Quantitative Analysis

Item Screening

The data were found to be appropriate for EFA (Kaiser-Meyer-Olkin=0.93; $\chi^2_{1431}=10,205.5$, $P<.001$). The

determinant suggested that there was multicollinearity, and inspection of the correlation coefficients revealed 2 pairs of items that were highly correlated (items 7 and 8=0.83; items 36 and 37=0.87); therefore, we removed 1 item from each pair of correlations (items 8 and 36). Items 13, 32, and 33 were removed, as the majority of interitem correlations were

nonsignificant ($P>.05$). Furthermore, we removed items 6, 19, 25, 26, 28, 31, and 47 as either all or all but one of the correlation coefficients was <0.4 . In total, we removed 12 items and then reran the EFA on the remaining 42 items.

The determinant again indicated that multicollinearity was an issue. We identified 3 pairs of correlations with coefficients >0.7 (items 10 and 11=0.76; items 29 and 49=0.76; items 35 and 37=0.71); therefore, we removed 1 item from each pair (items 10, 29, and 35) and reran the EFA on the remaining 39 items.

Exploratory Factor Analysis

The Kaiser criterion was met ($n=295$; average communalities 0.64) [32]. Therefore, the factor structure was determined based on eigenvalues >1 . The rotated factor solution suggested 7 factors, which explained 63.64% of the variance. However, 3 factors were not retained because they contained <3 items. The removal of these factors resulted in the removal of items 7, 23, 24, 27, 48, and 49. The resulting 33 items were entered into a final EFA. A 4-factor solution was suggested based on the eigenvalues and the scree plot, which explained 58.61% of the variance.

Factor 1 had 13 items that assessed respondents' support for VRT, including 6 reverse-worded items (factor 1: attitude toward VRT). Factor 2 had 9 items. These items, including 7 reverse-worded items, assessed the extent to which the respondents expected VRT to be immersive (factor 2: the expectation of presence). Factor 3 had 7 items asking respondents to compare VRT to aspects of face-to-face therapies (factor 3: preference for VRT). Factor 4 had 4 items each assessing different aspects of the cost-effectiveness of VRT

(factor 4: cost-effectiveness). Refer to [Multimedia Appendix 2](#) for the final factor structure.

Scale Reliability

After reverse-scoring the reverse-worded items, we computed Cronbach α values for each scale. All scales had strong internal consistency (all Cronbach $\alpha \geq .82$). The scale reliabilities could not be improved by removing any of the items. A higher score on each of the subscales suggested a more favorable attitude (factor 1), increased perceived presence (factor 2), a preference for VRT over traditional therapies (factor 3), and agreement that VRT is cost-effective (factor 4). The desired direction for each subscale to demonstrate support for VRT was high for factors 1, 3, and 4 and low for factor 2.

Relationship Between Scales and Lived Experience

There was a significant relationship between the participants' familiarity with VR and their scores on all the factors. Familiarity with VR was positively associated with a more favorable attitude toward VRT (factor 1), higher expectations of presence (factor 2), a preference over face-to-face therapy (factor 3), and a belief that VRT is cost-effective (factor 4). We also found significant positive correlations between factors 1, 2, and 3, but not factor 4, and familiarity with the VRT. There was no significant correlation between mental health familiarity and the scores for any factors. [Multimedia Appendix 2](#) presents the correlation coefficients and associated significance scores.

Qualitative Results

Qualitative Questions

[Table 2](#) presents the initial qualitative questions that all participants were asked.

Table 2. Initial qualitative questions (N=295).

Type of data	Question	Response, n (%)
Qualitative question 1	Which aspects of virtual reality therapy guided by a virtual coach would you like to know more about?	226 (76.6)
Qualitative question 2	How has your previous experience of virtual reality (minimal or extensive) influenced your perceptions of virtual reality therapy guided by a virtual coach?	236 (80)
Qualitative question 3	If you were offered virtual reality therapy guided by a virtual coach, where do you think the best place to do the therapy would be?	245 (83)

Which Aspects of VRT Guided by a Virtual Coach Would You Like to Know More About?

Of the 226 participants, 19 (8.4%) indicated that they did not want to know anything more. Those who provided reasons indicated that they did not want to try or did not know enough. Of them, 22 (9.7%) participants indicated that, as they did not know enough, they would like to find out more; 5 (2%) indicated that they would like to try out VRT; and 9 (3.9%) asked regarding its cost. In total, 13 (5.8%) participants were curious about the conditions that could be targeted with the VRT, specifically regarding its use for anxiety disorders, depression, and emotion regulation.

Many participants asked how it could be tailored or personalized for them (29/226, 12.8%). This meant thinking about their position within the interaction, asking about safety or how much

control they would have, and whether VRT might have a negative effect and how this would be monitored. Of 226 participants, 47 (20.8%) asked about the virtual coach, wanting to know how real it would be, how much of the language would be generic or responsive to them, and how they could build a relationship with a virtual coach. Of these, many wanted more information about whether there was a real therapist involved and how involved they would be (11/47, 23%), whether they would be able to meet them in person, whether they would deliver the therapy live or preprogram the coach, or whether the virtual coach would be completely artificially intelligent. The realness of the virtual coach and the VRT (16/226, 7.1%) was also an important question posed by participants, including asking whether it would be realistic enough and comparing it to "real" or face-to-face therapy.

Most additional responses indicated that participants would like to know more about the process (67/226, 29.6%). This included practical questions regarding the frequency of use, the length of sessions, and how it would be delivered (eg, in which location). Furthermore, many participants asked about the content (26/226, 11.5%), particularly not only the scenarios that could be represented but also other aspects including the appearance, the script, and how the content could link with face-to-face therapy. Of the 226 participants, 11 (4.9%) asked about the technical aspects including the development of the coach (eg, whether an algorithm or artificial intelligence was used) and what equipment would be used to deliver the VRT.

How Has Your Previous Experience of VR (Minimal or Extensive) Influenced Your Perceptions of VRT Guided by a Virtual Coach?

The largest group of those answering this question indicated that they had no previous experience (79/236, 33.5%). A few without experience were positive or curious (19/236, 8.1%) whereas others (8/236, 3.1%) expressed more negative perceptions about its effectiveness as a therapeutic tool, anticipating that it would not feel real or tailored enough to the individual. The second largest group (59/236, 25%) felt that their previous experience had helped them to be more positive and linked it to their own experience of mental health and how it could be used for treatment. Although several mentioned using VR for gaming, they felt that it was effective at producing a level of presence that would be conducive to therapy and help to invoke real emotions and responses. They felt it was easy to use, could potentially lower costs, make therapy more accessible, and even with negative experiences, such as motion sickness or technical difficulties, they still had a positive perception of VRT.

However, 34 (14.4%) of the 236 participants with a more negative perception reported nausea or dizziness, whereas others perceived VR as more suited to games. This included problems with the quality of their experience, feeling that the VRT had not offered enough presence. However, those with a negative experience comprised the smallest group (8/236, 3.1%). Finally,

the third largest group felt that their previous experience would not influence how they felt about VRTs guided by a virtual coach (40/236, 16.9%). For some, their previous experiences could not inform their perception of VRTs as it had been for entertainment purposes or they had too little experience to be able to make a judgment (13/236, 5.5%).

If You Were Offered VRT Guided by a Virtual Coach, Where Do You Think the Best Place to Do the Therapy Would Be?

The largest group of respondents who identified a single location felt that it would be best delivered within the home (84/245, 34.3%), whereas the second largest group felt that it would be best delivered in a more professional location (43/245, 17.6%). Several felt that it could be offered in both settings (38/245, 15.5%), whereas others suggested that access could first be through a clinic (12/245, 4.9%), where they could access technical or therapeutic support, or from home (4/245, 1.6%), where they would feel more comfortable. When respondents highlighted delivery from home, they described it as being safe, comfortable, and familiar. They felt that they might feel susceptible or disorientated when coming out of a VRT session and that being at home would be preferable. More professional locations, such as physician surgeries or clinics, were also described as safe and familiar, although by fewer people. Professional or clinical settings were often viewed as a better location because of the presence of support. Other reasons included the level of cleanliness offered and that there would be fewer distractions.

Those without a preference identified elements of the location that were necessary to optimize the experience, including having a space to move, feeling safe and secure (eg, in an enclosed space), having privacy and quiet, and having few distractions. They also felt it would need to consider the condition being treated (including severity) and the individual's preferences.

Factors With Item Responses

Table 3 presents those items where either strong agreement or disagreement elicited a qualitative response.

Table 3. Qualitative responses to items.

Question	Strongly agree, n (%)	Strongly disagree, n (%)
Factor 1: attitudes toward VRT^a (42 and 43)		
Item 41: If the virtual coach encouraged me to do something between sessions, I would try to do it. (n=19)	18 (95)	1 (5)
Item 51: I would never be willing to try virtual reality therapy. (n=63)	3 (5)	60 (95)
Item 50: I would be willing to try virtual reality therapy if I had more information about it. (n=24)	21 (87)	3 (13)
Item 52: I would encourage the people I care about to try virtual reality therapy, if it was offered to them. (n=16)	14 (87)	2 (13)
Item 53: I would discourage the people I care about to try virtual reality therapy, if it was offered to them. (n=25)	1 (4)	24 (96)
Item 54: I cannot imagine virtual reality therapy being useful for someone with mental health problems. (n=24)	2 (8)	22 (92)
Item 42: I would feel comfortable interacting with the virtual coach. (n=14)	10 (71)	4 (29)
Factor 2: expectation of presence (47, 49, 50, 52, and 40)		
Item 43: I would find the characters in the virtual reality therapy unsettling. (n=6)	1 (17)	5 (83)
Item 45: I am skeptical about the effectiveness of virtual reality therapy. (n=13)	6 (46)	7 (54)
Item 44: I think that the virtual reality therapy would make me feel present enough to be effective. (n=7)	3 (43)	4 (57)
Factor 3: preference for VRT (54, 39, 53, and 41)		
Item 39: I think virtual reality therapy would be better than face-to-face therapy. (n=29)	2 (7)	27 (93)
Item 40: I would trust a virtual coach the same amount as a real therapist. (n=20)	4 (20)	16 (80)
Factor 4: cost-effectiveness (46)		
Item 46: I think virtual reality therapy will be worth the cost. (n=9)	6 (66)	3 (34)
Nonfactor answers (45, 48, 44, and 51)		
Item 47: I think I would be able to use the virtual reality equipment easily. (n=26)	24 (92)	2 (8)
Item 49: I think that virtual reality equipment could spread diseases. (n=19)	0 (0)	19 (100)
Item 48: If my skills with technology were poor, I would feel confident using virtual reality therapy if the health care professional accompanying me was trained to a high standard. (n=19)	17 (89)	2 (11)

^aVRT: virtual reality therapy.

Factor 1: Attitude Toward VRT

Individuals who scored highly on this factor had a positive attitude toward VRTs and VRTs delivered by a virtual coach, whereas those who scored low had a negative attitude. Within the items where strong agreement or disagreement elicited a text response (items 41, 51, 50, 52, 53, 54, and 42), those with positive attitudes highlighted the value of having a choice in mental health therapies. They emphasized the need to be willing to try different treatments to find the one that worked, reflecting on how more automated and digital options can help to increase access. Those with more negative attitudes indicated that it would be a type of therapy that they would not choose.

Factor 2: Expectation of Presence

Individuals who scored highly on this factor felt that VR would not be real, that is, low presence. Individuals who scored low felt that VR was immersive. Within the items where strong agreement or disagreement elicited a text response (items 43,

45, and 44), the respondents indicated several factors that affected their expectation that VR would be “real enough.” Previous experiences appeared to be linked to the expectations of presence. People who enjoyed their experiences had higher expectations of presence. Those with lower expectations felt that VRT would be too much like a game, whereas others indicated that experiencing cybersickness meant they had not felt present.

Factor 3: Preference for VRT

Individuals who scored highly on this factor showed a preference for VRT, whereas those who scored low showed a preference for face-to-face therapy. Within the items where strong agreement or disagreement elicited a text response (items 39 and 40), there was a strong sense that those who preferred face-to-face therapy would feel the loss of human interaction most and feel that a real person was needed to build a relationship and trust. Those who were more in favor of VRT

and the virtual coach felt that it would be more convenient and potentially enable more disclosures related to their mental health.

Factor 4: Cost-Effectiveness

Individuals who scored high on this factor felt that VRT was cost-effective, whereas those who scored low did not. Within the item where strong agreement or disagreement elicited a text response (item 46), those who felt it was cost-effective highlighted the decreasing costs of equipment and the benefits this could bring to mental health services. For those who felt that VR was still too expensive, there was also recognition of the difficulties that services might have in adopting VR.

Discussion

Overview

This study aimed to develop a new instrument for assessing the public perception of VRT delivered by a virtual coach. We received 295 responses. We found that a 4-factor solution was the best fit for the AVRT Scale, with all subscales having excellent internal consistency. The 4 factors were (1) attitudes toward VRT, (2) expectation of presence, (3) preference for VRT, and (4) cost-effectiveness. We found that being more familiar with VR was correlated with more positive attitudes toward VRT (factor 1), a higher expectation of presence (factor 2), preference for VRT over face-to-face therapy (factor 3), and belief that VRT is cost-effective (factor 4). Familiarity with mental health was not associated with any factor. The qualitative data supported the quantitative findings, with many respondents stating that their previous experience with VR may have affected their perception of VRT. Respondents identified their homes and spaces that felt safe and quiet as the best locations for delivering VRT. The virtual coach was a salient concept throughout the qualitative responses, with participants wanting to better understand it and the relationships that could be facilitated.

Principal Findings

Previous literature has indicated a correlation between VR familiarity and more positive attitudes toward VRTs [14]; however, this is the first study to demonstrate this through a public survey. Although we do not know the direction of this association, the qualitative findings suggest that as the reach of VR headsets increases, VRTs will likely be viewed more positively. The perceptions of potential patients are important in determining the efficacy of VRT, as positive expectations of any psychological therapy are associated with better treatment outcomes [35,36]. Therefore, an increase in the popularity of VR kits may indirectly improve the efficacy of VRTs.

This study is the first to explore peoples' perceptions of VRTs guided by a virtual coach. Although most participants had no personal or professional experience of mental health therapy, many mentioned aspects relating to the virtual coach that draw parallels with "therapeutic alliance"; in psychotherapy, this denotes the importance of the relationship between the therapist and service user. In psychotherapy research, a strong therapeutic alliance is associated with better treatment outcomes [37]. The concept of therapeutic alliance has been studied more broadly in relation to VR-assisted therapies [30] and digital mental

health [38]. The effects are similar but may be predictive of treatment outcomes to a lesser extent and more so predict engagement.

Understanding whether it is possible to foster a "therapeutic alliance" with a virtual coach and, if so, the nature of this relationship is something that the public is concerned with and therefore requires further investigation. Our findings provide initial insights into how therapeutic alliances may operate in VRT with a virtual coach. Respondents who showed a preference for VRTs indicated that the presence of a virtual coach would aid disclosure. This may be because of the anonymity that this form of communication offers [39]. Furthermore, it is notable that many were curious about the level of automation and formulation offered by the virtual coach. Qualitative findings from a trial of VRT guided by a virtual coach found that the presence of a member of staff helped to reinforce learning, which may suggest that certain elements of therapy require a certain level of formulation [40]. Our data suggest that the public view personalization as an important component of therapy and that VRTs can be improved by offering a certain level of formulation.

Another novelty of this study is the exploration of presence in relation to VRTs. Previous research has suggested that increasing presence can increase the effectiveness of VRT [41]. Newer VR-enabled headsets provide a greater level of presence as the quality of graphics and functionality, such as interactivity and sensitivity of sensors (eg, eye tracking), have improved significantly. Therefore, we sought to explore the importance of this sense of presence in the general population. Our findings indicate that those with a greater expectation of presence are more positive and more likely to show a preference for VRTs. Notably, our findings indicate that even those who are familiar with VR share concerns regarding the lack of presence and immersion in VRTs. This suggests that developers and researchers must continue to develop and update their intervention designs to ensure that VRTs do not become stagnant and continue to elicit a sense of presence.

Most of those who viewed VRTs positively emphasized the need for a choice to help increase access to mental health treatment. More automated VRTs have been designed considering the pressure to deliver psychological therapies in mental health services and the lack of resources to meet this need [10,11]. Our findings indicate that the public is aware of this and views VRTs guided by a virtual coach as an acceptable solution. Our respondents also indicated that VRT guided by a virtual coach would be suitable for delivery at home, further alleviating resource pressures. However, this was not the case for all participants, with a notable proportion wanting to access VRTs in a location that was safe, familiar, free of distractions, and large enough to use the VRT. The flexibility of location in delivering VRT is an important consideration for increasing access and meeting the needs of service users, especially when considering the strong links between poor mental health and housing quality [42]. The delivery location for VRT should be considered on a case-by-case basis.

A further consideration for the implementation of VRT found in our study is the importance of information. Our qualitative

findings indicate that people were keen to better understand what was involved in VRT and the virtual coach. Preintervention expectations are key in managing service users' expectations while also fostering hopefulness, which in turn improves engagement [43]. This information can also help to allay any concerns service users might have about VRT and help developers to understand their needs to improve the design and implementation of VRTs. For example, a small number of participants opposed the use of VRTs, which when expanded in our qualitative data collection, indicated certain ethical and moral concerns about its use in mental health care. All these views were valid, but a few may be rooted in misconceptions about VR or expectations about how it will be implemented. Therefore, potentially increasing the public's awareness and understanding of VR and VRT may help to appease them and improve how it is deployed.

We found mixed findings regarding the impact of cybersickness on willingness to engage in VRT. For some participants, cybersickness would dissuade people from using VRT. However, this finding was not ubiquitous, with some saying that they were still interested in trying VRT even if they had experienced cybersickness. This contradicts previous research, suggesting cybersickness is a considerable barrier [17]. As technology progresses, cybersickness might become less important. We also included a question on hygiene, as our questionnaire was shared during the COVID-19 pandemic. However, this was excluded, suggesting that it was not a significant concern for the public.

Limitations

The questionnaire has only been validated using the EFA. Further validation is required before we can confidently recommend its widespread use. Specifically, we must confirm the factor structure in a new sample using confirmatory factor analysis and assess its concurrent and discriminant validity. If we are able to replicate the strong psychometric properties found in this study, this questionnaire can be used to understand attitudes toward VRTs delivered by virtual coaches. The scale will also need to be adapted to contexts outside the United Kingdom, for example, by amending items and further validation.

Most of our respondents were female and had no previous experience with mental health conditions or therapy. However, men and those with more experience with mental health conditions or therapy may have different perceptions of VRTs. A recent review found that gender differences might affect the use and acceptability of VR, specifically that women are more susceptible to cybersickness and therefore may be less willing to use VR [44]. On the basis of this, it may be assumed that if we were to conduct a survey with male participants, the attitudes toward VRT guided by a virtual coach could be even more

positive. We do not have any available evidence to indicate whether those who are living with or have lived with mental health conditions are likely to be more or less accepting of VRTs. Purposive sampling should be used in future studies to ensure that the views of these groups are included in future validation studies.

Furthermore, we sought text responses for strong agreement or disagreement with certain items. Notably, those with more neutral views may have offered additional insights, but we weighed this against the additional burden on respondents. This may also have led some participants to neutralize their views to avoid triggering a free-text question. However, there were no instructions in the questionnaire that responding differently removed the free-text responses. In addition, the range of scores indicated that this did not deter the participants from giving extreme answers. The qualitative data we captured were sufficient for our analysis.

Finally, the analysis of the relationship between familiarity and attitudes toward VR and VRT was correlational. We could not make any claim regarding the direction or causal nature of these associations. For example, those with more positive attitudes and a better understanding are more likely to become familiar with VR through continued use. However, our qualitative findings indicate that negative experiences with VR do not factor in a willingness to use VRT.

Recommendations

Future research should further validate this questionnaire. Once this has been accomplished, the questionnaire could be used to investigate the factors that improve or worsen attitudes toward VRT and VRT guided by a virtual coach. For example, asking questions such as whether trying VR improves perceptions or whether increasing sales of domestic VR kits is associated with improved attitudes. It is also important to explore how these attitudes translate into behavior, that is, whether positive attitudes predict patient preferences and engagement with VRTs. The impact of the level of automation versus the formulation of the virtual coach on attitudes should also be explored, as this was a salient concept within the qualitative data. The AVRT Scale could be adapted and applied to other areas where VR is used to deliver interventions, such as behavior change interventions, or as a training tool. The questionnaire can also be used alongside treatment development, evaluation, and implementation to explore the barriers and facilitators specific to VRT and VRT guided by a virtual coach or the perceptions of certain populations to aid the translation of research into practice [45]. In the long term, any research that considers barriers to the uptake, engagement, and adoption of VRT has the potential to alleviate the demand for trained therapists in clinical settings, thus improving access to psychological therapies.

Acknowledgments

This research did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors. ADGB was funded by the National Institute for Health and Care Research MindTech MedTech Co-operative. Abstract

Background: Empirical evidence has shown that virtual reality (VR) scenarios can increase the effects of relaxation techniques, reducing anxiety by enabling people to experience emotional conditions in more vivid settings.

Objective: This pilot randomized controlled study aims to investigate whether the progressive muscle relaxation technique (PMRT) associated with a personalized scenario in VR promotes psychological well-being and facilitates the recall of relaxing images more than the standard complementary intervention that involves the integration of PMRT and guided imagery (GI).

Methods: On the basis of a longitudinal, between-subject design, 72 university students were randomly exposed to one of two experimental conditions: (1) standard complementary procedure (PMRT and GI exposure) and (2) experimental procedure (PMRT and personalized VR exposure). Individuals were assessed by a therapist before and after 7 training sessions based on measures investigating anxiety, depression, quality of life, coping strategies, sense of presence, engagement, and side effects related to VR exposure. Heart rate data were also collected.

Results: Differences in changes between the 2 groups after the in vivo PMRT session conducted by the psychotherapist (T1) were statistically significant for state anxiety ($F_{1,67}=30.56$; $P<.001$) and heart rate ($F_{1,67}=4.87$; $P=.01$). Individuals in the VR group obtained lower scores both before ($t_{67}=-2.63$; $P=.01$; Cohen $d=0.91$) and after ($t_{67}=-7.23$; $P<.001$; Cohen $d=2.45$) the relaxation session when it was self-administered by participants (T2). A significant reduction in perceived state anxiety at T1 and T2 was observed for both groups ($P<.001$). After the VR experience, individuals reported feeling higher engagement in the experience than what was mentioned by participants in the GI group ($F_{1,67}=2.85$; $P=.03$; $\eta_p^2=0.15$), and they experienced the environment as more realistic ($F_{1,67}=4.38$; $P=.003$; $\eta_p^2=0.21$). No differences between groups regarding sense of presence were found ($F_{1,67}=1.99$; $P=.11$; $\eta_p^2=0.11$). Individuals exposed before to the VR scenario (T1) referred to perceiving the scenario recalled in-imagination at T2 as more realistic than what those in the GI group experienced ($F_{1,67}=3.21$; $P=.02$; $\eta_p^2=0.12$). The VR group had lower trait anxiety levels than the GI group after the relaxation session during session 7 (T2; $t_{67}=-2.43$; $P=.02$).

Conclusions: Personalized relaxing VR scenarios can contribute to improving relaxation and decreasing anxiety when integrated with PMRT as a complementary relaxation method.

Introduction

Background

In working adults and university students, the prevalence of depression, anxiety, and stress increases, predisposing them to physical diseases and general repercussions on well-being [1,2].

The situation has worsened owing to the COVID-19 outbreak, which affected individuals' general well-being worldwide [3,4]. Different types of standardized relaxation interventions (eg, mindfulness-based stress reduction, progressive relaxation techniques by Jacobson, autogenic training by Schultz, abdominal relaxations, and visualizations) before, during, and after the COVID-19 pandemic have been shown to reduce anxiety and stress symptomatology in university students [4,5], with a more significant effect when integrated with other complementary techniques such as guided imagery (GI) [6,7]. GI is useful in creating mental imagery and refocusing attention on pleasant and relaxing imagined visual, auditory, tactile, or olfactory sensations, resulting in specific psychological and physiological responses such as relaxation and reduction of the autonomic nervous system responses [6,8,9].

The integration of the progressive muscle relaxation technique (PMRT) and GI can promote a higher sense of relaxation during training sessions, allowing for the application of the complementary techniques to cope with the stress experienced in daily activities [6,10-14].

Virtual reality (VR) is a usable, engaging, and user-friendly technology that promotes full immersion in the virtual context and facilitates the control of disturbing external stimuli [15,16].

Various studies have demonstrated that being immersed in virtual natural environments through a head-mounted display (HMD) facilitates the reduction of anxiety and stress symptoms in college students [17] as well as in association with different types of relaxation training (eg, body scan and muscle relaxation training) [18-21].

Owing to the positive impact of GI with PMRT in promoting relaxation, it may be hypothesized that exposure to a more vivid, closer-to-reality VR experience could be a helpful strategy for improving the relaxation learning promoted by the PMRT and decreasing stress and anxiety symptomatology.

GI offers an undefined number of possibilities for personalizing the imagined scenarios in a safe context. The personalization of content in VR should be helpful in recreating situations close to users' needs to promote relaxation and can override the limits of GI. The personalization of VR environments is a crucial element to consider as it allows for relaxation and the perception of safety in the virtual context [18,22] owing to the possibility

of offering a more realistic emotional experience, reflecting the users' needs [23].

Furthermore, the first part of the PMRT, named "active PMRT," involves a series of active sessions in which people learn how to tense and release the different muscle groups from the bottom to the top of the body to recognize the subjective state of muscle relaxation and relax the muscle areas of the body, reducing tension interfering with skeletal muscle activity.

These previous active PMRT phases are essential and are typically administered face-to-face by a psychotherapist or health operator trained to conduct the PMRT. By considering the effective results of web-based interventions in reducing stress among college students [24] and the relevant advantages that web-based therapy can offer (eg, saving costs related to attending psychotherapy sessions, allowing for partial self-management of the relaxation training), we assumed that assessing the efficacy of PMRT in alternative settings may facilitate the administration of treatment when the implementation of the standard procedure is not possible.

In light of the evidence described, we hypothesized that VR is more effective than in-imagination exposure in allowing for relaxation and decreasing state anxiety because of a more realistic sensory experience, facilitating visualization.

Objectives

For this reason, our primary aim was to deploy the active PMRT sessions remotely via Zoom (Zoom Video Communications) and the last complementary session in the therapist's presence, exposing people to a passive progressive relaxation session with GI or VR.

More in detail, we investigated whether PMRT associated with a personalized relaxing scenario in VR can be more effective in reducing state anxiety, tension or activation, and heart rate.

The secondary purposes of this research pilot were to (1) understand whether VR promotes a better sense of presence and engagement in the scenario compared with GI after session 6 (T1) and whether it helps recall the image and be immersed in the relaxing scenario in session 7 (T2) and (2) investigate whether exposure to the VR scenario promotes a better perception of psychological well-being, stress, and trait anxiety symptoms.

Methods

Overview

This pilot study was a randomized, parallel-assignment, open-label, controlled, single-center trial based on a longitudinal, between-subject design conducted at the University of Padova (Italy) in collaboration with the Center for Digital Health and

Wellbeing–Fondazione Bruno Kessler (Italy). This study is part of a larger research protocol published by Pardini et al [25] (International Registered Report Identifier: RR2-10.2196/44183). The study's recruitment phase ended in February 2023.

Participants

Before study enrollment, during the T0 face-to-face assessment phase at the university, the participants signed a written informed consent form based on a paper-and-pencil form agreeing to participate in all the study sessions. They were informed that (1) their data would be confidential, (2) they could omit any information they did not wish to provide, and (3) they could withdraw from the study without explanation.

Study participants were recruited in Northeast Italy via social networking websites (on the web) and during university lectures (offline). Those individuals interested in participating were asked to attend a face-to-face assessment with the investigators to participate in the first evaluation phase (T0) to comply with the inclusion and exclusion criteria, provide written informed consent, and undergo a baseline evaluation.

Eligible participants were adults from the general population (aged ≥ 18 years) and native Italian speakers, owned a PC, and were able to use a PC and a smartphone.

Participants were excluded from the study if they had been diagnosed with a severe mental disorder or medical conditions (eg, neuromuscular disorders) or were undergoing current psychotherapeutic treatment.

Eligible participants were randomly allocated to one of the experimental conditions based on a simple blinded randomization via an Excel (Microsoft Corp) file using the "RAND" function. In total, 2 experimenters trained in cognitive

and behavioral therapy conducted the relaxation sessions in a balanced way, each administering the sessions to 50% of the sample of each group to control for possible biases related to the therapist's personality and competencies. During the allocation to one of the experimental conditions, participants were unaware of whether they had to undergo the trial in the VR or GI condition. Participants were then informed about the type of procedure. The random allocation sequence and participant enrollment were conducted by 2 experimenters trained in cognitive and behavioral therapy.

Intervention

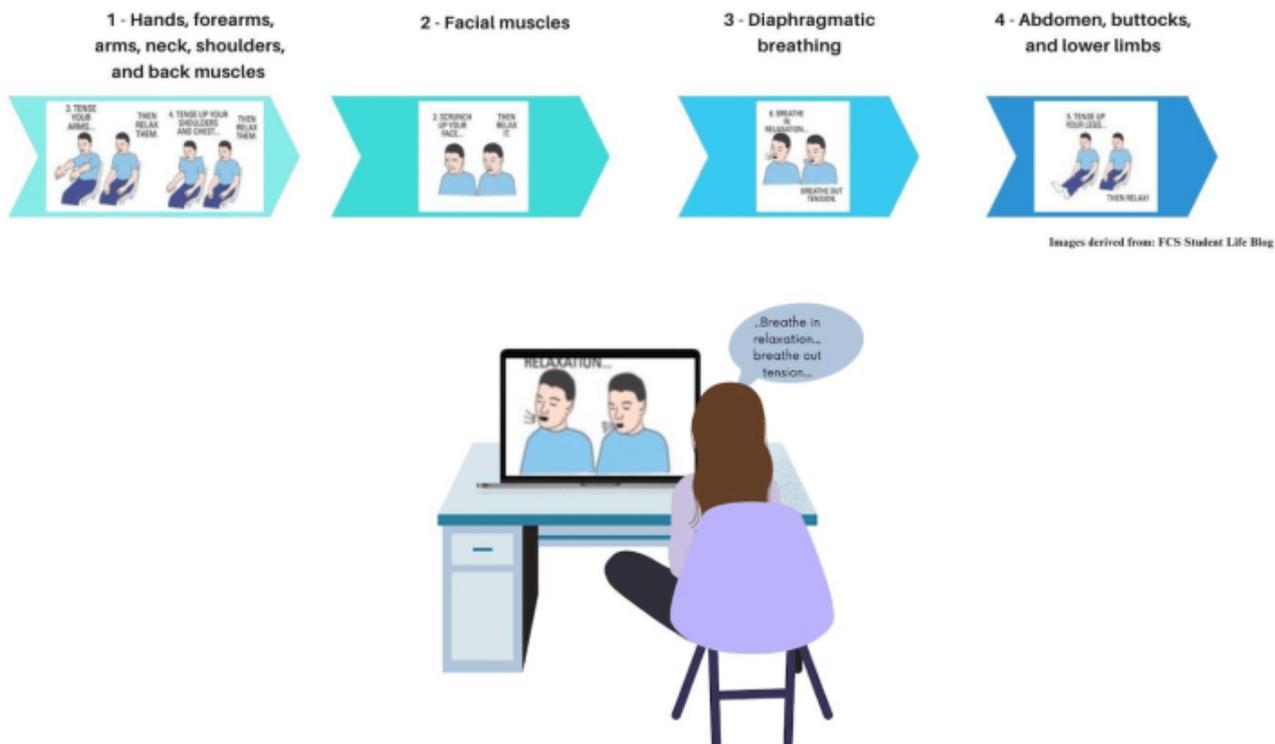

Hardware and Software Equipment

A commercially available VR headset (Meta Quest 2; Reality Labs) with an Alienware m15 Ryzen Edition R5" workstation and a link cable were used. The virtual scenarios were developed using the Unity framework (Unity Technologies) and the C# programming language (source of assets: Freesound [26], Unity, Poly Haven, and HDRIs). The code was versioned via GitLab. More detailed information about the virtual environment design is provided in the study by Pardini et al [18].

Procedure

For each group, the intervention implied previous learning of the adapted abbreviated PMRT [27] in 4 web-based active PMRT sessions. Each session required approximately 25 minutes (Figure 1). To check whether participants completed the active PMRT sessions, the therapists conducting the experimental procedure could check whether participants completed the assessment phases and the active PMRT sessions accessing Moodle (Moodle HQ). Therapists sent a reminder to participants a day before each session in the form of a direct message from the Moodle platform that was received as a personal email on the webmail university platform.

Figure 1. Illustrative examples of the relaxation exercises during the 4 web-based active progressive muscle relaxation technique sessions.

The first session focused on tensing and releasing the hands, forearms, arms, neck, shoulders, and back muscles; the second session focused on the facial muscles; the third session focused on teaching diaphragmatic breathing; and the fourth session focused on the abdomen, buttocks, and lower limbs (Figure 1).

The web-based sessions took place on the Zoom platform and were conducted by a cognitive behavioral therapist. Each Zoom session consisted of (1) filling out the State-Trait Anxiety Inventory–Form Y1 (STAI-Y1; state anxiety form), (2) sharing general standardized instructions for relaxation and the PMRT background with the participant, and (3) active PMRT session focused on a particular body section.

The fifth VR session was conducted at the VR laboratory at the University of Padova. All participants were asked to wear the Xiaomi 2 smartwatch to detect their heart rate frequency before, during, and after the relaxation session. A total of 5 measurements (1 per minute) were taken before the relaxation experience, 12 were taken during the entire exposure, and 5 were taken after the experience in the virtual context. Both the

PMRT with GI and the PMRT with VR sessions were approximately 12 minutes long. This duration was also established based on previous studies' outcomes and to avoid potential cybersickness symptoms [28,29].

Specifically, the compared groups' conditions were characterized as follows: (1) the *PMRT and GI condition* consisted of the deployment of a standard behavioral intervention based on 4 individual active PMRT sessions via Zoom (sessions 2-5; T1-T4), an in vivo PMRT relaxation session with GI conducted by the psychotherapist (session 6; T1) a week after the baseline assessment (session 1; T0), and a follow-up phase (session 7; T2) after 2 weeks consisting of recovering the in-imagination relaxing scenario and a PMRT session (Figure 2); and (2) the *PMRT and VR condition* consisted of 4 active PMRT sessions administered via Zoom (sessions 2-5; T1-T4), a passive PMRT session integrated with the exposure to personalized VR scenarios deployed using the Meta Quest 2 HMD (session 6; T1), and a follow-up phase consisting of the same activities as the PMRT and GI condition (session 7; T2; Figure 3).

Figure 2. Progressive muscle relaxation technique (PMRT) and guided imagery (GI) exposure.

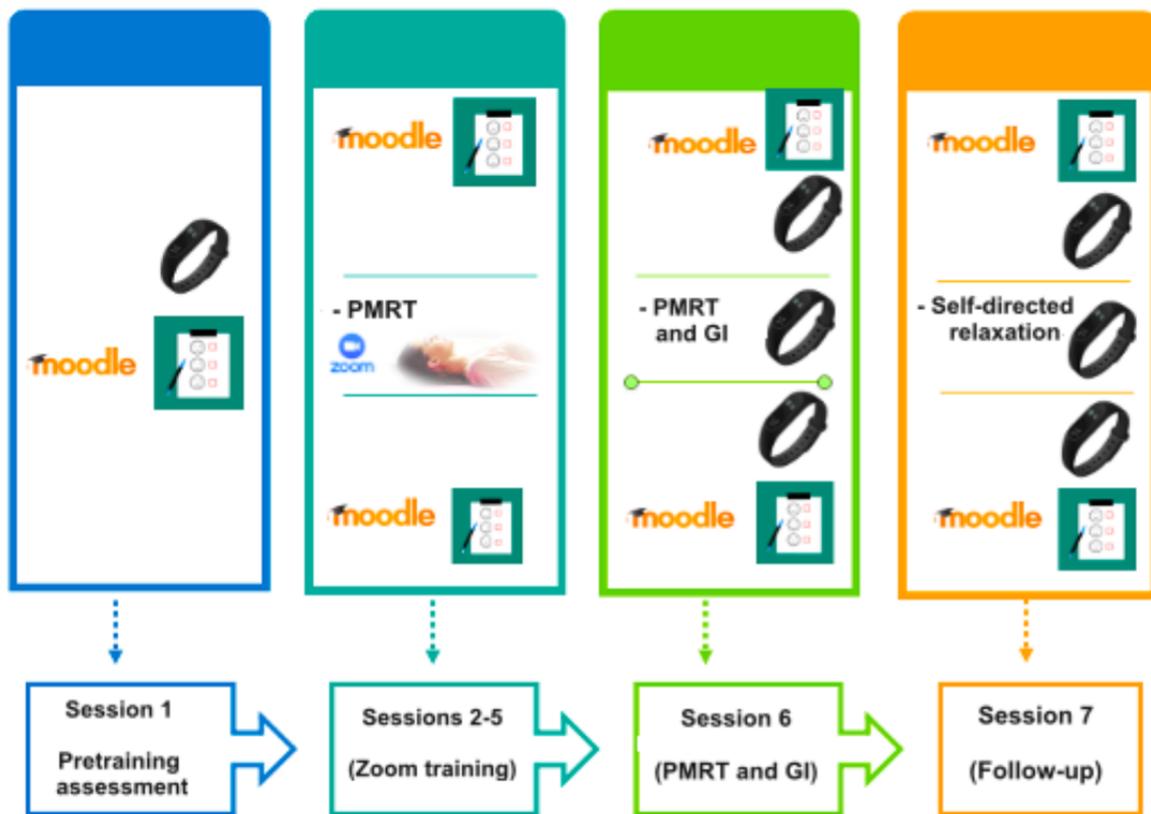

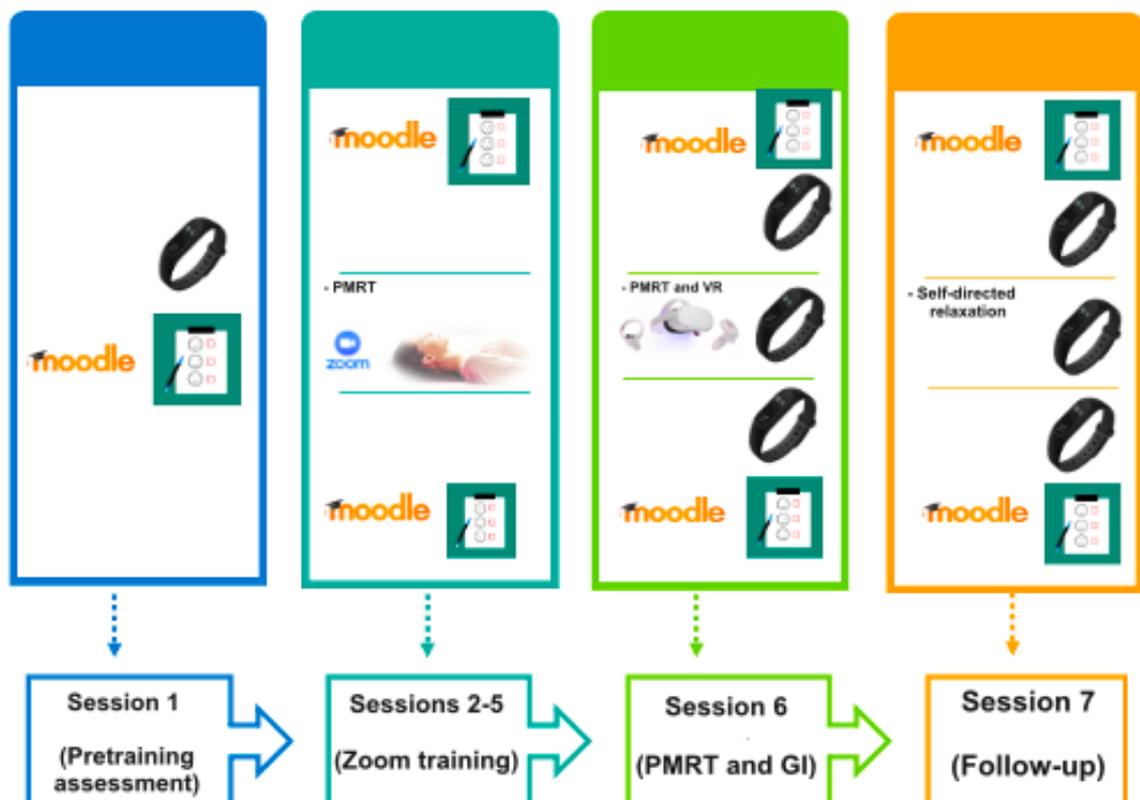

Figure 3. Progressive muscle relaxation technique (PMRT) and personalized virtual reality (VR) exposure.

The assessment phases were completed via the Moodle open-source learning platform. For this purpose, students could use their institutional accounts to access the platform. The administrator of the experimental procedure then created an ID profile for each participant. To access the Moodle platform, participants did not have to pay.

The assessment phases took place at baseline (T0); before and after each of the 4 active PMRT sessions; before and after the passive PMRT session administered with VR or GI (T1); and a week later, when participants were asked to lead the relaxation session autonomously (T2).

The T0 (baseline) assessment phase lasted approximately 40 minutes; it was the same for all participants and was administered at the VR laboratory at the University of Padova. It involved the administration of the following measures: (1) a demographic schedule [30]; (2) a series of self-report questionnaires investigating depression, anxiety, stress, quality of life, and distress coping strategies (State-Trait Anxiety Inventory–Form Y [STAI-Y]; Depression, Anxiety, and Stress Scale–21 [DASS-21]; Psychological General Well-Being Index [PGWBI]; and Coping Orientation to the Problems Experienced–*Nuova Versione Italiana* [COPE-NVI]); and (3) resting heart rate detection using the Xiaomi Mi Band 2.

Before and after each relaxation session (T1–T4), in approximately 20 minutes, the personal level of tension and relaxation was assessed using a visual analog scale (VAS) from 0 (no tension) to 10 (extreme tension level). The state anxiety level was evaluated based on the STAI-Y1. The 4 relaxation sessions were administered 2 to 3 days apart for all 3 groups. The assessment phase was web-based administered through Moodle, an e-learning platform used for data collection.

The T1 phase (day 7) took approximately 60 minutes and took place at the VR laboratory at the University of Padova. Before and after the relaxation session, states of tension and relaxation and anxiety were assessed using a 0 (no tension) to 10 (extreme tension level) VAS. The state anxiety level was evaluated based on the STAI-Y1. Participants were then exposed to a PMRT session merged with a VR or GI procedure. Before the in-imagination or VR experience, all the participants filled out the Vividness of Visual Imagery Questionnaire and the Test of

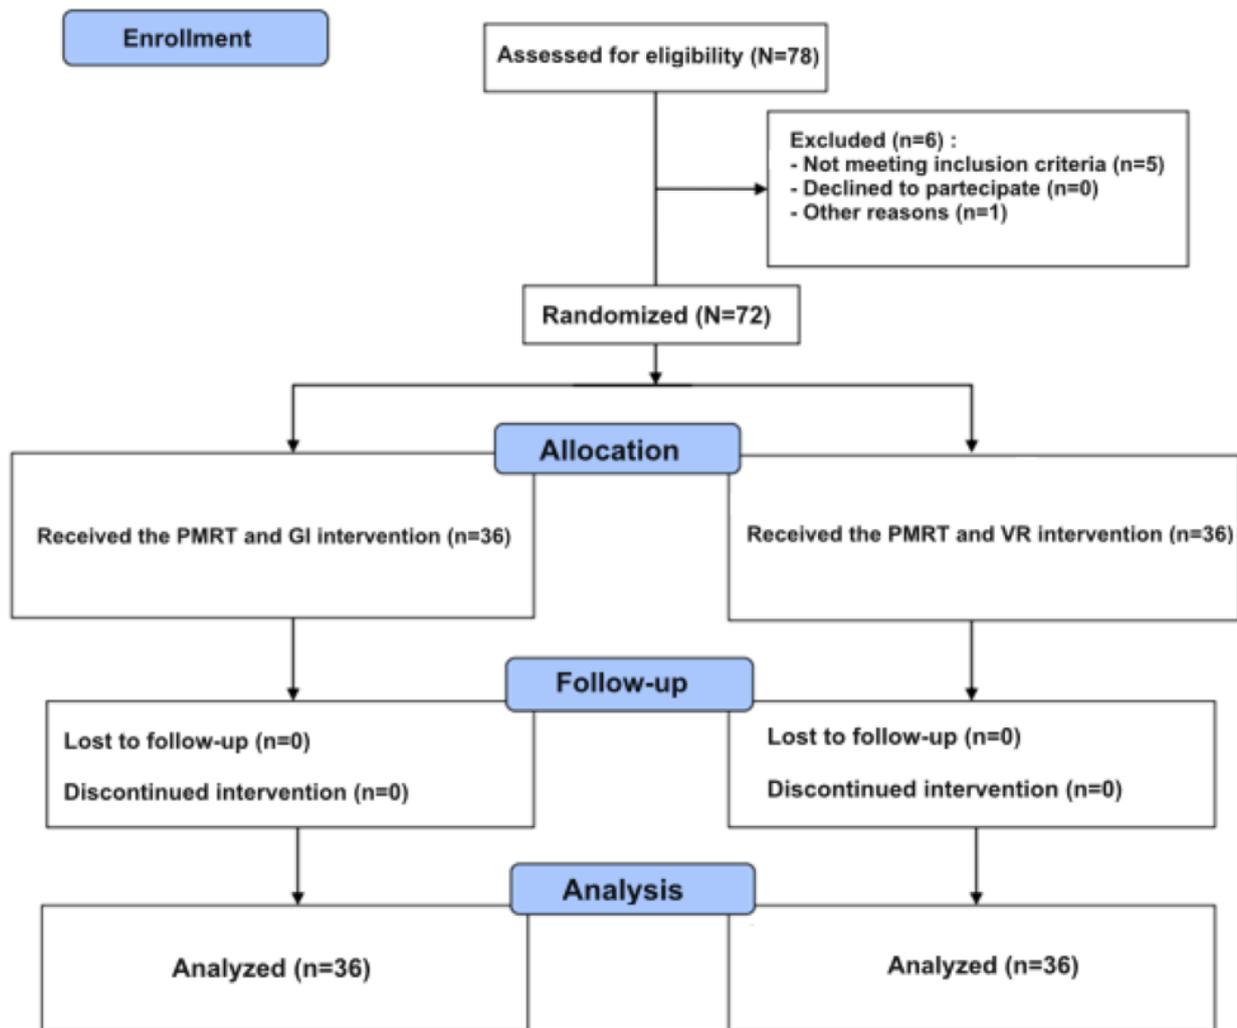

Visual Imagery Control. After the PMRT session, users filled out a series of self-report questionnaires investigating depression, anxiety, and stress (STAI-Y and DASS-21), and only the VR group filled out the Virtual Reality Symptom Questionnaire (VRSQ) to monitor VR-related side effects (eg, sickness) and the International Test Commission–Sense of Presence Inventory (ITC-SOPI) to assess the sense of presence at the end of the T1 phase. The Xiaomi Mi Band 2 was used during the entire T1 phase to detect resting heart rate activity. The assessment phase was administered through the Moodle e-learning platform.

