was very important based on whether AI played a big (365/500, 73%) versus small (253/500, 50.6%) role. This pattern remained consistent with a specific scenario regarding the use of an AI program in prescribing antidepressants, with many participants stating it was very important (355/500, 71%) or somewhat important (114/500, 22.8%) that their mental health

care professional informed them regarding the AI's involvement in this prescribing decision.

Explainability and Performance

In comparing AI that was not explainable (ie, it could not describe why it made a given diagnosis), participants were generally uncomfortable even with stated AI performance accuracies of 90% (383/500, 76.6% somewhat or very uncomfortable) and 98% (289/500, 57.8% somewhat or very uncomfortable).

Responsibility and AI

Participants answered a series of questions regarding who was responsible in the event of a medical error when AI was used in conjunction with their mental health treatment; answer options

included the following: the mental health professional who made the decision, the company that made the computer program, the hospital or clinic that bought the computer program, the government agency that approved the computer program, someone else, no one, and don't know. In the case where AI was used in collaboration with a single mental health professional, most participants (>80%) reported that the mental health professional would be the one responsible if a medical error (eg, wrong diagnosis or unnecessary treatment) occurred for both a specific (ie, sleep disorder) and a general scenario.

Participants were more divided on who had responsibility for ensuring an AI program for mental health care was safe, with the plurality stating the company that created the program was responsible (229/500, 45.8%), followed by the mental health professional (135/500, 27%) and then the health system (73/500, 14.6%), with fewer than 10% of the participants selecting each of the remaining answer options.

Effect of AI on Trust in Mental Health Care Professionals

Most participants (265/500, 53%) said that if an AI program that was accurate 80% of the time in detecting health issues related to sleeping, eating, and concentrating disagreed with

their mental health professional, it would make them question the health professional's assessment. Notably, nearly 30% (137/500) of participants said they "did not know" how such information would change their view of their mental health professional's assessment, with the remaining 17% (85/500) stating it would not change.

To better understand what participants valued the most related to AI for their mental health, we asked the importance of various ethical constructs, based on MITRE's ethical framework for consumer-generated health information [43], as they pertained to an example AI program used to support treatment for depression (Figure 3). Over 80% (range 80.2%-96%) of participants found each of the constructs somewhat or very important. Notably, the highest proportion of participants (402/500, 80.3%) viewed explainability and transparency, "explainability," to be very important. Participants tended to perceive decreasing the risk of negative outcomes as slightly more important than improving symptoms. Participants found AI not reducing trust in their mental health professional as the least important trait by comparison, although 37.2% (186/500) and 43% (215/500) rated this trait as very and somewhat important, respectively.

Figure 3. Importance of various values related to artificial intelligence (AI) use for mental health.

Qualitative Results

Participants provided free-text responses describing themes related to nuanced aspects of AI's performance, human-AI dynamics, and further values or concerns pertaining to AI. Free-text responses were mandatory, but some participants simply stated they had no additional concerns (165/500, 33%), or they did not provide sufficient detail for their responses to be categorized (7/500, 1.4%). Of the 1000 responses (2 per participant), 97 involved >1 code, so percentages listed subsequently reflect the proportion of total codes observed. On the basis of the results listed in Table 1 (sociodemographic

differences in the perceived benefits of AI for mental health care), quotes shown also provide the patients' gender, race, and self-rated literacy for context.

AI Performance

Table 4 provides the detailed codes, proportion of occurrence, and examples related to AI performance. Participants described issues related to AI's accuracy, biases in AI data or biases that may occur in the use of AI, potential errors AI may commit, and how these errors may affect the quality of care. Participants expressed mixed opinions regarding whether AI would improve or degrade the quality of mental health care.

Table 4. Detailed qualitative codes related to artificial intelligence (AI) performance.

Detailed code	Count (n=188, 17.9%), n (%) ^a	Example quotes
AI performance and error: accuracy	96 (51.1)	<ul style="list-style-type: none"> “I think the main concern would be potential for getting an inaccurate diagnosis or the wrong treatment. It would definitely take time to trust the reliability. Programming errors, for example, could potentially lead to fatal outcomes for patients” (White woman with self-rated adequate health literacy).
Bias in data and use	50 (26.6)	<ul style="list-style-type: none"> “I am concerned that the algorithms/data set that was utilized to train AI would be biased. For instance, if more white people seek mental health care, and AI is trained on their data, would AI be as good at diagnosing mental health conditions in people of color?” “It will be biased, sexist and racist. It will rely on old ideas of mental health care and not use current information. It will be used to ignore or bully patients” (White nonbinary individual with self-reported inadequate health literacy).
Risk of harm	29 (15.4)	<ul style="list-style-type: none"> “I think there is far too much on the line when it comes to mental health that it’s risky to rely on AI for it. I think my main concern would be being over-diagnosed and having to be put in a psychiatric ward. I think that would be horrific” (White woman with self-rated adequate health literacy).
Care quality	13 (6.9)	<ul style="list-style-type: none"> “I think that it might lessen the quality standard of hired healthcare professionals since the expertise of AI system could become more important” (Black man with self-reported adequate health literacy). “It would improve the quality of work” (White woman with self-rated adequate health literacy).

^aPercentages do not add to 100%, as “no additional concerns” and “indeterminable” codes are included in the count.

AI and Humans: Superior, Inferior, or Simply Better Together

Table 5 presents participant feedback related to human-AI dynamics. Participants described worry that AI may not be able to replicate things done by humans (AI capabilities, human reasoning and communication, and the importance of human connection). By contrast, some pointed out ways in which AI

may offer advantages to human cognition (AI capabilities). They also provided feedback on how AI and humans may (or may not) work together (human-AI collaboration and overreliance on AI), with many noting that AI should be overseen by humans and not work autonomously in mental health care applications. Finally, a few participants expressed concerns regarding how AI may take away jobs from humans.

Table 5. Detailed qualitative codes related to human–artificial intelligence (AI) dynamics.

Detailed code	Count (n=297. 28.3%), n (%) ^a	Example quote
AI capabilities	78 (26.3)	<ul style="list-style-type: none"> “A software program’s understanding of mental health will never be as nuanced as a real humans. There will always be less common variables that AI systems aren’t programmed to take into account. I am concerned that with AI driven healthcare, patient[s] with more unusual backgrounds, experiences and symptoms will not have access to human professional[s] who can more fully consider their circumstances” (Asian woman with self-rated adequate health literacy). “AI is better at playing human games than humans are - it’s already World Go Champion and World Chess Champion...” (Black man with self-reported adequate health literacy)
Human-AI collaboration	39 (13.1)	<ul style="list-style-type: none"> “While I think that AI will be useful in mental health scenarios, I think that oversight should still be done, just like how I would prefer a few doctors to confirm a diagnosis. I think that it will be good at detecting some trends that can help move people towards better help, but that the help itself should be a joint effort and more personalized” (White nonbinary individual with self-reported adequate health literacy). “Overall, the use of AI is to assist the doctor in providing an accurate diagnosis. It improves the reliability of the diagnosis” (Asian man with self-rated adequate health literacy).
Overreliance on AI	30 (10.1)	<ul style="list-style-type: none"> “The biggest ethical concern I can think of is a mental health professional being completely reliant on AI without taking a closer look into how the program works” (White woman with self-rated adequate health literacy)
Human reasoning and communication	54 (18.2)	<ul style="list-style-type: none"> “That it can’t pick up on the subtleties of some symptoms that a human can” (White man with self-rated inadequate health literacy).
Importance of human connection	90 (30.3)	<ul style="list-style-type: none"> “Human connection and understanding are crucial in mental health diagnosis and treatment. I finally found a doctor that made me feel understood, heard, and cared for. It resulted in an effective treatment for my major depression and suicidal ideology after many years. AI can’t do that” (White woman with self-rated adequate health literacy).
Jobs	6 (2.0)	<ul style="list-style-type: none"> “As someone who will be working in healthcare in the new future, I am concerned that AI in health scenarios will take away jobs from real people who put in all the work to be working there” (White woman with self-rated adequate health literacy).

^aPercentages do not add to 100%, as “no additional concerns” and “indeterminable” codes are included in the count.

Additional Values and Concerns

Respondents expressed further values and concerns beyond performance and human-AI dynamics, many of which were

also covered in the closed-ended survey responses, including trust, transparency, privacy, responsibility, and cost (Table 6).

Table 6. Detailed qualitative codes related to additional values and concerns regarding the use of artificial intelligence (AI) for mental health.