The T2 phase was deployed for approximately 45 minutes at the VR laboratory at the University of Padova. Before and after the relaxation session, states of tension and relaxation and anxiety were assessed using a VAS from 0 (no tension) to 10 (extreme tension level). The state anxiety level was evaluated based on the STAI-Y1. All users were exposed to a self-GI experience in which those who were part of the VR group were asked to recall the personalized VR scenario experienced during the T1 phase (day 7). The GI group retrieved instead the image that participants had used in association with the PMRT during the T1 phase (day 7). After the session, participants filled out a series of self-report questionnaires investigating depression, anxiety, stress, and quality of life (STAI-Y, DASS-21, and PGWBI) and an ad hoc version based on the ITC-SOPI to assess the sense of presence experienced during the imagery session. This assessment phase was administered based on the Moodle e-learning platform. The Mi Band 2 was used during the entire T1 phase administration (day 7) to detect resting heart rate activity.

Sample Size Estimation

To investigate whether the parameters based on our sample size could be acceptable, a formal sample size calculation was conducted using the G*Power (version 3.1) software [31]. As a statistical test, the repeated-measure ANOVA between the factors was considered. The effect size was 0.28, the Cronbach α was .05, and the power ($1 - \beta$ error probability) was 0.80. We had 2 separate groups and 3 measurements. On the basis of these parameters, it was estimated that at least 35 participants should be recruited for each group. The enrollment process is summarized in Figure 4.

Figure 4. CONSORT flow diagram. Progressive muscle relaxation technique (PMRT) and guided imagery (GI) condition: “As usual” intervention; PMRT and virtual reality (VR) condition: “Experimental” intervention.

Statistical Analysis

Quantitative statistical analyses were conducted using the SPSS (version 29.0; IBM Corp) software [32]. Frequencies, means, and SDs were measured to explore the sociodemographic features.

To examine the between- and within-subject differences, the 2 groups were evaluated using a repeated-measure multivariate analysis of covariance (MANCOVA) for mixed designs, multivariate MANCOVA, and *t* tests. To compare the differences between and within groups, pairwise comparisons with Bonferroni CI adjustment were calculated. Multiple linear regression analyses were conducted to investigate whether the sense of presence, engagement, and perception that the scenario was realistic could be predictive of the state anxiety level experienced after the VR exposure.

Outcome Measures

The measures were administered before and after each relaxation session. The heart rate frequency was recorded based on the Xiaomi Mi Band 2 before the session to obtain baseline data during and after the trials.

A sociodemographic schedule was filled out to obtain information about gender; age; mother tongue; marital status; years of education; occupation; psychological, medical, and neuromuscular problems; use of drugs; and whether participants had relaxation training experience or had used VR devices in the past.

The STAI-Y [33-35] is a self-report questionnaire that allows for the investigation of state and trait anxiety using 40 items on a 4-point Likert scale. Items are grouped into 2 scales focused on how participants generally feel (trait anxiety) or what they experience at particular times (state anxiety). The reliability and validity of the STAI-Y are good in the Italian sample. This study highlighted a moderate to acceptable internal consistency for the state and trait anxiety scales administered ($.70 < \text{Cronbach } \alpha < .84$).

The VAS for the tension and relaxation level is a measure of tension and relaxation intensity administered before and after each VR experience. Participants had to express how tense and activated they felt ($0 = \text{not at all}$; $10 = \text{completely}$). Lower scores indicated higher relaxation levels.

The DASS-21 [36-38] is a self-report questionnaire based on 21 items that provides information about anxiety, depression, and stress symptomatology on a 4-point Likert scale from 0 to 3. Internal consistency and convergent, divergent, and criterion-oriented validity are adequate in the original and Italian versions. On the basis of our sample, a moderate to acceptable internal consistency emerged for the total and the 3 subscales ($.77 < \text{Cronbach } \alpha < .87$).

The PGWBI [39-41] is a self-report questionnaire consisting of 22 items that provides a general subjective assessment of psychological well-being. It comprises 6 subscales: anxiety, depression, positivity and well-being, self-control, general health, and vitality. The scores for all subscales can be summarized to provide a summary score, which reaches a maximum of 110 points representing the best achievable "well-being." The tool's psychometric properties are good for the original version and Italian validation. Considering our sample, an acceptable internal consistency emerged for the total score (Cronbach $\alpha = .72$).

The COPE-NVI [42] is a 60-item self-report questionnaire on a 5-point Likert scale that investigates how often people use certain coping strategies with stressful or difficult events. Items are grouped into 5 subscales referring to different coping strategies: social support, avoidance strategies, positive attitude, problem-solving, and turning to religion. This tool is psychometrically valid to measure coping styles in the Italian context. Considering our sample, an acceptable internal consistency emerged for the total and the 6 subscales ($.72 < \text{Cronbach } \alpha < .89$).

The Vividness of Visual Imagery Questionnaire [43-46] comprises 16 items on a 5-point Likert scale and investigates individual differences regarding the ability to imagine visual contexts vividly. The participant is asked to generate 4 mental images and evaluate their vividness. On the basis of our sample, a good internal consistency was observed (Cronbach $\alpha = .89$).

The Test of Visual Imagery Control [45-47] is a measure that evaluates individual differences in the ability to control and modify mental images intentionally. For example, participants are asked to visualize a car and then transform the image according to 10 different descriptions. Responses are recorded. On the basis of our sample, a good internal consistency was found (Cronbach $\alpha = .86$).

The ITC-SOPI [48,49] is a questionnaire consisting of 42 items on a 5-point Likert scale that allows for the investigation of the sense of presence experienced in a VR context. It comprises 4 subscales investigating the sense of physical space, level of engagement experience in the virtual context, ecological validity, and negative effects of exposure. On the basis of our sample, a good internal consistency was found for all subscales ($.67 < \text{Cronbach } \alpha < .78$).

The VRSQ [50,51] assesses the general and eye-related physical symptoms of exposure to a VR environment. The score assigned to each item ranges from 0 to 6, with a maximum total score of 84 (48 for general symptoms and 36 for eye symptoms). Higher scores represent worse symptoms, with 0 corresponding to no adverse effects and 84 to serious adverse effects.

Ethical Considerations

The proposed study protocol was approved by the institutional review board of the Interdepartmental Ethical Committee of Psychology (17 Area) of the University of Padova (Italy; approval 4701; April 29, 2022). The study complied with the relevant ethical regulations of the Declaration of Helsinki (Italian law 196/2003; European Union General Data Protection Regulation 679/2016).

Results

Sociodemographic Features and Comparisons

The sociodemographic features of the study sample are outlined in [Table 1](#).

A multivariate ANOVA was conducted to investigate whether the groups differed in sociodemographic and psychological characteristics before the relaxation training. A difference between the groups was found only for age, years of education, and marital status (Table 1).

To control for the possible impact that baseline differences could have on the research outcomes, the effects of all these

variables were controlled for in the subsequent analyses. The psychological problems referred to by participants were related to problematic relationships with parents, low self-esteem, and relational problems. Moreover, for individuals in the VR group, the VRSQ was administered to assess the possible collateral effects of VR exposure–related nausea. On average, individuals showed light susceptibility to general and eye-related motion

sickness levels (VRSQ general score: mean 1.39, SD 1.32, range 0-4; VRSQ eye symptom score: mean 1.56, SD 1.32, range 0-5).

Objective 1: Investigate Whether PMRT Associated With a Personalized Relaxing Scenario in VR Can Be More Effective in Reducing State Anxiety, Tension and Activation, and Heart Rate Frequency

To investigate the differences between the “Virtual Reality” and “Guided Imagery” groups before and after the complementary relaxation experience in session 6 (T1) and session 7 (T2; Figures 2 and 3), we applied a repeated-measure MANCOVA. No significant within-subject main effect emerged ($F_{2,67}=1.01$; $P=.37$). A significant between-subject main effect was found ($F_{1,67}=30.56$; $P<.001$), and the VR group showed a

greater change after the VR exposure than the GI group did in state anxiety (STAI-Y1; $F_{1,67}=10.27$; $P<.001$). After the relaxation experience at T1 ($t_{67}=-7.82$; $P<.001$), the VR group displayed lower state anxiety levels than the GI group both before ($t_{67}=-2.63$; $P=.01$; Cohen $d=0.91$) and after ($t_{67}=-7.23$; $P<.001$; Cohen $d=2.45$) the relaxation session during session 7 (T2; Table 2). Pairwise comparisons between and within the groups were performed before and after the relaxation experience at T1 and T2 (see also Multimedia Appendix 1). After the relaxation sessions at T1 and T2, the VR and GI groups experienced a significant decrease in state anxiety ($P<.001$). Pairwise comparisons within groups highlighted a significant reduction in perceived state anxiety at T1 and T2 for both the VR and GI groups (Table 3).

^cRefers to the assessment filled out after the relaxation experience at T1 and T2.

^d $P < .001$.

Regarding the outcomes that emerged from the VAS, no significant differences were observed before the relaxation session at T1 (VR group: mean 3.71, SD 0.37; GI group: mean 4.13, SD 0.37; $t_{67} = -0.76$; $P = .44$; $\eta_p^2 = 0.009$), but the groups differed after the T1 session, with higher levels of tension experienced by participants in the GI group (VR group: mean 1.05, SD 0.30; GI group: mean 2.06, SD 0.30; $t_{67} = -2.23$; $P = .03$; $\eta_p^2 = 0.069$). The same pattern was observed at T2, with no differences between the groups before T2 (VR group: mean 3.52, SD 0.35; GI group: mean 4.17, SD 0.35; $t_{67} = -1.24$; $P = .22$; $\eta_p^2 = 0.022$) and higher scores in tension obtained by the individuals in the GI group after the relaxation session (VR group: mean 2.06, SD 1.71; GI group: mean 2.58, SD 1.80; $t_{67} = -2.06$; $P = .04$; $\eta_p^2 = 0.060$). Moreover, the levels of tension decreased in each group after the relaxation session at T1 (VR group: $t_{67} = 5.39$, $P < .001$, and Cohen $d = 5.05$; GI group: $t_{67} = 4.45$, $P < .001$, and Cohen $d = 7.20$) and T2 (VR group: $t_{67} = 8.55$, $P < .001$, Cohen $d = 7.90$; GI group: $t_{67} = 6.68$, $P < .001$, and Cohen $d < 6.15$).

Heart rate was assessed 3 times (before, during, and after the relaxation exposure). The Mauchly test of sphericity was adequate for the heart rate recorded in both sessions 6 and 7 ($P = .09$). Heart rate frequency was found to have a significant main effect between groups ($F_{1,67} = 4.87$; $P = .01$) but to be not

significant within groups ($F_{2,134} = 0.51$; $P = .73$). An interaction between the “time of assessment” and “group” factors for heart rate ($F_{2,134} = 2.22$; $P = .01$) was observed. Specifically, individuals in the VR group recorded lower levels of heart rate during (mean 68.26, SD 5.49) and after (mean 69.11, SD 4.98) the VR exposure at T1 than those of individuals in the GI condition (heart rate during: mean 72.86, SD 5.23; heart rate after: mean 72.22, SD 4.73; $-2.79 < t_{1,67} < -3.60$; $P < .01$). No significant outcomes were observed at T2.

Objective 2: Understand Whether VR Promotes a Better Sense of Presence and Engagement in the Scenario Compared With GI After Session 6 (T1) and Whether it Helps Recall the Image and Be Immersed in the Relaxing Scenario in Session 7 (T2)

Individuals in the VR group reported feeling higher engagement after the experience than participants in the GI group (ITC-SOPI–Engagement: $F_{1,67} = 2.85$; $P = .03$; $\eta_p^2 = 0.15$). Moreover, the VR group participants reported experiencing a more realistic environment than that experienced by individuals who used imagination to create the scenario (ITC-SOPI–Ecological Validity: $F_{1,67} = 4.38$; $P = .003$; $\eta_p^2 = 0.21$). No differences between the groups regarding sense of presence were found (ITC-SOPI–Sense of Presence: $F_{1,67} = 1.99$; $P = .11$; $\eta_p^2 = 0.11$; Table 4).

Table 4. Multivariate analysis of covariance.

Guided imagery (n=36)	40.36 (6.16)
ITC-SOPI–Ecological Validity (T2)	
Virtual reality (n=36)	17.44 (3.85)
Guided imagery (n=36)	14.17 (4.06)

^aITC-SOPI: International Test Commission–Sense of Presence Inventory.

To investigate whether VR facilitated image recall during session 7 more than the GI technique did, the sense of presence and engagement experiences were assessed after the relaxation experience in session 7 (T2). Individuals previously exposed to the personalized VR scenario referred to perceiving the same scenario recalled in T2 as more realistic than did individuals that, in the previous session (T1), were exposed to an imagined scenario (ITC-SOPI–Ecological Validity: $F_{1,67}=3.21$; $P=.02$; $\eta_p^2=0.12$). No differences emerged between the groups at session 7 (T2) for sense of presence (ITC-SOPI–Sense of Presence: $F_{1,67}=0.76$; $P=.55$; $\eta_p^2=0.04$) and engagement (ITC-SOPI–Engagement: $F_{1,67}=2.30$; $P=.07$; $\eta_p^2=0.12$; Table 4).

Objective 3: Investigate Group Differences Regarding Trait Anxiety, Depressive Symptoms, Stress, Coping, and Well-Being

To investigate the differences in trait anxiety, depressive symptoms, and stress between the VR and GI groups at baseline

(T0), after session 6 (T1), and after session 7 (T2), we applied repeated-measure MANCOVA. The Mauchly test of sphericity was adequate only for the State-Trait Anxiety Inventory–Form Y2 ($P>.05$). The Huynh-Feldt correction was adopted for the DASS-21 anxiety subscale. The Greenhouse-Geisser correction was adopted for the DASS-21 depression and stress subscales. A significant interaction between the variables “time of assessment” and “group” factors ($F_{2,140}=3.62$; $P=.02$) emerged. The “Virtual reality” group had lower trait anxiety levels than the “Guided Imagery” group after the relaxation session during session 7 (T2; $t_{67}=-2.43$; $P=.02$; Tables 5-7). No significant interactions between “time of assessment” and “group” were found for stress ($F_{1,16,81.41}=1.15$; $P>.05$), anxiety ($F_{1,89,132.58}=3.11$; $P>.05$), and depressive symptoms ($F_{1,16,81.23}=1.09$; $P>.05$) assessed using the DASS-21.

^bItalicization indicates that the *P* value is statistically significant.

Differences within and between groups in coping strategies and psychological well-being were investigated at baseline (T0) and after session 7 (T2). No significant differences were found between the “time of assessment” and “group” factors for both the PGWBI questionnaire ($F_{1,70}=0.63$; $P > .05$) and all the COPE-NVI subscales (COPE-NVI–Social Support: $F_{1,70}=0.95$ and $P > .05$; COPE-NVI–Avoidance Strategies: $F_{1,70}=3.01$ and $P > .05$; COPE-NVI–Positive Attitude: $F_{1,70}=3.59$ and $P > .05$; COPE-NVI–Problem-Solving: $F_{1,70}=0.28$ and $P > .05$; COPE-NVI–Turning to Religion: $F_{1,70}=3.71$ and $P > .05$).

Discussion

Principal Findings

Research on the use of personalized VR scenarios for promoting relaxation is growing, although few conclusions on their effectiveness have been reached. We know even less about the usefulness of integrating standardized and evidence-based relaxation techniques (eg, PMRT) with new technologies that could promote the independent use by patients, providing a more economical solution to treatment costs. As stated

previously, the possibility of personalizing audio and visual stimuli in a VR environment is a promising approach for meeting users' preferences and needs [22], and it has shown encouraging results in terms of both feasibility and potential impact on psychological well-being [18].

The general aim of this pilot study was to evaluate the impact of a novel complementary relaxation training composed of PMRT and the exposure to a personalized relaxing scenario in VR aimed at reducing anxiety and promoting relaxation in a sample of university students.

First, we were interested in investigating the differences in state anxiety between and within groups in the T1 session, where participants were directly exposed to a virtual or imaginative relaxation session. Although a reduction in state anxiety was observed in both the VR and GI groups, our results highlighted that being in a personalized virtual scenario promoted a more significant reduction in self-perceived state anxiety and tension than being in the imaginative condition. Our results are consistent with those of other studies that showed that VR could be a useful tool in reducing stress and promoting relaxation from an assessment based on self-reported measures [52]. Although the target user sample in the study by Hoag et al [53] comprised children and young adults with acute and chronic illnesses, our results align with their results, showing a significant decline in state anxiety from before to after VR exposure. Our data support the role of VR in facilitating a powerful distraction effect on users, reducing their focus on thoughts and external events that would elicit anxiety responses [54,55].

In addition, our data highlighted how engagement with VR scenarios contributes to reducing perceived anxiety after the VR experience. Indeed, it seems that exposure to the VR scenario instead of the imaginative one facilitates the reduction in anxiety levels after the relaxation session. Even if our results need to be further investigated with larger user samples, they are aligned with those of previous studies that underlined the potential benefit of using pleasant, relaxing, and immersive VR scenarios for facilitating relaxation and engagement in individuals from the general population [18,56,57]. A point of strength of this experimental design is the assessment of the impact that the ability to control and vividly picture mental images may have. As we did not find differences between the 2 groups in these abilities before the exposure to the relaxation session in T1, we can support the observed positive effect that exposure to a VR context can have on reducing anxiety.

Considering the VR group, our data showed similar outcomes regarding state anxiety as those investigated at T2. Indeed, when both groups were asked to self-administer the relaxation session, which consisted of recalling the personalized image they had experienced in VR or imagination at T1, those who had been previously exposed to the personalized VR scenario obtained lower state anxiety scores than those in the other group after session 7 at T2. Considering that individuals in the VR group obtained significantly lower scores both before and after the relaxation session in T2, we confirm the hypothesis that being exposed to the self-managed session at T2 further contributed to lowering the anxiety level in the VR group.

Moreover, the VR group participants perceived the recalled scenario at T2 as more realistic than individuals in the GI group did. In addition, participants in the VR group obtained additional benefits in terms of relaxation and state anxiety reduction related to a more realistic sensorial experience that played a substantial role in facilitating the visualization of the scenario and enabled users to focus their attention on the relaxation activities. Consistent with other studies [55-57], this core outcome confirms the role of immersive VR in promoting relaxation through visualization, engagement, and immersion processes. The prominent impact of being exposed to realistic scenarios in VR on the enhanced visualization at T2 is a key contribution of our study, shedding light on the impact that exposure to VR may also have in more ecological everyday settings, such as when people are not wearing the HMD but have the chance to transfer the relaxation skills learned in VR to real-world situations. Our data are consistent with those of studies that show that a graphical representation of a scenario is more effective in the retention and recall processes than an imaginative representation [58,59].

Even if the aim was to compare VR scenarios with a scene on a PC, our outcome is in line with that of the study by Krokos et al [60], which highlighted the prominent impact of VR scenarios on memory recall ability. The hypotheses of this study and that by Krokos et al [60] are anchored on classic studies in cognitive psychology based on the method of loci [61] and the context-dependent memory theory [62]. These theories imply the essential role of learning and mnemonic processes in creating an association between the mnemonic content and a mental frame of scenarios and then recalling contents by mentally visualizing the scenarios in which the learning and memorization processes took place [60]. As that presence, immersion, and engagement in the VR scenarios imply sensorimotor contingencies similar to those in the real world [63] and the way we create and recall mental constructs is influenced by perception and action in the environment [64,65], our data coherently confirm the potential of immersive virtual environments in enhancing learning and recall for the intervention of vestibular and sensorimotor inputs [66].

Regarding our collected data on heart rate activity, our findings showed a more significant decrease in heart rate frequency in the VR group than in the GI group but only in the session in which participants were directly exposed to 1 of the 2 experimental conditions (at T1) and not when individuals had to self-administer the relaxation session (at T2). We derive from the differences found at T1 that were absent in T2 that the experience in VR was stronger and more engaging than in the condition in which individuals had to recall the immersive image without HMD support. Our data supporting previous studies' outcomes highlighted the impact of VR relaxing scenarios in maintaining lower levels of heart rate frequency than normal [67], but additional research is needed to deeply investigate whether and how naturalistic and relaxing VR scenarios induce relaxation and stress reduction by providing feedback on changes, for example, in heart rate frequency and variability, respiration rate, or skin conductance.

An interesting result is also related to differences over time and between groups in trait anxiety scores. Indeed, our data showed

that, in the VR group, the decrease in trait anxiety scores found at T1 was maintained over time (at T2). Nevertheless, the same was not found for the GI group, in which a decrease in anxiety scores was observed at T1, but it significantly increased again at T2, returning to the baseline values (at T0). The 2 groups did not differ at T1, and both showed positive effects of the relaxation sessions. However, the most interesting fact is that, when anxiety was reevaluated after a week and we asked participants to respond considering how they had generally felt during the previous days, people who had used VR claimed to have a lower level of anxiety than that of participants in the other group. These data also need to be further investigated with more comprehensive samples of participants but support the claim that VR plays a crucial role in amplifying the effectiveness of already validated interventions, maintaining their effect over time.

No differences over time were highlighted in coping strategies and psychological well-being, and this could be because our sample was composed of individuals without a clinical diagnosis and high levels of distress at baseline, or it could even be traced back to the fact that these types of psychological constructs require more sessions and time to highlight an effective change.

Strengths and Limitations

This contribution adds new knowledge on the importance of customizing and personalizing digital interventions according to the users' perspectives, needs, and preferences [22]. Another point of strength of this experimental design is the assessment of the impact that the ability to control and vividly picture mental images may have. The outcomes were gathered from a well-designed pilot randomized controlled trial involving 2 selected groups of 72 university students whose sociodemographic and psychological characteristics were controlled for to balance their effect on the variables investigated. The experimental procedure adopted supports the reliability and validity of the results and conclusions presented in this paper. However, this study has some limitations that affect the generalizability of the findings. One limitation is that the results cannot be generalized to the entire nonclinical population as our sample consisted of students from a single university. Moreover, the fact that our sample comprised mainly young female participants may be considered as selection bias as the recruited sample may well be more receptive and motivated to participate in the intervention compared with people with other sociodemographic features [68]. In general, to further generalize and validate our results' effectiveness, the involvement of participants belonging to clinical and nonclinical populations, stratified according to different sociodemographic characteristics, should be considered. The use of VR can be helpful in overcoming several barriers that standard relaxation procedures present as it is less costly; promotes the availability of relaxing content that could be difficult to generate in the imagination; and is able to promote the sense of presence,

immersion, and engagement closer to what can be obtained in a real-world situation but in a safer context. This is also a reason for considering its further investigation based on clinical and nonclinical samples in future studies. The preliminary results of our study highlight the potential of VR in reducing the number of psychotherapy sessions and their cost as it allows for partial self-management of the treatment.

Furthermore, in the case of patients with medical problems, the integration of VR could facilitate the administration of the relaxation intervention during specific invasive treatments (such as chemotherapy). If the merged administration of a customized VR relaxation scenario and PMRT is effective in obtaining a better subjective perception of relaxation than the standard procedure, it could allow the users to relax with greater autonomy. For this reason, assessing the efficacy of the PMRT and GI in alternative ways could extend treatment administration, especially in situations in which the standard procedure is more challenging. Future studies should consider structuring the relaxation protocol with more VR sessions to better understand the impact of a virtual scenario on relaxation. Another aspect to be considered in further experimental designs is the introduction of a control group that receives the training session with the physical presence of a therapist. Considering the impact of customization on anxiety and on engaging users in the virtual scenarios, another important aspect that needs to be considered is the opportunity to introduce customized stimuli based on the personal life experience of each participant in the virtual environment. As an example, introducing olfactory stimuli could be another essential aspect to enhance the sense of realism, immersion, and presence in the virtual scenarios [69,70]. A further limitation of this study is the possible exclusion of people who are not familiar with social media. Another limitation regards the limited use of objective data (eg, psychophysiological outcomes) for measuring anxiety and relaxation and the limited range of customization settings offered to users to adapt the VR environment to their preferences. The limitations of this study can be overcome through further investigation.

Conclusions

The main objective of psychological interventions is to offer people the opportunity to learn strategies to manage their daily lives independently and effectively. The opportunity to deploy VR for promoting self-management of state anxiety also in real-world situations constitutes an interesting line of investigation to be further explored in future studies involving larger nonclinical and clinical populations (eg, patients with chronic pain) to validate and standardize relaxation protocols integrated with new VR tools. This study has shown that personalized VR scenarios can be effective in improving relaxation and decreasing anxiety when integrated with the PMRT as a complementary relaxation method, thereby highlighting the need for further investigation.

Acknowledgments

This research project was funded by the Fondazione Valorizzazione Ricerca Trentina with a grant for the project "ViRLab_Salute," second call of the Next Generation 2021 grant. The authors wish to thank the students from the University of Padova for participating

in the study and Dr Lucia Ronconi (“Statistical Consulting Service,” University of Padova) for her contribution in revising the analysis.

Data Availability

The data set generated and analyzed during this study is available from the corresponding author upon reasonable request.

Authors' Contributions

SP wrote the manuscript, designed the study protocol, ran the intervention trial, conducted data analyses, and contributed to manuscript editing and revision. SG contributed to the design of the study protocol, revised the analysis and the original manuscript, and contributed to manuscript editing and revision. SO contributed to the curation and formal analysis, wrote the manuscript, and contributed to manuscript editing and revision. FF contributed to the curation and formal analysis and to manuscript editing and revision. MD worked on the hardware and software components. SF contributed to the design of the study protocol. CL contributed to manuscript editing and revision. CN contributed to the design of the study protocol, revised the analysis and the original manuscript, and contributed to manuscript editing and revision. All the authors have read and agreed to the published version of the manuscript.

Abstract

Background: Social anxiety disorder (SAD) is a debilitating psychiatric disorder that affects occupational and social functioning. Virtual reality (VR) therapies can provide effective treatment for people with SAD. However, with rapid innovations in immersive VR technology, more contemporary research is required to examine the effectiveness and concomitant user experience outcomes (ie, safety, usability, acceptability, and attrition) of emerging VR interventions for SAD.

Objective: The aim of this systematic review was to examine the effectiveness and user experience of contemporary VR interventions among people with SAD.

Methods: The Cochrane Library, Emcare, PsycINFO, PubMed, ScienceDirect, Scopus, and Web of Science databases were searched between January 1, 2012, and April 26, 2022. Deduplicated search results were screened based on title and abstract information. Full-text examination was conducted on 71 articles. Studies of all designs and comparator groups were included if they appraised the effectiveness and user experience outcomes of any immersive VR intervention among people with SAD. A standardized coding sheet was used to extract data on key participant, intervention, comparator, outcome, and study design items.

Results: The findings were tabulated and discussed using a narrative synthesis. A total of 18 studies met the inclusion criteria.

Conclusions: The findings showed that VR exposure therapy-based interventions can generally provide effective, safe, usable, and acceptable treatments for adults with SAD. The average attrition rate from VR treatment was low (11.36%) despite some reported user experience difficulties, including potential simulator sickness, exposure-based emotional distress, and problems with managing treatment delivered in a synchronous group setting. This review also revealed several research gaps, including a lack of VR treatment studies on children and adolescents with SAD as well as a paucity of standardized assessments of VR user experience interactions. More studies are required to address these issues.

Introduction

Background

Social anxiety disorder (SAD; also known as social phobia) is a psychiatric disorder that is distinguished by a fear of humiliation or negative evaluation by others [1]. Current

guidelines highlight the use of cognitive behavioral therapy to treat SAD [2]. This can involve activities such as psychoeducation, relaxation, distraction, cognitive restructuring, exposure therapy, and relapse prevention [2]. Despite the efficacy of cognitive behavioral therapy for SAD treatment [3,4], many who are diagnosed do not go on to seek help [5]. This is partly due to the in vivo (real-life) nature of the exposure

therapy used to desensitize and habituate patients to feared situations. It takes significant time, effort, and resources to accurately recreate scenarios that will incite an appropriate level of fear response in social settings [6]. For example, to conduct in vivo exposure therapy with an individual with a fear of public speaking, a therapist would need to gather an audience in an appropriate context (ie, ensuring confidentiality and nonjudgment). Furthermore, social anxiety-provoking environments can be unpredictable, providing therapists with little control and a higher chance that a patient is embarrassed, leading to higher attrition rates [7]. To potentially overcome these issues with delivering in vivo exposure therapy, some researchers have examined the use of virtual reality (VR) technology [7].

VR Technology

VR technology provides a digital modality to deliver psychological interventions [7,8]. It involves the use of computer hardware and software technology (eg, stereoscopic displays of digital environments) to simulate real-world experiences [7]. For instance, one may enter a virtual environment that mimics a physical environment and could adopt a virtual avatar to interact with this virtual environment [9]. VR was first formulated in the 1960s, with the first commercial device developed in the 1980s [10]. As technology has developed, the quality of images has improved, and costs have been reduced.

VR systems can be divided into 2 categories: immersive and nonimmersive systems [11]. Immersive systems, such as head-mounted displays (HMDs) or cave automatic virtual environments (CAVEs), provide users with a realistic experience of VR environments, whereas nonimmersive systems, such as computer monitors, result in users not feeling as present [12]. Presence in VR refers to the extent of an individual's perception of being in a particular environment [13]. For VR therapy to be effective, an individual must feel present and immersed in the digital environment [14]. A CAVE system consists of an empty room with multiple screens arranged in a cubelike formation with users wearing stereoscopic glasses and interacting with virtual objects projected onto the screens [15]. Although CAVE systems have the potential to be more immersive than nonimmersive systems, they are expensive and complex to set up, require frequent physical and digital adjustments, and require dedicated personnel [16]. Conversely, a recent systematic review found that current HMDs offer a more immersive experience than CAVEs and are significantly more user-friendly in cost and setup, with a "plug-n-play" setup solution [15].

When integrated with therapy, VR technology can help address factors that influence the success of exposure-based treatments. For instance, VR allows for the creation of controlled digital environments, which enables therapists to predictably customize exposure scenarios to the specific needs and fears of individual clients [7]. VR can also improve accessibility to exposure therapy for individuals who find it logistically challenging or emotionally overwhelming to engage in real-world scenarios [17]. The immersive nature of VR helps bridge the gap between simulated experiences and real-life situations, fostering a sense of presence and engagement that can potentially enhance treatment adherence and effectiveness [17].

Effectiveness of VR for SAD

Virtual environments and avatars can be used to simulate socially distressing situations for SAD treatment. For example, a study immersed participants with SAD into a computer-generated classroom where they were asked to speak publicly on a topic while a therapist controlled the virtual audience's reactions according to the stage of therapy [18]. VR environments have also been shown to provide acceptable levels of presence and immersion that are necessary for exposure therapy in youth with social anxiety [19]. Several systematic reviews and meta-analyses have demonstrated the effectiveness of VR exposure therapy (VRET) in the treatment of SAD [6,20-24]. Indeed, researchers have established a large effect size for VRET versus waitlist ($g=0.90$), a medium to large effect size for VRET versus psychological placebo conditions ($g=0.78$) [21], a large overall effect size for VRET ($g=0.82$) [22], and a medium to large effect size for VRET at the 12-month follow-up ($g=-0.74$) [6]. This consistent pattern of symptom reduction can be observed across various contexts, such as participant countries (eg, the United States, France, Israel, and South Korea) and treatment settings (eg, universities, hospitals, and clinics) [6,20-24]. However, although existing reviews have explored VR-based therapy from an effectiveness standpoint (eg, reduction in anxiety symptoms), there are gaps in the literature on evaluating the VR user experience for people with SAD on key concomitant outcomes of safety, usability, acceptability, and attrition in different contexts.

User Experience of VR for SAD

Safety

Studies using VR for workplace training, physical rehabilitation, psychological therapy, and other settings highlight a significant safety issue: simulator sickness [25]. Simulator sickness (otherwise known as VR sickness or cybersickness) [26-28] is characterized by general discomfort, headache, eyestrain, nausea, difficulty concentrating, fatigue, blurred vision, dizziness, and vertigo. On the basis of postural instability theory, simulator sickness is arguably due to VR technology inducing sensory differences in the visual and vestibular systems, which coordinate balance and movement [28-30]. The human body may interpret these disparities as possibly deadly causes (ie, consuming poison) and seek to purge as a result [25]. Consequently, simulator sickness can have a negative impact on participants during VR use and for hours following use [31]. Other aspects of safety include physical injuries from repetitive strain, users colliding with objects in the real world, poor posture, headset discomfort, risk of inducing epileptic seizures, negative mood changes, and infection control [32]. Overall, these issues might put participants at risk of harm or cause them to discontinue using VR. Thus, a comprehensive examination of VR safety for SAD is necessary.

Usability

There does not yet appear to be a framework for the evaluation of VR usability in therapy-based applications. Nielsen [33] defines usability as a "quality attribute" that assesses how easy it is to interact with an interface. He highlighted 5 components: learnability (how easy it is for a beginner to use the interface),

efficiency (once the user has learned to use the interface, how quickly they can perform tasks), memorability (re-establishing proficiency after a period of absence), errors (frequency, severity, and recoverability of errors), and satisfaction (level of pleasure from using the interface) [33]. Although this framework is applied to website design, it can also be applied to participants' perceptions of the usability of VR. Furthermore, the application of VR in real-world settings (eg, in a therapy room) would likely be performed by a clinician rather than a specialized technician. It is important to note that usability issues may arise among clinicians. For example, they may give up on the technology if components fail to load or connect to each other. For this reason, this review included both clinician experiences in administering VR-based therapy and client experiences.

Acceptability

Acceptability is a crucial consideration when evaluating VR interventions [34]. It involves assessing the degree to which the new intervention and its components are received and aligned with the needs of the target population [34]. For example, a study examining VR use in adults with SAD defined acceptability as a participant's willingness to use a VR program [35]. They measured acceptability by observing rates of attrition and responses to the following question—"Would you recommend this program to others who might have problems similar to yours?"—and inviting further feedback. Participants' additional feedback was coded into 2 themes: satisfaction (sense of realism, insight, and utility) and perceived effects of the treatment (impact on anxiety). The findings indicated that VR was considered acceptable by participants on all measures [35]. Nevertheless, although there are recent systematic reviews that have addressed the acceptability of VR use for the general population [36], psychosis [37], panic disorder [38], and posttraumatic stress disorder [39,40], a review of the literature on the acceptability of VR in individuals with SAD does not yet exist based on our current knowledge.

Attrition

Attrition, the discontinuation of therapy before treatment completion and resolution of symptoms, can have profound negative effects [41]. These can include the client not fully benefiting from therapy and being discouraged from seeking treatment in the future [41] as well as the effect that this may have on the therapist (eg, loss of revenue, demoralization, and feelings of failure) [42]. A recent meta-analysis of VRET showed significant heterogeneity in attrition rates in the treatment of anxiety disorders, highlighting reasons such as failure to immerse in the virtual environments, simulator sickness, vision complications, and difficulty communicating with a therapist that the participant could not see [43]. A systematic review examining the available literature on rates of attrition of VR-based interventions (both VRET and non-VRET) with participants with SAD does not yet appear to exist based on our current knowledge.

This Study

This study aimed to systematically identify and review available evidence regarding the effectiveness and user experience (ie,

safety, usability, acceptability, and rates of attrition) of VR interventions in the treatment of SAD. The following objectives aided in the provision of a comprehensive and up-to-date account of the empirical status of VR therapy for SAD: (1) provide an overview of the existing literature and identify areas in which further research is needed on the treatment of SAD; (2) assess the potential of using VR as a treatment option for SAD, specifically in terms of effectiveness and user experience; and (3) provide guidance and recommendations for future research regarding the use of VR as a treatment option for SAD.

Methods

This systematic review was conducted using the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) checklist ([Multimedia Appendix 1](#)) [44]. The protocol of this systematic review was prospectively registered in the PROSPERO international database (CRD42022353891).

Eligibility Criteria

For articles to be included in this systematic review, the study participants needed to be people diagnosed with SAD regardless of age. If a study had a mix of people with and without SAD, that study would be included if subgroup analyses were available on the participants with SAD or if they made up the vast majority (ie, $\geq 80\%$). All studies needed to examine direct participant use of a VR intervention, which includes any system that incorporates immersive VR hardware (ie, HMD or CAVE systems). Only studies that were published after 2012 were included as this marked the introduction of widely available commercial HMD hardware such as the Oculus Rift [9]. Such hardware allowed for the delivery of VR experiences comparable with previously expensive commercial setups at a cheaper cost as well as easier accessibility to researchers [45]. Studies with research design comparators of any kind (eg, comparing VR with other non-VR interventions) were eligible for inclusion. All studies were required to report on VR intervention effectiveness and participant user engagement outcomes. This broadly included any standardized or unstandardized measure indicative of usability or acceptability (including attrition rates). Studies of all designs (ie, quantitative, qualitative, and mixed methods) were eligible for inclusion. No studies were excluded based on methodological quality. All the articles needed to be written in English and published in peer-reviewed journals.

Search Strategy

Prominent scientific research databases were searched between January 1, 2012, and April 26, 2022: Cochrane Library, Emcare, PsycINFO, PubMed, ScienceDirect, Scopus, and Web of Science. The following keywords were used to search the databases: ("virtual reality" or "VR") and ("social anxiety" or "social phobia"). The reference lists of eligible articles were also searched.

Article Selection

The search results for all databases were deduplicated, and the remaining article titles and abstracts were scanned. Full-text appraisal was performed on promising articles, and the final study inclusion was agreed upon by the researchers using the

eligibility criteria. Divergent views on inclusion were resolved through discussion and mutual agreement.

Data Extraction

Data from the included studies were extracted by one reviewer (SS) into a standardized coding sheet and then checked by a second reviewer (JK). The data types extracted from eligible papers included the following:

1. Reference source: author surnames, year of publication, and paper title.
2. Sample: country; sample size; and nonidentifiable participant characteristics such as age, sex, and diagnosis.
3. Study design: methodology, comparator trial arms, and measurement points (pretest, midtest, and posttest measurement and follow-up).
4. VR intervention details: intervention program name, purpose of intervention (eg, exposure therapy, cognitive distraction, or relaxation), virtual environment type, hardware (eg, HMD or CAVE system), and treatment length.
5. Effectiveness: standardized measure names, outcomes, and effect sizes.
6. User experience: reported outcomes of intervention safety, usability, acceptability, attrition, and intention-to-treat analyses.

Attrition in this review was defined and measured as the relative number of participants who began using the VR intervention but did not complete measurements during or after the intervention.

Quality Assessment

This systematic review included randomized controlled trial (RCT) and nonrandomized studies. Therefore, the Mixed Methods Appraisal Tool (MMAT) was used to assess the quality of all the included studies [46]. The MMAT was used as it assesses methodological quality across 5 study categories: RCTs, nonrandomized quantitative studies, quantitative descriptive studies, qualitative studies, and mixed methods studies.

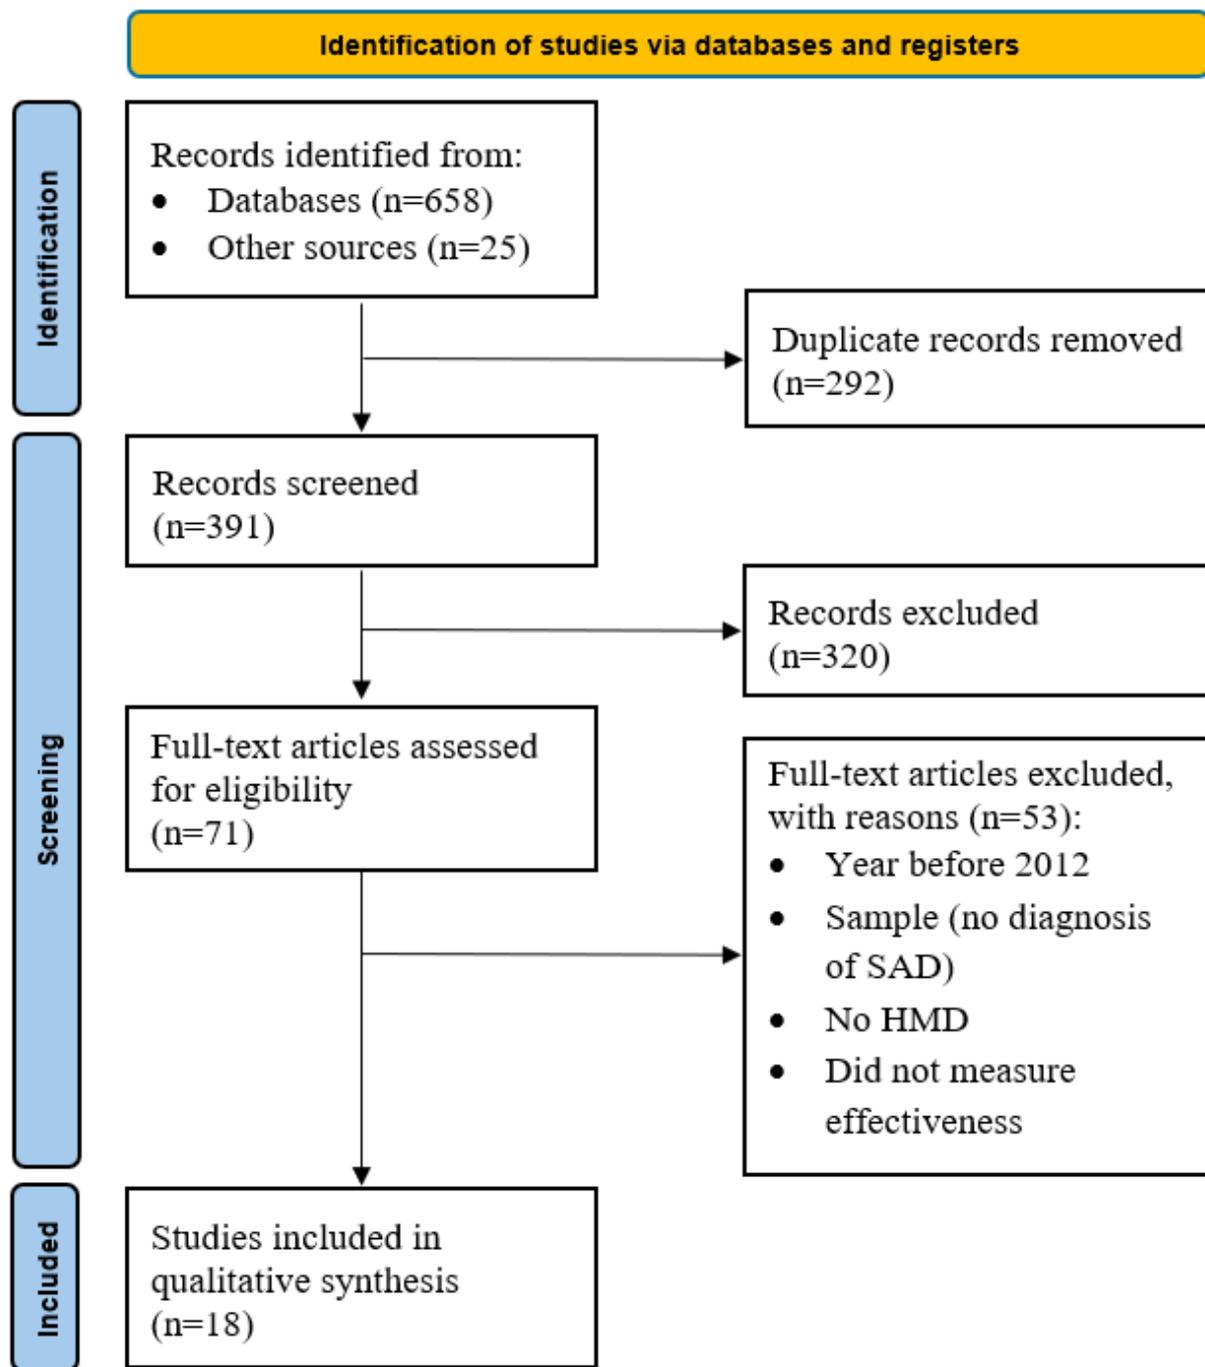

Data Analysis

A narrative synthesis approach was used in this systematic review. This involved summarizing and explaining the findings using text as a statistical meta-analysis was not possible because of data heterogeneity across the included studies.

Results

Study Selection

Figure 1 shows that the literature search yielded 683 articles, of which 391 (57.2%) remained after deduplicating citations. Of these 391 records, 18 (4.6%) met the eligibility criteria.

Figure 1. Flowchart of the systematic review search results. HMD: head-mounted display; SAD: social anxiety disorder.

Participant Characteristics

A total of 808 participants were recruited for the VR studies (Table 1). They were largely from South Korea (n=368), followed by the United States (n=163), the Netherlands (n=60), Canada (n=59), Sweden (n=23), Czech Republic (n=10), Denmark (n=9), and Brazil (n=2). The country of origin was missing for some participants (n=114). It is unclear whether participants were unique in 11% (2/18) of studies conducted by research teams with some of the same researchers [47,48]. The sample sizes ranged from 1 to 115 participants, with a median

of 48 participants. Participants' ages ranged from 18 to 65 years. Participants were mainly female, with an average sample proportion of 51.31% (SD 5.36%; range 0%-77.3%). Most participants were diagnosed with SAD. There were 9 participants with a diagnosis of flight phobia and 8 participants with a diagnosis of acrophobia; however, subgroup analyses were available for the participants with SAD in this study [49]. All participant diagnoses were obtained through clinical interviews delivered in person, by phone, or via videoconferencing. In total, 3 therapists were interviewed in addition to the sample of participants in one study [50].

Table 1. Description of participants and research designs in the reviewed studies.

Study	Country	Sample size ^a	Total sample mean age (years; SD)	Total sample age range (years)	Total sample percentage of female participants	Study design	Treatment conditions ^b	Measurements

ⁿVRS: virtual reality self-training.

^oVRCBT: virtual reality cognitive behavioral therapy.

^pAGT: attention guidance training.

Details of the VR Interventions

All the studies included VR-based exposure therapy. Nearly all the studies (15/18, 83%) tested a unique VR intervention except for the studies by Jeong et al [55] and Kim et al [47,48] (Table 2). VR hardware included standard computers, smartphones, and HMDs. In total, 17% (3/18) of the studies [49,51,61] did not identify the headset brands. The studies used custom-built software that immersed participants in VR environments that simulated social situations increasing in difficulty with audio,

video, text, and interactivity. The treatment lengths ranged from 1 to 14 sessions of exposure therapy, with a mode of 8. A total of 17% (3/18) of the studies [53,55,64] terminated the sessions early if habituation occurred before the completion of the sessions. Participant VR use time ranged from 5 minutes to 3 hours per session, and 17% (3/18) of the studies delivered the VR in a single session [49,59,62]. All VR interventions were tested with therapist or facilitator guidance even though 22% (4/18) [47,48,55,64] were designed to be delivered as self-help.

Table 2. Details of the virtual reality (VR) interventions.

Study	Virtual environments	Headset	Treatment length (duration)
Anderson et al [51]	Conference room, classroom, and auditorium	— ^a	4 exposure sessions (30 min each)
Arnfred et al [50]	Supermarket, meeting, cafeteria, party, and auditorium	Oculus Go	8 exposure sessions (45 min each)
Bouchard et al [52]	Meeting room, job interview, apartment, coffee shop, neighbors, store, and neutral	eMagin Z800	8 exposure sessions (20-30 min each)
Geraets et al [53]	Street, bus, café, and supermarket	Sony HMZ-T1	14 exposure sessions (40 min each)
Hur et al [54]	College student group	HTC Vive	6 exposure sessions (5-8 min each)
Jeong et al [55]	School, business, and daily life	Samsung Gear VR powered by Oculus	ET ^b (1-8 exposure sessions); NT ^c (9-10 exposure sessions); SE ^d (11-17 exposure sessions)
Kampmann et al [56]	Audience, stranger, clothes shopping, job interview, journalist interview, restaurant, and blind date	nVisor SX	7 exposure sessions (60 min each)
Kim et al [47]	School, business, and daily life	Samsung Gear VR powered by Oculus	8 exposure sessions
Kim et al [57]	College student group	HTC Vive	6 exposure sessions
Kim et al [48]	School, business, and daily life	Samsung Gear VR powered by Oculus	8 exposure sessions
Kovar [58]	Public speaking, telephone call, receiving criticism, job interview, refusal of job offer or unwanted product, and working lunch	HTC Vive	8 exposure sessions
Lindner et al [59]	Board room, conference room, and classroom	Oculus Go	1 exposure session (180 min)
Moldovan and David [49]	Presentation and interview	—	1 exposure session (90 min)
Perandré and Haydu [60]	Food court in shopping center	Oculus Rift	8 exposure sessions
Price and Anderson [61]	Conference room, classroom, and auditorium	—	8 exposure sessions
Rubin et al [62]	Conference room and auditorium	Oculus Rift DK2	1 exposure session (45 min)
Trahan et al [63]	Grocery store	Plastic HMD ^e bracket for mobile phone	12 exposure sessions (12-15 min each)
Zainal et al [64]	Dinner party and job interview	Pico Goblin VR	8 exposure sessions (25-30 min each)

^aBrand not reported.

^bET: early termination.

^cNT: normal termination.

^dSE: session extension.

^eHMD: head-mounted display.

Research Designs and Comparators

Table 1 summarizes the research designs and comparators. Nearly half (8/18, 44%) of the studies appraised participant VR use through RCT designs. Comparators included exposure group therapy, in vivo exposure, early and extended termination, attention guidance training using VR, psychotherapy, and waitlist control. All studies (18/18, 100%) had pre- and posttest

assessments of user outcomes, although 39% (7/18) also had follow-up assessments, with the longest being 12 months [51].

Effectiveness Measures and Outcomes

The details of the effectiveness measures and outcomes of VR treatment for SAD are summarized in Table 3. VR treatment effect sizes across all studies that reported them ranged from medium to large. Almost all studies (15/18, 83%) demonstrated a decrease in symptoms following VR treatment.

Table 3. Details on social anxiety measures and virtual reality (VR) effectiveness outcomes.

Study and measures	VR effectiveness outcomes
Anderson et al [51]	
PRCS ^a	Significant improvement in confidence as a speaker from before to after treatment ($d^b=1.19$; $P=.01$), with benefits maintained at the 3- and 6-month follow-ups.
FNE-B ^c	Significant decrease in fear of negative evaluation from before to after treatment ($d=0.29$; $P=.01$), with benefits maintained at the 3- and 6-month follow-ups.
BAT ^d	Significant improvement in speech length ($d=0.78$; $P=.01$) and peak anxiety ($d=0.70$; $P=.02$) from before to after treatment.
Arnfred et al [50]	
NSQ ^e	The virtual environments effectively induced immersion and anxiety in some but not all participants with social anxiety disorder.
Bouchard et al [52]	
LSAS-SR ^f	Significant decrease in social anxiety symptoms from before to after treatment compared with waitlist ($P<.001$) that was maintained at the 6-month follow-up.
BAT	Significant decrease in behavioral avoidance from before to after treatment ($P<.001$).
SPS ^g	Significant decrease in social phobia from before to after treatment ($P<.001$) that was maintained at the 6-month follow-up.
SIAS ^h	Significant decrease in social anxiety symptoms from before to after treatment ($P<.001$) that was maintained at the 6-month follow-up.
FNE ⁱ	Significant decrease in fear of negative evaluation from before to after treatment ($P<.001$) that was maintained at the 6-month follow-up.
Geraets et al [53]	
SIAS	Significant decrease in social interaction anxiety from before to after treatment ($d=0.9$; $P=.008$) that was maintained at the 6-month follow-up ($d=1.3$; $P=.003$).
Hur et al [54]	
SPS	Significant decrease in social phobia symptoms from before to after treatment ($P=.005$).
PERS ^j	Significant decrease in negative postevent rumination from before to after treatment ($P<.001$).
Jeong et al [55]	
FNE-B	Significant decrease in fear of negative evaluation from first to last session for the early, normal, and extended termination groups ($P<.001$).
LSAS	Significant decrease in social anxiety symptoms from first to last session for the normal ($P<.001$) and extended termination groups ($P=.002$).
SPS	Significant decrease in social phobia symptoms from first to last session for the normal ($P=.001$) and extended termination groups ($P<.001$).
SIAS	Significant decrease in social interaction anxiety from first to last session for the normal ($P<.001$) and extended termination groups ($P=.006$).
Kampmann et al [56]	
LSAS-SR	Significant decrease in social anxiety symptoms from before to after treatment compared with waitlist ($d=0.55$; $P=.01$) that was maintained at the 3-month follow-up.
FNE-B	No significant change in fear of negative evaluation compared with waitlist group from before to after treatment or the 3-month follow-up.
BAT	Significant increase in speech length from before to after treatment compared with waitlist ($d=0.56$; $P=.02$) that was maintained at the 3-month follow-up; however, there was no significant difference in speech performance.
Kim et al [47]	
HADS ^k	Significant decrease in anxiety symptoms from before to after treatment ($P<.001$).
LSAS-SR	Significant decrease in social anxiety symptoms from before to after treatment ($P<.001$).
SIAS	Significant decrease in social interaction anxiety from before to after treatment ($P<.001$).
Kim et al [57]	
SPS	Significant decrease in social phobia symptoms from before to after treatment ($P<.001$).

Study and measures	VR effectiveness outcomes
SIAS	Significant decrease in social interaction anxiety from before to after treatment ($P<.001$).
FNE-B	Significant decrease in fear of negative evaluation from before to after treatment ($P=.004$).
KSAD ^l	Significant decrease in social avoidance and distress from before to after treatment ($P<.001$).
LSAS ^m	Significant decrease in social anxiety symptoms from before to after treatment ($P=.04$).
Kim et al [48]	
HADS	No significant changes in anxiety symptoms from before to after treatment.
LSAS-SR	Significant decrease in social anxiety symptoms from before to after treatment ($P<.01$).
Kovar [58]	
FNE-B, SPIN ⁿ , SIAS, SADS ^o , and BAI ^p	Higher average decrease in symptoms on all these measures in the VR treatment group compared with the non-VR treatment group.
Lindner et al [59]	
PSAS ^q	Significant decrease in self-rated public speaking anxiety following the first 3-hour session ($d=0.77$; $P=.006$).
LSAS-SR	Significant decrease in social anxiety symptoms from before to after treatment ($P=.001$).
FNE-B	Significant decrease in fear of negative evaluation from before to after treatment ($P=.04$).
Moldovan and Price [49]	
FNE-B	Significant decrease in fear of negative evaluation from before to after treatment ($P<.05$).
SSPS ^f	Significant decrease in negative self-statements from before to after treatment ($P<.05$).
LSAS	Significant decrease in social anxiety symptoms from before to after treatment ($P<.05$).
Perandr� and Haydu [60]	
SPIN and BAI	Decrease in anxiety symptoms reported on both measures from the pretest measurement to the 3-month follow-up from treatment for both participants.
Price and Anderson [61]	
SSPS	Significant improvements on positive and negative self-statements from before to after treatment ($P<.01$).
PRCA-SF ^s	Significant decrease in public speaking anxiety from before to after treatment ($P<.01$).
Rubin et al [62]	
PRPSA ^t	Significant decrease in fear of public speaking from before to after treatment ($d=-1.11$) and at the 1-week follow-up ($d=-1.68$).
LSAS-SR	Significant decrease in general symptoms of social anxiety from before to after treatment ($d=-0.60$) and at the 1-week follow-up ($d=-2.07$).
Trahan et al [63]	
SUDS ^u	No significant change in subjective distress from before to after treatment for the participant ($P=.21$).
SADS	Score decrease of 52.6% in social anxiety from before to after treatment for the participant.
Zainal et al [64]	
SAD composite ^v	Significant decrease in social anxiety symptoms from before to after treatment compared with the waitlist group ($g^w=-4.77$; $P<.001$). No significant within-group change at the 3- ($g=0.12$) and 6-month follow-ups ($g=-0.13$).

Study and measures	VR effectiveness outcomes
MASI ^x	Significant decrease in job interview anxiety from before to after treatment compared with the waitlist group ($g=-4.17$; $P<.001$). No significant within-group change at the 3- ($g=-0.10$) and 6-month follow-ups ($g=-0.53$).

User Experience With the VR Interventions

The average attrition rate was 11.36% across all studies in the active VR treatment phase, with a range of 0% to 45.2% (Table 4). A total of 22% (4/18) of the studies reported the use of an intention-to-treat analysis. To measure VR user experience, 56% (10/18) of the studies used standardized measures, and 11% (2/18) of the studies used nonstandardized questions. A total of 67% (8/12) of these studies reported positive VR user

experience findings in various areas of presence, usability, acceptability, or satisfaction. Low levels of simulator sickness were reported in 75% (3/4) of the studies that used standardized questions; however, 25% (1/4) of these studies reported higher levels of simulator sickness in participants with SAD than in controls without SAD [47]. No other safety issues, such as physical injury, user collision, postural complaints, headset discomfort, seizures, or infection, were reported.

Table 4. Virtual reality (VR) interventions and user experience outcomes.

Study	Measures	VR user experience findings	Attrition (%)	ITT ^a
Anderson et al [51]	CSQ ^b	High satisfaction with VR was reported after treatment and maintained at the 12-month follow-up.	5/30 (17)	Yes
Arnfred et al [50]	NSQ ^c	A high level of presence in virtual environments for some participants but not all. There were technical issues with setting up and storing away equipment for the group. Wearing the HMD ^d in front of strangers was more anxiety provoking than the virtual environments for some participants. All patients found VR to be a meaningful addition to their therapy sessions, with several wanting more exposure.	0/9 (0)	— ^e
Bouchard et al [52]	SSQ ^f , PQ ^g , and GPQ ^h	No significant increases in simulator sickness after exposure sessions ($P>.20$). Good level of presence that increased with a higher number of exposures.	2/17 (12)	Yes
Geraets et al [53]	—	VR treatment was well tolerated and deemed acceptable for most participants.	2/15 (13)	—
Hur et al [54]	—	—	16/73 (21)	—
Jeong et al [55]	—	—	52/115 (45)	—
Kampmann et al [56]	—	Simulator sickness led one patient to drop out.	5/20 (25)	Yes
Kim et al [47]	SSQ	Participants with SAD ⁱ experienced significantly more simulator sickness than participants without SAD ($P=.003$).	2/54 (4)	—
Kim et al [57]	—	—	9/74 (12)	—
Kim et al [48]	SSQ	Low levels of simulator sickness.	3/24 (13)	—
Kovar [58]	—	—	0/10 (0)	—
Lindner et al [59]	NEQ ^j	High stress levels and low levels of satisfaction.	3/23 (13)	Yes
Moldovan and David [49]	ITQ ^k and PQ	No moderating effect of immersion and presence on pre- and posttest anxiety.	0/32 (0)	—
Perandré and Haydu [60]	SPI ^l	High sense of presence reported by both participants.	0/2 (0)	—
Price and Anderson [61]	—	From a randomly selected subset of videotaped sessions (14%), high participant compliance was found, with 92% of the VR treatment protocol being completed.	0/33 (0)	—
Rubin et al [62]	—	—	2/21 (10)	—
Trahan et al [63]	SUS ^m	High usability reported by the participant.	0/1 (0)	—
Zainal et al [64]	NSQ, IPQ ⁿ , and SSQ	Acceptable presence and low levels of simulator sickness. High levels of homework compliance. Participants (85%) would recommend it to others with SAD. High levels of acceptability and usability.	9/44 (21)	—

Quality Assessment Results

Multimedia Appendix 2 [47-64] contains a table of quality assessment results for the included studies. In all RCT studies

[48,49,51,52,56,61,62,64], randomization was reported, but schedule details were unclear in 11% (2/18) of the studies [48,61]. All RCT studies reported comparable baseline group

analyses. In total, 38% (3/8) of the RCT studies reported complete outcome data, which is defined as $\geq 80\%$ [49,56,64]. All but the RCT studies by Kim et al [48], Moldovan and David [49], Price and Anderson [61], and Rubin et al [62] reported blinding of outcome assessors, which was applied at the pretest measurements. All RCT studies except those by Bouchard et al [52], Kampmann et al [56], and Rubin et al [62] reported that participants adhered to their assigned VR interventions.

In the quantitative descriptive studies [53,60,63], the sampling strategy was relevant to the research question except in 33% (1/3) of the studies, in which details were unclear [53]. All quantitative descriptive study samples were representative of the target population, and the measures fulfilled the inclusion criteria. Nonresponse bias was low in all studies except one (2/3, 67%) [60]. Statistical analyses were appropriate to answer the research question in 33% (1/3) of the studies [53] but unclear in the other 2 [60,63].

In the quantitative nonrandomized studies [47,54,55,57-59], participants were representative of the target population, measurements were appropriate regarding both the outcome and intervention, and there were complete outcome data (defined as $\geq 80\%$) in all but 2 studies (4/6, 67%) [54,55]. Confounds were accounted for in the design and analysis of 50% (3/6) of the studies [54,55,59]. In total, 67% (2/3) of the quantitative nonrandomized studies reported that the intervention was administered as intended [54,55].

In the single qualitative interview study [50], the qualitative approach was appropriate to answer the research question; the data collection methods were adequate to address the research question; findings were adequately derived from the data; the interpretation of the results was sufficiently substantiated by the data; and there was coherence between qualitative data sources, collection, analysis, and interpretation.

Discussion

Principal Findings

Overview

SAD is a common and debilitating anxiety disorder that affects occupational and social functioning [2]. Current in vivo-based exposure therapies require significant time, resources, and effort, which results in limited treatment dissemination [6]. VR technology provides an alternative modality for treating SAD [19]; however, contemporary evidence on the user experience of VR for SAD is sparse. This systematic review was conducted to provide a comprehensive and up-to-date account of the available evidence regarding the effectiveness and user experience (ie, safety, usability, acceptability, and attrition) of VR interventions for the treatment of SAD.

Effectiveness of VR Interventions for SAD

Our review found that VR interventions can effectively treat SAD in adult populations, which is congruent with the existing literature [6,20-24]. It is interesting to note that, although our search terms and inclusion criteria were open to any VR-based intervention for treating people with SAD (eg, providing relaxation, cognitive distraction, exposure therapy, and

psychoeducation), all the included interventions were intended for exposure therapy. This indicates that VRET dominates the research field of VR-based interventions for SAD.

Studies including follow-up measures highlight the maintenance of SAD symptom improvement from 1 week [62] to 1 year [51], indicating that VRET can provide effective short- and long-term treatment for SAD symptoms. This is impressive given that the study showing maintained benefits for up to 1 year involved only 4 treatment sessions [51]. However, it is important to note that this study only included participants with a fear of public speaking as the primary social fear as opposed to other social situations (eg, going to dinner with friends), limiting the generalizability of the findings [65]. Nevertheless, our findings suggest that VRET can be a rapidly effective treatment for SAD with the potential to provide long-term symptom improvement.

Safety of VR Interventions for SAD

Simulator sickness was a common measure of safety in the reviewed studies. Participant simulator sickness was reportedly low in most studies. However, it was found that participants with an SAD diagnosis were more prone to simulator sickness when compared with participants without SAD in one study [47]. This could be because patients with anxiety tend to experience greater motion discomfort [66,67]. For example, patients with anxiety may be more susceptible to irregular breathing and hyperventilation, leading to dizziness and nausea when exposed to fear-inducing cues. This may exacerbate the body's interpretation of disparities in visual and vestibular systems as possible deadly causes (ie, poison) and potentially lead to nausea and vomiting [25]. Another safety consideration is the absence of other physical injuries (eg, collisions with real-world objects, poor posture, headset discomfort, and seizures) reported in the reviewed studies, which supports VR as a safe SAD treatment.

However, although the research safety findings are encouraging, the limitations of these studies are important to note. For example, most studies screened out participants who were unable to tolerate the VR environment and HMD or those who had a history of seizures. This would result in a sampling bias in favor of VR safety. Furthermore, all studies except for one [63] were conducted in controlled settings (ie, hospitals and clinics) that were supervised by clinicians, further reducing risks that would otherwise be significant when using VR alone. For example, an individual purchasing and using a VR system at home may collide with real-world objects without the intervention of a third party. As such, more research is required to evaluate the safety of VR for SAD in nonclinical, unsupervised settings.

Usability of VR Interventions for SAD

There was large variability in the VR software used for SAD. This is likely due to the infancy of VR for SAD. With such variability, it is inevitable that reports of usability will vary according to the hardware and software used, with some programs being easier to use than others.

A distinct hindrance in evaluating the usability of VR for SAD was the lack of an existing framework. The studies largely used nonstandardized questions and qualitative feedback to determine usability, making it difficult to generalize findings across

multiple studies. Although most studies did not comment on aspects of usability, those that did provided valuable information on the usability of VR for SAD. Studies in which practitioners delivered VR therapy to individual participants reported high levels of usability, such as the ease of setting up and navigating the hardware and software. However, reports of VR use in a group setting described low levels of usability, significant amounts of time spent on setting up and storing the equipment, and loss of focus on the exposure experience when therapists were helping others with their HMDs [50].

The differences in usability between individualized and group settings highlight important requirements for the use of VR interventions for SAD. Primarily, VR technology for SAD needs to be easy to learn by patients, and it is important that errors are limited in frequency and severity and that patients can recover from errors largely autonomously. As such, we propose a “VR usability framework” for the measurement of usability of VR for SAD that borrows elements from the usability heuristics by Nielsen [33]: (1) “learnability,” assessing how easy it is for a patient to set up and learn the VR technology; (2) “errors,” assessing the frequency, severity, and recoverability of errors autonomously by the patient; and (3) “memorability,” how easy it is to re-establish proficiency after a period of absence.

Using the VR usability framework, current trends show variability in the usability of VR for SAD. VR used in group therapy has a steep learning curve and requires substantial input from therapists to work through errors, and it is difficult to re-establish proficiency in it after a period of absence (eg, some participants wished they could take the equipment home) [50]. In contrast, VR used in individualized therapy is easy to learn, patients can autonomously handle errors, and they are familiar with the technology upon return [63,64]. Thus, VR may be more user-friendly in one-on-one therapy as opposed to a group setting, as articulated by the VR usability framework.

Acceptability of VR Interventions for SAD

The results we found regarding high VR acceptability in adult patients with SAD are congruent with earlier research by Saxena [35]. Empirical findings indicate that VR for SAD is generally acceptable to adult patients with SAD, with high scores on standardized measures of satisfaction reported by most patients. Positive qualitative responses suggest that VR allowed patients to gain more insights into their anxiety and a better understanding of the social situations that they would normally avoid or be too emotionally activated to observe [50]. For example, in real life, an individual with social anxiety may avoidantly play with their phone when someone sits next to them in a cafeteria rather than perceive the encounter as a valued learning experience. Therefore, it is likely that many adults with SAD who willingly undergo VR therapy will find the experience acceptable.

Conversely, one study [59] found that some patients reported that their expectations for the treatment were not fulfilled, and some reported feeling more stress during VR. It was also found that positive expectations of VR effectiveness as well as a positive working alliance with the therapist were significantly correlated with positive emotional changes [49]. Therefore, VR treatment may not be acceptable for all adults with SAD based

on individual differences regarding their previous VR experience, their perceptions of VR therapy helpfulness, their level of distress tolerance to exposure to digital stimuli before habituation [68], and the nature of their relationship with the therapist offering VR treatment.

Attrition of VR Interventions for SAD

This review found that the attrition rate across most studies was relatively low and within acceptable levels ($\leq 20\%$) [46]. Indeed, attrition rates for the use of VR interventions for SAD were found to be substantially lower than estimates from VRET in anxiety disorders [43]. Considering this, it appears that patients with SAD continue with treatment more than other patients with anxiety.

There may be several reasons for the low average attrition rate finding. First, patients with SAD may prefer to learn more about social situations in a VR space. An individual with SAD may be curious about learning about social situations but may struggle to overcome the anxiety associated with placing themselves in an environment where negative evaluation is possible. By engaging with VR, patients with SAD have the knowledge that they can exit the simulation at any point, giving them the opportunity to learn about social situations without real-world social consequences. Second, patients with SAD may be more tolerant of the potentially negative effects of VR (eg, simulator sickness) when compared with the general population with anxiety [43]. Third, patients with SAD may be more hesitant to drop out of therapy for fear of negative evaluation by examiners. For instance, patients with SAD may be more likely to remain in a study because of social desirability bias—the tendency to respond in a certain way to avoid criticism [69].

It is important to note that the observed attrition rates are heterogeneous. Some studies reported proportionally higher attrition rates than others [54,55]. This may be due to the differences in the number of sessions involved in different studies. For example, some studies were composed of single sessions [49,59,62], whereas the study with the highest attrition had 9 to 17 sessions [55]. As it takes longer to deliver all sessions, there is more opportunity for participants to drop out. Furthermore, attrition was defined in this review as those who did not complete measurements during or after intervention use, including completion of follow-up measures. Considering that some studies included follow-up measures of 3 months after the intervention or longer, it is plausible that participants may not have re-engaged in these measures for several reasons. These could potentially include both therapy-related factors (eg, intolerance of VR-induced anxiety, simulator sickness, and low satisfaction levels) or factors outside of therapy (eg, moving away, becoming too busy in everyday life, and major life events).

Recommendations

Safety

With regard to safety, the primary issue identified in this review was simulator sickness. Several factors appear to be related to the susceptibility to simulator sickness. If simulator sickness is exacerbated by physiological symptoms of anxiety (eg,

hyperventilation leading to dizziness) [66,67], it may be helpful to target these symptoms with clinical treatment before using VR technology. This is in line with other studies exploring attrition in anxiety disorders [43], which found that VRET attrition occurs early in treatment because of factors such as dizziness. As such, VR protocols for SAD should aim to improve retention at the beginning of treatment using a phase-based approach that includes strategies to tolerate negative emotions before immersion in VR. These may include implementation of relaxation and grounding techniques [70] or the prescription of anti-nausea medications. Changes in VR technology can also be applied to reduce simulator sickness [48]. Blurring or lowering the resolution of a VR image has been shown to reduce simulator sickness and improve the sense of reality [71,72].

Future Research

Presently, there are many research gaps in the literature regarding the user experience of VR for SAD. The development of a standardized measure to assess the usability of VR for SAD has the potential to identify prominent issues with usability and aid in the development of future VR programs. This measure may include elements identified in the VR usability framework discussed previously to assess learnability, error recoverability, and memorability. This may be applied to technical developments in VR that would likely improve VR's "plug-n-play" capability for SAD and other anxiety disorder treatments. Future research should also delve deeper into the study of simulator sickness in patients with SAD when compared with both healthy controls and patients with other anxiety disorders. This may lead to valuable information on reducing simulator sickness, thereby reducing the levels of attrition and improving the user experience of VR for SAD. Finally, there were no studies found that specifically targeted a child or adolescent population. Given that the onset of SAD typically

occurs around adolescence [1], future studies should evaluate the efficacy of early intervention of VR for SAD, particularly given adolescents' success with VR for psychological distress [32].

Limitations

This review has several limitations. First, our review did not perform a cost-benefit analysis of the hardware identified (eg, HMDs). Affordability could have implications for the acceptability of VR among consumers with SAD. Second, we included only English-language studies, and there may have been pertinent articles published in other languages. Third, this study conducted a qualitative review of studies with different designs. Although the MMAT [46] was used to assess the quality of the studies, there is still a risk of subjective reviewer bias in addressing its criteria. Finally, studies may have been missed in our search because of obscure nomenclature (eg, research publications that did not clearly specify the use of a VR intervention for SAD in their title and abstract).

Conclusions

Our review findings showed that VRET interventions can generally provide an effective, safe, usable, acceptable, and low-attrition treatment option for adults with SAD. Nevertheless, there are research gaps evident when appraising user experience outcomes. These include the need to conduct more VR research with children and adolescents with SAD. We also do not yet know the specific causes of elevated simulator sickness in patients with SAD compared with participants without SAD or how effective other VR-based interventions beyond exposure therapy (eg, focused on mindfulness, relaxation, or cognitive distraction) are in the treatment of SAD. Further experimental studies (eg, pilot feasibility studies and RCTs) are required to explore these domains.

Abstract

Background: Depression significantly impacts quality of life, affecting approximately 280 million people worldwide. However, only 16.5% of those affected receive treatment, indicating a substantial treatment gap. Immersive technologies (IMTs) such as virtual reality (VR) and augmented reality offer new avenues for treating depression by creating immersive environments for therapeutic interventions. Despite their potential, significant gaps exist in the current evidence regarding the design, implementation, and use of IMTs for depression care.

Objective: We aim to map the available evidence on IMT interventions targeting depression treatment.

Methods: This scoping review followed a methodological framework, and we systematically searched databases for studies on IMTs and depression. The focus was on randomized clinical trials involving adults and using IMTs. The selection and charting process involved multiple reviewers to minimize bias.

Results: The search identified 16 peer-reviewed articles, predominantly from Europe (n=10, 63%), with a notable emphasis on Poland (n=9, 56%), which contributed to more than half of the articles. Most of the studies (9/16, 56%) were conducted between 2020 and 2021. Regarding participant demographics, of the 16 articles, 5 (31%) exclusively involved female participants, and 7 (44%) featured participants whose mean or median age was >60 years. Regarding technical aspects, all studies focused on VR, with most using stand-alone VR headsets (14/16, 88%), and interventions typically ranging from 2 to 8 weeks, predominantly in hospital settings (11/16, 69%). Only 2 (13%) of the 16 studies mentioned using a specific VR design framework in planning their interventions. The most frequently used therapeutic approach was Ericksonian psychotherapy, used in 56% (9/16) of the studies. Notably, none of the articles reported using an implementation framework or identified barriers and enablers to implementation.

Conclusions: This scoping review highlights the growing interest in using IMTs, particularly VR, for depression treatment but emphasizes the need for more inclusive and comprehensive research. Future studies should explore varied therapeutic approaches and cost-effectiveness as well as the inclusion of augmented reality to fully realize the potential of IMTs in mental health care.

Introduction

Background

Depression is a debilitating disorder characterized by a persistent low mood and a loss of interest in everyday activities, significantly affecting various dimensions of life [1]. Globally, approximately 280 million people are afflicted by this condition [2]. However, only 16.5% of people with depression worldwide receive treatment, indicating a substantial treatment gap [3]. The scarcity of mental health professionals exacerbates this issue, with figures in low- and middle-income countries being particularly low at 1.4 to 3.8 per 100,000 population [4]. This shortage of resources highlights the urgent need for innovative solutions in mental health care [5].

Digital technologies, now more crucial than ever, have emerged as vital tools in bridging health care gaps [6]. Among these, immersive technologies (IMTs) such as virtual reality (VR) and augmented reality (AR) stand out for their potential to revolutionize depression care. These technologies offer computer-generated immersive experiences that blend virtual and real environments, with VR providing entirely virtual experiences and AR overlaying virtual objects onto the real world [7].

The application of IMTs in mental health leverages their ability to create controlled immersive environments, offering a safe space for individuals to explore coping exercises and techniques [8,9]. This digital modality encompasses immersive sensory experiences that allow users to interact with a virtual environment [10,11]. Such interactions have been shown to increase engagement in health care-related tasks [12,13], which is a crucial challenge in the treatment of anxiety and depression [14], providing a novel approach to mental health care. Furthermore, continual improvements in IMT device technology, exemplified by the Meta Quest VR headsets, have further broadened the accessibility of these interventions globally. Moreover, IMTs have proven effective in treating a wide range of mental health conditions, such as anxiety, posttraumatic stress disorder, autism spectrum disorders, and various phobias [15-22].

Objectives

Although some reviews have examined the use of IMTs in treating depression [23-25], they have not focused primarily on depression as the assessment goal; nor have they focused on IMT applications specifically aimed at treating depression or on the psychotherapeutic aspects of these interventions. Moreover, the available literature did not address relevant elements, such as the design or implementation of IMT interventions.

Therefore, we aim to map the most rigorous available evidence on IMT interventions targeting depression treatment and identify the gaps related to the design and implementation of these interventions. Given the emerging nature of IMTs in mental health and our specific research focus, a scoping review was deemed the most appropriate methodology. This approach

allows for a broad overview of the existing literature, identifying key concepts and highlighting gaps in the research. Furthermore, we decided to focus on randomized clinical trials (RCTs) to ensure a robust and reliable evidence base. RCTs are considered the gold standard in clinical research, providing high-quality data to inform clinical practice and guide future research. By concentrating on RCTs, we aim to capture the most rigorous and scientifically valid studies, thereby enhancing the credibility and applicability of our findings in this emerging area of mental health care.

Methods

Overview

This scoping review adheres to the framework formulated by Arksey and O'Malley [26], expanded upon by Levac et al [27] and Daudt et al [28] and summarized by the JBI Manual for Evidence Synthesis [29]. Accordingly, we followed five main steps for conducting the scoping review: (1) identifying the research questions; (2) identifying relevant studies; (3) selecting the studies; (4) charting the data; and (5) collating, summarizing, and reporting the results.

Regarding reporting, our study aligns with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) 2020 guidelines [30] (Multimedia Appendix 1). The protocol was preregistered on Open Science Framework [31].

Step 1: Identifying the Research Questions

The primary research question guiding this study is *What is the available scientific evidence and what are the gaps that exist in this evidence concerning the use of IMTs to address depression among adults?*

The study also seeks to address the following secondary questions:

- From which regions or countries does the evidence come?
- Which technical aspects of IMTs have been reported in the evidence?
- What therapeutic approaches were used?
- What are the barriers and facilitators to implementing IMT interventions for depression treatment?
- What outcomes have been evaluated in studies examining the impact of IMT interventions on addressing depression?

Step 2: Identifying Relevant Studies

We conducted a systematic search of the following electronic databases: MEDLINE (via PubMed), Scopus, Web of Science, Embase, PsycINFO (via EBSCO), IEEE Xplore, and Cochrane Library. The search strategy incorporated the keywords "virtual reality," "augmented reality," "depression," and "randomized clinical trial." An example of the search query performed in PubMed is presented in [Textbox 1](#), and the search queries for each database are detailed in [Multimedia Appendix 2](#). The search was limited to articles published in English and spanned from the inception of each database to October 10, 2023.

Textbox 1. PubMed search query.**Search query**

- (“Depression”[MeSH] OR “Depressive Disorder”[MeSH] OR depressive*[tiab] OR depression[tiab]) AND (“Virtual Reality”[MeSH] OR “virtual reality”[tiab] OR “Augmented Reality”[MeSH] OR “augmented reality”[tiab] OR “VR headset”[tiab] OR “VR glasses”[tiab] OR “virtual environment”[tiab] OR “virtual world”[tiab] OR metaverse[tiab] OR meta-verse[tiab]) AND (“Randomized Controlled Trial”[Publication Type] OR “Randomized Controlled Trials as Topic”[MeSH] OR “randomized clinical trial”[tiab] OR RCT[tiab] OR (randomized[tiab] AND “clinical trial”[tiab]))

Step 3: Study Selection

The inclusion and exclusion criteria are detailed in [Textbox 2](#). Secondary studies were excluded, but their references were

consulted to identify primary research studies that fulfilled our selection criteria. Similarly, protocols were not included, but registration IDs were consulted in the web to find preliminary or primary results published in articles.

Textbox 2. Inclusion and exclusion criteria (we defined immersive technologies as all augmented reality and virtual reality—only applications that belong to the degree of full immersion, according to the definitions provided in the literature [7,10]).

Inclusion criteria

- Articles must include randomized clinical trials and be published in peer-reviewed journals.
- All participants must be aged at least 18 y.
- Depression must be a primary outcome measured either through clinical assessment or validated screening tests.
- At least 1 group of participants should have received, or should have been exposed to, immersive technologies using glasses, headsets, or other head-mounted display devices, with or without using other complementary devices.

Exclusion criteria

- Secondary studies (systematic, umbrella, narrative, and scoping reviews) and protocols were not considered.
- Articles in which the immersive technology interventions only focused on exercise as a treatment were not considered.

We searched the various databases of scientific articles and exported all records as RIS format files. These records were imported into EndNote X9 (Clarivate) for automatic and manual duplicate checking. Subsequently, the selection process was carried out on the Rayyan web platform (Rayyan Systems Inc) in 2 phases. First, the records were screened by title and abstract by independent reviewers using the platform. In the second phase, full-text evaluations were conducted to determine compliance with the inclusion criteria. Each document was assessed independently by a pair of reviewers (CMRR and KDC as well as CMRR and PDS) to ensure that they met the eligibility criteria. Review disagreements were solved through consensus, and a third reviewer (DVZ) made a final decision in case disagreements persisted. The reasons for exclusion were documented ([Multimedia Appendix 3](#)). Before the selection process, reviewers undertook a pilot test with 10 articles to standardize the process and gain expertise in using the Rayyan platform.

Step 4: Charting the Data

Two pairs of reviewers (CMRR and KDC as well as CMRR and PDS) independently collected data using a collection form developed for the study protocol and refined at the data collection stage. The reviewers performed a pilot test with 2 documents to standardize information extraction criteria. The collected data included general and study characteristics (country of study, study design, participants’ characteristics, the type of depression outcome, and intervention and control descriptions), IMT intervention technical aspects (devices, the amount of time used and frequency of use, the setting of use, duration, IMT

design framework consulted, and the degree of guidance), therapeutic approach used, and implementation characteristics (implementation framework used, implementation stage, and barriers and enablers). Study designs were categorized following the clinical trial classification formulated by Hopewell et al [32]. The implementation stages were defined as follows: (1) *preliminary*, if it was a pilot or feasibility study; (2) *implementation*, if it was mentioned that the RCT had been developed after a pilot or feasibility study; and (3) *unclear*, if there was no mention of it being a pilot or feasibility study, and there was no reference either to the results from these studies.

Step 5: Collating, Summarizing, and Reporting the Results

We used a narrative approach to synthesize data [33]. We describe the information in the *Results* section using frequencies and percentages. Detailed information for each included article is presented in cross-tables. In addition, the geographic location of the studies is visualized as a bubble plot, categorized by year.

Results

Overview

Our search strategy identified 1052 records; after removing 477 (45.34%) duplicates, the remaining 575 (54.66%) records were screened by title and abstract. Of these 575 records, 52 (9%) underwent full-text review. Of these 52 records, 36 (69%) were excluded, mainly on account of being the wrong type of publication (n=15, 42%); thus, 16 (31%) reports [34-49] from 15 studies were included in the review ([Figure 1](#)).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 flowchart outlining the search and selection process.

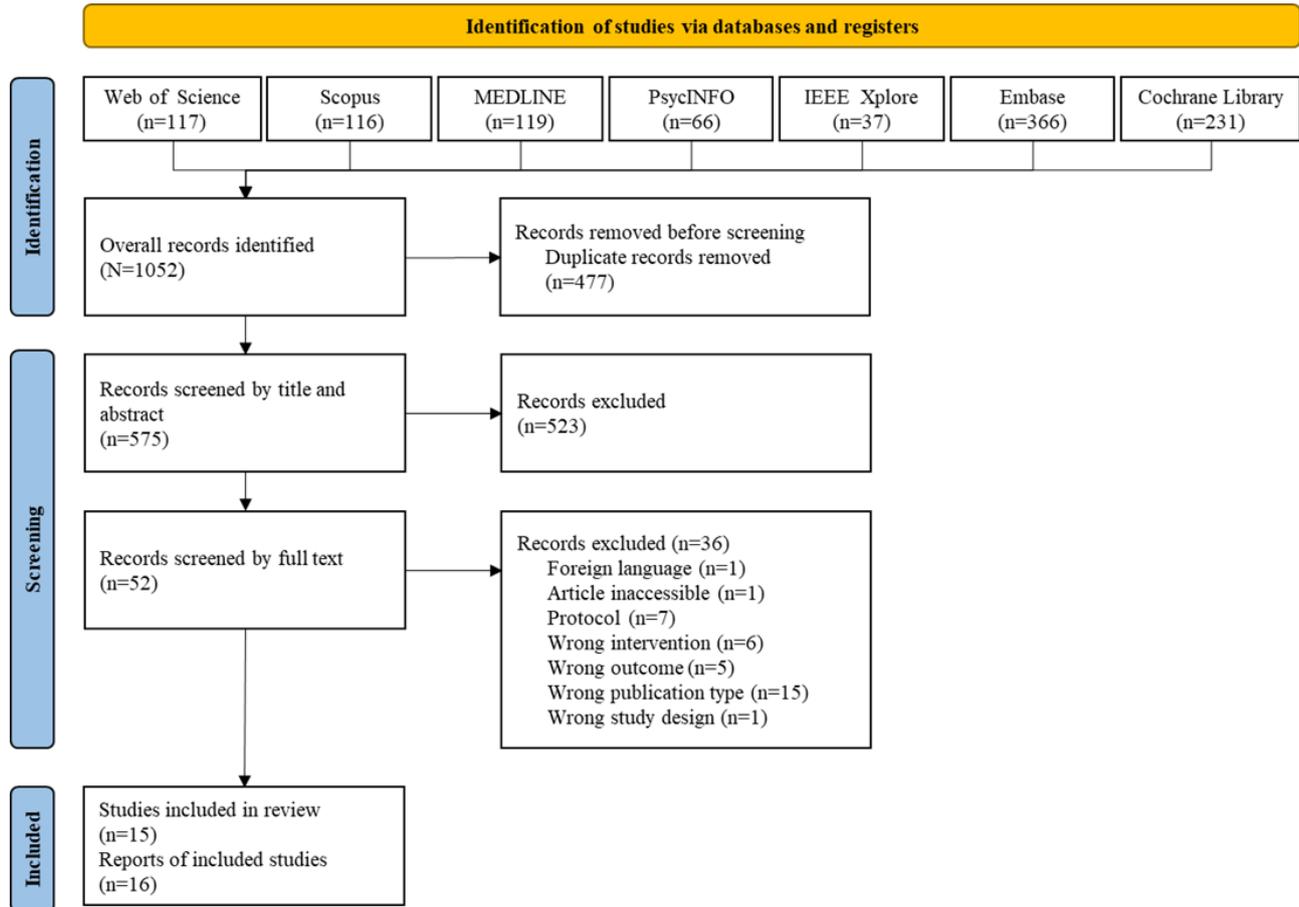

Figure 2 illustrates an uneven distribution of research evidence on IMT interventions for depression management across different regions and income levels. European countries dominate the research landscape (10/16, 63%) [34,35,37-39,43-47], with Poland alone contributing more than half of the reports (9/16, 56%) [34,35,37-39,43-46] between 2021 and 2023. However, Poland showed a decreasing trend; of the 9 reports in this review, 5 (56%) were published in 2021, while only 1 (11%) was published in 2023. China maintains a steady presence in Asia with a study each in 2022 [48] and 2023

[49], amounting to 13% (2/16) of the total. By contrast, the United States [41], Australia [40], Brazil [42], and Iran (the only lower-middle-income country contributing to this research field) [36] contributed only 1 (6%) study each to the total of 16 studies. The trend analysis indicates a fluctuating global interest in the field, with a concentration of research in Europe (10/16, 63%) [34,35,37-39,43-47], intermittent contributions from other regions, and a spike in publications during 2022 (7/16, 44%) [35,39,41,42,44,47,48].

Figure 2. Trends of publication by geographic location of the reports.

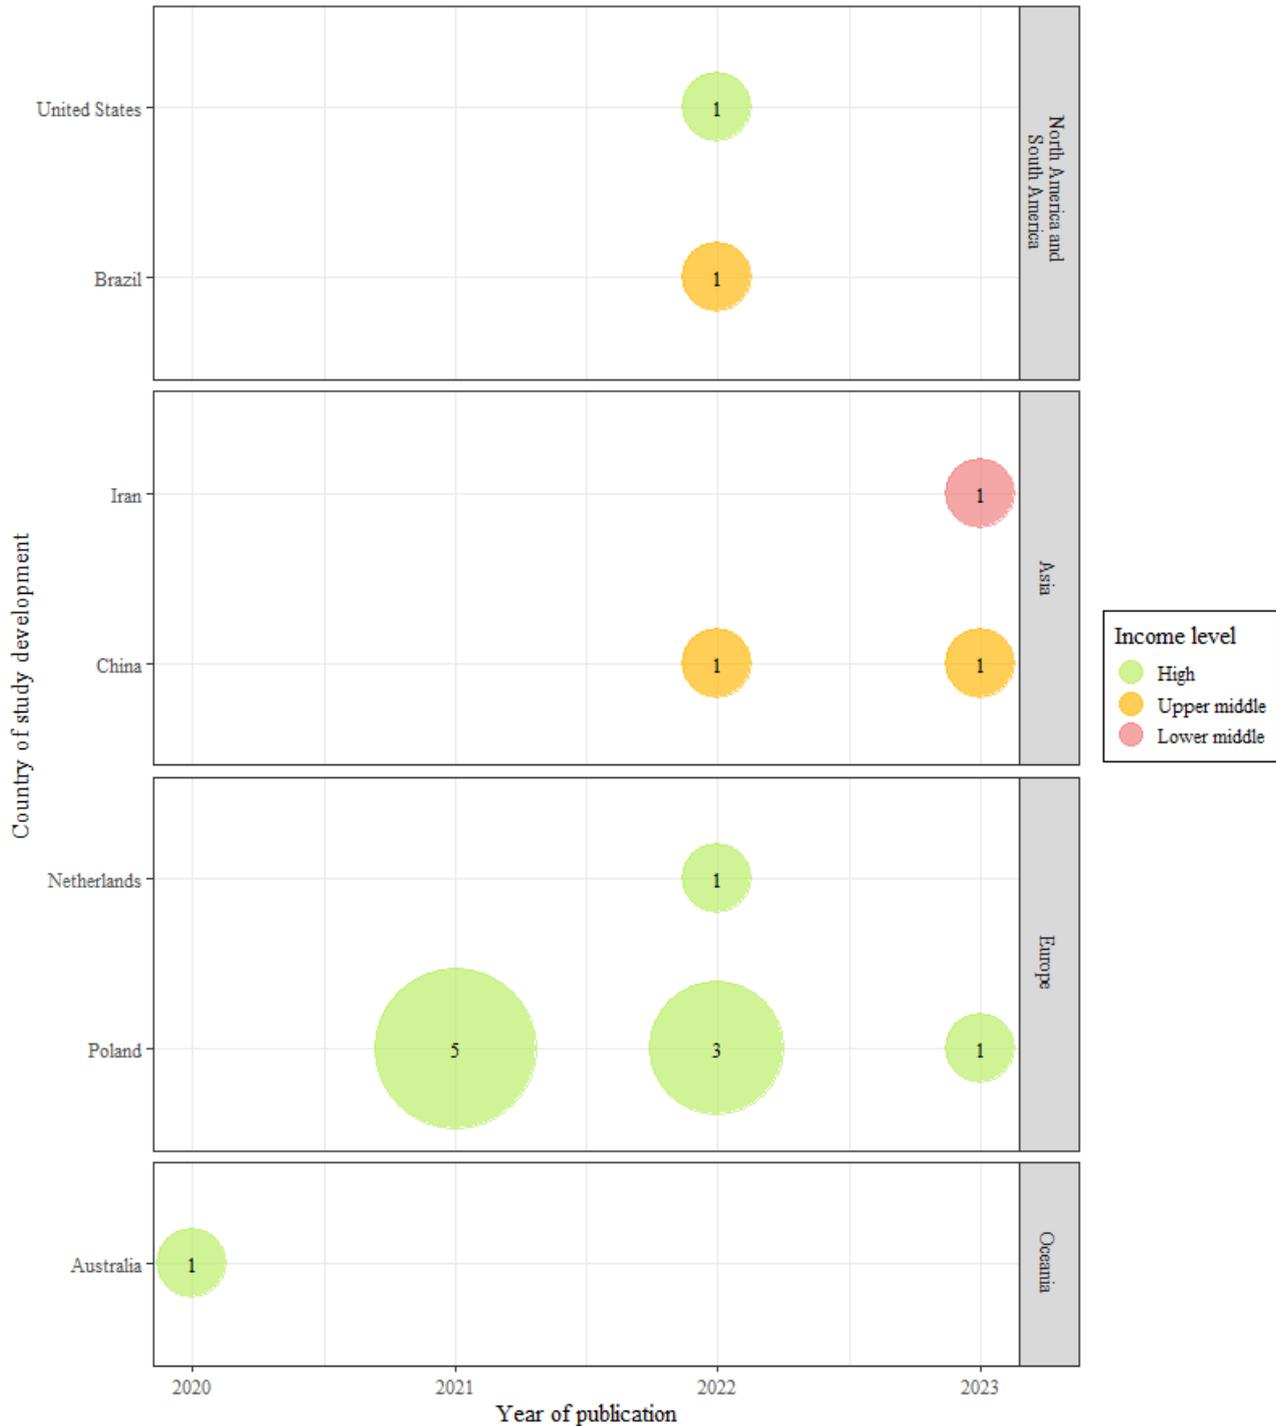

Table 1 illustrates the general characteristics of the selected reports. The majority (15/16, 94%) [34-40,42-49] adopted a parallel group design, while a single study (1/16, 6%) used a crossover trial design [40]. Among the 16 reports, only 1 (6%) featured 3 arms (2 control groups alongside 1 VR intervention

group) [41]. Regarding the research timeline, most of the studies (9/16, 56%) were conducted between 2020 and 2021 [36,38,39,41-44,47,48]. However, for 3 (19%) of the 16 studies, the specific study period was not reported [35,37,45].

Table 1. Characteristics of included studies.

^eICU: intensive care unit.

^fVR-CALM: Managing Cancer and Living Meaningfully based on VR.

Participant demographics showed that, of the 16 reports, 5 (31%) exclusively involved female participants [34,35,37,46,48]; furthermore, 7 (44%) included participants whose mean or median age was >60 years [34,37-39,43,45,46], while only 2 (13%) included participants whose mean age was <45 years [41,49]. Comorbid conditions were noted as inclusion criteria in 15 (94%) of the 16 studies. Among these 15 studies, cancer [35,48,49], heart disease [37,38,45], and COVID-19 infection [42,44,47] were reported in 3 (20%) studies each. Other conditions such as chronic obstructive pulmonary disease [43], social isolation [36], stroke [39], and spinal cord injury [40] were also mentioned.

Of the 16 reviewed reports, 14 (88%) assessed depressive symptoms [34-38,40-45,47-49]. The most widely used instrument was the Hospital Anxiety and Depression Scale (8/16, 50%) [37-39,42-45,47]. Other questionnaires used to measure depressive conditions included the Beck Depression Inventory [35], the Patient Health Questionnaire-8 [40], the Patient Health Questionnaire-9 [41], the Center for Epidemiological Studies Depression Scale [49], the Depression Anxiety Stress Scale-21 [36], and the Self-Rating Depression Scale [48]. In addition to depressive symptoms, older adult

depression was explicitly evaluated in 3 (19%) of the studies [34,39,46], using the Geriatric Depression Scale-30.

Regarding the effects of IMTs on depression, only 1 (6%) of the 16 studies reported no improvement in depression scales [47]. Among the 15 studies that demonstrated a positive effect, 11 (73%) reported statistically significant results [34-37,39,43-46,48,49]; 1 (7%) reported nonsignificant results [38]; 2 (13%) reported mixed results [40,42], indicating variability in statistical significance across different measures or outcomes; and 1 (7%) did not perform any statistical analysis [41].

Technical Aspects of IMT Interventions

The reports included in this review all feature VR interventions, showcasing a broad spectrum of technical characteristics (Table 2). The VR interventions varied, with a majority of the studies (9/16, 56%) implementing the *Virtual Therapeutic Garden* intervention [34,35,37-39,43-46] and 13% (2/16) conducting VR exposure sessions using content from the National Geographic app and the YouTube VR app [40,41]. Unique interventions included *COVID Feel Good* [36], *ICU-VR* [47], *VR-CALM* [48], general VR therapy [42], and individually tailored VR meditation programs.

Table 2. Technical characteristics of the immersive technology interventions.

Reports	VR ^a intervention	Device characteristics	Amount of time used and frequency of use	Intervention duration	Setting of use	Usability assessment	VR design framework used	Degree of guidance
Ciešlik et al [34], 2023	Virtual Therapeutic Garden	Type: headset+controllers; specific type: VR TierOne device (VR HTC Vive goggles+HTC Vive controllers)	20 min/session, twice a wk	4 wk	Unclear	Not mentioned	Not mentioned	Self-administered therapy
Czech et al [35], 2022	Virtual Therapeutic Garden	Type: headset+controllers; specific type: VR TierOne device	15 min/session, daily	2 wk (8 sessions)	Hospital (it is not clear whether participants were ambulatory or inpatients)	Not mentioned	Not mentioned	Unclear
Farahi-manesh et al [36], 2023	COVID Feel Good	Type: unclear; the study mentions that a head-mounted display or cardboard headset could be used, but there is no information about the VR device type used; specific type: unclear	20 min/session, daily	7 days	Unclear	Not mentioned	Not mentioned	Unclear
Jóźwik et al [37], 2021	Virtual Therapeutic Garden	Type: headset+controllers; specific type: VR TierOne device	Unclear time per session and frequency	Unclear	Hospital (it is not clear whether participants were ambulatory or inpatients)	Not mentioned	Not mentioned	Unclear
Jóźwik et al [38], 2021	Virtual Therapeutic Garden	Type: headset+controllers; specific type: VR TierOne device (HTC Vive PRO VR goggles+unspecified controllers)	20 min/session, 3 times a wk	3 wk (8 sessions)	Hospital (ambulatory)	Not mentioned	Not mentioned	Unclear
Kiper et al [39], 2022	Virtual Therapeutic Garden	Type: headset+controllers; specific type: VR TierOne device (HTC Vive PRO VR goggles+unspecified controllers)	20 min/session; frequency unclear	3 wk (10 sessions)	Hospital (inpatient)	Not mentioned	Methodology of VR clinical trials in health care by an international working group	Unclear
Lakhani et al [40], 2020	VR session of environment exposure using the National Geographic App and the YouTube VR app	Type: headset; specific type: Oculus Go	20 min/session, daily	1 wk (3 sessions)	Hospital (ambulatory)	Not mentioned	Not mentioned	Unclear
Paul et al [41], 2022	VR session of environment exposure using YouTube VR videos	Type: headset; specific type: Limbix	Time per session and frequency unclear	3 wk	Home based	Not mentioned	Not mentioned	Self-administered therapy

Reports	VR ^a intervention	Device characteristics	Amount of time used and frequency of use	Intervention duration	Setting of use	Usability assessment	VR design framework used	Degree of guidance
Rodrigues et al [42], 2022	VR therapy (360-degree videos with images of landscapes and mindfulness techniques)	Type: smartphone VR headset; specific type: Oculus Realidade Virtual 3D Gamer Warrior JS080 (adaptable with smartphone)	10 min/session, once	1 session	Hospital (inpatient)	Not mentioned	Not mentioned	Predominantly self-help
Rutkowski et al [43], 2021	Virtual Therapeutic Garden	Type: headset+controllers; specific type: VR TierOne device	20 min/session, 5 times a wk	2 wk	Hospital (it is not clear whether participants were ambulatory or inpatients)	Not mentioned	Not mentioned	Unclear
Rutkowski et al [44], 2022	Virtual Therapeutic Garden	Type: headset; specific type: VR TierOne device (VR goggles+controllers)	Unclear time per session, 5 times a wk	3 wk	Hospital (inpatient)	Not mentioned	Not mentioned	Unclear
Szczepańska-Gieracha et al [45], 2021	Virtual Therapeutic Garden	Type: headset; specific type: VR TierOne device (HTC Vive PRO VR goggles+unspecified controllers)	20 min/session, twice a wk	4 wk (8 sessions)	Hospital (inpatient)	Not mentioned	Methodology of VR clinical trials in health care by an international working group	Predominantly self-help
Szczepańska-Gieracha et al [46], 2021	Virtual Therapeutic Garden	Type: headset+controllers; specific type: VR TierOne device	20 min/session, twice a wk	4 wk	Unclear	Not mentioned	Methodology of VR clinical trials in health care by an international working group	Unclear
Vlake et al [47], 2022	ICU-VR	Type: headset+headphones; specific type: Oculus Go+unspecified headphones	14 min/session, once	1 session	Hospital (ambulatory)	Not mentioned	Not mentioned	Predominantly self-help
Zhang et al [48], 2022	VR-CALM	Type: headset+controllers; specific type: unclear	30 min/session; frequency unclear	3 mo (6 sessions)	Hospital (inpatient)	Not mentioned	Not mentioned	Minimal-contact therapy
Zhang et al [49], 2023	Tailored VR meditation	Type: headset; specific type: PRO 6 DOF (Beijing Iqiyi Intelligent Technology)	20 min/session, daily	14 d	Hospital (inpatient)	Not mentioned	Not mentioned	Predominantly self-help

^aVR: virtual reality.

The immersion devices predominantly used were stand-alone VR headsets (14/16, 88%) [34,35,37-41,43-49]. Of the remaining 2 studies, 1 (50%) used VR headset adapters for smartphones [42], whereas 1 (50%) did not specify the type of device used [36]. The types of specific VR devices varied, with the VR TierOne device (9/16, 56%) [34,35,37-39,43-46] and Oculus Go (2/16, 13%) being the most commonly reported [40,47].

The duration of VR interventions ranged from a single session to daily sessions over up to 8 weeks. However, most of the interventions (10/16, 63%) were administered over a period of 1 day [42,47] to 3 months [48], with 3 weeks (4/16, 25%) being the most common intervention period [38,39,41,44]. The frequency of sessions varied, with daily sessions reported in 4

(25%) of the 16 reports [35,36,40,49] and less frequent sessions noted in the others (12/16, 75%). The majority of the interventions (9/16, 56%) were to be used for 20 minutes per session [34,36,38-40,43,45,46,49]; 3 (19%) of the 16 reports did not specify the session length [37,41,44].

The settings for the interventions were predominantly hospital based (11/16, 69%), with a mix of inpatient, ambulatory, or unclear settings. Only 2 (13%) of the 16 reports specified the intervention as self-administered therapy, with the remaining studies (14/16, 88%) not clearly reporting the degree of guidance provided. None of the reports mentioned usability evaluation as part of their methods or results.

Regarding the VR design framework, only 2 (13%) of the 16 reports mentioned using the *methodology of VR clinical trials in health care by an international working group*. The rest of the reports (14/16, 88%) did not mention any design framework used.

Therapeutic Approaches

The analysis of therapeutic approaches used in the IMT interventions reveals a varied landscape of techniques (Table

3). Ericksonian psychotherapy was used in 9 (56%) of the 16 reports, indicating its recognized role in VR-based interventions. Mindfulness-based cognitive therapy was the second leading therapeutic approach featured, used in 13% (2/16) of the reports, while cognitive behavioral therapy and behavioral activation were mentioned in only 6% (1/16) of the reports each. Other therapeutic methods included personal psychotherapy based on Managing Cancer and Living Meaningfully (1/16, 6%) [48] and the Roy Adaptation Model (1/16, 6%) [49].

Table 3. Therapeutic approaches used in the immersive technology interventions.

Implementation Characteristics

Regarding the stages of implementation, 2 (13%) of the 16 articles were at a *preliminary* stage (pilot or feasibility study). By contrast, 6 (38%) of the 16 studies had progressed to the *implementation* stage (referring to prior feasibility results); the remaining articles (8/16, 50%) did not clearly delineate their implementation phase. No article reported an implementation framework used, nor were barriers or enablers of implementation identified.

Most of the reports (15/16, 94%) declared no conflicts of interest; an exception was found in 1 (6%) of the 16 articles, where a potential conflict was disclosed due to an author's corporate affiliation, emphasizing the importance of transparency in research affiliations and possible biases. Funding sources varied, with half of the studies (8/16, 50%) reporting no external funding, suggesting that a significant portion of research in this area is conducted independently of external financial support. Notably, individual studies were supported by grants from prominent institutions such as the National Science Foundation of China as well as national research grants, demonstrating the global investment in health VR intervention

research. All included reports reported ethical oversight, ranging from institutional review boards to national ethics committees.

Discussion

Principal Findings

Our scoping review, conducted in accordance with the framework formulated by Arksey and O'Malley [26], identified a total of 16 peer-reviewed articles focusing on the use of IMTs in treating depression. In comparison, other reviews using similar methodologies and research questions have reported varying numbers of studies; for instance, Fodor et al [23] found 24 studies examining the effects of VR interventions on depressive outcomes, whereas Zeng et al [24] included only 5 studies in their review. The larger number of studies in the first review can be attributed to the inclusion of several articles that measured depression as a secondary outcome, which is a common approach in the literature on VR interventions. By contrast, our scoping review strictly included reports that explicitly measured depression as a primary outcome. This was done to specifically target papers that focused on designing and developing interventions addressing this mental disorder.

Regarding the second review, the limited number of studies included can be primarily attributed to the authors' focus on exercise interventions using VR. However, this explanation might not be complete. During our full-text review phase, we identified numerous studies assessing VR interventions related to exercise among the excluded studies (36/52, 69%). Another possible explanation for the limited number of studies is the year of the review's development: 2018. Bibliometric studies on VR in health care [50] and specifically in depression [51] have shown a significant upward trend since that year, likely linked to the increased availability of VR technologies [52]. This aligns with our findings, where we observed a clear upward trend over the years.

Secondary Questions

From Which Regions or Countries Does the Evidence Come?

Research on IMT interventions for depression care was predominantly conducted in Europe (10/16, 63%), with Poland contributing the most studies (9/16, 56%), indicating a robust regional focus within the field. Our results align with what has been previously observed in the literature, where it is noted that most articles published on VR in depression originate from Europe [51]. This trend denotes a divergence in the topics related to VR in health because most articles on VR in health, in general, have been published in the United States [50].

These figures suggest that European high-income countries exhibit a more consistent and robust research trajectory related to IMT-based treatments for depression. By contrast, other high-income countries such as the United States and Australia and upper-middle-income countries such as Brazil show sporadic participation. Nevertheless, it is essential to approach these figures cautiously, recognizing that the frequency of publications within specific years might not accurately reflect ongoing research interest or the immediacy of research outputs, given the cyclical nature of research funding, project development, and publication processes.

Which Technical Aspects of IMTs Have Been Reported in the Evidence?

In our review, no study reported using AR; instead, stand-alone VR headsets emerged as the primary technology, underscoring a trend toward self-contained IMT devices in treating depression. This observation aligns with existing evidence; for example, a systematic review concentrating on the mental health applications of AR did not reveal any applications of this particular IMT modality in either the treatment or the assessment of depression [53].

In terms of duration, most of the VR interventions in our review (10/16, 63%) ranged from 2 to 8 weeks, encompassing 1 to 10 sessions. This aligns with the range of 1 to 16 sessions reported in similar VR studies [23]. In addition, we observed that the predominant setting for these interventions was hospital based (11/16, 69%), with only 6% (1/16) being delivered in home settings. This finding aligns with existing evidence in mindfulness VR interventions, where only 1 of 15 studies was home based [54]. Such a trend indicates a current focus on clinical settings for VR intervention delivery, suggesting

potential areas for expansion into more accessible home-based environments.

Only 2 (13%) of the 16 studies reported using a specific IMT design framework, pointing to a potential area for standardization in future research. Conceptual and methodological frameworks are pivotal because they provide a structured approach, align the study's methodology with its objectives, and facilitate the integration of technology to achieve therapeutic goals [55]. Their application in IMT research is essential for producing reliable and applicable results, particularly in the intricate mental health field [56]. This underuse highlights the need for a more structured and theoretically informed approach in future research, which could enhance the quality, applicability, and standardization of IMT interventions for treating depression.

What Therapeutic Approaches Were Used?

Ericksonian psychotherapy was the most common therapeutic approach incorporated into the VR interventions (9/16, 56%). The Ericksonian approach to psychotherapy and hypnosis is based on three key assumptions: (1) the belief in an altered state of consciousness and the existence of specific markers indicating this altered state, (2) the superiority of indirect over direct suggestion in therapy, and (3) the view that a patient's hypnotizability is a function of the hypnotist's skill. However, empirical support for the validity of these critical assumptions is limited [57]. Notably, most studies using this approach originated from Poland (9/16, 56%), indicating a geographic concentration of the evidence. Therefore, there is a need to evaluate this intervention in diverse settings to validate its efficacy more broadly. Despite the geographic concentration of Ericksonian therapy within VR interventions, the use of hypnosis and mindfulness techniques can be advantageous in both face-to-face psychotherapy and virtual contexts. These techniques can alleviate life problems and symptoms associated with mental disorders, including depression [58].

Mindfulness-based cognitive therapy has shown effectiveness in reducing depressive symptoms and elucidating the active mechanisms during mindfulness [59,60]. By contrast, cognitive behavioral therapy and behavioral activation are considered therapies with solid evidence for reducing depression [61]. Thus, behavioral therapies may possess a more robust theoretical basis than other treatment models in IMT interventions for depression care, suggesting a potential direction for future research and application.

What Are the Barriers and Facilitators to Implementing IMT Interventions for Depression Treatment?

The included studies do not provide evidence on barriers and facilitators to implementation. One possible reason is that we did not include qualitative studies in our scoping review (qualitative research focuses on these types of outcomes). However, a framework for implementing digital mental health interventions identified the key elements: access to the intervention, cost-effectiveness, and user satisfaction, in addition to the evaluation of the effectiveness of the intervention [6].

The primary facilitator for the implementation of IMT interventions for depressive symptoms described in the literature

is the availability of evidence supporting the efficacy of the treatment [23,24]. There is also evidence of VR's acceptability, feasibility, and user satisfaction in mental health settings [62]. However, the cost of VR equipment and the cost of training health professionals may be barriers to access in low- and middle-income countries. In addition, we found no evidence of the cost-effectiveness of IMT interventions on mental health outcomes within the health care system. Therefore, cost-effectiveness and cost-utility studies compared with usual care or other psychological interventions must be developed to provide sufficient evidence to evaluate the implementation of IMT interventions within public health systems.

What Outcomes Have Been Evaluated in Studies Examining the Impact of IMT Interventions on Addressing Depression?

In general, all studies used a psychometric scale to assess the impact of the intervention on depressive symptoms, and the instruments used have evidence of reliability and validity; therefore, we considered the results to be adequately assessed. However, there was a high degree of heterogeneity in the instruments used. Some studies used scales focused on hospital settings (eg, the Hospital Anxiety and Depression Scale), others used scales designed for geriatric use (eg, the Geriatric Depression Scale-30), and still others used specialized instruments developed for population use (eg, the Patient Health Questionnaire). Although all instruments assess depressive symptoms, they may assess different forms of the presence of depressive symptoms. Older adults should be considered to have manifestations of depression that are clinically different from those of adults with depression [63]. Therefore, it is essential to consider the setting in which each study was conducted when comparing results.

Strengths and Limitations

To our knowledge, this study is one of the first to comprehensively identify the current state of research regarding the use of IMT interventions specifically focused on depression. Our work fills essential gaps in existing literature by mapping the current evidence and providing insightful recommendations for future research development. Additional strengths of this study include providing valuable insights into the geographic distribution of research efforts and the range of therapeutic approaches used. This contributes significantly to a deeper understanding of the field and highlights areas where further research is needed.

This study has significant limitations that deserve consideration. First, our selection process, involving screening by title and abstract followed by full-text review, may have introduced selection bias if relevant studies were inadvertently excluded due to inadequate information in titles or abstracts. To mitigate this risk, we used a thorough screening process with multiple reviewers for each study, aiming to reduce selection bias.

Second, our search was limited to articles published in English, potentially leading to language bias by excluding relevant studies in other languages. While future reviews could include studies in multiple languages for a broader range of evidence, this limitation did not significantly narrow the scope of our

review because a substantial portion of the evidence in this field is published in English.

Third, the studies included were restricted to RCTs. While RCTs are considered the gold standard in clinical research because they provide high-quality evidence on the efficacy of interventions, this restriction may have limited the comprehensiveness of our review. Specifically, valuable exploratory, observational, and qualitative studies that could provide insights into the implementation, user experience, and broader contextual factors related to IMTs in depression care were excluded. Future reviews could consider including a wider range of study designs to provide a more holistic view of the field, thereby enhancing our understanding of the efficacy of these technologies and their practical application, barriers to implementation, and patient perspectives.

Fourth, we did not consider the high cost of IMT equipment, the training of health professionals, and other economic aspects in the study extraction process, which could be significant barriers, especially in low- and middle-income countries. This oversight underscores the necessity for cost-effectiveness and cost-utility studies to assess the feasibility of IMT interventions in diverse health care settings.

Fifth, the considerable variability in the psychometric scales used across the studies could impact result comparability. We recognize this heterogeneity and recommend that future research consider setting and population-specific scales to improve comparability.

Finally, our scoping review did not include a formal quality appraisal of the included studies. However, it is important to note that our review focused exclusively on RCTs published in peer-reviewed journals. This focus on RCTs, combined with the peer-review process, increased the likelihood that high-quality studies were included. While this approach does not guarantee the quality of each study, it does suggest that the evidence base we have mapped is likely to be more rigorous and high-quality research compared to broader inclusion criteria.

Conclusions

Our scoping review on the use of IMTs for treating depression identified 16 peer-reviewed articles predominantly focused on stand-alone VR headsets. Most of the research was concentrated in Europe (10/16, 63%), specifically Poland (9/16, 56%), suggesting a need for more geographically diverse studies. Furthermore, the therapeutic approaches in these studies largely centered around Ericksonian psychotherapy; however, given the limited empirical support for the fundamental assumptions of Ericksonian psychotherapy and the geographic bias, there is a clear need for exploring a variety of therapeutic approaches in IMT interventions for depression care.

A notable gap in the literature is the absence of AR approaches for depression treatment in the studies reviewed. This points toward an opportunity for future research in this area. In addition, while VR shows promise in mental health settings, concerns about the cost and accessibility, particularly in low- and middle-income countries, highlight the need for more research into the cost-effectiveness of these interventions.

In summary, while the use of IMTs in treating depression shows promise, our review indicates the need for more diverse, inclusive, and comprehensive research. Future studies should address the identified gaps, particularly in AR, cost-effectiveness, and geographic diversity, to fully harness the potential of IMT interventions in depression care.

Abstract

Background: Given that signage, messaging, and advertisements (ads) are the gateway to many interventions in suicide prevention, it is important that we understand what type of messaging works best for whom.

Objective: We investigated whether explicitly mentioning suicide increases engagement using internet ads by investigating engagement with campaigns with different categories of keywords searched, which may reflect different cognitive states.

Methods: We ran a 2-arm study Australia-wide, with or without ads featuring explicit suicide wording. We analyzed whether there were differences in engagement for campaigns with explicit and nonexplicit ads for low-risk (distressed but not explicitly suicidal), high-risk (explicitly suicidal), and help-seeking for suicide keywords.

Results: Our analyses revealed that having explicit wording has opposite effects, depending on the search terms used: explicit wording reduced the engagement rate for individuals searching for low-risk keywords but increased engagement for those using high-risk keywords.

Conclusions: The findings suggest that individuals who are aware of their suicidality respond better to campaigns that explicitly use the word “suicide.” We found that individuals who search for low-risk keywords also respond to explicit ads, suggesting that some individuals who are experiencing suicidality search for low-risk keywords.

Introduction

Over the past decade, there has been a growth in the different types of interventions for people contemplating suicide. For

example, apps can help people keep themselves safe during a suicidal crisis [1]; phone booths are installed at frequently used locations, which give rapid access to a suicide hotline [2]; or an online banner containing a suicide hotline number may appear if individuals search for suicide-related terms using a search

engine [3]. Despite these help-seeking pathways, recent research has shown that less than half of individuals contemplating suicide seek professional help before a suicide attempt [4]. Thus, in parallel to developing new interventions, it may be important to understand how best to promote help seeking and access to help for individuals contemplating suicide for existing services and products.

Help-seeking prompts may function as a gateway to these interventions and come in various forms. In this case, a help-seeking prompt refers to any media encouraging service use. For example, a person may prompt an individual to see their general practitioner (GP) for their mental health, a description on an app store may prompt them to download a suicide prevention app, signage at frequently used locations may point them toward a phone booth, or text on an internet search page may encourage them to call a hotline. All these help-seeking prompts play an important role in being the first point of engagement for the individual, introducing the intervention and promoting its use. If the advertisement (ad) cannot encourage the individual to engage with the intervention, it cannot fulfil its role.

One way we can investigate how different types of prompt messaging affect engagement is by using internet search ads. Previous studies have shown that individuals may search for suicide-related terms on the internet before a suicide attempt [5], that search volumes for a particular region correspond to the suicide rate for that region [6], and that internet searches are used to seek help [7]. For example, an individual may use the internet to find the closest crisis center, a local psychiatrist, or an app to help manage their suicidal thoughts. Searching for “suicide help” yields over 1 billion results on Google, and previous studies have shown a high frequency of searches, with over 120,000 searches over a 19-day study period for suicide- and distress-related keywords in Australia alone [7]. Thus, the search page may be an ideal place to intervene and investigate what messaging is most effective for individuals contemplating suicide.

Internet search ads are triggered when keywords from a prepared list are used, presenting an ad at the top of the search results that links to a relevant page or intervention. Internet search ads also offer the ability to assess how different types of messaging perform with people in different cognitive states, reflected by their search terms. For example, individuals searching for keywords associated with suicide but not explicitly communicating suicidality (eg, loneliness, hopelessness) may engage differently with a particular ad wording than individuals searching for keywords explicitly indicating suicidality or seeking help. This allows us to assess what messaging is best for different risk or distress levels.

The reach and effectiveness of these ads are measured with the impressions (how many times an ad is shown), clicks (the number of clicks on the ad), and conversions (specific behaviors performed on the linked website). Engagement is specifically measured with the click rate (the proportion of individuals who saw the ad and then clicked on it), the conversion rate (the proportion of individuals who clicked on the ad and then engaged with the website), and the total conversion rate (the

proportion of individuals who saw the ad and then engaged with the website) [7].

A previous study has highlighted that one major discussion area regarding communicating with an individual contemplating suicide is the explicit use of the word “suicide” in the ad [8]. In one component of this study, lived experience advisors indicated that the use of the word “suicide” in ads might alienate some individuals who may indeed be experiencing thoughts of suicide but may not recognize, acknowledge, or identify their thoughts as being of suicide. The advisors elaborated that by not using the word “suicide,” we may be able to reach individuals at a precrisis phase for early intervention.

Conversely, other lived experience advisors from the same study communicated that it is imperative to be clear on the subject matter by using the word “suicide.” These advisors communicated that by being explicit, we can overcome the stigma associated with the word and the individual contemplating suicide may be more likely to engage with the service as it is specific to their needs or current situation. This is further supported by contemporary suicide first aid programs, which encourage the explicit use of the word “suicide” for the same reason [9]. Furthermore, all lived experience advisors highlighted the importance of understanding what wording is effective for different suicide risk levels to maximize engagement. For example, nonexplicit wording may be particularly effective for individuals contemplating suicide but not in a suicidal crisis, as they may not identify their thoughts being that of suicide—and vice versa.

In this study, we sought to compare engagement with two internet ad campaigns, one with explicit suicide wording in its ad and the other with nonexplicit suicide wording. We also investigated whether the pattern of engagement differed by the type of keyword searched (low risk, high risk, help seeking, or means specific). In addition, we examined engagement by gender, age, and time of day.

First, we hypothesized that the campaign with explicit wording related to suicide would perform better for individuals searching for high-risk, help-seeking, or means-specific keywords. Given that these individuals are explicitly experiencing suicidal ideation and can identify and communicate it, they may respond better to an ad that is explicit in what issue it is addressing. Second, we hypothesized that for individuals searching for low risk-keywords, nonexplicit wording would have higher engagement as the explicit wording may alienate individuals who do not identify as having suicidal thoughts. Third, given that the key manipulation is in the ad’s wording and not the linked web pages, we hypothesized that we should see this increased engagement in the click rate but not the conversion rate (and, as such, also see increased engagement in the total conversion rate).

Methods

Study Design

The study used a 2-arm quasi-experimental design (explicit vs nonexplicit wording) with 4 initial pathways (individuals searching for different types of keywords: low risk, high risk,

help seeking, and means specific; these categories are described in more detail later).

Participants

Individuals over the age of 18 years and currently residing in Australia were included in the study. Google infers the age and gender of individuals through multiple sources of information, primarily the age and gender inputted when creating a Google account, as well as past browsing history (eg, websites visited and engagements) collected through website cookies.

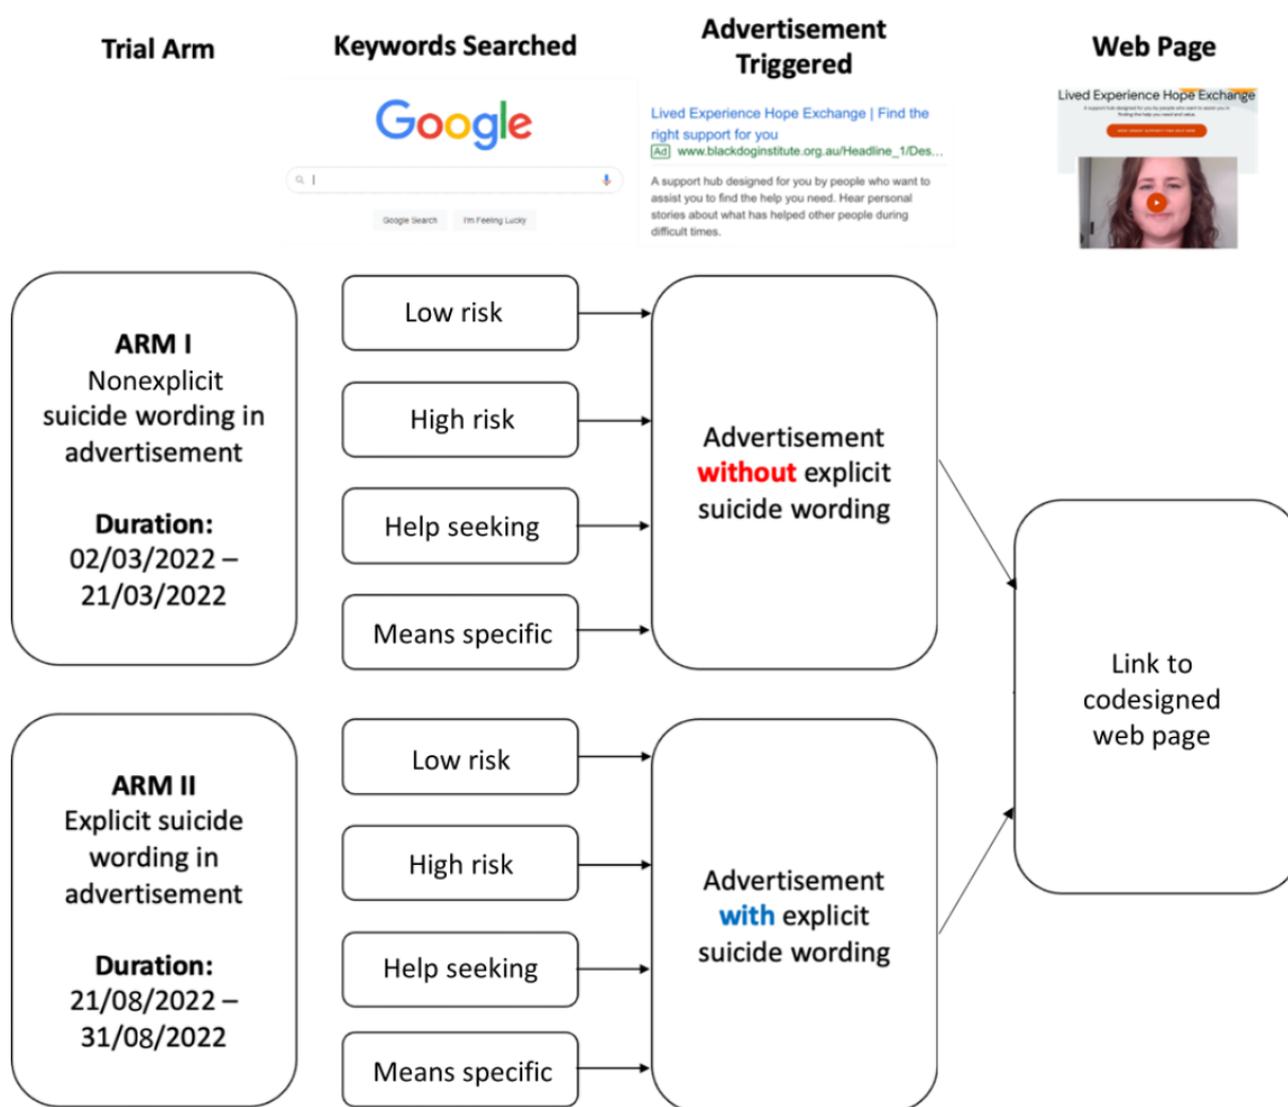

Ethical Considerations

The University of New South Wales Human Research Ethics Committee approved this study (HC210827).

Intervention

The first arm used ads without explicit suicide wording and ran from March 2 to March 21, 2022. The second arm used ads with explicit suicide wording and ran from August 21 to August 31, 2022. The first arm was run as part of another larger study pertaining to the effectiveness of Google Ads campaigns in reaching individuals thinking of suicide and has been reported elsewhere [7]. The 2 arms of the trial were run sequentially, not concurrently. Thus, there was no randomization present. Full details of the keyword generation, ad and landing page codesign process, and content of the landing pages and linked pages can be found elsewhere [8]. A schematic of the campaign can be found in Figure 1.

Figure 1. Schematic of Google Ads campaign.

Keywords

Together with lived experience advisors, researchers, and a Google Ads agent, we generated 4 lists of keywords: low-risk keywords, which included keywords people are likely to search for when in distress or situations associated with suicide, without explicitly mentioning suicide (eg, “feeling so alone,” “debt”); high-risk keywords, which included keywords explicitly

communicating suicidal ideation or help seeking (eg, “I want to die”); help-seeking keywords, which included keywords explicitly searching for help for suicidal thoughts (eg, “suicide help”); and means-specific keywords, which were related to searching or using specific means [10]. When keywords are entered into Google Ads, the ad is also triggered when semantically similar search terms are entered; thus, the total

number of keywords that trigger the ad is substantially larger than what is inputted.

Advertisements

The ads were codesigned alongside a group of lived experience advisors and investigators. The codesign process yielded 6 ads, 3 (50%) explicit suicide wording and 3 (50%) without explicit suicide wording, while controlling as much as possible for other content. Each ad was as closely matched as possible to its counterpart; that is, the first ad in the explicit condition had the same messaging and content as the first ad in the nonexplicit condition, save for explicit suicide wording in the first sentence. We developed more than 1 ad for each condition to allow our findings to be more generalizable and to reflect larger themes found in our codesign process [8] rather than specific wording.

All the ads across both conditions were controlled for the number of characters and number of words, with a range of 38-43 words and 215-234 characters. The absolute difference in the character and word count between each ad and its counterpart was between 1 and 5 characters and 1 and 3 words, respectively.

The codesigned text for the nonexplicit ads is specified next. All character counts include spaces.

Lived Experience Hope Exchange. Find the right support for you. A support hub designed for you by people who want to assist you to find the help you need. Hear personal stories about what has helped other people during difficult times. (237 characters, 41 words)

Looking for some support? Designed with Lived Experience. Our Hope Exchange has been designed by people who may understand how you're feeling. There are lots of ways to seek help. We want to find the right one for you. (220 characters, 39 words)

Find the right support for you. Lived Experience Hope Exchange. We want to help you to find the help that you need and value during challenging times. Hear stories and advice from people who may have felt the way you're feeling now. (234 characters, 42 words)

The matched text for the explicit wording ads was as follows:

Are you feeling suicidal? Lived Experience Hope Exchange. Support designed for you. Designed by people who want to assist you to find the help you need. Hear personal stories about what has helped other people during difficult times. (235 characters, 38 words)

Help for suicidal thoughts. Looking for some support? Designed with Lived Experience. Designed by people who may understand how you're feeling. There are lots of ways to seek help. We want to find the right one for you. (221 characters, 38 words)

Dealing with suicidal thoughts. Find the right support for you. Lived Experience Hope Exchange. We want to help you to find the help that you need and value. Hear stories and advice from people who may have

felt the way you're feeling now. (241 characters, 43 words)

In each campaign condition, ads were shown to users independently of which category of keywords were searched. When an ad was triggered, 1 of 3 ads in that condition would be randomly shown, resulting in equal presentations across the study.

Landing Page

In collaboration with lived experience advisors, we codesigned a series of landing pages containing lived experience stories, calming and distracting activities, and links to support services and hotlines with descriptions of what the individual will likely experience when engaging in these services. Details of the pages can be found elsewhere [8].

Outcomes

Data on impressions, clicks, the click rate (clicks/impressions), conversions, the conversion rate (conversions/clicks), the cost per click, and the cost per conversion were extracted from Google Ads in a deidentified, aggregated form. The total conversion rate was manually calculated (conversions/impressions). Currently, the total volume of searches for each category is not available through Google Ads.

The primary outcome was the click rate (engagement with the ad) as our manipulation was on the search page rather than on the landing page. Our secondary outcomes were the total conversion rate (total engagement with the campaign, that is, all things being equal, the conversion rate per impression) and the conversion rate (engagement with the landing page).

Conversions contained behaviors the investigators, the lived experience advisors, and the collaborative team considered positive. Triggering any of these conditions was considered a conversion, including:

- Clicking the Get Help button to see available support services
- Downloading any file pertaining to the modules to help de-escalate a crisis or for self-help for suicidality
- Clicking on a link to call a support service
- Spending more than 2 minutes on the website that was designed to promote help seeking and de-escalate crises, as an indication that the individual was engaging with content on the website

Statistical Analyses

In the main analysis, each combination of outcome metric (click rate, conversion rate, and total conversation rate) and keyword type (high risk, low risk, and help seeking) was considered separately. The outcome metric rates associated with the explicit and nonexplicit wording were compared using an incidence rate ratio (IRR) from the *rateratio* function in the *fmsb* package in R (R Foundation for Statistical Computing), which calculates the exact mid-p double-sided *P* value and calculates the CI using the exact Poisson method [11,12].

Interaction terms were considered if at least 1 significant difference between explicit and nonexplicit wording was identified for an outcome measure. In this case, a keyword

category with a significant difference due to wording was compared to the other keyword categories. To test the interactions, we first calculated a difference term between the explicit and nonexplicit conditions for a single keyword type. For example, we calculated the difference term for the click rate and low-risk keywords as follows:

This difference term was compared with the other keyword difference terms using the *ratedifference* function in the *fmsb* package in R, which uses a chi-squared test to test for a significant incidence rate difference (IRD) [12]. Thus, this analysis assessed interaction by assessing a difference of a difference.

Where a significant difference of differences (ie, an interaction) was identified in the outcomes, post hoc tests were conducted

to determine whether there were underlying differences in the relevant outcome metrics for the explicit or nonexplicit wording conditions or both.

Results

Campaign Metrics

A total of 153,768 impressions, 7263 clicks, and 1657 conversions were achieved during the study periods. The engagement metrics, reported by trial condition, age, and gender, are reported in [Table 1](#).

Due to the exceptionally low numbers in the means-specific group (n=11, 0.01%, impressions; n=1, 0.01%, click; and 0 conversions), these campaigns were excluded from subsequent analyses.

Table 1. Engagement metrics by trial condition, age, and gender.

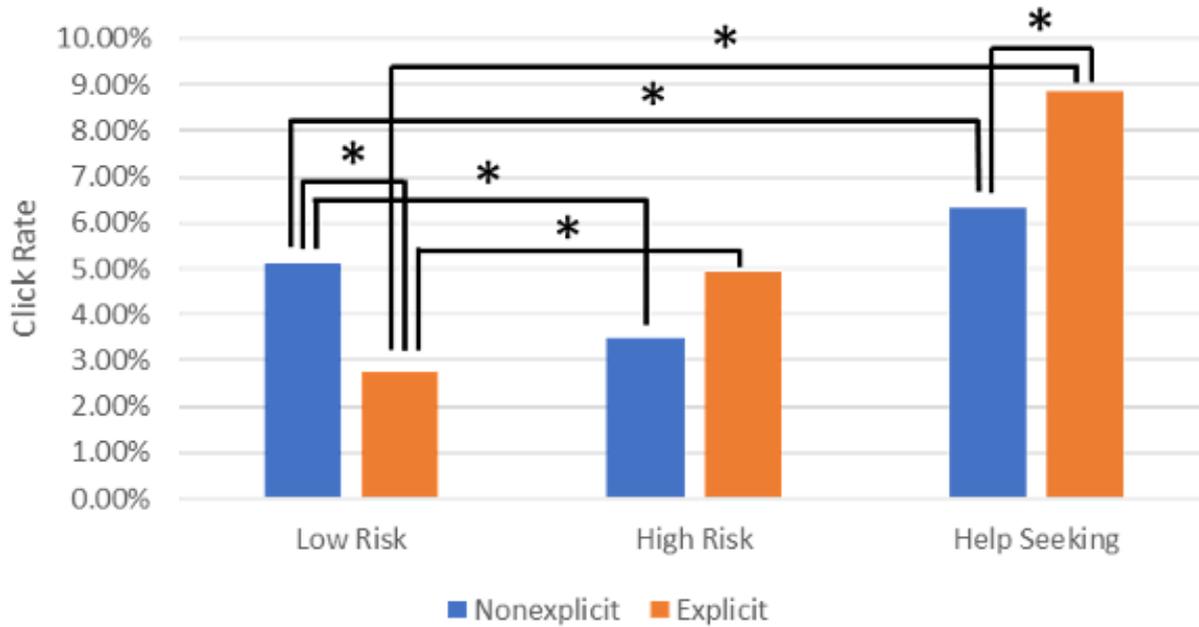

Trial condition, gender, and age (years)	Impressions (N=153,768), n (%)	Clicks (N=7263), n (%)	Click rate, %	Conversions (N=1657), n (%)	Conversion rate, %	Total conversion rate, %

Click Rate

The click rate using explicit and nonexplicit wording for each keyword category is shown in [Figure 2](#). A significant difference between explicit and nonexplicit wording for low-risk keywords was found (IRR=1.848, 95% CI 1.718-1.987, $P<.001$), in which there was a higher click rate for nonexplicit versus explicit keywords (5.11% vs 2.77%). For help-seeking keywords, there

was a significantly higher click rate for explicit versus nonexplicit keywords (3.50% vs 4.93%; IRR=0.715, 95% CI 0.599-0.854, $P<.001$). A similar pattern was observed for high-risk keywords, with a higher click rate for explicit versus nonexplicit keywords, although this was only marginally nonsignificant (6.33% vs 8.85%; IRR=0.711, 95% CI 0.503-1.005, $P=.052$).

Figure 2. Click rate by keyword type and condition. * $P < .05$.

Next, we investigated the presence of 2-way interactions between the 3 groups (low risk and high risk, low risk and help seeking, high risk and help seeking). All 2-way interactions were significant (high risk and help seeking: IRD=0.0109, 95% CI 0.000146-0.0217, $P = .047$; high risk and low risk: IRD=0.0301, 95% CI 0.0301-0.0453, $P < .001$; low risk and help seeking: IRD=0.0472, 95% CI 0.0405-0.0541, $P < .001$).

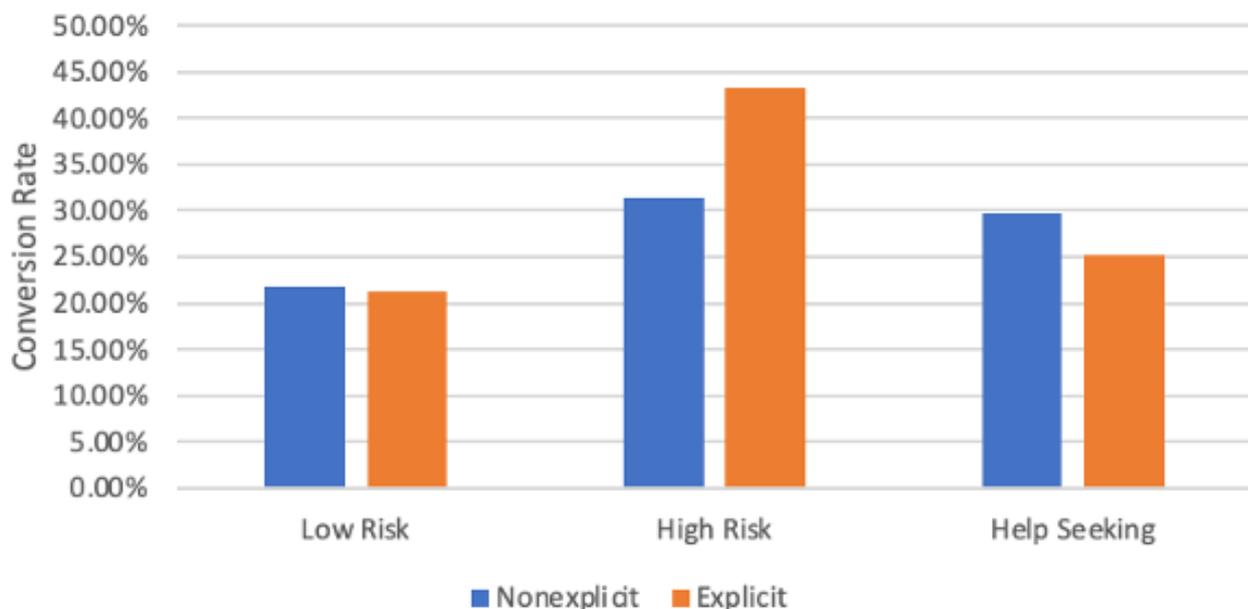

Post hoc tests revealed a significant difference in the click rate between the low- and high-risk keywords in the explicit condition (2.77% vs 4.93%; IRR=0.5612, 95% CI 0.4144-0.7784, $P < .001$) and the nonexplicit condition (5.11% vs 3.50%; IRR=1.459, 95% CI 1.216-1.766, $P < .001$). Significant differences were also found in the click rate between the

low-risk and help-seeking keywords in the explicit condition (2.77% vs 8.85%; IRR=0.312, 95% CI 0.263-0.373, $P < .001$) and the nonexplicit condition (5.11% vs 6.33%; IRR=0.807, 95% CI 0.740-0.881, $P < .001$).

Conversion Rate

A graphical representation of the conversion rate data is shown in Figure 3. There were no significant differences between the nonexplicit and explicit conditions (low risk: 21.86% vs. 21.17%; IRR=1.0326, 95% CI 0.882-1.209, $P = .69$; high risk: 31.36% vs 43.18%; IRR=0.726, 95% CI 0.418-1.263, $P = .25$; help seeking: 29.74% vs 25.16%; IRR=1.182, 95% CI 0.835-1.674, $P = .35$). Thus, interaction effects were not explored.

Figure 3. Conversion rate by keyword type and condition.

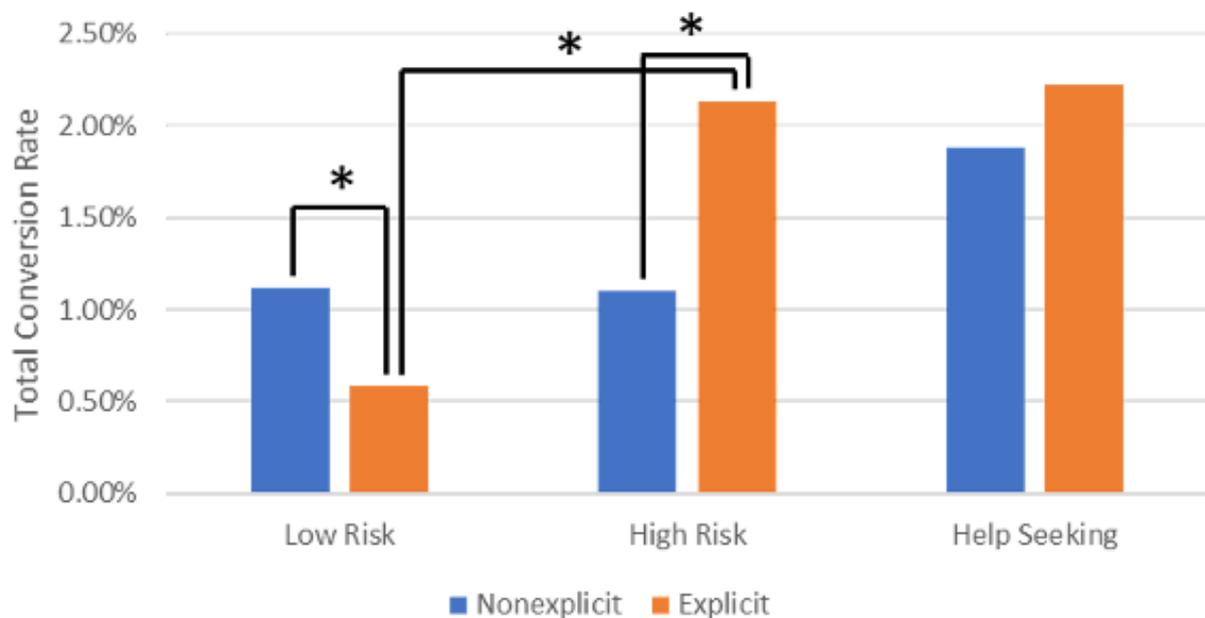

Total Conversion Rate

A graphical representation of the total conversion rate can be seen in [Figure 4](#). There was a significant difference in the total conversion rate for low-risk keywords (IRR=1.908, 95% CI 1.630-2.234, $P<.001$), in which the nonexplicit wording had a higher rate (1.12% vs 0.59%), and high-risk keywords (IRR=0.846, 95% CI 0.297-0.896, $P=.02$), in which the explicit wording had a higher rate (1.10% vs 2.13%); however, there was not enough evidence to suggest a difference between explicit and nonexplicit wording (1.88% vs 2.23%) when an individual was searching for help-seeking keywords (IRR=0.846, 95% CI 0.597-1.197, $P=.34$).

Possible interactions between the 3 groups (low risk and high risk, low risk and help seeking, high risk and help seeking) were

Figure 4. Total conversion rate by keyword type and condition. * $P<.05$.

explored. A significant interaction was identified between low-risk and high-risk keywords (IRD=0.00875, 95% CI 0.00613-0.0114, $P<.001$), as well as between low-risk and help-seeking keywords (IRD=0.0156, 95% CI 0.00901-0.0222, $P<.001$). However, there was no significant interaction between high-risk and help-seeking keywords (IRD=-0.00685, 95% CI -0.0141 to 0.000345, $P=.06$).

Post hoc tests revealed a significant difference in the total conversion rate between the low- and high-risk keywords in the explicit condition (0.59% vs 2.13%; IRR=0.275, 95% CI 0.171-0.442, $P<.001$) but not in the nonexplicit condition (1.12% vs 1.10%; IRR=1.017, 95% CI 0.733-1.411, $P=.92$).

A summary of the analysis outcomes can be seen in [Table 2](#).

Table 2. Summary of analysis outcomes.

Metric and keyword type	Significant comparisons	Significant interactions
Click rate		
Low risk	Nonexplicit > explicit	Low risk × high risk Low risk × help seeking High risk × help seeking
High risk	Explicit > nonexplicit ^a	Low risk × high risk Low risk × help seeking High risk × help seeking
Help seeking	Explicit > nonexplicit	Low risk × high risk Low risk × help seeking High risk × help seeking
Conversion rate		
Low risk	N/S ^b	— ^c
High risk	N/S	—
Help seeking	N/S	—
Total conversion rate		
Low risk	Nonexplicit > explicit	Low risk × high risk Low risk × help seeking
High risk	Explicit > nonexplicit	Low risk × high risk Low risk × help seeking
Help seeking	N/S	Low risk × high risk Low risk × help seeking

^aMarginal significance ($P < .06$).

^bN/S: not significant.

^cNot available. This was used when interaction analyses were not conducted due to nonsignificant comparisons.

Discussion

Principal Findings

In this study, we compared the impact of explicit and nonexplicit suicide wording in an online ad campaign and webpage targeting those searching for suicide- and distress-related keywords. Analysis of the click rate revealed that for low-risk keywords, nonexplicit wording had a higher click rate; for high-risk keywords, there was marginal evidence that explicit wording had a higher click rate; and for help-seeking keywords, explicit wording had a higher click rate. For the conversion rate, there was no evidence of any differences between conditions. Analysis of the total conversion rate revealed that for low-risk keywords, nonexplicit wording had a higher total conversion rate; for high-risk keywords, explicit wording had a higher total conversion rate; and for help-seeking keywords, there was no evidence of a difference.

Further analysis of the click rate revealed 2-way interactions between low- and high-risk keywords, low-risk and help-seeking keywords, and high-risk and help-seeking keywords, suggesting that the effect of explicit wording in the ad differed among these groups. Further exploratory analysis revealed significant differences between low-risk and high-risk keywords, as well as between low-risk and help-seeking keywords, in the explicit and nonexplicit conditions. These findings further support the

suggestion that the effect of wording differentially impacts engagement in keyword groups, rather than an interaction emerging due to the manipulation only affecting one group but not the other. Together, these findings suggest that ads with explicit suicide language are less likely to be clicked on than those with nonexplicit language when individuals are searching for low-risk keywords. The reverse was observed when searching for high-risk or help-seeking keywords (although the former did not reach significance), where ads with explicit language were more likely to be clicked on. This pattern of findings may partly contribute to the pattern of findings in the total conversion rate, in which analysis revealed 2-way interactions between low- and high-risk keywords and between low-risk and help-seeking keywords, suggesting that the effect of explicit wording in the ad differed among these groups. Exploratory analysis revealed that the interaction between low- and high-risk keywords may be driven by a higher total conversion rate when explicit wording is used with high-risk versus low-risk keywords, whereas there was no apparent difference between high-risk and low-risk keywords when nonexplicit wording was used. These findings suggest that having explicit wording has opposite effects, depending on the search terms used: explicit wording reduces the total conversion rate for individuals searching for low-risk keywords but increases the total conversion rate for those using high-risk keywords. There is no evidence to suggest that explicit or

nonexplicit wording affects the total conversion rate when help-seeking keywords are used. These findings support both recommendations from lived experience advisors, both for and against the use of explicit wording, as perhaps both are appropriate for individuals in different cognitive states.

Overall, these findings suggest that individuals who search for help-seeking or high-risk suicide keywords respond more to ads and campaigns with explicit suicide wording, demonstrated by the higher click rate and total conversion rate, respectively. Alternatively stated, an ad campaign targeting individuals searching for high-risk keywords is likely to lead to more desirable behaviors if explicit wording is used. This may be because individuals may respond more strongly to a campaign that specifically targets their current situation. Given that the ad explicitly communicates and labels their current issue, the individuals may be more inclined to seek help. As the nonexplicit ad contained no indication that the campaign is for suicidality, the users may not have been certain that the webpage was able to meet their needs.

Furthermore, the high-risk search terms in this study excluded individuals who were explicitly searching for help for their suicidality. Thus, our findings suggest that explicitly naming the issue can improve help seeking for individuals at high risk of suicide but who may not be actively seeking help, as revealed in the total conversion rate. This finding is consistent with current practices in suicide prevention first aid (eg, applied suicide prevention skills training [9]), where directly addressing and asking about suicide are strongly encouraged. This study demonstrated that the benefit of explicit wording for individuals in crisis is generalizable beyond suicide first aid and direct face-to-face communication. This finding may have implications for other forms of communication when addressing individuals at high risk of suicide.

The results also showed that individuals searching for low-risk suicide terms respond less to campaigns with explicit suicide wording. Since the low-risk keywords in this study were broad (eg, loneliness), many individuals searching for these terms may not have been suicidal—hence the lower click rate. However, despite being low, we still observed a click rate by individuals searching for low-risk keywords on the explicit campaign compared to the industry standard of 3.17% [13]. This suggests that individuals who may not be searching for explicit keywords may be experiencing suicidality and that targeting low-risk keywords is still beneficial. Conversely, we may have seen an elevated click rate for the low-risk, nonexplicit condition due to people clicking on the ad not realizing it was for individuals experiencing suicidality. Nevertheless, in the low-risk, nonexplicit condition, we still observed a conversion rate of over 20%, relative to the industry standard of 3.75%, suggesting that the landing page was still fulfilling a need. This may be because by using explicit suicide wording, we may alienate individuals who, for various reasons, may not recognize, identify, or acknowledge that their feelings are those of suicide. Thus, when visiting the page, their needs are met. However, one possibility is that some individuals searching for low-risk keywords are unaware that they are suicidal, and using the word “suicide” may help bring awareness to these underlying feelings [8]. Thus, explicit and nonexplicit keywords may have their

own benefits; however, our findings suggest that overall, using nonexplicit keywords will reach more people. Although many people searching for low-risk keywords may not be experiencing suicidality, we must ensure that little effort is needed to access suicide-related resources and help, given that there are still individuals searching for low-risk keywords who are experiencing suicidality. Further research is needed to understand how best to tailor the ads to individuals searching for low-risk keywords.

The findings suggest that individuals experiencing suicidality and who could explicitly communicate it have higher engagement patterns with a campaign when the word “suicide” is used in the ad regardless of whether they are explicitly seeking help. However, for individuals experiencing general distress but not searching for suicide-specific terms, using explicit suicide wording leads to lower engagement with the campaign. Thus, in response to the finding that some lived experience advisors advocated for the explicit use of the word “suicide,” while others advocated against it, perhaps both are true for individuals in different cognitive states.

We recommend that the development and design of help-seeking prompts for suicide consider at what stage the individual is. If the prompt is intended for individuals with a lower risk of suicide, such as public media campaigns, then the use of the word “suicide” may decrease engagement; however, if the prompt is intended for individuals at high risk of suicide, whether they are or are not actively seeking help, then the use of the word “suicide” is likely to increase engagement. Furthermore, these findings suggest the need to codesign with a range of individuals who have experienced the spectrum of suicidality to understand their needs, the thought process, and how they speak about and internally conceptualize their distress and suicide to formulate different terms that promote help seeking and engagement.

Given that this pattern of finding has been found across 2 modalities (suicide first aid and internet ads), future research should seek to investigate the generalizability of these findings to other help-seeking prompts in suicide prevention, for example, signage at frequently used locations, safety planning app notifications, or the wording on the suicide hotline banner if individuals search for suicide-related terms. Further, future research should further understand what type of ad wording works for whom. For example, previous evidence has suggested that men and women respond differently to tailored ad campaigns [14]. Using Google Ads, we can further investigate what type of ad best engages men and women.

There was a low number of searches and engagement for means-specific keywords in this study. There may be several possibilities for this. First, these numbers may reflect true rates and only a few individuals were searching for these terms. Another possibility is that individuals at the planning stage do not primarily turn to search engines but may use other means of information seeking, as means selection has been found to be influenced by prior familiarity with the means itself [15]. Another possibility is that more individuals were searching for these terms but our current keyword list and Google’s function of generating permutations of the keyword list could not capture

the range of search terms. This could be rectified by experimenting with keyword setting iterations in Google Ads to capture a wider variety of expressions. Finally, one possibility is that there are cultural differences in search behaviors. For example, a previous study found high incidences of method-related searches in Japan [16], suggesting that cultural differences may exist. Given that a key finding in previous research was that individuals who attempted suicide had searched for means-specific keywords [5], future research should investigate how individuals search for information regarding means and how we can best intervene at this stage.

Future studies may also investigate whether these findings generalize to other psychological or health domains. For example, an individual who is acutely depressed and can identify it may respond better to an ad for therapy explicitly communicating that this is for individuals experiencing depression. Conversely, an individual who may also be experiencing depressive symptoms but is either unfamiliar that they are experiencing depressive symptoms or is from a background where depression is strongly stigmatized may respond better to an ad without explicitly using the word “depression.” Future studies should carefully consider conversion actions, as we cannot measure directly whether an individual is processing the information presented to them, and thus, we use proxy measures common to the marketing field (eg, time spent on a page). Given the growing interest in online interventions, standardized methods for measuring engagements should be established.

Limitations

The study has several limitations. One limitation is that due to resourcing constraints, there was a large difference in the

number of participants in the 2 conditions. Furthermore, the data were collected at different times of the year, so there may be seasonal or cohort effects; future studies should run campaigns with explicit and nonexplicit wording at the same time. In addition, as research with this type of data is still in its infancy, future research should focus on understanding whether, when, and how search metrics should be normalized against variations in time. Another limitation is that we could only infer cognitive states from search results but did not measure suicidality directly. For example, a person may search for a high-risk keyword as part of a study but not be suicidal. Thus, there is added noise in the data.

Strengths

Our study also has several strengths. The study was run nationwide, allowing us to sample the entire target population rather than just a specific subset. The components of this study, such as the ad wording, landing page, and keywords used to trigger the ad, were codesigned with individuals with lived and living experiences of suicide. Furthermore, by providing data on click rates and conversion rates, we obtained greater mechanistic insight into the findings for the total conversion rate.

Conclusion

Our study demonstrates different engagement levels with an online suicide prevention campaign due to the word “suicide” in the search page ad. Future research should further explore what type of messaging works best for whom, and when paired with the flexibility of the advertising industry, we may be one step closer to ensuring that each person is met with a message that leads to the highest probability of them engaging services, using resources, or seeking help.

Abstract

Background: Internet-based cognitive behavioral interventions (iCBTs) are efficacious treatments for depression and anxiety. However, it is unknown whether adding human guidance is feasible and beneficial within a large educational setting.

Objective: This study aims to potentially demonstrate the superiority of 2 variants of a transdiagnostic iCBT program (human-guided and computer-guided iCBT) over care as usual (CAU) in a large sample of university students and the superiority of human-guided iCBT over computer-guided iCBT.

Methods: A total of 801 students with elevated levels of anxiety, depression, or both from a large university in the Netherlands were recruited as participants and randomized to 1 of 3 conditions: human-guided iCBT, computer-guided iCBT, and CAU. The primary outcome measures were depression (Patient Health Questionnaire) and anxiety (Generalized Anxiety Disorder scale). Secondary outcomes included substance use-related problems (Alcohol Use Disorder Identification Test and Drug Abuse Screening Test—10 items). Linear mixed models were used to estimate the effects of time, treatment group, and their interactions (slopes). The primary research question was whether the 3 conditions differed in improvement over 3 time points (baseline, midtreatment, and after treatment) in terms of depression and anxiety symptoms. Results were analyzed according to the intention-to-treat principle using multiple imputation. Patients were followed exploratively from baseline to 6 and 12 months.

Results: In both short-term and long-term analyses, the slopes for the 3 conditions did not differ significantly in terms of depression and anxiety, although both web-based interventions were marginally more efficacious than CAU over 6 months (P values between .02 and .03). All groups showed significant improvement over time ($P < .001$). For the secondary outcomes, only significant improvements over time (across and not between groups) were found for drug use ($P < .001$). Significant differences

were found in terms of adherence, indicating that participants in the human-guided condition did more sessions than those in the computer-guided condition ($P=.002$).

Conclusions: The transdiagnostic iCBT program offers a practical, feasible, and efficacious alternative to usual care to tackle mental health problems in a large university setting. There is no indication that human guidance should be preferred over technological guidance. The potential preference of human support also depends on the scale of implementation and cost-effectiveness, which need to be addressed in future trials.

Introduction

Background

University students face various challenges, both academically and personally [1]. During the phase of emerging adulthood (18-25 years of age), difficulties may arise in facing these challenges [2]. Recent large-scale studies among undergraduate students have shown that between 20% and 30% of students experience a mental disorder, most notably depression and anxiety disorders [3-5]. In addition, student life has been associated with excessive alcohol consumption, with some studies indicating that 20% of students are hazardous drinkers [6]. Symptoms of common mental disorder impact the ability to face key challenges of emerging adulthood, such as identity formation and building new, intimate relationships [7,8]. Mental distress may also contribute to students performing poorly academically or even dropping out. This may give rise to concerns about career prospects and finding a place in society [7-9]. These dynamics may lead to a vicious cycle of increasing feelings of failure, which may further exacerbate occurring symptoms. Thus, timely intervention in this group is needed [10,11].

Despite the availability of local services at or around the university, most students do not receive the help they need, and some do not even seek help in the first place [12]. Auerbach et al [4], based on surveys in 21 countries, found that less than 20% of students with a recent or current mental disorder received *minimally adequate treatment* for this disorder, and this rate is even lower in lower middle-income to low-income countries. Even with severe symptoms of a common mental disorder, the 12-month treatment rates did not exceed 45.1%, meaning that half of all students with longer-lasting severe symptoms do not receive help for their problems [12]. Impediments to find help include both factual (eg, lack of skilled therapists, waitlists, lack of time, and financial hurdles) and perceived barriers (eg, skepticism on treatment effectiveness, lack of perceived urgency, and fear of stigmatization) [13-17]. High levels of unmet treatment needs emphasize the urgency to explore alternative possibilities for intervention and potentially a reallocation of resources for this vulnerable group [12].

To address some of these barriers, innovative, scalable, and low-threshold interventions are required. Web-based treatment may meet some of these requirements and has been shown effective for this target group, particularly for depression and anxiety [18-20]. Another potential advantage of web-based interventions is that they require less human investment in terms of time compared with face-to-face clinical care and thus may reduce costs, although this should be quantified in future studies explicitly aimed at assessing cost-effectiveness (not the objective of this study). Moreover, young adults may prefer easily accessible and relatively anonymous and self-directed interventions with limited therapeutic contact [14,17]. Meta-analytic findings have indicated that older people are more likely to respond better to web-based treatments for depression; thus, methods to increase efficacy for young adults need to be found [21].

Transdiagnostic web-based approaches may broaden the scope and impact of interventions. This is particularly relevant given the high comorbidity of symptoms among students [5]. There is a growing consensus that depression and anxiety, although often classified as distinct disorders, share common etiological and perpetuating factors, such as proneness to internalization and high levels of negative affect [22,23]. Targeting anxiety and depression in one treatment program may appeal to a large variety of students. However, at the same time, studies using web-based transdiagnostic interventions among students have reached inconsistent findings, although these studies had limited scope and compared treatment to a waitlist control group only [24,25]. In general, the potential of transdiagnostic interventions for large-scale implementation should not be underestimated, and they could have secondary effects on related problems, such as substance use issues [26].

Evidence is accruing that *guided* (cognitive behavioral therapy [CBT]) interventions should be preferred over *unguided* or self-guided interventions with only limited (ie, technological) support, given their greater efficacy and positive impact on adherence [27,28]. Karyotaki et al [27], for example, found some advantageous effects of guided versus unguided internet-based CBT (iCBT) for depression, but these differences disappeared at the 6-month and 12-month follow-up. This has important practical implications, as offering human support exerts greater pressure on extant resources and could thus limit implementation on a large scale (ie, in a university setting).

Guided and unguided web-based interventions have rarely been compared head-to-head among students with mental health issues [28]. In this study, we use a slightly different terminology for the guided and unguided iCBT conditions, as we think these terms are unfortunate for several reasons (for a discussion, see the study by Koelen et al [28]).

Aims of This Study

In this study, we compared 3 conditions simultaneously in a large sample of both undergraduate and graduate (including doctoral) university students (henceforth, students): a human-guided iCBT transdiagnostic program, a computer-guided iCBT transdiagnostic program, and care as usual (CAU). This study built upon a previous study [10] comparing a human-guided (transdiagnostic) iCBT against CAU in a sample of students ($n=100$). This previous study [10] yielded no significant differences ($P>.05$) between conditions on any of the examined outcomes, at any of the time points (including the 6-month and 12-month follow-up), which may in part be attributable to limited power to detect small effects. In addition, this previous study [10] included only students with mild to moderate anxiety and depression symptoms. As other iCBT trials indicate that interventions are more efficacious when offered to individuals with higher levels of anxiety and depression symptoms [25,27], we also included students with elevated levels of anxiety and depression beyond mild symptoms in this study.

The aims of this study were two-fold: (1) to examine the efficacy of a transdiagnostic iCBT program in a large sample of students with mild, moderate, or severe levels of anxiety, depression, or both, when compared with CAU, and (2) to examine whether the addition of human guidance resulted in greater efficacy when compared with computer guidance. It was expected that (1) individuals who followed either human-guided or computer-guided iCBT would improve more than those in the CAU condition on the primary outcomes of depression and anxiety after treatment and (2) individuals who followed human-guided iCBT would improve more on the primary measures compared with computer-guided iCBT. Exploratory analyses were performed up until 6 and 12 months after baseline and for the secondary outcomes. Higher adherence rates were expected for the human-guided compared with the computer-guided condition [28].

Methods

Design

This study was a 3-arm, randomized controlled superiority trial conducted at the University of Amsterdam (UvA) in the Netherlands. A web-based, personalized, and transdiagnostic intervention (iCare Prevent) [29] with human guidance was compared with the same intervention with computer guidance. Both web-based interventions were also compared with CAU. CAU in this context refers to the standard mental health care that is accessible in the university setting, including help provided by the (student) general practitioners, student psychologists, and study advisers, as well as the secondary services in the broader community (psychologists and psychiatrists). Participants were followed up to 12 months after

randomization. Measurements were administered at baseline (t1); midtreatment (5 weeks after randomization; t2); after treatment (8 weeks after randomization; t3); 6-month follow-up (t4); and 12-month follow-up (t5).

Ethical Considerations

This study was approved by the medical ethical committee of the *Centrale Commissie Mensgebonden Onderzoek* (METC number 2018_085, NL64929.018.18).

Participants

Participants were young adults who were enrolled as bachelor's, master's, or PhD students at the UvA. Before inclusion in the randomized controlled trial, students participated in an e-survey to screen for elevation of symptoms of anxiety or depression (mild, moderate, or severe) [30]. Students were recruited between February 2019 and March 2022 and were included in the randomized controlled trial based on the following inclusion criteria: (1) aged ≥ 16 years and (2) mild, moderate, or severe symptoms of depression (as defined by a score within the range of 15 to 60 points on the Center for Epidemiological Studies Depression Scale) [31], anxiety (as defined by scoring above the cut-off score of 4 on the Generalized Anxiety Disorder scale-7 items [GAD-7]) [32] on the e-survey, or both.

Participants were excluded when they fulfilled one or more of the following criteria: (1) comorbid bipolar disorder or psychotic disorder according to the Mini International Neuropsychiatric Interview (MINI) [33]; (2) active high suicide risk according to the MINI; (3) currently receiving psychological treatment for depression or anxiety; (4) having a slow or no internet connection; and (5) no provision of providing written informed consent before participation.

Procedures of Screening and Intervention Phases

Students enrolled at the UvA received an invitation via email from the secured, central research-dedicated platform (LOTUS). LOTUS contained the students' email addresses, from which links for the e-survey platform Qualtrics and other messages were sent, depending on the phase of the study and the forms completed. The invitation email contained general information about the study and a unique link. Participants who clicked on the invitation link were referred to the e-survey platform. Here, they could find an information letter and were asked to provide informed consent and complete the survey. Invitations were sent in separate cohorts to control the participant flow throughout the study's distinct phases. Following the original invitation, 2 reminder emails were sent (1 and 2 weeks after the first invitation). In addition, study advisers and study counselors of the UvA were informed about the study. They were asked to refer students interested in participating in the study to the research team. The study spanned 4 academic years (2018/2019 to 2021/2022), and participants were asked at the beginning of the screening if they consented to being invited again later that academic year. Participants could opt out of the study at any time, and they could also indicate that they did not want to receive further emails. During the COVID-19 pandemic (April 2020 until the end of the study), the screening e-survey contained several additional questions about their activities and coping style (for details, see the study by Koelen et al [34]).

Participants who scored above the cut-off on either anxiety symptoms, depressive symptoms, or both received an email with a web-based information brochure and informed consent document. Participants could also choose to receive the information brochure and informed consent document through the post. Likewise, informed consent could be signed on the web, returned by post, or handed in at several *collection points* at the university campus. Next, they were telephoned by the administrators of the project to book an appointment to conduct the MINI diagnostic interview (see the *Measures* section). When eligibility was confirmed, participants were immediately randomized to one of the 3 conditions. The participants who were randomized to either intervention were instructed to create an account on the intervention platform (Minddistrict).

Participants were reimbursed for completing the 6-month and 12-month follow-up assessments. In the initial phases of the trial, participants were paid €10 (US \$10.8) when they completed both assessments. To increase adherence, students were paid €5 (US \$5.4) for each of the assessments separately in the final stages of the trial. A raffle to win a tablet or e-reader was held among every hundred participants that completed both the 6-month and 12-month assessments.

Randomization, Blinding, and Treatment Allocation

Participants who were eligible to participate in the study were randomly assigned to either the human-guided intervention, the computer-guided intervention, or CAU (1:1:1 allocation ratio) group directly following the baseline measurement, which was done automatically through an algorithm built into the LOTUS platform. Randomization was based on computer-generated random numbers. Participants were stratified by gender and anxiety and depressive symptoms to guarantee an even distribution of male and female participants and symptom severity across conditions. Allocation was concealed from psychologists involved in this study; 2 of the psychologists who provided guidance were also administrators with access to the backend of the software. Owing to the nature of the intervention, participants and psychologists could not be blinded to the

assigned treatment condition. Participants were informed about the 3 conditions and whether they were assigned to either an intervention condition or CAU. It was not specified to participants to which intervention (human-guided or computer-guided) they were assigned. Psychologists were aware of the participants' intervention condition because they provided participants with personalized feedback in the human-guided condition. The assessments were all conducted on the web and were not accessible for the psychologists (ie, blinded), except for the pre-session questions that were available through the intervention platform.

Interventions

The web-based transdiagnostic intervention that was used in this study, *iCare Prevent*, was originally developed by Weisel et al [35] for the German-speaking general population and translated and adapted by Bolinski et al [29] for a Dutch undergraduate student population into Dutch and English (see [Textbox 1](#) for modules of *iCare Prevent*). For this study, we created a second English version of the intervention for PhD students that included a small adaptation of the examples to match their situation. The intervention is based on principles from CBT for anxiety and depression and includes web-based exercises and homework assignments. The intervention comprised 7 regular sessions (45-60 min/session) and 1 booster session (4 weeks after the completion of the last session). From the second session onward, participants were able to follow 8 additional optional modules based on their personal needs, including sleep, perfectionism, alcohol use, rumination, self-worth, acceptance, appreciation and gratitude, and rest and relaxation. In sessions 5 and 6, participants could decide to either engage in content directed at changing negative cognitions or at exposure to fear situations. They could decide to choose 1 additional module per session, and they were free to repeat this module or choose other modules in later sessions. It was advised to do at least 1 and no more than 2 treatment sessions per week. For a full description of the intervention, see the study by Karyotaki et al [10].

Textbox 1. Overview of content of the iCare Prevent training.

Sessions

1. Behavioral activation: reducing incongruence
2. Behavioral activation: overcoming difficulties and pleasant activity scheduling
3. Psychoeducation
4. Cognitive restructuring
5. Problem solving I or exposure I
6. Problem solving II or exposure II
7. Plan for the future
8. Booster session (after 4 week)

Optional modules (sessions 2-7)

1. Rumination and worries
2. Acceptance
3. Relaxation
4. Reducing alcohol
5. Self-worth
6. Perfectionism
7. Appreciation and gratefulness
8. Sleep

Guidance

During the intervention, participants in both web-based conditions received support in the form of brief standardized emails (reminders) in the chat function of the web-based environment in case they were inactive. Participants received up to 3 weekly reminders by email. Moreover, participants in both web-based conditions could use the chat or messaging function to ask technical or user-related questions (eg, problems getting web-based access).

Participants in the computer-guided condition received automatically generated feedback messages upon completion of a module with the main aim of motivating students to carry on. In contrast, in the human-guided condition, the counselors provided detailed therapeutic feedback based on the student's output of the modules. The counselors spent approximately 30 minutes on providing feedback per session. On average, participants received feedback on 3.9 (SD 2.0; range 0-12) days after they completed their session. The counselors were 6 female bachelor's-level psychologists, 5 female and 1 male master's-level psychologist, and 1 male PhD-level health care psychologist with over 10 years of prior clinical experience, who also supervised the web-based guidance and baseline intakes weekly.

CAU Condition

Participants in the CAU condition were informed about or referred to conventional care services, both internal and external to the UvA. It should be noted that information about the available services was also provided to participants in both intervention groups. However, students in the CAU group were

strongly advised to seek support. Medical health services used during the trial were monitored in all groups through self-report questions after treatment (t3), at 6-month follow-up (t4), and at 12-month follow-up (t5). Participants in the CAU group were assessed at the same time points (with the same measures) as in the 2 intervention conditions.

Safety Monitoring

Ample attention was paid to warrant safety and decrease adverse effects during the trial. For this purpose, a *suicide protocol* was developed, describing in detail what the collaborating psychologists should do in case of an alert, which is available (only in Dutch) upon request (see [Multimedia Appendix 1](#) for details about the safety measures). To monitor for sharp increases in complaints, the Patient Health Questionnaire (PHQ; PHQ-4) [36] was administered before each treatment session or weekly via email (CAU). Suicide risk was monitored using item 3 ("feeling down, depressed, or hopeless") of the PHQ-4 and item 9 ("thought that you would be better off dead, or of hurting yourself") of the Beck Depression Inventory-II [37]. All items were rated on a 0 to 3 scale. The counselors and main researchers received an automatic alert and contacted the participant by telephone if they (1) reported feeling down, depressed, or hopeless "more than half the days" or "nearly every day" (score>1) and reported having thoughts that they would be better off dead "several days" (score>0) or (2) reported having thoughts that they would be better off dead "more than half of the days" or "nearly every day" (score>1). The counselors then interviewed the participant using 6 standardized questions to rate the suicide risk and took the necessary precautions after consulting a supervisor (JK). When deemed necessary, participants were called once more, and then referred

to the appropriate services. Of those allocated to 1 of the web-based intervention groups, 13.3% (71/534) had at least 1 alert and were contacted. Participants in the CAU condition were also contacted, but their data were not stored for pragmatic reasons.

Measures

Participants who fulfilled the inclusion criteria were telephoned by appointment by a trained psychologist. The MINI [33] was administered by telephone to establish *Diagnostic and Statistical Manual of Mental Disorders* (Fourth Edition) classifications with respect to mood and anxiety disorders, bipolar disorder, psychosis, and suicidal ideation. After the interview, students were briefly informed about their complaints and whether they could be included in the study.

The primary outcome measures were the PHQ (depression; PHQ-9) and the GAD-7, which both have good psychometric properties and are often used in the context of web-based interventions. The PHQ-9 [38] is a 9-item self-report questionnaire focused on depressive symptoms experienced over the past 2-week period, such as mood, sleep, and appetite. Items are rated from 0 (not at all) to 3 (nearly every day), with total scores ranging from 0 to 27. The PHQ-9 is suited for samples at risk for depression, with high specificity (0.94) and somewhat low sensitivity (0.77) in an unselected primary care sample, which is comparable to a student sample [39]. PHQ-9 scores of 5, 10, 15, and 20 represented mild, moderate, moderately severe, and severe depression, respectively [39]. The Cronbach α value in this study was .81 at baseline. The 7-item GAD [32] is a self-report questionnaire measuring anxiety symptoms (eg, “Not being able to stop or control worrying” and “Feeling nervous, anxious, or on edge”). Items are rated from 0 (not at all) to 3 (nearly every day), with total scores ranging from 0 to 21. Mild, moderate, and severe levels of anxiety are indicated by cut-off scores of 5, 10, and 15 on the GAD-7, respectively [32]. The GAD-7 questionnaire has good psychometric properties, including a good test-retest reliability (intraclass correlation coefficient=0.83) [32] and a good internal consistency (.79<Cronbach α <.91) [40]. The Cronbach α level in this study was .84 at baseline.

Secondary outcome measures for alcohol and drug use were administered at all time points. The Drug Abuse Screening Test–10 items [41] was used to screen for drug abuse over the past 12 months. The 10 items can be answered with “yes” (score=1) or “no” (score=0), and 1 item (“Are you always able to stop abusing drugs when you want to?”) is reverse keyed. In the case where the first item (“Have you used drugs other than those required for medical reasons?”) was answered with no (0), the other items were not administered because all remaining items are concerned with problems related to drug use. The internal consistency of this scale in this study was 0.70 at baseline. Alcohol use was measured using the abbreviated Alcohol Use Disorder Identification Test [42]. This 3-item instrument assesses the quantity and frequency of drinking and binge-drinking sessions. Items are ranked from 0 to 4; total scores range from 0 to 12. Higher scores indicate more hazardous drinking. Alcohol Use Disorder Identification Test

has been validated in student populations [6]. The internal consistency of this scale in this study was 0.73 at baseline.

We examined the quality of life with the subjective health item (visual analog scale) from the EQ-5D-5L at all time points except for midtreatment [43]. Medical service use was assessed with 2 items from the Treatment Inventory of Costs in Patients with Psychiatric Disorders [44] after treatment and at 6 months and 12 months. The first item includes the frequency of contact with conventional care services (eg, general practitioner, study adviser, psychologist or psychiatrist, medical specialist), and the second item includes the use of medication. We did not use this questionnaire to calculate implicit medical costs but to compare the use of medical services across treatment groups. Client satisfaction was assessed after treatment with the Client Satisfaction Questionnaire (CSQ-8) [45]. The CSQ-8 consists of 8 items (eg, “In an overall, general sense, how satisfied are you with the web-based health support you have received?”), scored on a 1 (“quite dissatisfied”) to 4 (“very satisfied”) scale, with total scores ranging between 8 and 32. A higher score on the CSQ-8 indicates a higher level of satisfaction related to the intervention. The CSQ-8 is a standardized satisfaction measure reporting very good internal consistency (Cronbach α =.83 to .93) and high validity [46]. The internal consistency of this measure was 0.93 in this study after treatment.

Finally, treatment adherence was measured by tracking the activities in Minddistrict. As outcome measures, we collected the average number of sessions completed and whether participants completed all sessions [47]. For descriptive purposes, we also extracted the duration of the treatment for those completing it and the number of times they scored above the cut-offs for a “suicide trigger.”

Statistical Analysis

Descriptive statistics, ANOVAs (for categorical and continuous data), and χ^2 tests (for categorical data only) were used to determine whether patient characteristics (sociodemographic and clinical) or use data (adherence) were similar across experimental conditions. To handle missing values for the main outcomes, multiple imputation was used. The Markov Chain algorithm was used to impute 50 data sets, with a maximum of 100 iterations for each imputation. This approach is particularly useful in case of high attrition (approximately 50%), as it minimizes the loss of statistical power when examining the relationship between variables [48]. On the basis of all 48 variables in our imputation model (including auxiliary variables), the (research) attrition rate was 48.7%. Note that recent studies have shown that the proportion of missing data should not be used as a guide for imputation per se, and when done responsibly, imputation for large amounts of missing data can still reduce bias [49]. Continuous data were imputed using predictive mean matching, while categorical variables were imputed using logistic regression. Various sociodemographic variables (eg, age, gender, and student status), the allocated experimental condition, and some auxiliary variables (eg, social anxiety, social phobia, and loneliness) were used as predictors only. In addition, all main outcomes of this study were used as predictors as well as values to be imputed. In the main analyses, the results were pooled across the 50 imputed data sets using

the rules to account for the uncertainty introduced by the imputation process by Rubin [50]. Our a priori power calculations were based on the mixed factors 3×3 interaction difference between the 3 treatment arms and 3 time points (baseline, midtreatment, and after treatment), and taking a dropout rate of 35% into account, as well as a correlation between repeated measures of $r=.50$. A total sample size of 276 (92 in each group) would be needed to estimate a small within-between interaction effect [11]. With a corrected P value of .025 based on 2 primary outcomes, the total sample size required would be 369, which is amply exceeded by our sample size of 801.

Linear mixed models were used to estimate treatment effects over time. We included a fixed between-subjects effect for intervention group and a fixed within-subjects effect for time (ie, assessments at 3 or 5 sequential time points, respectively), as well as their 2-way interaction. We modeled linear, quadratic, or asymptotic effects of time by, including first or flattened second-degree polynomials created with the `poly` function in R statistical software (R Foundation for Statistical Computing) [51] and compared their fit. We only interpreted results from the best-fitting model. This was a convex pattern for complaints (depression, anxiety, and drug and alcohol use) and a concave pattern for health concerning the long-term outcomes, and a linear pattern for the short-term primary outcomes. As we compared 3 groups in the main analyses, we coded condition as a factor with 3 levels. We also estimated a random intercept to allow for individual variations in the intercepts for each subject. We imposed an autoregressive structure to the residual covariance matrix to correct for autoregression of repeated assessments within the same subject. It assumes that correlations between any 2 elements are equal to (Pearson) r for adjacent elements, r^2 for 2 elements separated by a third, and so on.

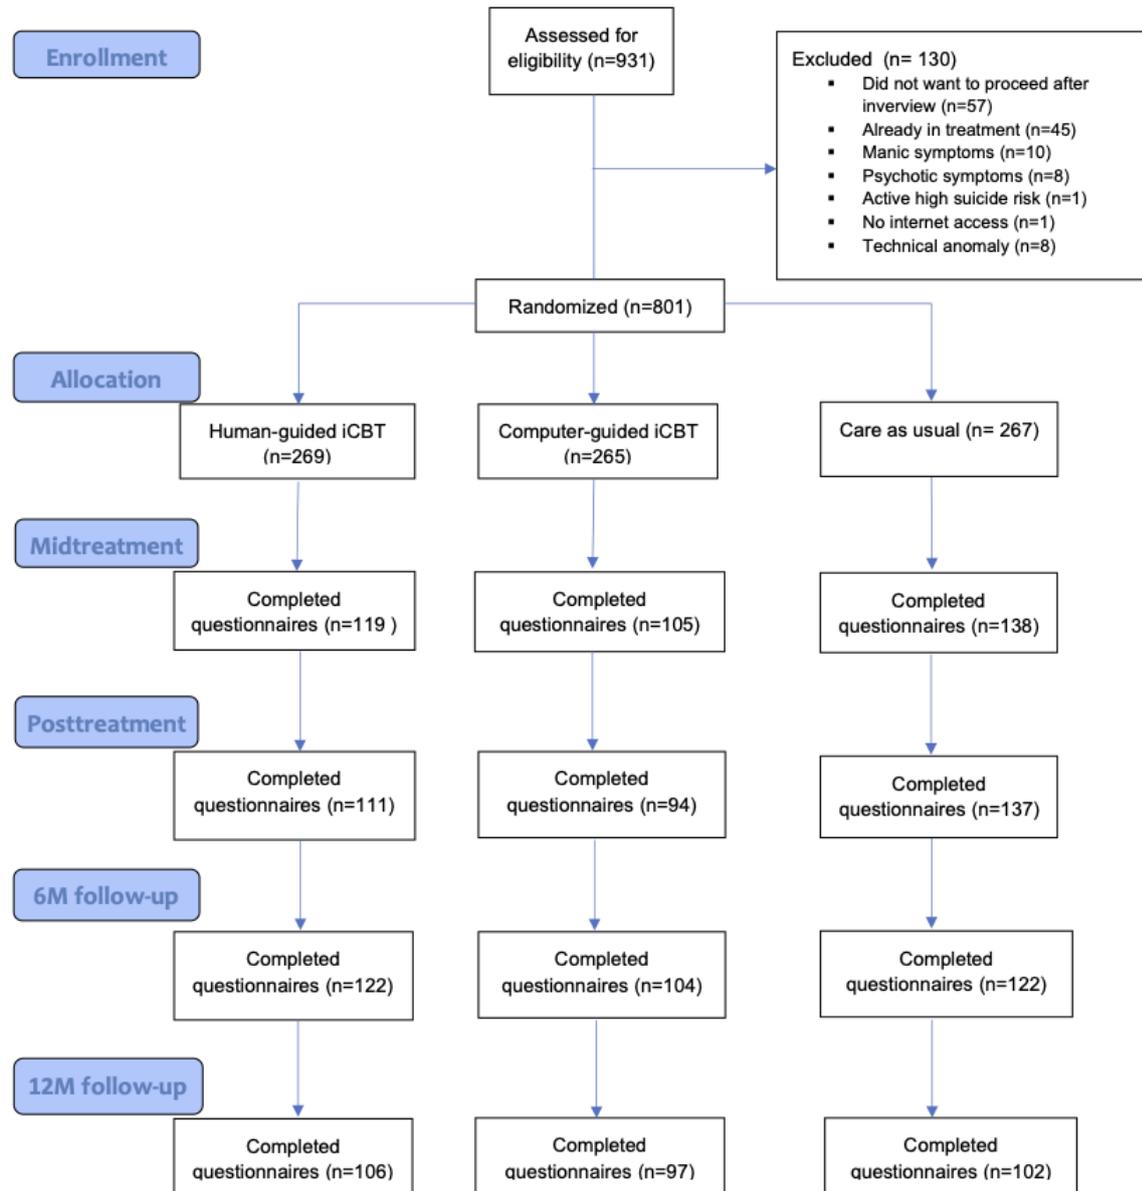

Maximum likelihood was used as the overall estimation method. Plots were made using the Grammar of Graphics framework (`ggplot`) in R statistical software.

For the primary outcomes, both short-term (t3) and long-term (t4 and t5) analyses were performed based on the 3 conditions, using CAU as the reference group and subsequently computer-guided iCBT as the reference group (for pairwise comparisons). For the secondary outcomes, only long-term outcomes were analyzed (t5). Bonferroni corrections were applied to all exploratory multilevel models to control for type I error related to multiple testing, while avoiding an increased risk for type II error. Thus, based on approximately 30 tests, corrected P values $\leq .002$ were considered statistically significant. P values between .002 and .025 were considered marginally significant. Effect sizes were calculated for marginally significant interactions, transforming t values to Pearson r [52]. For all main analyses, SPSS (version 28.0.1.0; IBM Inc) [53] was used.

Results

Random Allocation and Characteristics of Participants

A total of 801 participants were eligible and thus randomized across conditions: 269 were allocated to the human-guided group, 265 to the computer-guided group, and 267 to CAU group (Figure 1). The average age of participants was 23.9 (SD 4.6, range 17-55) years; 71.5% (573/801) were female, and 7.5% (6/801) of the participants indicated that their gender was *Other*. The sample contained 387 (48.3%) undergraduate students (mean age 21.6, SD 3.6 y; range 17-55 y), 315 (39.3%) master's students (mean age 25.5, SD 3.9 y; range 18-53 y), and 89 (11.1%) PhD students (mean age 29.4, SD 4.8 y; range 24-51 y).

Figure 1. Flow diagram illustrating the progression of participants through the stages of the study. iCBT: internet-based cognitive behavioral therapy.

The average level of alcohol use (mean 3.72, SD 2.09) was below the average for students and far below the cut-off for harmful drinking [6]. At baseline, the average number of classifications according to the MINI was 1.79 (SD 1.74). The most common diagnosis was a current depressive episode (287/801, 35.8%), followed by generalized anxiety disorder

(154/801, 19.2%). Around half of the sample had either no classification (222/801, 27.7%) or 1 potential disorder (219/801, 27.3%); the other half (360/801, 45%) had more than 1 potential disorder. For an overview of diagnostic classifications, see Table 1.

Table 1. Diagnostic and Statistical Manual of Mental Disorders (Fourth Edition) classifications based on the Mini-International Neuropsychiatric Interview administered at baseline (N=801).

^fBased on a lower number of participants (n=771).

^gBased on a lower number of participants (n=717).

Adherence and Satisfaction

For the human-guided condition, the largest groups were composed of those doing either 0 sessions (63/268, 23.5%) or 8 sessions (48/268, 17.9%). For the computer-guided condition, the most common number of sessions completed was also 0 (81/264, 30.7%), followed by 1 (53/264, 20.1%). The average number of sessions completed in the human-guided condition was 3.32 (SD 3.02; median 2, IQR 6); in the computer-guided condition, this was 2.54 (SD 2.75; median 1, IQR 4; $F_1=9.85$; $P=.002$). The completion rate (defined as 7 or 8 sessions done) for the human-guided condition was also significantly higher

than that for the computer-guided condition: 26.9% (72/268) versus 15.5% (41/264) cases completed treatment (n=532; $\chi^2_1=10.2$; $P=.001$). Finally, participants in both the human-guided and computer-guided conditions were significantly more satisfied after treatment compared with those in the CAU condition ($F_2=45.2$; $P<.001$).

Optional Modules and Psychological Care

Only those participants who completed more than 1 session were enabled to choose optional modules (289/534, 54.1%). Among those participants, a total of 28.5% (83/291) completed

1 optional module, 21.6% (63/291) completed 2 modules, and 49.8% (145/291) completed 3 to 6 modules (median 2, IQR 3). There were no significant differences between the iCBT conditions in terms of optional modules made ($F_1=0.74$; $P=.39$). Of those enabled to choose an optional module, 13.7% (40/291) of participants chose the optional module for alcohol use-related problems. Asked retrospectively at 6 months, participants in the CAU condition reported to have visited a psychologist or psychiatrist more often (65/265, 24.5%) during the 6 months prior than the participants in the human-guided (38/269, 14.1%)

or computer-guided (49/267, 18.3%) conditions ($n=795$; $\chi^2_2=7.96$; $P=.02$).

Efficacy Over Time

For the course of symptoms over time across the 3 conditions, see [Figure 2](#) (depression) and [Figure 3](#) (anxiety). For the estimated marginal means of the 2 primary outcome measures across treatment groups at each assessment point, see [Tables 2](#) and [3](#).

Figure 2. Mean depression over time by condition. PHQ-9: Patient Health Questionnaire–9 Note. Vertical lines represent error bars (with a 95% confidence interval); non-overlapping error bars indicate that the true means are likely to be different from each other.

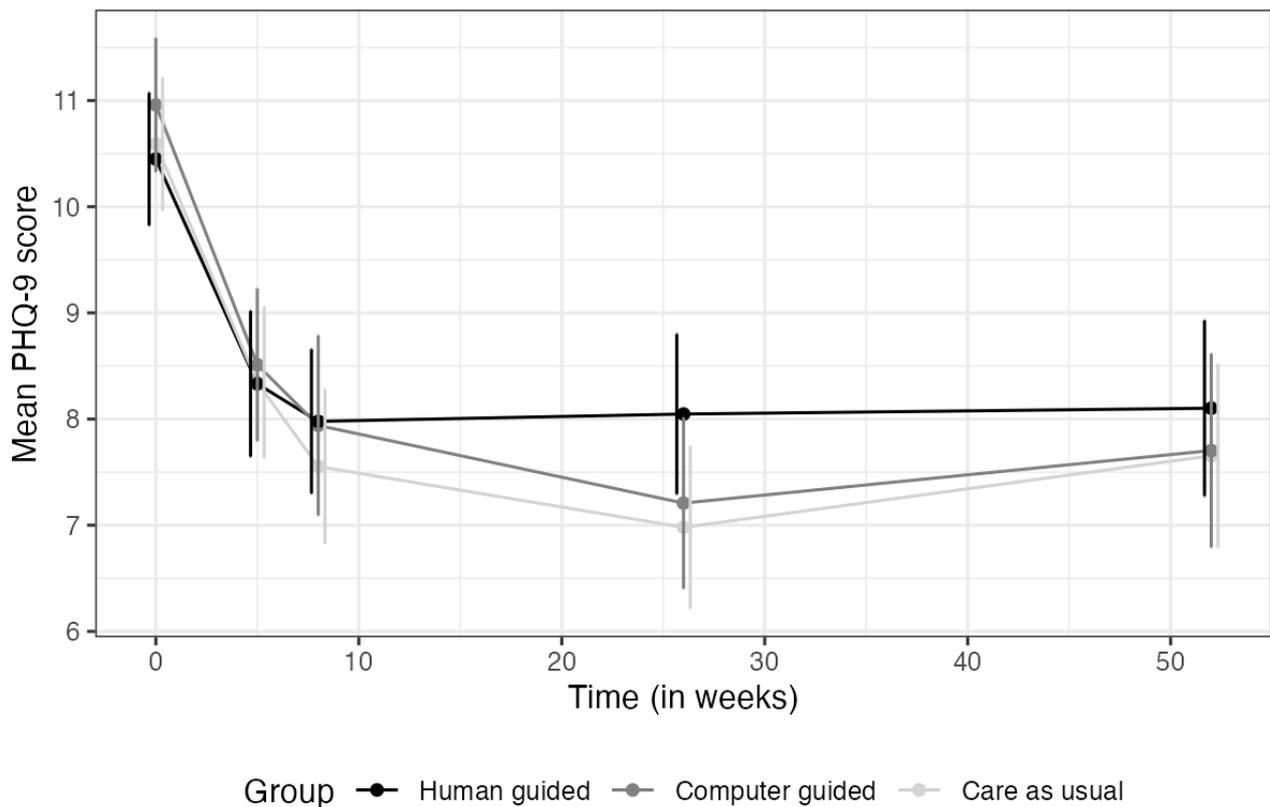

Figure 3. Mean anxiety over time by condition. GAD-7: Generalized Anxiety Disorder scale–7 items. Note. Vertical lines represent error bars (with a 95% confidence interval); non-overlapping error bars indicate that the true means are likely to be different from each other.

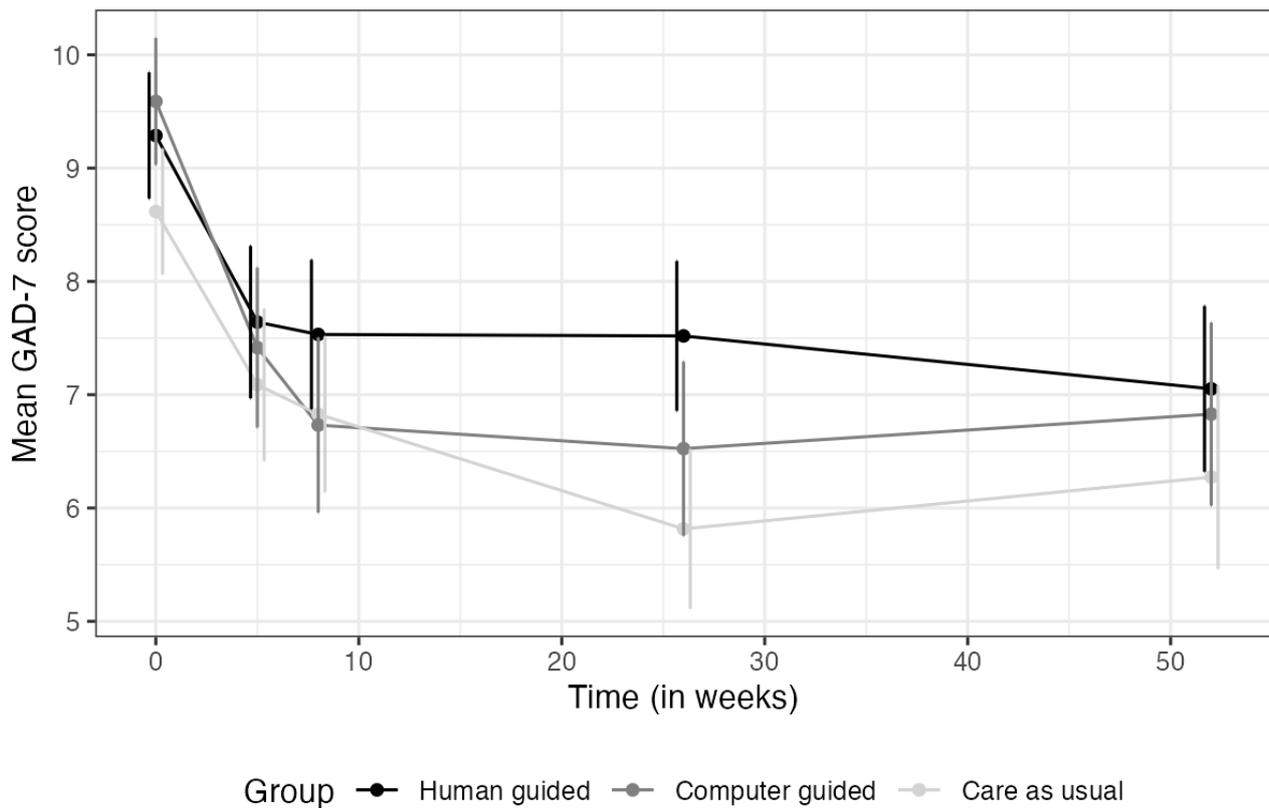

Table 2. Estimated marginal means and SEs for the primary outcome measures at all assessment points for the 3 conditions—depression (Patient Health Questionnaire–9).

Condition	Time				
	Baseline, mean (SE)	Midtreatment, mean (SE)	After treatment, mean (SE)	6 months, mean (SE)	12 months, mean (SE)
Human guided	10.591 (0.318)	8.345 (0.363)	7.553 (0.371)	6.980 (0.391)	7.654 (0.441)
Computer guided	10.958 (0.321)	8.511 (0.366)	7.940 (0.432)	7.208 (0.411)	7.703 (0.465)
Care as usual	10.449 (0.319)	8.332 (0.350)	7.978 (0.347)	8.047 (0.385)	8.102 (0.422)

Table 3. Estimated marginal means and SEs for the primary outcome measures at all assessment points for the 3 conditions—anxiety (Generalized Anxiety Disorder scale–7 items).

Condition	Time				
	Baseline, mean (SE)	Midtreatment, mean (SE)	After treatment, mean (SE)	6 months, mean (SE)	12 months, mean (SE)
Human guided	8.617 (0.283)	7.088 (0.342)	6.828 (0.350)	5.816 (0.359)	6.273 (0.412)
Computer guided	9.589 (0.285)	7.416 (0.360)	6.732 (0.394)	6.524 (0.392)	6.829 (0.412)
Care as usual	9.288 (0.284)	7.641 (0.343)	7.532 (0.336)	7.519 (0.337)	7.052 (0.373)

Short-Term Efficacy (t3)

According to our preregistered protocol, we analyzed the efficacy over time until after treatment (t3) for the 2 primary outcome measures. For depression, no significant time×group interaction was observed when comparing both the human-guided (B=.08, 95% CI –.05 to .21; P=.25) and the computer-guided (B=.06, 95% CI –.09 to .21; P=.43) conditions to CAU. For the direct comparison between human-guided and

computer-guided iCBT, no significant time by treatment interaction was found (B=.02, 95% CI –.14 to .17; P=.86).

For anxiety, none of the interventions differed significantly from CAU over time: *human-guided versus CAU* (B=.01, 95% CI –.11 to .13; P=.89) and *computer-guided iCBT versus CAU* (B=.13, 95% CI –.003 to .27; P=.05). No significant differences were found when comparing human-guided and computer-guided iCBT directly with each other (B=–.12, 95% CI –.26 to .01; P=.08).

Long-Term Efficacy for the Primary Outcomes (t4)

Next, we analyzed the primary outcomes until t4 (6 months) follow-up. Over 6 months, no significant time by condition interactions were found for either depression or anxiety, indicating that the slopes for the 3 conditions were similar. Some comparisons were marginally significant (see [Tables 4 and 5](#) for coefficients). Next, we added the covariate of “psychological care” to control for this higher level of care in the CAU condition. For both depression and anxiety, results remained

marginally significant for both intervention conditions compared with CAU yet did not reach the corrected P value of .002. For depression, human-guided iCBT was marginally more efficacious than CAU ($B=3.21$, 95% CI 0.54-5.89; $P=.02$; $r=0.08$). The computer-guided condition was also marginally more efficacious compared with CAU ($B=3.33$, 95% CI 0.61-6.05; $P=.02$; $r=0.08$). For anxiety, similar results were obtained: *human-guided iCBT versus CAU* ($B=3.08$, 95% CI 0.77-5.40; $P=.01$; $r=0.09$) and *computer-guided iCBT versus CAU* ($B=3.12$, 95% CI 0.62-5.62; $P=.02$; $r=0.08$).

Table 4. Long-term (6-month) results of linear mixed model for pairwise comparisons of conditions (depression).

Fixed effects	Comparison					
	Human guided vs care as usual		Computer guided vs care as usual		Human guided vs computer guided	
	B (SE)	P value	B (SE)	P value	B (SE)	P value
Intercept	8.22 ^a (0.29)	<.001	8.22 (0.29)	<.001	7.66 (0.30)	<.001
Time	4.49 (0.97)	<.001	4.49 (0.97)	<.001	7.39 (0.98)	<.001
Condition	-0.56 (0.41)	.18	-0.30 (0.44)	.50	-0.26 (0.43)	.55

^aItalicized values are statistically significant ($P<.05$).

Table 5. Long-term (6-month) results of linear mixed model for pairwise comparisons of conditions (anxiety).

Fixed effects	Comparison					
	Human guided vs care as usual		Computer guided vs care as usual		Human guided vs computer guided	
	B (SE)	P value	B (SE)	P value	B (SE)	P value
Intercept	7.72 ^a (0.25)	<.001	7.72 (0.25)	<.001	6.59 (0.27)	<.001
Time	3.40 (0.83)	<.001	3.40 (0.83)	<.001	6.01 (0.88)	<.001
Condition	-1.13 (0.36)	.002	-0.65 (0.41)	.11	-0.48 (0.40)	.23
Time×condition	2.61 (1.15)	.02	2.84 (1.27)	.03	-0.24 (1.29)	.85

^aItalicized values are statistically significant ($P<.05$).

Long-Term Efficacy for the Primary and Secondary Outcomes (t5)

All material related to the outcomes at t5 can be found in [Multimedia Appendix 2](#) for the primary outcomes and [Multimedia Appendix 3](#) for the secondary outcomes. In summary, none of the interactions between time and treatment

conditions were significant. However, time effects for depression, anxiety, and drug use were highly significant, indicating that all groups improved over time ($P<.001$). The time effects for alcohol use and subjective health were not significant ($P=.08$ and $.30$, respectively). Figures for the secondary measures are shown in [Figures 4-6](#).

Figure 4. Alcohol use over time. AUDIT-C: Alcohol Use Disorder Identification Test alcohol consumption questions. Note. Vertical lines represent error bars (with a 95% confidence interval); non-overlapping error bars indicate that the true means are likely to be different from each other.

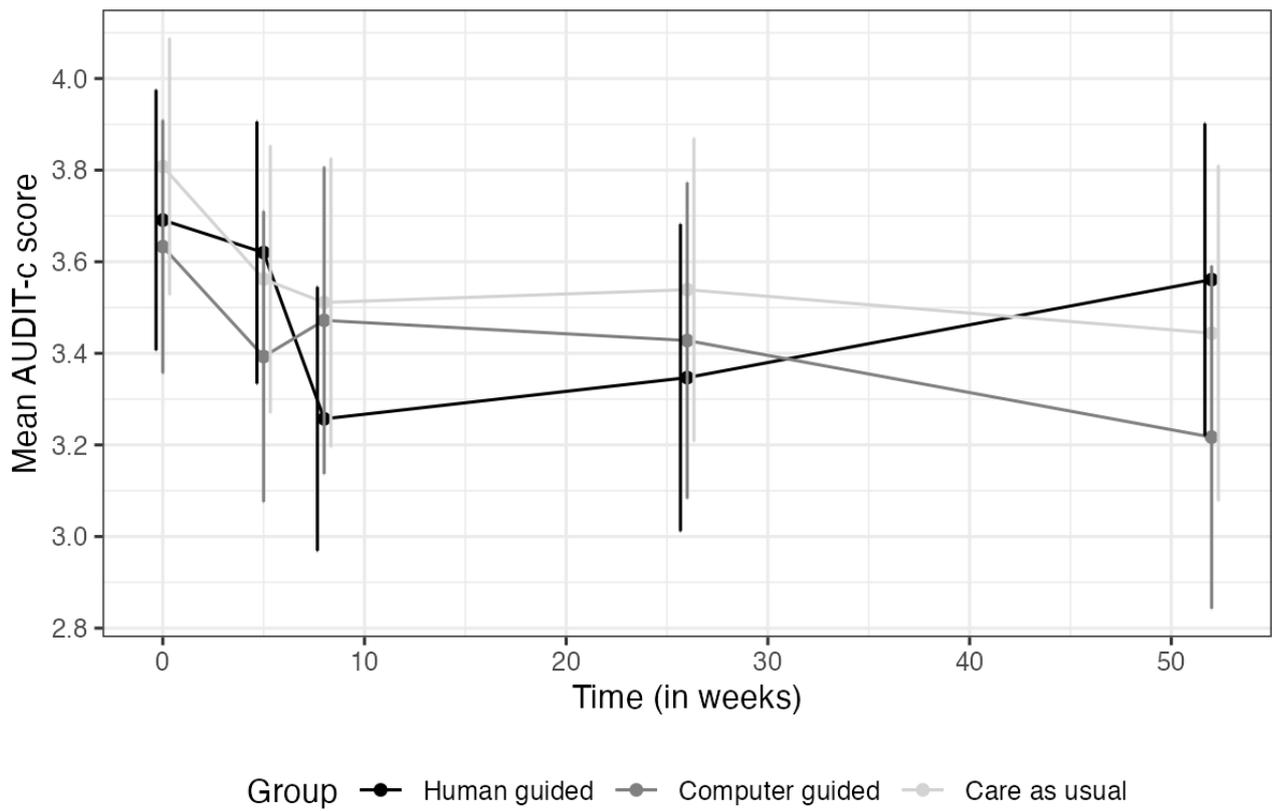

Figure 5. Drug use over time. DAST-10: Drug Abuse Screening Test–10 items. Note. Vertical lines represent error bars (with a 95% confidence interval); non-overlapping error bars indicate that the true means are likely to be different from each other.

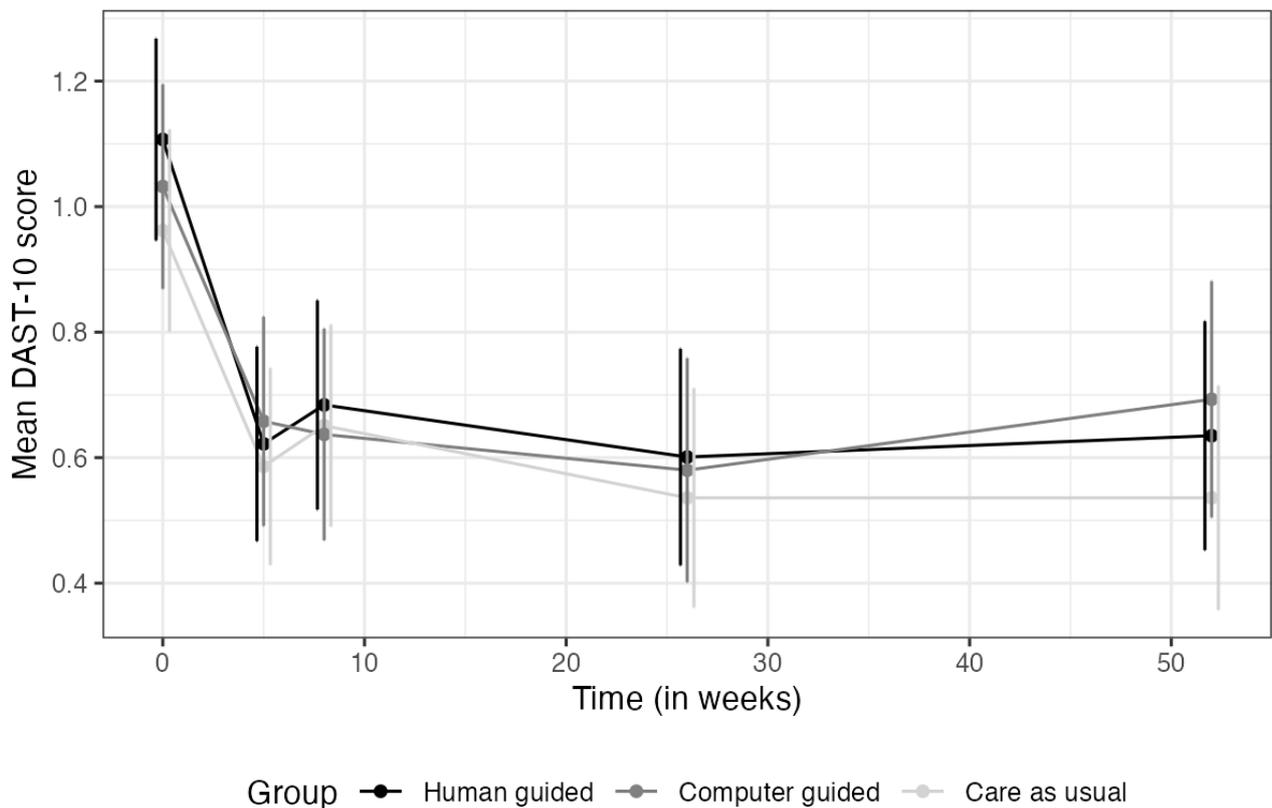

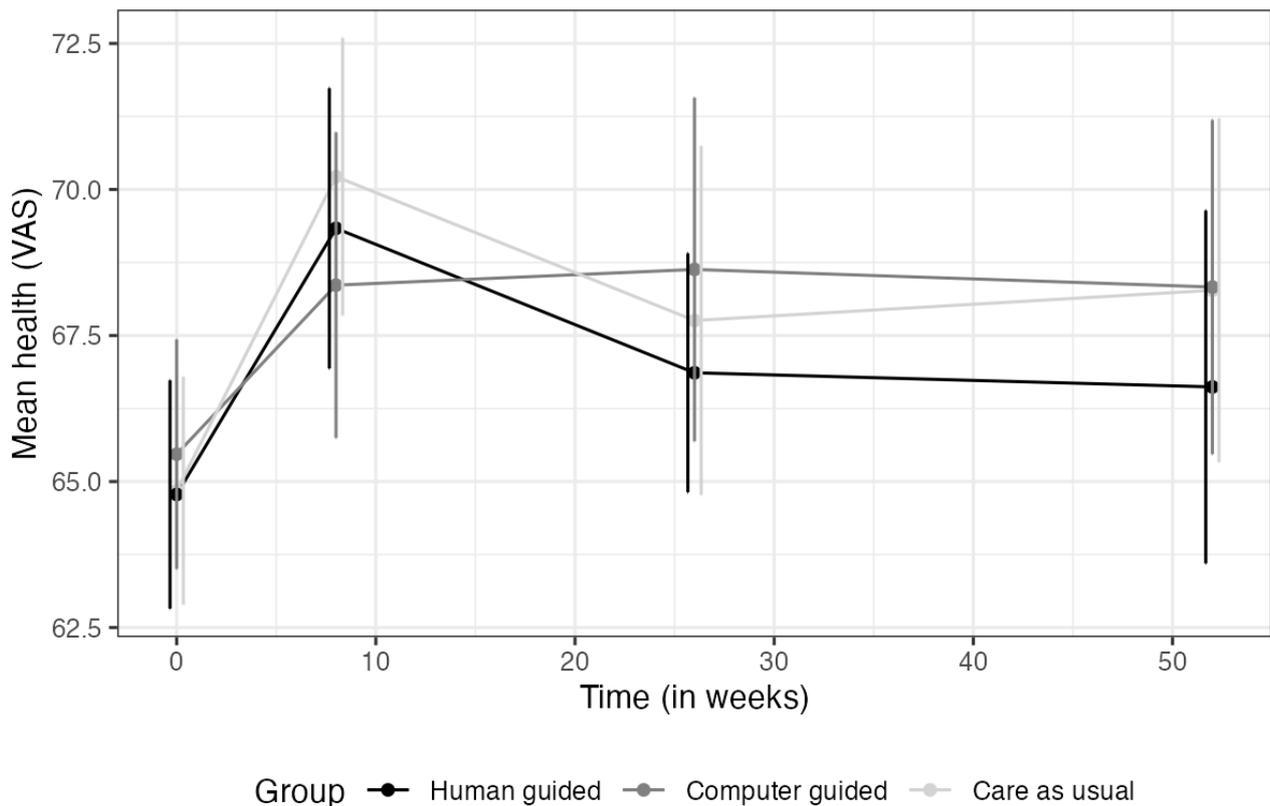

Figure 6. Subjective health over time. VAS: visual analog scale. Note. Vertical lines represent error bars (with a 95% confidence interval); non-overlapping error bars indicate that the true means are likely to be different from each other.

Sensitivity Analyses (t4)

To add further validity to our results, we included 2 additional sensitivity analyses (see [Multimedia Appendix 4](#) for details). First, we reran analyses on the groups that did at least 1 session (655/801, 81.8%), excluding those who did 0 sessions. The intent of this analysis was to assess whether those with at least some adherence to treatment, regardless of completed assessments, had a similar outcome compared to the whole group (this is an imputed data set). For both depression and anxiety, human-guided and computer-guided iCBT were marginally more efficacious than CAU ($.02 < P < .05$; $0.07 < r < 0.09$).

Second, we reran the analyses for the original data set without imputation. This latter data set contained all subjects, yet most of them had at least 1 missing value which was not corrected for. With this analysis, we examined a potential difference between the imputed and the unimputed data set, which may indicate a bias. For both depression and anxiety, human-guided and computer-guided iCBT were significantly more efficacious than CAU ($P < .001$; $0.11 < r < 0.16$).

Discussion

Principal Findings

In this study, we compared 2 types of web-based interventions with CAU, both regarding the short and long-term outcomes in a large sample of university students with elevated levels of depression and anxiety symptoms. Overall, reductions in anxiety

and depression were seen in all 3 conditions over time, yet no significant differences between conditions were observed over time.

In the CAU group, approximately one-quarter (65/265, 24.5%) of participants sought care from a mental health care professional during the intervention period. When controlling for this psychological care in the CAU condition, both iCBT conditions were marginally more efficacious compared with CAU across the 6-month period. This implies that iCBT is a viable alternative for CAU in a large educational setting. It seems that most students found the help they needed, or at least felt reassured to know that help was available.

No significant differences in symptoms were found in the direct comparison between the human-guided intervention and computer-guided intervention. However, as expected, the difference between human-guided and computer-guided was present for the adherence measures; students in the human-guided condition completed more sessions and subsequently did more optional modules that focused on specific problem areas. It could be that human guidance encouraged students to persist with the intervention. However, higher adherence to the human-guided intervention was not necessarily associated with larger benefits, as indicated by our analyses of symptoms. This could be due to the small yet significant difference in adherence between the conditions (approximately 1 session), which may be too small to yield an observable and clinically relevant difference. Future studies could test the hypothesis whether human guidance indirectly impacts symptom

outcomes through its effect on adherence (ie, mediation analysis).

Comparison to Previous Studies

In line with Karyotaki et al [10], both web-based interventions did not outperform the CAU condition. Our finding replicates and extends this previous finding, as our study included more students and students with higher levels of anxiety and depression. Some studies suggested that therapist-guided iCBT is more efficacious for individuals with elevated levels of anxiety or depression [25,27], but this assumption was not supported by our findings. The fact that the interventions were not more efficacious than CAU could have several reasons. First, it could be considered that our pattern of findings reflects regression to the mean, which is typical in longitudinal studies in which participants are selected on the basis of elevated scores at baseline [54]. Any potential effect of the interventions may have been overshadowed by the effect of this statistical artifact, which would have been present in all conditions. Second, although comparable to other web-based intervention studies, the adherence rates in this study were rather low, resulting in a potential loss of efficacy. Only a quarter (72/268, 26.9%) of the participants completed the human-guided intervention. In the computer-guided condition, only half (130/264, 49.2%) of the participants did ≥ 2 sessions. The attrition rates are generally high in internet interventions (especially in so-called unguided formats), and this should be improved in future trials [28]. A third explanation could be that students who do not seek help on their own initiative may have a diminished treatment response, due to factors of decreased intrinsic motivation, low awareness of their illness burden, and unrealistic expectations about the time investment required.

The lack of any significant differences between human-guided and computer-guided conditions (P values $>.025$ as per preregistration) is not in line with previous findings from a meta-analysis showing that human guidance is slightly yet significantly more efficacious than *technological guidance* [28], at least in the short run, and begs further explanation. It could be a result of the fact that the intensity of guidance in both conditions was quite similar. Although students in the human-guided condition received weekly personalized feedback from psychologists, students in the computer-guided condition received a considerable amount of support as well, including automated feedback, regular reminders sent by a psychologist, personalized responses to queries in the chat, and phone calls in case of suicide alerts. Of those who were actively engaged on the eHealth platform, around 13.3% (71/534) received such phone calls. This may have led to the impression among students in the computer-guided condition that they did receive personalized support and that they perceived a sense of *therapeutic presence*, that is, someone in the outside world that had their concerns in mind. An alternative reason could be that psychologists in the human-guided condition, although they received supervision, were not specifically trained for this intervention and they were not delivering therapy in a strict sense, but rather some form of support, which may have been experienced as disappointing for some students, who expected more e-therapy, as qualitative interviews after the trial suggested (JA Koelen, unpublished data, April 2024). Third, students in

the computer-guided condition received immediate, automatized feedback, whereas human guidance was delivered after relatively long intervals between sessions, which took an average of 3.9 (SD 2.0) days. Further research should aim to clarify to what extent these factors contribute to varieties in effectiveness. A final explanation could be that the differences between *guided* and *unguided* web-based interventions (often iCBT) reported in the literature refer to short-term outcomes, as emerging evidence indicates that the differences may be short-lived [27].

The lack of a significant difference between the human-guided and computer-guided conditions also raises questions concerning the working mechanisms of web-based therapy [55]. As with regular therapy, it is still unclear whether web-based therapy works through mechanisms common to all therapies (eg, the therapeutic alliance, the mobilization of hope), or those specific to certain types of therapies (eg, cognitive restructuring in CBT), or both. Notably, technical components of iCBT (ie, specific mechanisms) were present in both conditions, and the nonexistent difference between conditions would plea for the effectiveness of such components. Previous qualitative analyses of emails from web-based counselors providing iCBT suggested that interventions that were regarded as most helpful (and were associated with better outcomes) were best classified as *common factors* [56,57]. These interventions included validation of completed exercises, anticipation of pending assignments (ie, changing expectations of personal effectiveness), as well as empathy and self-disclosure of web-based counselors. Some of these interventions were also provided with the automated feedback in the computer-guided condition, which could also explain the absence of significant differences between conditions.

Strengths and Limitations

A major strength of this trial, first, is that we compared a human-guided and a computer-guided form of iCBT head-to-head, and to an active control group. Second, our sample was relatively large, enabling us to detect small interaction effects. Third, we included students with elevated levels of symptoms, with nearly three quarters of the students (579/801, 72.3%) presenting with at least one potential mental disorder, which makes this a representative sample of students in terms of burden of disease [3]. Finally, we assessed the long-term outcome of our interventions.

Several limitations need to be considered when interpreting the results of this study. First, nearly all participants were included during the COVID-19 pandemic, which reached its first peak in the Netherlands in May 2020. More precisely, only 1.9% (15/801) of the participants completed the entire study before the onset of the COVID-19 pandemic. Intervention effects may have been distorted due to this crisis, for instance, due to an increase in symptoms during the trial [34]. Second, the number of PhD students included in this study was relatively low, which needs to be considered when extrapolating our findings to US student samples. This small number is mainly attributable to the clear distinction between master's and PhD students that is made in the Netherlands, where a Master of Science degree is the typical end point of study and only few students are selected to do a PhD trajectory. Third, as expressed by some students,

the modules were *text heavy* and lacked interactive functionalities, which may have diminished its attractiveness, so this could be improved. Yet, the intervention had been adapted especially for students, and the text was enriched by elements of persuasive design, which are known to increase adherence, such as creating an overview, use of metaphors, and creating a sense of control and purpose [58]. Fourth, in hindsight, we might have recruited more psychologists for guidance, which would have resulted in swifter feedback, although it is debatable whether swifter feedback results in greater efficacy [59]. Fifth, the relatively large amount of missing data could have introduced a bias in our data. However, we limited that risk of bias by using the Markov Chain algorithm, which is adept at capturing data dependencies, and maintaining data set integrity [60]. A recent meta-analysis [28] of web-based interventions found an average of 48% attrition for human-guided interventions and an even higher percentage (51%) for those using technological guidance only. These figures are comparable to those reported in this study. Nevertheless, a major interest of future studies should be to decrease dropout. Sixth, future research could aim to clarify the optimal length and intensity for web-based treatments, as we followed a classic format with weekly session. Some studies of regular (face-to-face) therapy have shown, for example, that a more concentrated approach (ie, an equal number of sessions with

increasing frequency) can bring about more optimal outcomes [61]. Seventh, some studies have shown that rewarding students for completing questionnaires, as was done in this trial, could lead to an underestimation of intervention effects [20]. Eighth, we could not establish the effect of sessions made irrespective of the intervention type because the number of sessions completed was contingent upon the allocated condition. This requires another type of experimental research. Ninth, future studies should pay more attention to individual differences and moderators of outcome. Finally, we assessed the outcome only in terms of symptoms, and not in terms of underlying vulnerabilities (eg, elevated levels of negative affect), which would have suited a transdiagnostic approach.

Conclusions

In conclusion, the results of this study indicated both iCBT interventions were not inferior to CAU (which did include the possibility to visit other mental health care professionals, who had a limited capacity). Moreover, we found that 1 type of iCBT (human-guided) was not more efficacious than the other (computer-guided). We conclude that iCBT offers a feasible and viable alternative for the regular health services in a university setting, which are often hard to access for students. Future studies should also examine cost-effectiveness to determine whether the additional investment in web-based psychologists is worthwhile.

Acknowledgments

The authors would like to thank Ruben Atteveld, Matilda Nottage Chantalle Roetink, Dieuwke Vanwersch, Pieta Vanwersch, Lotte van der Vegt, Sabine de Vet, and Anne Vonk for their contributions as web-based counselors. This study was funded by the University of Amsterdam (UvA). Open access publication fees were paid for by the UvA Student Physicians. We are indebted to Peter ten Klooster at the University of Twente for his invaluable support with the data imputation

JK was affiliated with the University of Amsterdam, Amsterdam, Netherlands at the time of the trial and is currently affiliated with the University of Twente, Enschede, Netherlands.

Abstract

Background: Responsible digital care refers to any intentional systematic effort designed to increase the likelihood of a digital care technology developed through ethical decision-making, being socially responsible and aligned with the values and well-being of those impacted by it.

Objective: We aimed to present examples of action opportunities for (1) designing “technology”; (2) shaping the “context” of use; and (3) adjusting the behavior of “users” to guide responsible digital care for people with intellectual disabilities.

Methods: Three cases were considered: (1) design of a web application to support the preparation of meals for groups of people with intellectual disabilities, (2) implementation of an app to help people with intellectual disabilities regulate their stress independently, and (3) implementation of a social robot to stimulate interaction and physical activity among people with intellectual disabilities. Overall, 26 stakeholders participated in 3 multistakeholder workshops (case 1: 10/26, 38%; case 2: 10/26, 38%; case 3: 6/26, 23%) based on the “guidance ethics approach.” We identified stakeholders’ values based on bottom-up exploration of experienced and expected effects of using the technology, and we formulated action opportunities for these values in the specific context of use. Qualitative data were analyzed thematically.

Results: Overall, 232 effects, 33 values, and 156 action opportunities were collected. General and case-specific themes were identified. Important stakeholder values included quality of care, autonomy, efficiency, health, enjoyment, reliability, and privacy. Both positive and negative effects could underlie stakeholders’ values and influence the development of action opportunities. Action opportunities comprised the following: (1) technology: development of the technology (eg, user experience and customization), technology input (eg, recipes for meals, intervention options for reducing stress, and activities), and technology output (eg, storage and use of data); (2) context: guidelines, training and support, policy or agreements, and adjusting the physical environment in which the technology is used; and (3) users: integrating the technology into daily care practice, by diminishing (eg, “letting go” to increase the autonomy of people with intellectual disabilities), retaining (eg, face-to-face contact), and adding (eg, evaluation moments) certain behaviors of care professionals.

Conclusions: This is the first study to provide insight into responsible digital care for people with intellectual disabilities by means of bottom-up exploration of action opportunities to take account of stakeholders’ values in designing technology, shaping the context of use, and adjusting the behavior of users. Although part of the findings may be generalized, case-specific insights and a complementary top-down approach (eg, predefined ethical frameworks) are essential. The findings represent a part of an ethical discourse that requires follow-up to meet the dynamism of stakeholders’ values and further develop and implement action

opportunities to achieve socially desirable, ethically acceptable, and sustainable digital care that improves the lives of people with intellectual disabilities.

KEYWORDS

ethics; value-based health care; digital technology; intellectual disability; digital care

Introduction

Digital Care

As digital tools have shown great potential to enhance health care and well-being services, digital care plays a central role in the policies and plans of governments and care organizations to continue to provide good care efficiently [1-3]. Digital care refers to technology and data that inform and improve health care provision [4]. Unfortunately, today, digital care is often not aligned with the needs and values of its users and other stakeholders [5,6]. Not aligning digital care with stakeholders' needs and values results in low technology uptake. Although the importance of involving all relevant stakeholders in digital care innovation is widely accepted [7,8], they are insufficiently involved and, often, involved very late in digital care innovation [9]. Consequently, time and effort are wasted [10], and the clinical appropriateness and usability of digital care are compromised [11].

Digital care is found to have a significant impact on people's lives, especially for those with intellectual disabilities who often receive life-long care. For people with intellectual disabilities, technologies are not only applied to promote health but also to enhance independence and quality of life, such as being able to participate in the society, which creates more educational, vocational, and leisure opportunities [12-14]. In long-term care organizations, integrating technology in daily practice for people with intellectual disabilities requires insight into the needs and values of the people with intellectual disabilities themselves, as well as those of their care professionals who guide them through daily life and need to adapt their guiding strategies, the IT support staff of the care organization who provide technical support for the digital solutions, the human resources professionals who need to integrate the technology in their regular training programs within the care organization, and the data specialists who need to make decisions about incorporating the data provided by the digital care technology. Considering the increasing influence of digital care on several domains of the life of people with intellectual disabilities [13], the design and implementation of technologies should be well considered.

Responsible Design and Implementation

Ideally, the design and implementation of digital care for people with intellectual disabilities are "responsible": to include any intentional systematic effort designed to increase the likelihood of a digital care technology developed through ethical decision-making, being socially responsible and aligned with the values and well-being of those influenced by it [15]. Values, defined as "convictions or matters that people feel should be strived for in general and not just for themselves to be able to lead a good life or realise a good society" [16], are commonly

considered within ethical discourse. These values function as moral compasses that guide certain actions, for example, in the design and implementation of technology. However, the ethics of digital care is not a common subject of study [17,18]. There is limited empirical evidence describing how to address stakeholders' values within their context, in this case, the context of long-term care for people with intellectual disabilities, even though it is broadly recognized that responsible design and implementation of digital care require insight into and sensitivity toward specific contexts of use [17,19,20]. There is a need for context-specific studies about how certain values matter to the stakeholders of particular technologies and how these values can be accounted for in technology design and implementation.

Guidance Ethics

The "guidance ethics approach" [21] is a relatively new method for reflection about and guidance for the responsible design and implementation of technologies in the context of use, developed by the ECP (Platform for the Information Society), the Netherlands. The approach is applied in various fields, such as municipalities, government, security, police, and health care sector, and regarding various cases, such as a biofeedback app for people with profound intellectual and multiple disabilities and challenging behavior or the use of artificial intelligence for nighttime monitoring in disability care [22]. The guidance ethics method involves a multistakeholder workshop, in which stakeholders' values are identified based on an exploration of the experienced and expected positive and negative effects of using a specific technology. Subsequently, workshop participants mutually formulate action opportunities to account for these values in the specific context of use. In this study, we used this method to identify stakeholders' values and formulate action opportunities for the responsible design and implementation of specific technologies used in long-term care for people with intellectual disabilities.

The guidance ethics approach—more extensively described in the *Methods* section—has several advantages compared with other research methods focused on ethics in design. One of the most well-known methodologies considering ethics through values in design is "Value Sensitive Design" [23]. Although the idea of embedding values in technology originated from this method, it does not provide the tools to empirically study values. However, guidance ethics is practical and hands-on, allowing stakeholders in a workshop to contribute to identifying the values affected by the use of technology. There are tools, such as the "interactive technology assessment" [24], that also provide hands-on tools, but these solely focus on studying the values of 1 user. Guidance ethics enables to involve a diverse group of stakeholders to identify a comprehensive set of values [7] and facilitates stakeholders to better understand the position of others [25]. Although there are methods, such as an

evidence-informed, deliberative process approach to a health technology assessment [7,26] that involves multiple stakeholders also, this method, in contrary to guidance ethics, does not translate insights into concrete action opportunities for responsible technology use. To the best of our knowledge, guidance ethics is the only method that enables the study of values involving multiple stakeholders and directly translates these into concrete action opportunities.

Objective

In this study, we applied the guidance ethics approach to three digital care technologies that are currently being developed or implemented within care organizations for people with intellectual disabilities:

1. The design of “Kookapp for groups” (developed by care organizations *Amerpoort* and *Reinaerde* and IT company *Ilionx*, Utrecht): this is a web application to support group workers with the preparation of healthy and tasty meals for groups of people with intellectual disabilities, from choosing recipes and buying ingredients to cooking and serving the meals.
2. The implementation of the “SignaLEREN” app (developed by care organization *Koraal* and IT company *Ivengi*, Maastricht): this app is used by people with intellectual disabilities or autism spectrum disorder to regularly gauge their emotional state; in the case of increased stress, they can choose a personalized stress-reducing activity within the app, such as watching a video clip or listening to certain music.
3. The implementation of SARA (developed by *SARA Robotics*, Eindhoven): this is a social robot that provides activities (eg, exercises, games, and music) during day care to stimulate interaction and physical activity among older people with intellectual disabilities.

With these 3 cases, we aimed to present examples of action opportunities to guide the responsible use of digital care for people with intellectual disabilities.

Methods

Participants

The 4 care organizations of the 3 cases participated in the Innovation Impulse Disability Care, a 3-year program initiated by the Dutch Ministry of Health, Welfare, and Sport in 2019. This program aimed to accelerate digital transformation in long-term care by providing support in implementing technology in the everyday practice of 26 disability care organizations [27]. In each organization, the implementation started by defining a topical care issue from the perspective of and together with people with a disability, followed by the selection of a technology that contributed to the solution of this care issue. In addition, organizations evaluated their IT and organizational readiness to implement the selected technology [28,29]. The care issues included, for example, improving day structure [30] or sleep-wake patterns [31], lowering stress levels, and increasing independent living [32]. Digital care technologies included sensors, domotics, social robotics, and apps. The Innovation Impulse program also entailed researching the factors influencing the implementation (NM Siebelink, unpublished data, 2024).

All 26 care organizations were invited to apply for participation in this study. Guidance ethics workshops were conducted in 4 care organizations, for the 3 cases described previously. Project leaders of the Innovation Impulse program within each care organization invited a purposefully diverse group of workshop participants from their organizations, for example, people with intellectual disabilities, relatives, care professionals, policy advisors, managers, members of the board of directors, IT staff, and technology developers.

In total, 26 individuals participated in this study. Participants’ characteristics are presented in Table 1. No personal data such as sex or age were collected. Almost all participants had some knowledge about the specific technology: of the 26 participants, 13 (50%) considered themselves informed, 9 (35%) had practical experience with the technology, and 4 (15%) were unfamiliar with the respective technology before participating in the workshop.

Table 1. Study participants’ characteristics.

Participant	Case 1: Kookapp for groups (n=10), n (%)	Case 2: SignaLEREN app (n=10), n (%)	Case 3: social robot, SARA (n=6), n (%)
People with intellectual disabilities (or a representative)	2 (20)	0 (0)	0 (0)
Management or policy maker	2 (20)	1 (10)	1 (17)
IT staff or technology developer	1 (10)	2 (20)	2 (33)
Care professional or team leader	4 (40)	3 (30)	2 (33)
Other (eg, project leader or consultant)	1 (10)	4 (40)	1 (17)

Procedure and Materials

This study had a qualitative research design, using guidance ethics workshops to collect data. In total, three 3.5-hour multiple stakeholder workshops were conducted by trained workshop

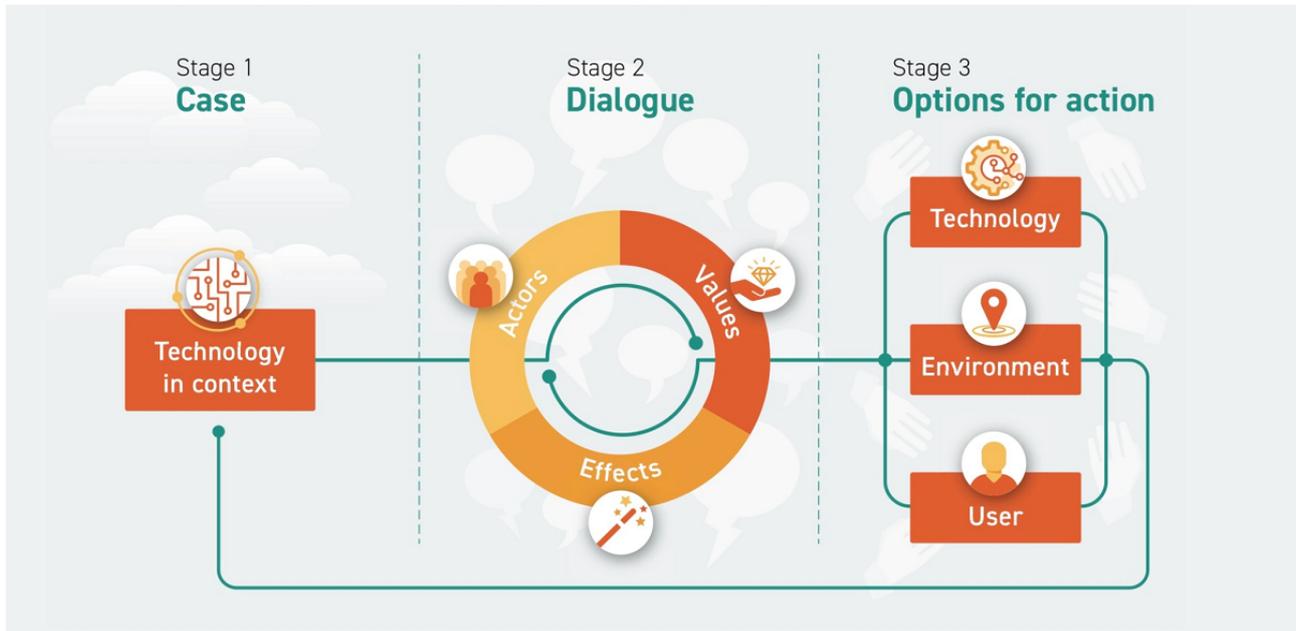

leaders from ECP (2 per workshop). The workshops were attended in person in May, June, and September 2022. Data were collected by means of a questionnaire (described in this section) completed on paper by the participants during the workshop. In addition, the information that the workshop leaders

wrote on the flip charts was collected by taking photographs of the flip charts. In total, 2 researchers (KNvD and NMS or AvdP) were present during each workshop to observe and explain the study and the questionnaire; they did not engage in the workshop.

The questionnaire—constructed by researchers (NMS and KNvD) for this study—followed the workshop outline (Figure

1 [21,33]). In stage 1 of the workshop (case), the project leader presented the case, that is, information about the technological solution, its aim, the way it works, for which target group, and in which daily (care) process. Thereafter, data about the participants' characteristics and their familiarity with the technology were collected.

Figure 1. Outline of the guidance ethics approach (adapted from Verbeek and Tijink 2020 [21], which is published under Creative Commons Attribution 4.0 International License [33]).

In stage 2 (dialogue), participants were first asked to call out all actors that are or should be affected by or involved with the use of the technology; the workshop leaders wrote these actors on a flip chart. Second, participants were asked to write down any positive and negative effects of the technology they could think of, not only from their own perspective but also any effect that came to mind. Next, all of them were asked to mention an effect until all effects were called out. Again, the workshop leader wrote these effects on a flip chart, and the effects were discussed, supplemented, and clustered by the workshop leaders and participants. Third, the workshop leaders identified values based on the clustered effects, and these values were adjusted in discussion with the participants. Finally, in stage 2, each participant determined the top 3 values that they deemed most important for their professional role in the particular case. These values were marked on the flip chart and discussed, after which the top 3 values of the total group were determined.

For stage 3 (action opportunities), participants were divided into 3 subgroups with diverse stakeholders in each subgroup. These subgroups were invited to come up with action opportunities to achieve a highly value-driven use of the respective technology in the context of the specific case, using the top 3 values of the group as starting point. A slight deviation from the protocol was that the group of the third case (social robot, SARA)—which was relatively small—was not divided into subgroups in stage 3 and did not explicitly focus on the top 3 values. The subgroups were instructed to come up with action opportunities for the following (respectively): the design of the

technology (technology), shaping the environment or context of use (context), and adjusting the behavior of the users (users). Workshop leaders explained the meaning of “action opportunities” by using the example of the technology “car.” Driving a car should be safe (value); therefore, cars have seat belts and automatic brakes (action opportunities for the technology to improve safety), traffic lights and other infrastructure guide drivers (action opportunities for the environment to improve safety), and drivers practice driving and learn the rules before receiving a license (action opportunities for the user’s behavior to improve safety). Participants were asked to write down the action opportunities that came to mind, which were then discussed and collected on a flip chart in the subgroups. Each subgroup presented their action opportunities, which were discussed plenary. At the end of the workshop, participants were asked to write down in the questionnaire any new effects, values, or action opportunities that came to mind that were not mentioned during the workshop.

Ethical Considerations

Participants were informed about the study and privacy statement, and they provided consent by completing the questionnaire anonymously. The local Medical Research Ethics Committee Oost-Nederland deemed the research in the Innovation Impulse program not subject to the Medical Research Involving Human Subjects Act (“Wet medisch-wetenschappelijk onderzoek met mensen”; file 2021-8293).

Analyses

Data from the questionnaires about positive and negative effects, values, and action opportunities were entered in Excel (Microsoft Corporation; 2018). The data set was checked for completeness using notes of the workshop observations, pictures of the flip charts from the workshops, and the workshop reports made by ECP's workshop leaders. Analyses were conducted using a bottom-up approach: participants' descriptions were the starting point leading to the derivation of themes. First, 2 researchers (KNvD and NMS) independently derived themes from the "effects data" per case. That is, effects regarding a similar subject were given a descriptive name. For example, "joyous end users" and "end users can experience more enjoyment" were named "enjoyment of end users," which was then considered an effect theme. The 2 researchers compared and discussed their effect themes until consensus was reached. Next, the effect themes of all 3 cases were written on digital Post-it notes and visually arranged, so that related effect themes were near each other. Digital Post-it notes on which values were presented were added for each theme from which the values were abstracted. Furthermore, 2 researchers (KNvD and NMS) also derived themes from the action opportunity data per case. Next, analyses and discussions were conducted regarding which values were represented by the action opportunity themes. For example, the action opportunity theme "Give the person with intellectual disability some self-direction in the use of the technology" is mainly related to the value "autonomy," whereas

the action opportunity theme "keep the goal in mind and deploy technology as a means rather than a goal in itself" is related to the value "quality of care." The preliminary results were presented and discussed in an interpretation meeting with workshop leaders and project leaders from the care organizations (participants from all 3 workshops were present). Input and feedback from this meeting were used for further analyses through an iterative process.

Results

Overview

The 3 workshops provided insight into how effects were translated into values and, subsequently, how values were translated into action opportunities for technology, context, and users of a specific technology. The numbers of collected effects, values, and action opportunities for each of the 3 cases are presented in [Table 2](#). An overview of their content is provided in [Multimedia Appendix 1](#); for readability, effects and action opportunities were shortened, and similar ones were combined in the overview.

Data about values and action opportunities were missing from a participant who could only attend the first part of the workshop. Furthermore, the person with intellectual disability from case 1 formulated effects and action opportunities together with a care professional.

Table 2. Number of participants per case and the amount of data collected.

Case	Participants (n=26), n (%)	Effects (n=232), n (%)	Values (n=33), n (%)	Action opportunities (n=156), n (%)
1—Kookapp for groups	10 (38.5)	102 (43.9)	13 (39.4)	74 (47.4)
2—SignalEREN app	10 (38.5)	66 (28.4)	7 (21.2)	54 (34.6)
3—Social robot, SARA	6 (23.1)	64 (27.6)	13 (39.4)	28 (17.9)

Examples of Action Opportunities

[Table 3](#) presents examples of action opportunities for (1) designing "technology"; (2) shaping the "context" of use; and (3) adjusting the behavior of the "users" to guide the responsible use of digital care for people with intellectual disabilities. Given that describing all results (which can be found in [Multimedia](#)

[Appendix 1](#)) is beyond the scope of this paper, [Table 3](#) highlights 1 example per case based on one of the most prominent values in that case, and we have described the effects and action opportunities linked to that value. Following the examples, we have reflected about general observations within and overarching the 3 cases.

Table 3. Examples of combinations of effects, a value, and action opportunities for the 3 cases.

Cases and categories	Examples
Case 1: Kookapp for groups—a web application to support healthy cooking for groups of people with intellectual disabilities	
Selected value	<ul style="list-style-type: none"> Quality of care
Positive effects	<ul style="list-style-type: none"> Connectedness through choosing, cooking, and eating together Continuity of meal quality; not being dependent on care professionals' skills Awareness of the importance of good nutrition More time for the people with intellectual disabilities Equality (differences regarding meals for people with intellectual disabilities between care organizations become small when they use the web application)
Negative effects	<ul style="list-style-type: none"> Excessive focus on health compared with enjoying tasty food
Action opportunities—technology	<ul style="list-style-type: none"> None mentioned regarding the selected value
Action opportunities—context (care organization)	<ul style="list-style-type: none"> Evaluate efficiency, health, and eating pleasure continuously Provide the care professionals with instructions about how to use the web application along with a manual
Action opportunities—users (care professionals)	<ul style="list-style-type: none"> Invest in understanding the web application to use it properly Have a backup plan for situations in which the web application does not work Know the dietary preferences and needs of each person with intellectual disability in the group Know what to do when a person with intellectual disability does not want to participate (or experiences less fun) in cooking with the web application
Case 2 : SignaLEREN app—an app to support people with intellectual disabilities in autonomously dealing with stress or anxiety	
Selected value	<ul style="list-style-type: none"> Autonomy
Positive effects	<ul style="list-style-type: none"> The following were the positive effects for the people with intellectual disabilities: <ul style="list-style-type: none"> More self-direction, independence, and personal autonomy An extra support option besides support from care professionals Increased awareness of own stress and its causes
Negative effects	<ul style="list-style-type: none"> Counterproductive effects of the app on stress if it does not work Less autonomy when using the app feels obligatory The app as a barrier to seeking contact with the care professional
Action opportunities—technology	<ul style="list-style-type: none"> Enable people with intellectual disabilities to make choices themselves: <ul style="list-style-type: none"> Set the regularity of question pop-ups in the app Disregard the notifications at unsuitable moments by choosing the response option “I don’t want to answer this question (right now)” Delete data Schedule an appointment with their care professional via the app
Action opportunities—context	<ul style="list-style-type: none"> Give people with intellectual disabilities access to the back end of the app, so that they can adjust specific content in the app themselves
Action opportunities—users	<ul style="list-style-type: none"> Give people with intellectual disabilities some self-direction regarding the use of the app: <ul style="list-style-type: none"> Discuss what using the app entails and what happens with the data Give guidance in setting up and using the app at their own pace Evaluate app use and effects frequently during coaching moments Support people with intellectual disabilities in a different way, eg, redirect them to the app first, “Have you completed the app?”
Case 3: Social robot, SARA—a robot to support the physical and social activities for people with intellectual disabilities	
Selected value	<ul style="list-style-type: none"> Privacy
Positive effects	<ul style="list-style-type: none"> None mentioned regarding the selected value
Negative effects	<ul style="list-style-type: none"> Risk of privacy infringement owing to storage and sharing of personal data Insufficient insight into what data are collected and stored when the functionalities of the robot are expanded

Cases and categories	Examples
Action opportunities—technology	<ul style="list-style-type: none"> • Differentiate between accounts for administrators and care professionals using the robot to restrict access to personal data • Establish a maximum storage period for personal data before they are automatically deleted
Action opportunities—context	<ul style="list-style-type: none"> • Train the care professionals using the robot in accordance with the privacy law • Restrict the number of people who have access to personal data • Read and reconsider the consent statements annually with people with intellectual disabilities (or their representatives) who use the robot—taking into account any changes in the functionalities of the robot and therefore storage of other data • Revise the organization’s privacy policy • When people with intellectual disabilities use the robot to have contact with relatives, the privacy of both should be protected: <ul style="list-style-type: none"> • Use headphones during this contact • Create a cozy private “corner” in the location
Action opportunities—users	<ul style="list-style-type: none"> • None mentioned regarding the selected value

Observations About and Differences and Similarities Among the Cases

Effects

Part of the effects that were collected was case specific. For example, effects regarding healthy food were mentioned only in case 1 (Kookapp for groups), effects regarding insight into

the stress of the person with intellectual disability were mentioned only in case 2 (SignalEREN app), and effects regarding activation or development of cognitive skills of the person with intellectual disability were mentioned only in case 3 (social robot, SARA). Apart from case-specific effects, several general themes that were extracted from the effects across all 3 cases are presented in [Table 4](#).

Table 4. General (ie, not case specific) effect themes, values, and action opportunity themes.

Categories and themes found across the 3 cases (Kookapp for groups; SignalEREN app; and social robot, SARA)	Actors to whom the themes mainly apply
Positive effects	
Customization of care	People with intellectual disabilities
Increase in self-reliance or self-direction	People with intellectual disabilities
Ease of work or job satisfaction	Care professionals
Efficiency or labor saving or time saving	Care organizations
Negative effects	
Dependency on IT infrastructure	People with intellectual disabilities, care professionals, and care organizations
Risks related to the storage of privacy-sensitive data	People with intellectual disabilities, care professionals, and care organizations
Perception of having “yet another system”	Care professionals
Cost or time investment	Care organizations
Values	
Quality of care	People with intellectual disabilities
Autonomy	People with intellectual disabilities
Privacy	People with intellectual disabilities, care professionals, and care organizations
Job satisfaction	Care professionals
Efficiency or affordability of care	Care organizations and society
Action opportunities	
Keep the content (recipes, interventions, and activities) up to date	Care professionals
Train the care professionals regarding how to use the technology well	Care organizations
Connect the use of the technology to goals in the individual care plan or electronic health record	Care professionals and technology developers
Focus on upscaling (more users of the technology in the care organization)	Care organizations

Values

Table 5 shows the values that were identified as the top 3 values during the 3 workshops. Note that only in case 1 (Kookapp for groups), participants chose 4 values. Values identified in all 3 cases were “quality of care,” “autonomy,” “privacy,” “job satisfaction,” and “efficiency or affordability of care” (Table

4). In all 3 cases, certain values apply to a specific actor. For example, “job satisfaction” applied to care professionals, whereas “autonomy” was primarily related to people with intellectual disabilities. Other values applied to several actors (eg, “reliability”) or an actor group; for example, “efficiency or affordability of care” was related to the care organization or even society.

Table 5. Top values identified during “guidance ethics” workshops, based on the personal top 3 values of all participants per case.

Case	Top values
1—Kookapp for groups	Quality of care, efficiency, health, and enjoyment
2—SignalEREN app	Quality of care, autonomy, and reliability
3—Social robot, SARA	Quality of care, autonomy, and privacy

Action Opportunities

Action opportunities regarding the technology comprised the development of the technology itself (eg, optimization of user experience and customization), input into the technology (eg, recipes for meals in case 1—Kookapp for groups; intervention options for reducing tension in case 2—SignalEREN app; and activities in case 3—social robot, SARA), and output of the

technology (eg, storage and use of data). Action opportunities regarding the context covered the need for guidelines, training and support, policy or agreements, and adjustments to the physical environment in which the technology is used. Action opportunities regarding the users mainly focused on how care professionals can integrate the technology into their daily care practice. Some behaviors need to be diminished (eg, care professionals need to “let go” instead of “take over” to give the

person with intellectual disability more autonomy), some behaviors must be retained (eg, face-to-face contact moments), and some behaviors need to be added (eg, evaluation moments). Although some general themes across all 3 cases were identified (Table 4), most action opportunities were context specific.

For case 1 (Kookapp for groups), most action opportunities were listed for the value “user convenience.” Action opportunities included optimizing the user experience with the web application (eg, using icons and less text) and providing resources (eg, placing magnets on the kitchen wall to hold tablets while cooking). Action opportunities that stood out because they were mentioned by several participants were related to an attractive design and ease of operation of the web application. Although the value “health” was a top value in case 1, relatively few action opportunities were formulated for this value.

For case 2 (SignalEREN app), none of the values stood out, but 4 values were evenly represented among most action opportunities: “quality of care,” “autonomy” (Table 3), “reliability,” and “efficiency.” “Quality of care,” “autonomy,” and “reliability” were the top 3 values. For “quality of care,” action opportunities included keeping the goal in mind and deploying the app as a means rather than a goal in itself (eg, personal goals of the person with intellectual disability as starting point for the conversation about how to use the app), training the care professionals on the use of the app, and having a person-centered approach (ie, customizing the app). Action opportunities for the value “reliability” included continuous provision of easily accessible support (eg, assigning SignalEREN coaches and arranging a 24-h helpdesk) and the maintenance of the app organized within the own organization. Finally, action opportunities for the value “efficiency” included integrating the app in the care process (eg, embedding the use of the app in a particular care methodology), scaling up the use and adoption of the app (eg, deploying the app with all care professionals to whom it applies), and extracting and using data from the app (eg, built-in notifications in the app for when the person’s stress level is likely to become very high). The more frequently mentioned action opportunities included giving the person with intellectual disability access to the personal settings of the app (eg, frequency of prompts and data access rights), securing face-to-face contact of the person with intellectual disability and care professional, using data from the app to provide insights into stress level trends, connecting the app with the electronic health record, and assigning a SignalEREN coach.

For case 3 (social robot, SARA), most action opportunities were related to the value “privacy” (Table 3). Action opportunities that stood out because they were mentioned by several participants included linking the use of the robot to individual care goals, connecting the robot with the electronic health record, and expanding the content that the robot can present. Although the value “autonomy” was a top value in case 3, relatively few action opportunities were related to this value, whereas relatively many action opportunities were linked to “effectiveness” (eg, optimizing the content that the robot can present and recurrent evaluation), which was not chosen as a top value.

Discussion

Relevance

Often, the development, implementation, and use of digital care does not entail an intentional and systematic effort to include the ethical considerations of all involved stakeholders [34]. Therefore, new technologies and the processes to integrate them into daily practice are often not aligned with the values and well-being of those influenced by them [15]. Instead, ethics is merely considered a separate area of attention (eg, a separate line of investigation or work package within projects) discussed by a distinct group of experts [35].

This study illustrates the types of insights that are gained when various stakeholders are involved in the reflection about the ethical impact of specific technologies and how this impact can be influenced for the better. This is illustrated using 3 cases of different digital care technologies for people with intellectual disabilities: a web application for cooking for groups (Kookapp for groups), an app for stress regulation (SignalEREN app), and a robot for interaction and physical activity (social robot, SARA). Our findings may help researchers, innovators, and users of technology to move from a rather abstract thinking about ethics and responsible innovation toward effective practical approaches in which all stakeholders can be involved.

Principal Findings

In a short amount of time (three 3.5-h workshops), relatively much information was gathered in a multistakeholder setting regarding (1) positive and negative effects for various stakeholders of a specific digital care technology for people with intellectual disabilities; (2) values underlying these effects; and (3) action opportunities to take into account important values in the design, implementation, and use of the specific technology. The effects were primarily case specific, as they described the implementation of a technology in a specific context, but several general themes were also recognized. The latter included the effects of the technology on customization of care, dependency on IT infrastructure, self-reliance or self-direction of people with intellectual disabilities, risk of privacy infringement, care professionals’ ease of work, workload, and efficiency and investment. When all the effects were abstracted into values, several values were identified in all 3 cases and were found to be related to the general effects. These values were quality of care, autonomy, privacy, job satisfaction, and efficiency or affordability of care. Most action opportunities were related to the top values from the respective cases, as can be expected when the guidance ethics approach (stage 3) is followed. Hence, many action opportunities from case 1 (Kookapp for groups) were related to “enjoyment,” “efficiency,” and “quality of care.” However, relatively few action opportunities involved the top value, “health.” Notably, most action opportunities from case 1 were related to “user convenience”; however, this was not identified as a top value. In case 2 (SignalEREN app), most action opportunities were related to the top values (“quality of care,” “autonomy,” and “reliability”) and to “efficiency.” In case 3 (social robot, SARA), the top values, “quality of care” and “privacy,” were well represented among the action opportunities, but few were related

to the top value, “autonomy,” and relatively many were related to “efficiency” and “effectivity.”

Although action opportunities can only be described in relation to specific sociomaterial contexts [36] (ie, specific technologies in their contexts of use), our study reveals that, at a higher level, there are similarities regarding effects, values, and action opportunities for different cases. Thus, it may be wise for stakeholders of digital care technologies to not only learn how technologies can be responsibly used within their own context but also seek inspiration from similar contexts in which other technologies are used and from different contexts in which the same or comparable technologies are used. However, caution should be exercised when generalizing case-specific effects, values, and action opportunities to a broad scope.

Comparisons With Previous Studies

This is the first study to provide a broad overview of actual action opportunities for responsible digital care for people with intellectual disabilities. In their 2020 reports, the Dutch Centre of Ethics and Health advised the Dutch Ministry of Health, Welfare, and Sport about ethics regarding digital care such as apps and robots [37,38]. The themes discussed in the report regarding apps are cost savings, increase of autonomy, increase of well-being, unrest, information overload, decrease of human contact, overemphasis on health that can lead to medicalization, and increase of differences in health and inequality [37]. Notably, the diametrically opposed side of inequality was raised in our study, namely that differences between care organizations would decrease if they would organize meals using the Kookapp for groups. The report regarding care robots discusses meaningful contact, dignity, autonomy, dependency, privacy, and justice [38]. Apart from information overload and justice, all themes also appeared in ≥ 1 of the 3 cases in our study. This shows that our results covered most of the essential topics that ethics experts recognized.

Studies of ethics and health often describe themes that have a positive or negative load (eg, increase of autonomy or increase of inequality, respectively) or identify ethical harms [17,18,37,39]. Our data revealed that, in most cases, 2 sides of the same coin were considered in the multistakeholder setting, for instance, technology as a facilitator and a burden for care professionals’ work (all cases); cost or labor savings and high costs or time investment (all cases); positive and negative effects of the focus on a health theme (Kookapp for groups: awareness of the importance of healthy food vs a lot of emphasis on health at the cost of enjoying tasty food; SignalEREN app: improving the stress signaling plan vs risk of medicalization of normal stress); and increase and risks of autonomy (SignalEREN app: person with intellectual disability is less dependent on care professional but possibly also less “visible”). The advantage of using values—instead of themes or harms—as a starting point for fostering responsible use of digital care is that values are neutral and hence facilitate the consideration of both sides of the same coin [40].

Strengths and Limitations

As this study illustrates, the guidance ethics approach can be a valuable and low-key method to gain insight into different

stakeholders’ experienced and expected positive and negative effects and values affected (or at stake) when using a specific technology and insight into action opportunities for responsible digital care. However, we recognize that the insights gained in this respect may fall short in terms of correctness (ie, being in agreement with facts or with what is generally accepted), concreteness (ie, being specific and detailed), and completeness (ie, the extent to which all relevant effects, values, and action opportunities have been identified) [41].

The correctness of our results about effects may be limited owing to, among others, a general lack of methodologically sound studies of the effects of digital care for people with intellectual disabilities. Hence, there was little to no evidence from scientific studies of the specific care technologies to be presented in stage 1 of the workshops. Therefore, the collected positive and negative effects are mainly based on subjective effects but from stakeholders with lived experience with the specific technology. In addition, an inherent characteristic of qualitative data analysis is that deriving themes from the data (including identifying values based on the effects of the technology) involves interpretation by the analyst. To limit subjectivity, values were discussed during the workshop with all participants, and themes were created independently by 2 researchers and discussed until consensus was reached. Another discussion point linked to correctness is that the values were discussed and presented as relatively stable entities, while they are neither stable nor singular [42,43]. Values may be affected by time and thus constantly defined and redefined (value dynamism), for instance, because users have gained experience with technology [41,43]. Although it may be challenging for researchers, innovators, and other stakeholders to continuously respond to this dynamism, a starting point could be to regularly collect the stakeholders’ perspectives about effects, values, and action opportunities.

The method used in this study has advantages regarding concreteness. For example, although the values are abstract, their definitions are embedded in the concrete effects from which they are derived. Moreover, the method results in relatively concrete output (action opportunities) compared with most ethics research on digital care [44,45], and action opportunities apply to the specific context of use. However, it was not always deducible from the workshop data what a participant specifically meant by an effect or action opportunity or to whom (eg, care professional or person with intellectual disability) specific insights applied. In the cases used in this study, it is not straightforward who is meant by the “user” of the care technology. To improve this, workshop leaders should be alert and ask participants to clarify whether they mean the care professional or the person with intellectual disability.

Regarding completeness, this study did not aim to be exhaustive in collecting effects, values, and action opportunities. However, we aimed to include a diverse sample of participants. Despite the accessibility of the workshops for people with intellectual disabilities, a participant with intellectual disability was included only in case 1 (Kookapp for groups). In case 3 (social robot, SARA), the person with intellectual disability withdrew on the morning of the workshop (with a valid reason), and in case 2 (SignalEREN app), no person with intellectual disability was

invited. In addition, other relevant stakeholders were absent, for example, relatives of the people with intellectual disabilities, the board of directors, or representatives of health insurers. Although all relevant stakeholders that participants could think of were identified during the workshop and participants were asked to keep them all in mind, some perspectives may be missing in the results. Including people with disabilities requires special attention, as this is not common in the co-design or cocreation of digital care technologies [46]; however, this is upcoming [13,47,48]. To improve stakeholder inclusion in general, it may be useful to consult “design principles” for stakeholder engagement [49].

Furthermore, the method of deriving values from effects is suitable for identifying “proximal” values on the micro level that are specific to the technology and context of use [21], but mesolevel or macrolevel effects and more “distal” values may be missed [50] (such as “social justice,” which is an important theme in studies of ethics and digital care [45,51,52]). Whenever missed in bottom-up ethical dialogues (such as in this study), proximal and distal values (or principles) from predefined ethical frameworks could be brought in as “top-down” guidance. At the same time, the bottom-up approach is a strength of the guidance ethics approach, revealing important topics such as enjoyment of the person with intellectual disability or job satisfaction, which may be missed when an ethical theory is applied to a case instead [17,53]. In this sense, we argue that the top-down and bottom-up approaches are complementary.

Hence, we suggest moving back and forth between the perspectives of stakeholders affected by technology when implementing digital care and ethical frameworks or perspectives of experts about digital care ethics [19,54].

Finally, the action opportunities identified in this study require follow-up in practice. Responsible use of technology requires being continuously responsive and adaptive to new insights that are gained regarding effects, values, and action opportunities, from early design to local implementation and use [55,56]. In addition, it is conceivable that trade-offs between action opportunities need to be made owing to value conflicts (eg, autonomy vs duty of care [57]) and costs. Future studies may shed light on how action opportunities, once formulated, are further operationalized and applied by technology designers, user organizations, and individual end users of the technology and on what factors withhold stakeholders from doing so. Previous studies indicated that ethical concerns of stakeholders might considerably slow the pace of digital care innovation, implying that responsible innovation could be a core catalyst for the progress of digital care overall [18]. Through explicit attention to and communication about responsible digital care, not only are ethical concerns taken into account but also support and acceptance among the involved stakeholders are generated. This increases the chances for the successful implementation of socially desirable, ethically acceptable, and sustainable digital care that improves the lives of people with disabilities.

Acknowledgments

This study was conducted as a part of “Innovation Impulse Disability Care” (in Dutch: Innovatie-impuls Gehandicaptenzorg), a 3-year program funded by the Dutch Ministry of Health, Welfare, and Sport. The authors thank the workshop leaders of the Platform for the Information Society and all study participants for their participation.

Authors' Contributions

NMS, DRML, MS, BB, and AvdP were involved in conceptualization. NMS, BB, and AvdP contributed to the methodology. NMS and KNvD were responsible for the software, conducted the validation and formal analysis, were responsible for the resources, and performed data curation and visualization. NMS, KNvD, and AvdP conducted the investigation. NMS, KNvD, DRML, MS, BB, and AvdP wrote the original draft and were involved in reviewing and editing. AvdP and BB were involved in supervision and funding acquisition. NMS and AvdP were involved in project administration.

Conflicts of Interest

None declared.

Abstract

Background: Telehealth implementation can be challenging for persons with serious mental illness (SMI), which may impact their quality of care and health outcomes. The literature on telehealth's impacts on SMI care outcomes is mixed, necessitating further investigation.

Objective: We examined the impacts of facility-level telehealth adoption on quality of care metrics over time among patients with SMI.

Methods: We analyzed Veterans Affairs (VA) administrative data across 138 facilities from January 2021 to December 2022. We performed longitudinal mixed-effects regressions to identify the relationships between the proportion of facility-level telehealth visits and SMI specialty care quality metrics: engagement with primary care; access and continuity of care across a range of mental health services including psychotherapy or psychosocial rehabilitation, SMI-specific intensive outpatient programs, and intensive case management; and continuity of mental health care after a high-risk event (eg, suicide attempt).

Results: Facilities with a higher proportion of telehealth visits had reduced access and continuity of physical and mental health care for patients with SMI ($P < .05$). Higher telehealth adoption was associated with reduced primary care engagement ($z = -4.04$; $P < .001$), reduced access to and continuity in SMI-specific intensive case management ($z = -4.49$; $P < .001$; $z = -3.15$; $P < .002$), reductions in the continuity of care within psychotherapy and psychosocial rehabilitation ($z = -3.74$; $P < .001$), and continuity of care after a high-risk event ($z = -2.46$; $P < .01$). Telehealth uptake initially increased access to intensive outpatient but did not improve its continuity over time ($z = -4.47$; $P < .001$). Except for continuity within SMI-specific intensive case management ($z = 2.62$; $P < .009$), continuity did not improve over time as telehealth became routinized.

Conclusions: Although telehealth helped preserve health care access during the pandemic, telehealth may have tradeoffs with regard to quality of care for some individuals with SMI. These data suggest that engagement strategies used by SMI-specific intensive case management may have preserved quality and could benefit other settings. Strategies that enhance telehealth implementation—selected through a health equity lens—may improve quality of care among patients with SMI.

Introduction

Telehealth accelerated during the COVID-19 pandemic and is likely to persist. Although telehealth is accepted by most psychiatric patients, individuals with primary or co-occurring serious mental illness (SMI; ie, psychotic spectrum disorders and bipolar disorders) show lower engagement [1,2] and are less likely to use video-based services [3,4] than other diagnostic

groups. A systematic review found that individuals with (vs without) SMI use telehealth at lower rates, despite much higher in-person mental health care (MH) use among individuals with SMI [2]. A study of patients with SMI who use telehealth during the pandemic found that, although many patients with SMI maintained engagement, individuals with schizophrenia were the least likely to engage in telehealth [3]. Despite lower telehealth engagement among patients with SMI (defined variably in the literature, but often equated to the aforementioned

diagnostic categories [5]), few have evaluated the impact of telehealth expansion on this population's quality of care.

Literature on telehealth's impacts on care outcomes for individuals with SMI is mixed. Prepandemic, county-level research linked telehealth uptake to modest increases in the proportion of patients with SMI receiving minimum levels of MH. Though telehealth resulted in a greater likelihood of posthospitalization follow-up, no changes in medication adherence and slight increases in acute care use were seen [6]. During the first 6 months of the pandemic, rapid telehealth growth was associated with lower MH use among individuals with SMI [7]. A recent study of specialty mental health practices with higher telehealth use found that Medicare patients with SMI had more visits per year, but no differences in medication refills, postpsychiatric hospitalization follow-up, or all-cause mortality [8].

The Department of Veterans Affairs (VA), which serves more patients with SMI than any other US health care system, is an opportune setting to examine telehealth's impact on quality of care. VA maintains a comprehensive performance measurement system for outcome monitoring and quality improvement at national and facility levels [9]. This report analyzes national VA administrative data to characterize the impacts of facility-level telehealth adoption on SMI performance metrics, and interaction effects on quality metrics over time as telehealth was routinized.

Methods

Overview

National VA administrative data (from Corporate Data Warehouse) were used to extract all outpatient visits (across specialties) with SMI-specific *International Statistical Classification of Diseases, Tenth Revision (ICD-10)* codes as primary or secondary diagnostic codes. In total, 6 of 8 SMI-specific VA performance measures were examined; 2 measures had an expanded definition of SMI, encompassing visits with *ICD-10* codes for severe depression and posttraumatic stress disorder. Visits were stratified by modality (video telehealth vs face to face) and quarter from January 2021 to December 2022.

SMI-related performance metrics were collated across 138 VA facilities. Eight measures assessing access to care and care continuity for individuals with SMI were examined: (1) engagement with primary care (PC; ie, assigned to PC provider and ≥ 1 PC visit within the last year); (2) access to psychotherapy or psychosocial services (ie, proportion of patients with SMI who visited ≥ 1 psychotherapy or psychosocial rehabilitation within the last year); (3) continuity (ie, 5 psychotherapy or psychosocial rehabilitation visits within 10 weeks); access to care within 2 SMI specialty programs: (4) intensive outpatient programs (IOPs; ie, ≥ 3 visits in the past year); (5) intensive case management (ICM; VA's brand of Assertive Community Treatment; ie, ≥ 5 visits in the past year); continuity in these

SMI specialty programs, with (6) ≥ 3 IOP visits over 90 days and (7) ≥ 12 ICM visits over 90 days; and (8) continuity of MH after a high-risk event like psychiatric hospitalization or suicide attempt (ie, ≥ 1 visit per 6 months over the past year).

Stata (version 15.0; StataCorp LLC) was used to perform longitudinal mixed-effects regressions evaluating whether facility unstandardized scores changed in relation to total volume of SMI telehealth visits. We controlled for facility size approximated by facility-level volume of SMI visits and time (as telehealth was routinized after the initial pandemic emergency). Separate models were fit for each measure. Models initially included linear and quadratic time to assess whether scores on quality measures varied across the 2-year period. Initial models included all 2-way interactions between linear and quadratic time and total SMI visits and telehealth SMI visits to evaluate whether associations between SMI visit volume and quality measures changed over time. Nonsignificant interactions were not retained.

Ethical Considerations

Procedures were approved by the VA San Diego Institutional Review Board (V201253). As an operations/quality improvement project, these data were collected in routine clinical care. Informed consent was not required, and no compensation was provided.

Results

No interactions were observed between time and SMI visit volume, and interactions were omitted. Table 1 displays our findings. In total, 7 of 8 measures (all but access to psychotherapy) were significantly associated ($P < .05$) with total SMI volume, telehealth SMI volume, or both.

Four measures were positively associated with facility total SMI volume but negatively associated with facility telehealth volume, including continuity of psychotherapy or psychosocial care ($z = -3.74$), PC engagement ($z = -4.04$), and ICM program access and continuity ($z = -4.49$; $z = -3.15$). Access to IOPs was negatively associated with total SMI visit volume but positively with telehealth volume. Total SMI visit volume was negatively associated with continuity of MH after high-risk events ($z = -2.46$) and positively associated with continuity of IOP ($z = 2.24$); neither measure was associated with telehealth visit volume.

In total, 6 of 8 measures changed over time. Access to psychotherapy, PC engagement, and continuity of MH after high-risk events were positively associated with linear time ($z = 4.39$ or 2.54 or 8.18) but negatively with quadratic time ($z = -3.78$ or -2.34 or -6.37); these 3 measures demonstrated an inverted U shape over time, with initial improvement followed by a decline back toward baseline. Continuity of psychotherapy ($z = -2.99$) and IOP ($z = -4.47$) declined significantly and linearly over time, whereas continuity of ICM ($z = 2.62$) exhibited a linear increase over time.

Table . Summary of models testing associations between SMI^a visits by modality and unstandardized scores on SMI-related quality measures across 138 Veterans Affairs facilities nationwide. *z* scores greater than 0 indicate a positive association between the quality measure and the time- or SMI visit volume-based predictor; *z* scores less than 0 reflect a negative association.

Quality measure	Definition	Linear time		Quadratic time		Total SMI visits ^b		Telehealth SMI visits	
		<i>z</i> score	<i>P</i> value	<i>z</i> score	<i>P</i> value	<i>z</i> score	<i>P</i> value	<i>z</i> score	<i>P</i> value
Access to psychotherapy	≥1 visit within past year	4.39	<.001	-3.78	<.001	-0.10	.92	0.46	.64
Continuity of psychotherapy	≥5 visits within 10 weeks past year	-2.99	.003	— ^c	—	6.15	<.001	-3.74	<.001
Access to primary care	Assigned primary care team + ≥1 primary care visit past 12 months	2.54	.01	-2.34	.02	2.12	.03	-4.04	<.001
Continuity of mental health care after high risk event	≥1 visit per 6 months in past year	8.18	<.001	-6.37	<.001	-2.46	.01	0.46	.65
Access to ICM ^d	≥5 visits within past year	-0.30	.76	—	—	2.22	.03	-4.49	<.001
Continuity of ICM	≥12 visits within 90 days	2.62	.009	—	—	3.88	<.001	-3.15	.002
Access to IOP ^e	≥3 visits past year	-0.46	.65	—	—	-4.62	<.001	2.66	.008
Continuity of IOP ^f	≥3 visits within 90 days	-4.47	<.001	—	—	2.24	.02	-1.58	.11

^aSMI: serious mental illness.

^bSMI encompassing schizophrenia and other psychotic disorders and bipolar disorders.

^cNot applicable.

^dICM: intensive case management.

^eIOP: intensive outpatient program.

^fMeasures for access to and continuity of IOP include a broader definition of SMI including severe depressive disorders and posttraumatic stress disorder.

Discussion

Principal Findings

In VA facilities with higher telehealth adoption, patients with SMI had diminished engagement with PC, lower access and care continuity in ICM programs, and reduced psychotherapy or psychosocial continuity. Although telehealth uptake initially increased access to IOP care for patients with SMI, IOP continuity was not improved. Larger sites, measured by total SMI volume, performed better in PC engagement, access and continuity for ICM, and continuity of psychotherapy, adjusted for telehealth use.

Higher telehealth adoption at the facility-level may have reduced access to physical and MH for patients with SMI. Although

telehealth helped preserve health care access during COVID-19, these findings suggest potential tradeoffs in quality metrics for individuals with SMI, particularly in PC engagement and continuity of care in psychotherapy or psychosocial rehabilitation settings and ICM programs. Though others report that practice-level telehealth use was associated with more visits per year for individuals with SMI [8], a subset of patients with SMI may require more robust supports (eg, from peers or case managers) to use telehealth without reducing access. Training and technical support may be necessary to overcome barriers such as hardware and software needs, broadband access, technological illiteracy, and condition-related aversions to technology mediated communication (eg, delusions) [10,11].

Access to primary and MH as well as continuity of MH after a high-risk event initially improved but returned to baseline over time. Continuity of psychotherapy and IOP declined over time. These findings suggest quality metrics did not improve as service providers and patients habituated to telehealth. Perhaps flexibility with modality and platform decreased as telehealth was routinized, or patients open to telehealth as a temporary measure were less open to it long term. The only metric to improve over time was continuity of SMI-specific ICM, suggesting more intensive strategies (eg, frequent in-person case management visits) may have facilitated successful engagement. Such strategies could be scaled to support telehealth implementation for SMI populations in other settings.

In addition to condition-specific barriers to care, individuals with SMI face social and economic inequities, including lower socioeconomic status, education, employment, and higher rates of homelessness, affecting their ability to engage in telehealth [12]. Access and continuity of care are crucial for this group because of their impact on health outcomes and mortality [13]. Our data suggest that reliance on telehealth may exacerbate disparities in health care access and quality, raising concerns about health equity for this vulnerable population.

These analyses are limited by a focus on VA, which differs from community systems in services and patient population. VA's

ICM and IOP programs have programmatic elements and performance metrics that may differ from other settings. These analyses used operations data intended for quality improvement; facility-level characteristics (eg, patient complexity) that could explain associations were not available. Future research could explore the impact of characteristics related to facility (eg, urbanicity or rurality), patients (eg, average age or facility), organization (eg, staffing), and provider attitudes regarding telehealth. Such investigations might assess the extent to which quality of care is impacted by telehealth enabling access to individuals previously disengaged from services altogether.

Conclusions

These findings raise concerns about facility-level impacts of telehealth adoption on quality of care and service engagement for individuals with SMI. Though telehealth is effective for persons with SMI [14], it may contribute to quality gaps for some individuals with SMI, negatively impacting facility-level quality metrics. Strategic telehealth supports are likely needed to reduce inequities for individuals with SMI, such as telehealth literacy screening [15], telehealth skills training [16], or in-person support to enable telehealth access. Given existing health disparities among individuals with SMI [10,12], centering health equity in the identification of implementation supports is warranted to ensure equitable and effective service provision for this vulnerable population.

Abstract

Background: Therapist-guided exposure and response prevention (ERP) for the treatment of obsessive-compulsive disorder (OCD) is frequently conducted within clinical settings but rarely at places where patients are usually confronted with OCD symptom-provoking situations in daily life (eg, at home).

Objective: This study aimed to investigate patients' views on 1 ERP session at home via videoconference and its impact on treatment outcome.

Methods: A total of 64 inpatients with OCD received 1 session of therapist-guided videoconference-based ERP at home in adjunction to a multimodal inpatient treatment between 2015 and 2020.

Results: Compared with 64 age- and sex-matched controls who received a multimodal inpatient treatment without 1 session of videoconference-based ERP at home, patients who received 1 session of videoconference-based ERP in adjunction to a multimodal inpatient treatment showed stronger reductions in OCD symptom severity from admission to discharge. Before the videoconference-based ERP session, patients reported high rationale credibility and treatment expectancy. After the videoconference-based ERP session, patients reported medium-to-high positive mood as well as depth and smoothness of the session, and they perceived the working alliance as high.

Conclusions: Results highlight the importance of administering therapist-guided ERP sessions in patients' natural environment to enhance treatment response in OCD. Videoconference-based ERP as add-on to treatment as usual is, therefore, a promising approach to facilitate the application of ERP in patients' natural environment and foster the generalization of ERP conducted in clinical settings.

Introduction

Background

Obsessive-compulsive disorder (OCD) is a mental disorder characterized by intrusive and disturbing thoughts as well as repetitive patterns of behavior [1,2]. These are often multifaceted, that is, they include different obsessions and compulsions related to unwanted intrusive thoughts, fears of diseases, and contamination, among others [2,3]. OCD is a common disorder with a lifetime prevalence ranging from 1% to 3% and often has debilitating consequences on the daily functioning, well-being, and quality of life of affected persons as well as family members [4,5]. It usually emerges in late adolescence or early adulthood and has a chronic course if effective treatment is lacking [6,7]. Yet, OCD is often underrecognized and missed in primary care settings [8]. Thus, the duration of untreated illness in adults often exceeds 10 years, which creates a large treatment gap [9].

Exposure and Response Prevention in the Treatment of OCD

Cognitive-behavioral therapy (CBT) with exposure and response prevention (ERP) is the first-line, evidence-based psychotherapeutic treatment for OCD and is recommended as the psychotherapeutic method of choice [10-12]. ERP is a crucial element in CBT for OCD and requires patients to “engage in repeated, prolonged exposure to obsessions while refraining from compulsions” ([13], p. 85) [14]. Recent evidence stemming from inhibitory learning theory suggests that patients learn new associations during ERP (eg, “dirt—no fatal disease”), which in turn inhibit existing maladaptive associations (eg, “dirt—fatal disease” [15]). This acquisition of associations is enabled by expectancy violation that is a mismatch between patients’ expectancy and outcome [15]. Although ERP is particularly useful in reducing OCD symptomatology, many patients find it difficult to endure upcoming unpleasant cognitions, feelings, and bodily sensations [16].

Besides the challenging nature of ERP itself, patients with OCD receiving CBT with ERP have to face a variety of difficulties [16]. First, patients are required to understand the underlying principles and measures of a treatment that is referred to as rationale credibility [17]. Second, patients need to expect that the treatment they are undergoing is effective [17-19]. Finally, it is beneficial if a positive working alliance is established between the patient and psychotherapist as it appears to predict treatment outcome [20]. Despite patients having to face various challenges when undergoing ERP, this psychotherapeutic intervention is highly effective for many people with OCD [21].

Home-Based ERP

The most commonly applied form of ERP is therapist-guided ERP in clinical settings (eg, at inpatient wards and in offices of psychotherapists), although the intervention can possibly be provided in several ways and facilities [22]. However, as persons with OCD often face the occurrence of obsessions and compulsions at home and feared situations or triggers cannot be replicated in a hospital or office, it can be hypothesized that home-based ERP may be beneficial in the treatment of OCD

[23]. Although the theoretical framework of administering ERP at patients’ homes may sound reasonable, evidence on this treatment variant is mixed. Although some studies found that ERP at home was slightly advantageous in terms of symptom reduction [24,25], others reported that home-based ERP was no more effective than standard office-based ERP [23].

There are a variety of reasons why home-based ERP is not administered on a regular basis by the majority of psychotherapists. Specifically, many clinicians lack time or familiarity with this intervention [22,26,27]. Additionally, specialized hospitals are not always located close to the patient’s home, making therapist-guided ERP in the patient’s living environment difficult to conduct. Even with outpatient therapy close to the patient’s home, there is the challenge of therapists having to travel to the patient’s place, which is difficult to implement due to limited time resources of therapists. Therefore, patients often receive outpatient treatment that only includes a limited number of therapist-assisted exposure sessions, if any [22,28].

To achieve a better care situation for patients with OCD, there are 2 cost-effective ways of implementing therapist-guided home-based ERP. The first option is telephone-supported ERP, which was shown to be effective in 2 studies [29,30]. With advancing technologies, the second option is videoconference-based ERP, which can also be considered an adequate tool that comes with significant reductions in obsessive-compulsive symptoms, especially in persons with moderate OCD symptoms [27,31-33]. Videoconference-based psychotherapy has several advantages over in-person psychotherapy. First, by using videoconference-based psychotherapy, treatment with ERP can easily be delivered to patients who are homebound or living in rural areas [31,34]. Second, the administration of home-based in vivo exposures allows the generalization of treatment effects to other contexts [31,34]. Third, the therapist is in charge of accompanying and supporting the patient during ERP [35]. Fourth, therapist-assisted ERP has been shown to be more effective than non-therapist-assisted ERP [36], and using videoconference at home might allow for even more therapist-assisted ERP.

This Study

As research on videoconference-based ERP is still limited, we examined treatment effects in patients who received inpatient treatment with an additional videoconference-based ERP at home compared with an age- and sex-matched group of patients who received inpatient treatment without an additional videoconference-based ERP at home. Second, we assessed patients’ views on the current intervention (ie, treatment expectancy and rationale credibility) before undergoing the videoconference-based ERP session. Third, we examined patients’ evaluations of the videoconference-based ERP session (ie, depth, smoothness, positivity, and arousal) and working alliance with the therapists after having received videoconference-based ERP. We expected stronger reductions in OCD symptom severity in patients who received inpatient treatment with an additional videoconference-based ERP session at home compared with inpatients who received multimodal inpatient treatment without an additional videoconference-based

ERP session at home from admission to discharge. Furthermore, we expected high ratings on rationale credibility and treatment expectancy before as well as high ratings on satisfaction with the therapeutic sessions and quality of the therapeutic relationship from the patients' perspective after the videoconference-based ERP session at home.

Methods

Sample Characteristics

This study was a nonrandomized, 2-group design study, in which a subset of patients who voluntarily participated in the study (videoconference exposure group) were compared with another subset of patients who did not participate in the study (control group). Although this design has disadvantages compared with a randomized controlled trial (RCT; see the *Discussion* section), it can be conducted more conveniently (eg, is less expensive and requires less resources) and may even have higher external validity as randomization may influence participation and

outcomes when patients have a treatment preference [37]. Inpatients with OCD treated at the Schoen Clinic Roseneck (Prien am Chiemsee, Germany) between 2015 and 2020 were investigated. In Germany, inpatient treatment is indicated if at least 1 of the following factors applies: absence of or nonresponse to guideline-based disorder-specific outpatient treatment, danger to life, severe neglect, compulsive and avoidant behavior that is either severe or habitual resulting in an inability to maintain a normal daily routine and adherence to outpatient treatment, severe suffering and impairment of psychosocial functioning, psychological or somatic comorbidities aggravating outpatient treatment, and a particularly disease-promoting environment [10,38]. The treatment provided at the Schoen Clinic Roseneck adheres to the German S3 guidelines for the treatment of OCD [10]. Thus, the therapeutic concept is multimodal and consists of symptom-specific, individual CBT and ERP sessions, and other treatment elements, depending on indication (eg, psychopharmacological medication; see Table 1).

Table 1. Sample characteristics (N=128).

Characteristic	Videoconference exposure group (n=64)	Control group (n=64)	Test statistics				
			Chi-square (df)	U	V	P value	r_{rb} (d)

^aICD-10: International Classification of Diseases, Tenth Revision.

^bN/A: not applicable.

^cInformation missing for 7 patients in the videoconference exposure group and 19 patients in the control group.

A total of 88 inpatients participated in this study, that is, received 1 videoconference-based ERP session at home in addition to inpatient treatment. As inpatient treatment at the Schoen Clinic Roseneck consists of 3 phases (psychoeducation and motivation, ERP, and transfer to the patients' homes), participating patients

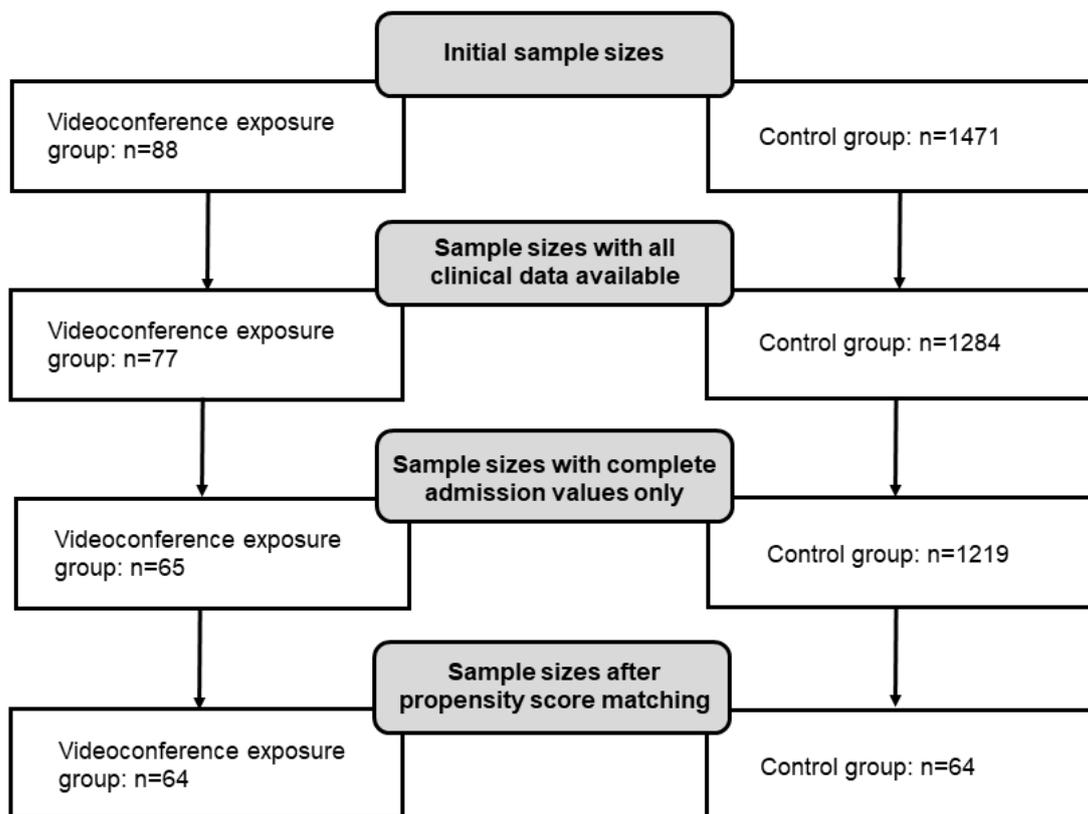

were in the third phase of inpatient treatment. Psychotherapists at the hospital who had undergone technical training on videoconference-based ERP were authorized to offer the intervention to their patients. Patients were free to choose whether or not to receive the additional videoconference-based

ERP session at home. On average, persons who received videoconference-based ERP at home had moderate OCD symptom severity according to the self-report version of the Yale-Brown Obsessive-Compulsive Scale (Y-BOCS; mean sum score 23.63, SD 5.33; Table 1; see recommendations by Cervin et al [39]).

Inpatients with OCD who were treated at the hospital within the same time period but who did not receive a videoconference-based ERP session at home were selected as the control group. Yet, these patients also received therapist-guided ERP in the hospital. Similar to the persons having received the videoconference-based ERP session, persons in the control group had, on average, moderate symptom severity according to the Y-BOCS (mean sum score 22.57, SD 6.51; Table 1; see recommendations by Cervin et al [39]). At the Schoen Clinic Roseneck, data from diagnostic assessments (eg, age, sex, diagnoses, medication, length of stay, and questionnaire scores) are automatically transferred to a database from which they can be exported without any identifying information by authorized employees. Thus, accessing individual patient charts is not necessary.

Between 2015 and 2020, a total of 1471 patients with OCD were treated in the hospital who did not receive videoconference-based ERP at home, that is, did not take part in the study. Because of missing data, 1219 patients were available for matching with 65 of the 88 patients in the videoconference exposure group (Figure 1). Groups were matched based on propensity score matching without replacement using the FUZZY extension for SPSS (version 27.0; IBM Corp) [40]. Data were matched in regard to the variables age, sex, any comorbidity, length of stay, Obsessive-Compulsive Inventory–Revised (OCI-R) scores at admission, and Y-BOCS scores at admission. Using a match tolerance with which all 65 persons in the videoconference exposure group were retained did not result in well-matched groups (ie, groups still differed in age and length of stay). Thus, a match tolerance of 0.019 was chosen, which led to the exclusion of 1 person from the videoconference exposure group, resulting in a final sample size of 128 (ie, 64 persons per group; Table 1).

Figure 1. Participant flowchart.

Measures

OCI-R Questionnaire

The OCI-R [41,42] was used to examine obsessive-compulsive symptoms. The OCI-R is an 18-item self-report questionnaire

with 6 subscales: washing, checking, ordering, obsessing, hoarding, and neutralizing. Responses are recorded on a 5-point scale ranging from 0 (not at all) to 4 (extremely) and refer to the extent of distress during the past month due to OCD symptoms. In a previous study, internal reliability coefficients

for the 6 subscales ranged between $\alpha=.76$ and $.95$. In this study, the internal reliability coefficient for the total scale was $\omega=0.82$ at admission and $\omega=0.86$ at discharge.

Y-BOCS Questionnaire

The self-report version [43] of the Y-BOCS [44,45] was used to examine OCD severity. The Y-BOCS is a 10-item self-report questionnaire comprising 2 subscales: obsessions and compulsions. Responses are recorded on a 5-point scale ranging from 0 (no symptoms) to 4 (extreme symptoms). Internal reliability coefficients ranged between $\alpha=.78$ and $.88$ in 2 validation studies [46,47] and between $\omega=0.83$ and 0.91 in this study. Convergent validity has been supported by high correlations with other measures for obsessive-compulsive symptomatology, and divergent validity has been supported by moderate correlations with measures for related but distinct constructs such as worry [48-50].

Credibility Expectancy Questionnaire

The Credibility Expectancy Questionnaire (CEQ) [17] was used to assess the rationale credibility and treatment expectancy of the patient. The CEQ is a 6-item self-report questionnaire with 2 subscales: rationale credibility and treatment expectancy. Responses are recorded on a 9-point scale ranging from 1 (not at all) to 9 (very much). Internal reliability coefficients for the subscales ranged between $\omega=0.71$ and 0.88 .

Session Evaluation Questionnaire

The Session Evaluation Questionnaire (SEQ) [51] was used to examine the patients' satisfaction with the therapeutic sessions. The SEQ is a 21-item self-report questionnaire with 4 subscales: depth, smoothness, positivity, and arousal. Responses are recorded on a 7-point scale ranging from 1 (unpleasant) to 7 (pleasant). Internal reliability coefficients for the subscales ranged between $\omega=0.61$ and 0.87 . A closer inspection revealed that 2 items (1=slow, 7=fast; 1=moved, 7=composed) contributed to a low internal reliability of the arousal subscale. After removing those items, the remaining items of the arousal subscale had an internal reliability of $\omega=0.76$. Thus, internal reliability coefficients for the subscales then ranged between $\omega=0.76$ and 0.87 .

Working Alliance Inventory—Short Revised

The Working Alliance Inventory—Short Revised (WAI-SR) [52] was used to examine the quality of the therapeutic relationship from the patient's perspective. The WAI-SR is a 12-item self-report questionnaire with 3 subscales: task, goal, and bond. Responses are recorded on a 7-point scale ranging from 1 (never) to 7 (always). Internal reliability coefficients for the subscales and the total scale ranged between $\omega=0.84$ and 0.88 .

Procedure

The videoconference app "VidyoMobile" by Vidyo, Inc was used to enable visual and auditory communication between the patient and therapist [25]. Patients were taught by a research staff member on how to use the smartphone, the tripod, and the videoconference app. Moreover, therapists prepared ERP sessions with their patients in close detail in a preceding session in the hospital. Before the ERP session, patients completed the

CEQ. Patients received 1 videoconference-based ERP session each at home either on Friday afternoon or Monday morning. Each session had a duration of 2 hours on average. All videoconference-based ERP sessions were conducted by therapists specialized in CBT and ERP, and only the patient and the therapist were attending the session. The primary goal of the videoconference-based ERP session was to practice difficult situations associated with obsessions and compulsions in the patient's home. The therapist's role was to encourage the patient to face upcoming unpleasant feelings, emotions, and bodily sensations and to accompany them emotionally [16]. The exact execution of actions during ERP (ie, turning off the stove without checking, washing hands only once, etc) was not controlled by the therapist so as to give the patient a sense of personal responsibility in their own home.

After the ERP session, patients completed the SEQ and WAI-SR. In addition, after the videoconference-based ERP session, patients were asked to continue practicing the exposure exercise on their own. These exercises were not accompanied by the therapist, but debriefing followed in subsequent therapy sessions. Questionnaires assessing symptom severity (ie, OCI-R and Y-BOCS) were completed by the patients at admission and discharge.

Data Analyses

Group differences on categorical variables (OCD subtype, sex, comorbid mental disorders, and antidepressant medication) were tested with χ^2 tests and on continuous variables (age, length of stay, and questionnaire scores at admission) with Mann-Whitney U tests. Due to missing data at discharge (OCI-R: $n=28$, Y-BOCS: $n=26$), we examined changes of OCI-R and Y-BOCS total scores from admission to discharge as a function of a group with robust linear mixed models, which include cases with missing data in the maximum likelihood estimation. For this, we used R [53] and RStudio [54] and, specifically, the R package *robustlmm* [55]. The 2 models (1 for OCI-R scores and 1 for Y-BOCS scores) included fixed effects of time (admission vs discharge), group (videoconference exposure group vs control group), and their interaction term as well as a random intercept (ie, person-level random variability in scores at admission). As the package *robustlmm* does not produce parameter-specific P values, we used the workaround by Geniole et al [56]. Specifically, nonrobust models were fitted with the *lme4* package [57], P values were obtained with the package *lmertest* [58], and Satterthwaite-approximated degrees of freedom generated by the *lme4* models were combined with the output of the *robustlmm* model [56,59].

Ethical Considerations

The study was approved by the ethics committee of the Psychological Department of the Philipps University of Marburg, Germany. According to the guidelines by the institutional review board of the LMU Munich, retrospective analyses on already available anonymized data are exempt from requiring ethics approval. All participants in the videoconference exposure group signed informed consent before taking part in the study.

Results

As can be seen in Table 1, both groups did not significantly differ in age, sex, having any comorbid mental disorder, OCD subtype, antidepressant medication, OCI-R total scores at admission, and Y-BOCS total scores at admission. Robust linear mixed models revealed statistically significant interactions for group time for OCI-R ($b=6.27$; $P=.01$) and Y-BOCS ($b=4.58$; $P<.001$) scores, indicating that OCD symptom changes from admission to discharge differed as a function of group. As can be seen in Figures 2 and 3, the videoconference exposure group had larger OCD symptom reductions from admission to discharge than the control group. Descriptive statistics for obsessive-compulsive symptoms (total scores for OCI-R and

Y-BOCS) at admission and discharge in the videoconference exposure and control groups are displayed in Table 2. On a scale ranging from 1 to 9, patients had mean (SD) values of 8.03 (0.74) on the subscale *rationale credibility* and 7.24 (1.13) on the subscale *treatment expectancy* on the CEQ. On a scale ranging from 1 to 7, patients had mean (SD) values of 5.87 (0.97) on the subscale *depth*, 3.60 (1.29) on the subscale *smoothness*, 4.61 (1.43) on the subscale *positivity*, and 4.11 (1.30) on the (reduced) subscale *arousal* on the SEQ. On a scale ranging from 1 to 7, patients had mean (SD) values of 6.25 (0.65) on the subscale *therapeutic tasks*, 6.52 (0.60) on the subscale *therapeutic goals*, 6.34 (0.75) on the subscale *therapeutic bond*, and 6.37 (0.57) on the total scale of the WAI-SR.

Figure 2. Mean sum scores of the Obsessive-Compulsive Inventory—Revised at admission and discharge as a function of group. The error bars indicate the SE of the mean. Effect sizes (rank biserial correlation coefficients r_{rb} and Cohen d) refer to the changes within each group from admission to discharge.

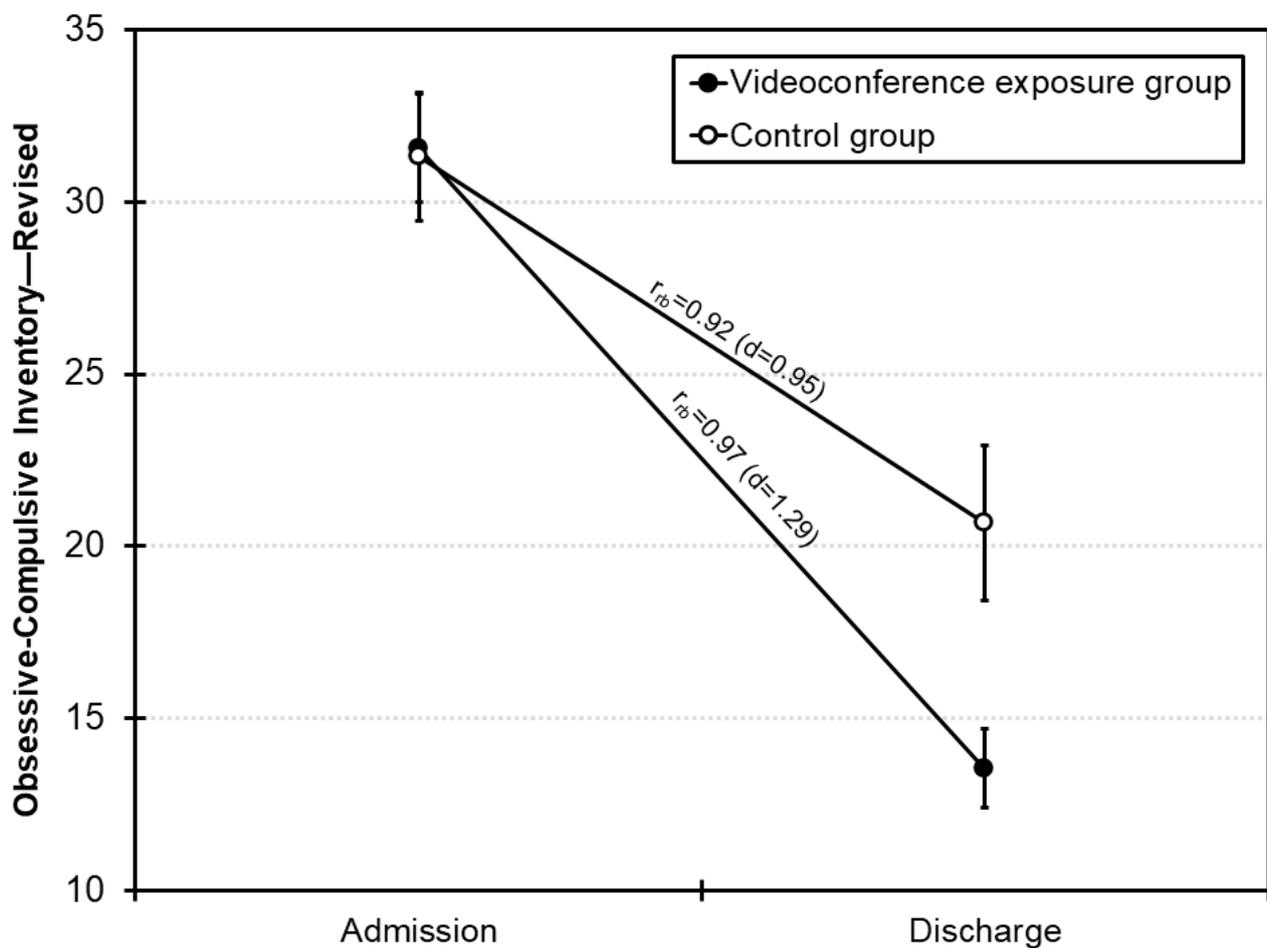

Figure 3. Mean sum scores of the Yale-Brown Obsessive-Compulsive Scale at admission and discharge as a function of group. The error bars indicate the SE of the mean. Effect sizes (rank biserial correlation coefficients r_{rb} and Cohen d) refer to the changes within each group from admission to discharge.

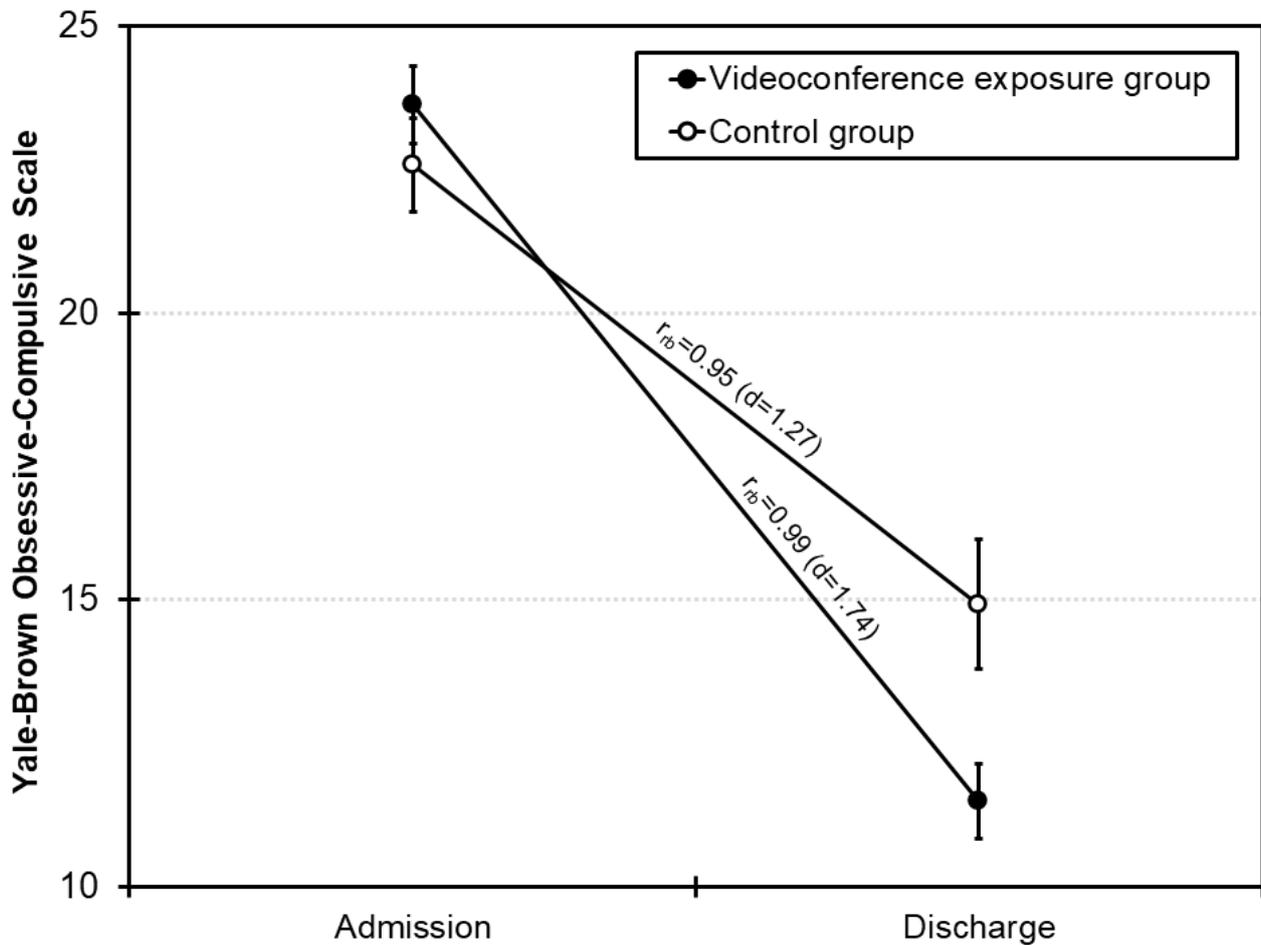

Table 2. Descriptive statistics for obsessive-compulsive symptoms at admission and discharge in the videoconference exposure and control groups.

Time point and statistic	Videoconference exposure group			Control group		
	n (%)	Mean (SD)	Range	n (%)	Mean (SD)	Range
Admission						
Obsessive-Compulsive Inventory—Revised	64 (50)	31.56 (12.62)	6-56	64 (50)	31.32 (14.89)	3-59
Yale-Brown Obsessive-Compulsive Scale	64 (50)	23.63 (5.33)	9-36	64 (50)	22.57 (6.51)	5-35
Discharge						
Obsessive-Compulsive Inventory—Revised	57 (44.5)	13.54 (8.59)	1-35	43 (33.6)	20.67 (14.81)	3-56

Discussion

Summary of Results

This study showed that the group that had an additional therapist-guided, videoconference-based ERP session at home showed greater improvements during inpatient treatment for OCD, that is, displayed larger decreases in OCD symptomatology compared with treatment as usual.

Obsessive-compulsive symptoms from admission to discharge decreased for patients who received a videoconference-based ERP session at home as well as for patients who received treatment as usual without a videoconference-based ERP session with medium to large effect sizes. Yet, obsessive-compulsive symptoms decreased even stronger for patients who have received inpatient treatment and a videoconference-based ERP session as an add-on. Furthermore, patients had high treatment expectancy and perceived the rationale as credible before

receiving videoconference-based ERP. After undergoing videoconference-based ERP, patients perceived depth (ie, potency and value), smoothness of the session (ie, comfort and relaxation), and mood after the session (ie, positivity and arousal) as medium to high. Patients who received videoconference-based ERP rated working alliance (ie, agreement on therapeutic tasks and goals as well as therapeutic bond) with their therapist as high.

Possible Mechanisms of Videoconference-Based ERP-Enhanced Symptom Reductions

Our results revealed that patients who received videoconference-based ERP at home in adjunction to a multimodal inpatient treatment had higher symptom reductions from admission to discharge with higher effect sizes than the control group. This might be significantly attributable to patients being able to generalize and extend their progresses achieved in the hospital to their own home; that is, with the help of the personal support of their therapist, they are more successful in giving up avoidance behavior at home as well [60]. Yet, it must be considered that there was no randomization in this study, which is why factors other than the additional videoconference-based ERP session might have also contributed to the reduction in OCD symptomatology from admission to discharge.

Alternative explanations for higher OCD symptom reductions in the videoconference exposure group might be that mostly patients who were highly motivated decided to participate in the additional videoconference-based ERP session or that the psychotherapists who treated patients receiving videoconference-based ERP were more motivated compared with other psychotherapists who treated the other patients with traditional ERP in the hospital only. Additionally, it might be possible that psychotherapists themselves expected that the additional ERP session at home would be beneficial for the patients and, thus, were highly engaged in the therapeutic sessions in the hospital as well, which particularly helped patients in reducing their OCD symptoms.

Despite methodological restrictions in nonrandomized study designs such as this study, there are also several disadvantages in RCTs that must be taken into account. First, participants are no passive recipients of interventions and do have treatment preferences. Patients with specific treatment preferences might, thus, refuse to take part in RCTs to avoid being randomized to the nonpreferred treatment, which reduces external validity [37]. Second, patients included in RCTs are strongly preselected, which was not the case in this study. Thus, the characteristics of patients included in this study correspond more to the real care situation. Third, internal validity of RCTs could be reduced as randomization to the nonpreferred treatment might influence patient adherence to the treatment protocol [37]. Accordingly, as this study was a nonrandomized study, patients were able to express and act on their treatment preferences as they could choose to receive the additional videoconference-based ERP session at home. This might have substantially increased patient adherence, which could, in turn, have been a factor contributing to reductions in OCD symptomatology. Furthermore, the 2 groups in this study were matched based on propensity score

matching, which aims to account for absent randomization as it imitates some of the characteristics of an RCT [61]. Propensity score matching helps to strengthen causal arguments in observational studies by reducing selection bias [62].

Besides significant reductions in OCD symptomatology from admission to discharge in patients in the videoconference exposure group, the current results indicate that patients mainly had positive views on the videoconference-based ERP session, which became apparent in positive subjective ratings of the sessions. The positive effects of the videoconference-based ERP session on OCD symptomatology might be due to several change factors (ie, treatment expectancy and working alliance) that appear to be targeted in the videoconference setting to a sufficient degree. Several studies have provided evidence that treatment expectancy and understanding of the underlying treatment rationale are powerful predictors of psychotherapy outcome in general [18]. Additionally, as patients rated working alliance in the videoconference setting as high, this might also substantially contribute to the effects shown in this study. Previous studies have already shown that the videoconference setting enables the patient and psychotherapist to establish a strong and stable working alliance that is comparable to that in traditional face-to-face treatment [63,64]. Several studies even highlight that a positive working alliance is predictive of substantial decreases in symptomatology [31]. Although this study cannot show causal associations between working alliance and symptom reductions, a positive working alliance might substantially be linked to improvements of the patients' condition in the face-to-face and videoconference setting.

Limitations

As in every study, interpretation of the current results is limited to the persons and methods investigated. First, the examination of obsessive-compulsive symptoms was based on self-report, and—although the instruments used (OCI-R and Y-BOCS) are characterized by high validity and reliability—future studies may include therapist-rated measurements (eg, Y-BOCS interview version, Clinical Global Impression-Improvement Scale, and Global Assessment of Functioning [65,66]) as the inclusion of multiple views on the patients' OCD symptomatology allows for an even more comprehensive evaluation. Second, due to limited material and human resources in the hospital, only a subset of patients treated at the hospital received an additional videoconference-based ERP session at home. Therefore, future studies might make the treatment available to a larger sample and replicate the effect. Third, future studies might examine the effects of multiple videoconference-based ERP sessions as the current add-on intervention included only 1 ERP session. Fourth, there was no randomization in this study. Hence, there might also be a number of factors other than the additional videoconference-based ERP session at home that might have contributed to significant OCD symptom reductions (eg, motivation to engage in ERP might have differed between the 2 groups and different therapists administered ERP sessions). Thus, conducting RCTs is recommended for future studies.

Conclusions

Altogether, this study showed that the group that received a 1-time home visit of videoconference-based ERP in adjunction to a multimodal inpatient treatment had greater improvements, that is, larger decreases in OCD symptomatology, during inpatient treatment of OCD compared with treatment as usual. In addition, patients' ratings showed that the videoconference

setting as well as working alliance with therapists was largely perceived as pleasant. Overall, it is recommended to provide patients with OCD with therapist-guided ERP at home. If it is not possible to accompany the intervention in person due to time constraints or other issues, videoconference-based therapy is a promising alternative to facilitate the application of ERP in patients' natural environment and foster the generalization of treatment effects achieved in clinical settings.

Data Availability

The data sets generated during and/or analyzed during this study are available in the Open Science Framework repository (<https://osf.io/pybhw/>).

Abstract

Background: Several studies show that intense work schedules make health care professionals particularly vulnerable to emotional exhaustion and burnout.

Objective: In this scenario, promoting self-compassion and mindfulness may be beneficial for well-being. Notably, scalable, digital app-based methods may have the potential to enhance self-compassion and mindfulness in health care professionals.

Methods: In this study, we designed and implemented a scalable, digital app-based, brief mindfulness and compassion training program called “WellMind” for health care professionals. A total of 22 adult participants completed up to 60 sessions of WellMind training, 5-10 minutes in duration each, over 3 months. Participants completed behavioral assessments measuring self-compassion and mindfulness at baseline (preintervention), 3 months (postintervention), and 6 months (follow-up). In order to control for practice effects on the repeat assessments and calculate effect sizes, we also studied a no-contact control group of 21 health care professionals who only completed the repeated assessments but were not provided any training. Additionally, we evaluated pre- and postintervention neural activity in core brain networks using electroencephalography source imaging as an objective neurophysiological training outcome.

Results: Findings showed a post- versus preintervention increase in self-compassion (Cohen $d=0.57$; $P=.007$) and state-mindfulness ($d=0.52$; $P=.02$) only in the WellMind training group, with improvements in self-compassion sustained at follow-up ($d=0.8$; $P=.01$). Additionally, WellMind training durations correlated with the magnitude of improvement in self-compassion across human participants ($\rho=0.52$; $P=.01$). Training-related neurophysiological results revealed plasticity specific to the default mode network (DMN) that is implicated in mind-wandering and rumination, with DMN network suppression selectively observed at the postintervention time point in the WellMind group ($d=-0.87$; $P=.03$). We also found that improvement in self-compassion was directly related to the extent of DMN suppression ($\rho=-0.368$; $P=.04$).

Conclusions: Overall, promising behavioral and neurophysiological findings from this first study demonstrate the benefits of brief digital mindfulness and compassion training for health care professionals and compel the scale-up of the digital intervention.

Introduction

Health care professionals receive intensive hands-on education and training so they may serve as resilient healers. Yet, with high workloads and multitasking demands, physicians can become vulnerable to workplace stress while making critical life-altering decisions for patients [1,2]. Evidence shows high rates of physician burnout (“workplace stress that has not been successfully managed,” *International Classification of Diseases*, World Health Organization), currently estimated at 44%, which is much higher than burnout in other professions [3,4]. Such chronic stress among physicians, in turn, may reduce the quality of physician-patient interactions and can lead to unprofessional behavior and attitudes [5,6]. Consistent with this, a study showed that burnout was associated with self-reported unprofessional conduct and less altruistic professional values among medical students at 7 US schools [7]. The COVID-19 pandemic also exacerbated distress in health care workers and has been shown to be associated with significant emotional pain, drop out from training, and reductions in work hours [8,9], which eventually affect the entire health care system. Hence, there is an emerging need for interventions that can help alleviate physician stress and prevent burnout [10].

Previous research has shown that once burnout develops, both individual-level and organizational strategies can result in clinically meaningful reductions in burnout [11], but organizational-level interventions (reducing work hours, increasing staffing, etc) have a larger overall effect size. [12] Notably, research has suggested that individual-level characteristics, particularly those related to mindfulness and self-compassion, may help to prevent burnout from developing [13-15]. Importantly, these are skills that can be developed. Research shows that when mindfulness and interoceptive-awareness exercises are provided as part of continuing medical education to primary care physicians, they help to reduce physician work-related stress and enhance well-being [11,16]. In a recent qualitative study among radio-oncologists, higher-trait mindfulness was found to be a protective factor from burnout and positively associated with life fulfillment [17]. Similarly, studies suggest that compassion training can promote well-being in medical students and improve the quality of clinical care [18]. Research has also shown that quality of care, health care costs, and the well-being of the clinician workforce are interlinked domains [19]. Hence, feasible, scalable, and effective mindfulness strategies delivered early may have far-reaching socioeconomic benefits for the health care system.

Compared to classroom approaches, digital training approaches can be highly scalable. Participants can flexibly engage with these trainings as per their convenience, so it is not a burden on busy work schedules [20]. Further, without the need for a teacher guide for digital training, the motivation for the practice is intrinsic and not reliant on teacher expertise. There are very few empirical studies among health care professionals that examine

the efficacy of an app-based mindfulness program and its objective neural implications. A recent study in physician assistants showed a decrease in sleep dysfunction, enhanced connectivity between the medial prefrontal cortex and the superior temporal gyrus, as well as between regions critical for working memory after 8 weeks of intervention [21].

We have previously tested digital meditation approaches in adolescents and healthy young adults and shown positive neuro-cognitive outcomes [22,23]. Moreover, these digital trainings have integrated gamification, feedback, and rewards within closed-loop design systems to drive high user adherence [24].

In this study, we implemented a brief digital closed-loop training for health care professionals that involved an attention-to-breath practice with integrated compassion prompts. Respecting the time constraints of health professionals, each session provided 5-10 minutes of practice, and trainees had access to up to 60 digital sessions. Relative to a no-contact or business-as-usual control group, we evaluated the primary outcomes of change in mindfulness and self-compassion and monitored sessions of training engagement. While we additionally measured burnout, we did not expect this outcome to change with individual-focused training because it has been shown that organization-directed workplace interventions are more effective at addressing burnout [1,25] and burnout was also observed to be low in our sample. Thus, our main goal in this study was to examine whether mindfulness and compassion can be enhanced by brief digitally delivered practice sessions for health care professionals. Positive results from such a study may then serve as a rationale for future implementation integrated within an organizational framework to prevent burnout from developing.

Finally, this study also uniquely assayed objective neurophysiological plasticity associated with the training alongside subjective behavioral changes. For this, we measured electroencephalography (EEG)-based brain signals on an interoceptive attention-to-breathing task, assessed before and after training. The rationale for selecting such a task for neurophysiological measurements is that interoceptive attention to breathing is a core feature of several meditation practices [26,27]. On this task, we were particularly interested in neurophysiological activity within the default mode network (DMN), which has been shown to be modulated by meditation [28-31]. The DMN is a functional network that has not only been consistently associated with autobiographical memory and self-referencing but also on-task behavioral variability, mind-wandering, and rumination [32-37]. We hypothesized that mindfulness and compassion training would suppress DMN activity. Our ultimate analyses focused on whether objective modulation of the DMN relates to subjective behavioral changes in self-compassion and mindfulness.

Methods

Participants

A total of 43 human participants recruited in the study (mean age 28.77, SD 4.13; range 23-43 y; 20 male participants). All human participants were fluent in English. Participants were recruited from the University of California San Diego (UCSD) School of Medicine from Spring 2021 to Fall 2022 academic quarters through email advertisements and campus flyers.

Participants provided demographic data with regards to age, gender, and ethnicity. All participants were healthy adults, that is, they did not have any current medical diagnosis nor were taking any current psychotropic medications. Healthy status and affiliation to the UCSD School of Medicine were the only eligibility criteria.

Participants completed the Maslach Burnout Inventory (MBI) at the time of screening; MBI scores did not reflect high burnout in our sample as all scores were less than the midscore of the MBI score range (see the *Results* section).

Study Design

The study design was interventional and cluster randomized. Of the total 43 study participants, 22 were enrolled in the digital WellMind intervention group, and 21 were part of the no-contact control group. Participants were cluster randomized based on the academic quarter of enrollment to the WellMind or control group. Specifically, all participants recruited during Spring 2021, Spring 2022, and Fall 2022 academic quarters were assigned to the WellMind group, and the no-contact control group participants were recruited during Fall 2021. This was done because individuals within each academic quarter (but not across quarters) were working or studying together and, hence, knew each other professionally and could reveal components of the study intervention to each other. The WellMind group participants received the digital app intervention and had periodic email contact from our research team during the intervention, at about once every 2 weeks, to ensure compliance and help troubleshoot any issues faced by the participants. On the other hand, the no-contact control group had no interaction with the study research team or any digital training resource provided to them between their pre- and postintervention time points.

Sample Size and Power

The sample size within each group was powered to detect medium effect size for pre- or postintervention differences (Cohen $d > 0.6$) at β power of 0.8 and α level of 0.05. Between-group differences met criteria for investigating only large effect size outcomes (Cohen $d > 0.8$) at β power of 0.8 and α level of 0.05. Effect sizes were calculated a priori using the G*Power (Axel Buchner) software [38].

Intervention

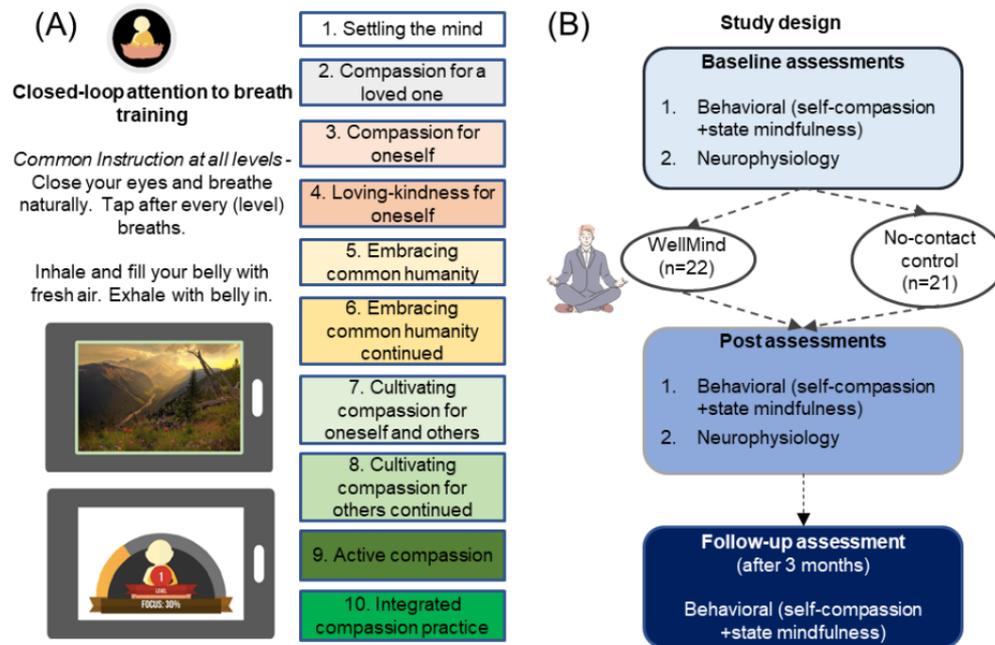

The WellMind digital intervention was deployed on the BrainE platform, implemented in Unity Game Engine (Unity

Technologies), and available on both iOS and Android phone devices [39]. This digital program is Health Insurance Portability and Accountability Act (HIPAA) compliant and secured by password protection, and each user interacts through an alphanumeric study ID that is not linked to any personal health information. Participants accessed the app in their own free time and engaged in breath-focused mindfulness training, with each session lasting 5-10 minutes for up to 60 sessions. The training was delivered in a game-like format and was performance adaptive. Specifically, individuals were requested to close their eyes, pay attention to their breathing, and tap the mobile screen after a specific number of breaths. The app monitored the consistency of tap responses. If the user was distracted based on the low consistency of breath monitoring taps, a gentle chime reminded the user to let go of the distraction and revert their attention back to mindful breathing. Initially, at level 1, participants tapped the screen after each breath. If they were able to do this consistently for 3 repeats of level 1 of 1 minute duration each, they graduated to level 2 and tracked 2 breaths at a time for 2 minutes, and so on. Thus, in the performance-adaptive task, the level reflected the number of minutes spent at that level and the number of breaths the participant was requested to repeatedly monitor. The maximum achievable level was level 10, that is, monitoring 10 breaths at a time for up to 10 minutes. When the user graduated to the max level, they stayed at this level until the end of all assigned sessions, that is, 60 sessions. Also within the game-like format, when the participant opened their eyes at the end of a level, a peaceful nature scene would slowly unfold as a form of training reward.

Overall, this digital meditative practice is considered closed loop because of its performance-adaptive feature [22,23]. Consistent attention to breathing is emphasized over other types of breathing techniques, such as deep breathing. The moment-to-moment performance tracking further allows quantification of the attentive focus during each session, which is not possible with traditional nondigital meditation.

Finally, the training also introduced standard compassion cultivation instructions as audio and text prompts before the start of each session's breath practice. Prompts were updated every 6 sessions, with a total of 10 prompts gradually increasing in complexity over 60 sessions. These prompts were designed per guidance from the Compassion Cultivation Training program [40] and included (1) settling the mind, (2) compassion for a loved one, (3) compassion for oneself, (4) loving kindness for oneself, (5) embracing common humanity, (6) embracing common humanity continued, (7) cultivating compassion for oneself and others, (8) cultivating compassion for others continued, (9) active compassion, and (10) integrated compassion cultivation practice. The WellMind training app and study design are summarized in Figure 1. Participants received in-app notifications once a day, reminding them to complete their training.

Figure 1. Brief digital mindfulness and compassion training. (A) The WellMind app delivered closed-loop, that is, performance-adaptive, attention to breath training. Common instruction across 10 levels of training is shown. At each level, the user tapped the mobile screen after (certain level) number of breaths while keeping their eyes closed. Feedback included auditory chimes to guide consistent performance and signal the end of training. A distinct, calming nature scene is unveiled at the end of each block in the session, along with focus feedback based on consistency of performance. Levels of breath monitoring were tied to 10 levels of cultivating compassion instructions. (B) The study design incorporated behavioral and neurophysiological assessments at pre- and posttraining and continued behavioral assessments at follow-up conducted in the WellMind training group relative to a no-contact control group.

Behavioral Assessments

At baseline (T1), postintervention completion (T2; or a 3-month no-contact period for the control group), and at follow-up (T3; 6 months following baseline), participants completed validated behavioral self-report scales of self-compassion: a 12-item self-compassion scale [41], and mindfulness: a 14-item Mindful Attention Awareness Scale [42]. These measures served as the primary outcomes. MBI measures were obtained as exploratory outcomes at T1 and T2. The Cronbach α measure of reliability was calculated for each of these behavioral measures at baseline.

Neurocognitive Assessments

In addition, participants completed an objective neurophysiological assessment of interoceptive attention to breathing at T1 and T2. For these assessments, all participants made individual study visits at the Neural Engineering and Translational Labs at the UCSD. Assessments were deployed on the BrainE platform with simultaneous EEG [43], delivered on a laptop (running on the Windows 10 operating system) at a comfortable viewing distance. The Lab Streaming Layer protocol was used to time stamp all user response events in this assessment [44].

In the interoceptive attention to breathing task, participants were instructed to close their eyes, breathe naturally, and respond every 2 breaths by tapping on the spacebar [45,46]. The computer screen appeared gray for the 5-minute duration of the task, implemented in two 2.5-minute blocks. A beep signaled the end of the task, at which time participants opened their eyes.

The median response time (RT) on the interoceptive task was monitored for all human participants so that we could identify and contrast neurophysiological activity on high consistency, that is, attentive breath monitoring trials (trials with $RT \leq 1$ median absolute deviation of median RT) versus low consistency, that is, distracted trials (trials with $RT > 1$ median absolute deviation of median RT) in each human participant.

EEG data were collected using a 24-channel cap with saline soaked electrodes following the 10-20 system and a wireless SMARTING amplifier (mBrainTrain). The signals were digitized with a sampling rate of 500 Hz and 24-bit resolution and stored as .xdf files.

Behavioral Data Analyses

For behavioral subjective scales, scores on self-compassion and mindfulness were calculated at T1, T2, and T3 and for MBI at T1 and T2. T2 versus T1 and T3 versus T1 scores were compared within each group using 2-tailed paired t tests or its nonparametric equivalent Wilcoxon signed rank test depending on the distribution of the behavioral scores; the normality of distributions was checked using the Levene test. For mindfulness, we compared state mindfulness across the 3 time points, which is a component of the dispositional trait mindfulness scale [47], as we expected state mindfulness but not trait mindfulness to be malleable with training.

Cohen d effect sizes were calculated for both within and between-group differences. Repeated measures analyses of variance comparing between-group behavioral differences were not conducted in this first study given the large effect sizes

($d > 0.8$) needed to observe significant group differences with adequate power.

To investigate the relationship between outcome gains and training engagement, behavioral changes in the WellMind training group were correlated with the number of training sessions completed by participants using Spearman correlations.

Neurocognitive Data Analyses

We applied a uniform processing pipeline to all EEG data published in several of our studies [43,45,46,48-53]. This included (1) EEG channel data processing and (2) cortical source localization of the EEG data to estimate source-level neural activity. Details of this analysis are provided in the [Multimedia Appendix 1](#) [51,53-68].

Alpha band EEG data were trial averaged for high versus low consistency (ie, attended vs distracted) breath monitoring trials on the interoceptive attention task. These trials were compared for within-group pre- versus postintervention activity differences in the fronto-parietal network (FPN), cingulo-opercular network (CON), and DMN using paired t tests. Effect sizes were also calculated for neural data, reported as Cohen d : 0.2=small, 0.5=medium, and 0.8=large [69]. Given that we have observed large effect size neural outcomes ($d > 0.8$) in our previous digital

training studies [22,23,70], repeated measures ANOVA was conducted to analyze between-group post- versus preintervention network effects; the Greenhouse-Geisser significance correction was applied to adjust for lack of sphericity. Finally, Spearman correlations were used to analyze neurobehavioral associations.

Ethical Considerations

Each participant gave written informed consent in accordance with the Declaration of Helsinki before participating in the experiment. All the experimental procedures were approved by the institutional review board of the University of California San Diego (protocol #180140). All data is de-identified, and up to US \$150 in compensation was provided as an e-Gift card to all participants for completing all aspects of the study, including assessments and intervention procedures.

Results

Baseline Group Comparisons

There were no demographic differences between the 2 groups for age, gender, and ethnicity (Table 1). Age comparisons were made using the Wilcoxon sum rank test, and gender and ethnicity comparisons were made using chi-square tests.

Table 1. Summary of participant demographics and baseline behaviors. Data were checked for normality, and WellMind and control groups were appropriately compared using the t test if normal, or else using the nonparametric Wilcoxon sum rank test. Gender and ethnicity variables were compared using chi-square tests.

Demographics and baseline behaviors	WellMind (n=22)	Control (n=21)	Group difference P value
Age (years), mean (SD)	27.91 (3.15)	29.67 (4.96)	.32
Gender n (%)			.55
Men	8 (36)	12 (57)	
Women	14 (64)	8 (38)	
Ethnicity n (%)			.19
Asian	8 (36)	8 (38)	
Black or African American	0 (0)	1 (5)	
American Indian or Alaska Native	0 (0)	0 (0)	
White	10 (46)	9 (43)	
More than 1 ethnicity	3 (14)	2 (10)	
Other	1 (5)	1 (5)	
Trait mindfulness, mean (SD)	3.18 (0.66)	3.14 (0.77)	.84
Self-compassion, mean (SD)	2.69 (0.57)	3.09 (0.73)	.05
MBI ^a emotional exhaustion, mean (SD)	16.27 (4.45)	24.05 (10.22)	.02 ^b
MBI personal accomplishment, mean (SD)	21.41 (3.63)	32.86 (6.73)	<.001 ^c
MBI depersonalization, mean (SD)	5.36 (3.33)	9.29 (7.93)	.23

^aMBI: Maslach