Detailed code	Count (n=222, 21.2%), n (%) ^a	Example quote
Privacy	98 (44.1)	<ul style="list-style-type: none"> “I would be concerned about the company that owns the AI and if they could share the data with third parties. I’d also be concerned about what happens if someone admitted suicidal thoughts” (White woman with self-rated adequate health literacy).
Transparency	22 (9.9)	<ul style="list-style-type: none"> “I would worry about how my data is used to make AI based decisions. I would also wonder about the type of data being used” (White man with self-rated adequate health literacy).
Ethics	23 (10.4)	<ul style="list-style-type: none"> “One worry is that AI might be used to diagnose and treat mental health conditions without a person’s consent. This could lead to people being treated for conditions they do not have, or not receiving treatment for conditions they do have...” (White man with self-rated inadequate health literacy).
Trust	26 (11.7)	<ul style="list-style-type: none"> “I am just not comfortable with any machine diagnosing and treating any symptoms of mine, bottom line” (White man with self-rated adequate health literacy).
Appropriate use	19 (8.6)	<ul style="list-style-type: none"> “Yes, that a manipulative enough person could sway the machine into getting what they want rather than what they need” (White man with self-rated adequate health literacy).
Responsibility	14 (6.3)	<ul style="list-style-type: none"> “I wonder who would be held liable in the event a patient dies or experiences bad side effects due to the diagnosis or advice of AI. Would it be the AI itself or would the specialist also be held accountable?” (White woman with self-rated adequate health literacy)
Cost	20 (9.0)	<ul style="list-style-type: none"> “I think if the purpose is to provide better and more thorough health care, then it is a good endeavor. If the purpose is to decrease the costs of providing health care while maximizing profits, the project is specious. That’s why I can see it as a diagnostic tool to help healthcare providers come to a more accurate and thorough diagnosis. But I think it’s about maximizing profits and all stages of the healthcare process” (Asian woman with self-rated adequate health literacy)

^aPercentages do not add to 100%, as “no additional concerns” and “indeterminable” codes are included in the count.

Discussion

Principal Findings

This is one of the first studies to explore public perspectives of the use of AI for mental health-related applications. Our results expand upon other works studying public perceptions of AI for non-mental health care applications and raise important considerations regarding patient involvement in AI use for their mental health [31,44]. We also focused on various applications of AI to mental health care, differentiating our results from previous user-centered design studies that have elicited participant perceptions of a single, specific AI tool under development. Our study highlights the nuances of patients’ perspectives regarding AI for mental health care, revealing that their comfort with AI use depends on the purpose of the AI (tasks it performs), use process (when it is used and what factors drive predictions), and performance of the AI (how well it works and what happens when it is wrong) [45].

Perceived Benefits of AI for Mental Health Care (RQ 1)

Just under half (245/497, 49.3%) of the respondents in our study reported that they thought AI would make mental health care better or somewhat better. This is similar to a study conducted in Germany where 53% of patients reported positive or very positive attitudes toward AI, but not specifically for mental health [46]. Participants in other studies asking perceptions regarding more specific applications of AI (eg, a radiology image interpretation study in Saudi Arabia and a pregnancy and postpartum exploration in Spain) had stronger positive attitudes toward AI [47,48]. This is consistent with qualitative studies that have found patients with specific health challenges more readily connected with AI’s potential benefits. Our study also found that women were associated with lower perceived benefits of AI for mental health, while lower self-rated health literacy and Black or African American race were each associated with more positive perceptions. The previously cited study conducted in Germany had similar findings related to lower perceived benefit among women [46]. However, it is interesting that this result remained consistent for mental health care applications, in light of the fact that women have reported lower levels of

stigma regarding mental health care than men [49,50]. Our study also detected an interesting paradox that those having lower self-reported health literacy had more positive perceptions toward AI for mental health, although this finding warrants further replication and investigation. Regardless of patient perceptions, the inclusivity of patient-facing information regarding AI, ensuring those of various levels of literacy and numeracy may equitably comprehend its functions, remains critically important. Those of African American and Black race in the United States consistently report greater stigma and lower levels of trust toward mental (and other) health institutions due to biases, discrimination, and systemic racism [51,52]. The greater perceived benefit of AI for mental health care may represent a view that AI can be more just and without the biases of humans. This notion also requires further exploration, particularly given that the biases of human can often be embedded into the AI because training data embody previous human behavior.

Concerns Regarding AI for Mental Health Care (RQ 2)

Participants in our study cited concerns consistent with previous work related to AI accuracy, risk of harm (eg, wrong diagnosis and inappropriate treatment) [44,53,54], decreased human communication and connection [35,44,48,53], and issues pertaining to confidentiality [35,44,48,54-57]. Issues related to privacy were also the most commonly mentioned concern in the qualitative feedback. Participants also qualitatively described concerns about the performance of AI and doubts in AI's ability to truly replicate human reasoning. In our study, participants expressed some concern related to rising costs, although, as found in other studies, this worry was less pronounced [35,58]. These results continue to stress the importance of contextualization for patients in terms of the following: the accuracy of AI, harms and how they are mitigated, and data use and protections. As described in previous studies, continuing to support human connection is particularly needed in mental health care applications given the importance of the patient–mental health care professional therapeutic relationship.

Comfort With AI Accomplishing Mental Health Care Tasks (RQ 3)

Our study provided further evidence that patients' comfort with AI varies based on what the AI does. People were the least comfortable with diagnosis delivery tasks, which lends further support to the importance of continuing to keep health professionals in the loop related to AI [35]. Similar to a previous study of pregnant people in Spain [47], patients were most comfortable with tasks that recommended general wellness strategies or talk therapy. These results also suggest that AI for tasks patients are less comfortable with may require greater care to explain and also emphasize how the AI works with the health professional.

Despite the rapid proliferation of chatbots [37,59], less than half of the participants (237/500, 47.4%) were comfortable sharing mental health information with a chatbot, which may simply signify that these types of tools should be used on an opt-in basis. Previous studies have suggested that it may be easier for someone to share these sensitive feelings with a

computer or AI [60], and this may be true for certain people, but our findings did not universally support this assertion. It was also notable that approximately a quarter of the sample was not comfortable sharing mental health information with a mental health care professional. We acknowledge this may have been impacted by the types of mental health information listed in our survey, but it may also represent a continued stigma related to sharing mental health concerns.

Values Related to AI for Mental Health Care (RQ 4)

Findings in our study related to patients' values for AI for mental health care revealed challenges that AI integration may present to the patient–health professional relationship. In individual scenarios, patients overwhelmingly found mental health care professionals responsible for AI-related errors. While this does reflect similarity to the current standard of practice (ie, that health professionals are held responsible for medical errors even when computer systems are involved), future work should consider how this affects health professional well-being given the challenges related to burnout and shortages in trained mental health care workers. It also supports programs, such as AI programs falling under the US Food and Drug Administration's purview and the European Union's AI Act of 2023, where algorithms may be reviewed before use and subject to regulations [61]. Participants also noted that their trust in their mental health care professional would decrease if their assessment disagreed with AI. However, this was somewhat at odds with relatively fewer patients viewing issues with AI decreasing trust in their mental health care professional as “very important.” It was also notable that approximately one-third (137/500, 27.4%) of participants said they “did not know” how this scenario would affect their trust in their mental health care professional, which seems to highlight that patients may still be wrapping their heads around feelings regarding emerging technologies, such as AI.

Patients desired a high degree of transparency related to AI use, with >90% of participants considering it important that they be told when AI played even a small role in their care. Participants also valued explainability, as most participants (289/500, 57.8%) were not comfortable with highly accurate AI that could not explain how it made its predictions and as “understanding individual risk factors” was rated as the most important value related to AI for mental health care applications. It is at best unclear what patients are typically told regarding when AI is used for their care; how explainable it is; and to what extent, if at all, they are informed what factors drive predictions regarding their care. These results suggest that patient values may be at odds with the current standard of practice for patient communication. Similar to the concerns previously described, participants also highly rated the importance of AI not leading to errors and helping with their mental health symptoms.

Implications and Future Challenges

Implications regarding our findings are organized topically and include concrete recommendations, which have been italicized for emphasis.

Navigating the Patient–Health Professional Relationship

The therapeutic relationship between a patient and their health professional is crucial in mental health care settings. Our study revealed issues that will need to be reconciled if AI is to be safely, transparently, and acceptably used for mental health care. From our results, it is clear that patients want mental health care professionals to be the ultimate decision makers, using AI to support (but not make) decisions when it is deemed safe and effective [36]. Participants also overwhelmingly viewed mental health care professionals as the people responsible if an error occurred related to treatment where AI had been used.

Future work should investigate shared regulations for AI responsibility, health professional competencies for AI use (Russell et al [62]), and interfaces that support shared decision-making when using AI.

Specifically, designs should support collaborative patient–health professional decision-making in a way that fosters trust instead of degrading it while also not creating undue burden for the health professional. Previous studies have described how clinicians should be able to contest AI, such as ignoring it (when it is not relevant or appropriate), trusting it when it is appropriate, or being able to uncover explanations to negotiate in borderline cases [63]. Such systems should be able to track health professional decisions in relation to the AI, possibly allowing health professionals to provide brief rationale that they may use in conversations with patients. In creating such systems, usability and model explainability will be critical. While these systems may be difficult to study in situ given the sensitivity of mental health conversations, *solutions may first be evaluated in realistic clinical simulation environments to ensure safety and usability prior to larger scale deployment.*

Communicating AI-Related Information to Patients

Participants in this study desired various information regarding the use of AI for their mental health care; that is, they wished to know when, for what, and why it was used; how accurate it was; and the risk factors that drove a decision. Even with highly predictive AI, patients were still not comfortable with AI that could not explain how it arrived at a result, and they qualitatively expressed concerns related to misdiagnosis and improper treatment that could result from AI use. They also reported “understanding individual risk factors” as the most important value. It is unclear as to how much if any “information” patient receive, and there seems to be a mismatch between the current deployment of AI for mental health care and patients’ desires. *At minimum, we recommend promoting transparency in AI’s use, the communication of its accuracy, and including individual risk factors to help patients and clinicians decide when AI may be appropriate for use in health-related applications. Communications should also address how potential biases (eg, in the training data) have been evaluated and mitigated in the resultant AI tool.*

Communicating the desired information to patients, however, is not straightforward, as concepts such as AI performance and process involve complex mathematical concepts. Furthermore, this desire for additional information regarding AI is also at odds with how patient communication has traditionally been

practiced. When we consider other non–AI-based diagnostic or decision support tools (eg, magnetic resonance imaging, blood tests, and screening assessments), communicating information regarding how they work (ie, their process) or their performance is far from standard practice. AI seems to be held to a higher standard than other diagnostic tools related to transparency in performance. *Future work should consider not only communicating the process and performance of AI but also providing this information in the context with the performance of the existing approach to a given task.* This would allow health professionals and patients to determine whether the potential benefits of AI outweigh their concerns.

Providing patients with explanations of AI performance and factors driving prediction will require extensive study involving experts in human-centered, inclusive design working alongside AI developers, mental health care professionals, and patients. *There is a need for laboratory-based studies to understand what information regarding AI balances recognizing patient values, but also supports comprehension of important concepts and fostering appropriate trust.* These issues raise many questions for numeracy and data visualization experts regarding how information may be conveyed inclusively to patients with different needs so that the benefits of AI may be equitably realized.

Individuality and Autonomy

Our study detected differences in who may find AI beneficial and for what tasks they may be comfortable using it. *Future work should explore how we may respect individual autonomy with regard to the use of AI applications so that patients and health professionals may collaboratively make decisions about the appropriate application of AI to mental health care issues.*

Limitations

Our study was limited in that the sample was recruited using a web-based platform, which may not generalize to those with technology, literacy, and other barriers to web-based survey completion. The sample was representative of the adult US population in terms of age, gender, and race distributions (Prolific/academic researchers), leading to most of the survey respondents being White due to >70% due to the US demographic makeup (US Census Bureau [64]). Therefore, important perspectives from other racial and ethnic groups may be limited. Our results may also be subject to response bias, as those who had strong feelings regarding topics pertaining to AI, mental health, or their intersection may have been more likely to respond. For example, a higher-than-anticipated proportion of respondents (215/500, 43%) reported having a history of mental illness. We did attempt to control for this in RQ 1, and the history of mental illness was not found to significantly affect responses regarding participants’ perceived benefits of AI for mental health care. We, however, did not have a mechanism for evaluating how preexisting attitudes of AI may have affected responses, and this may be addressed with validated measures of AI attitudes in future surveys (Schepman and Rodway [65]). Given the scope of this paper, we were unable to assess sociodemographic differences (eg, based on race and literacy) across all outcomes. Future work may use this or other data sets

to provide a more nuanced picture of differing views related to specific questions regarding AI for mental health.

Conclusions

Our study found that approximately half (245/497, 49.3%) of the US adults surveyed perceived some benefit for the use of AI in mental health care applications. These perceived benefits were lower among women but higher among Black or African American participants and those with lower self-rated health literacy. Participants also expressed nuanced differences in the types of tasks they would be comfortable with AI completing, showing the greatest discomfort with AI handling clinical

diagnosis, diagnosis delivery, and the recommendation of medication. Those surveyed valued high-performing AI that could explain individual risk factors driving predictions. In general, participants were concerned that AI may mean a loss of human connection, and they perceived humans as the ultimate decision makers, with AI serving as an additional data point when appropriate. Qualitative feedback also revealed participants' deep-seated fears regarding the use of AI for their mental health care. These findings stress the importance of working with patients and mental health care professionals to understand whether and how AI may be safely, ethically, and acceptably implemented for mental health care applications.
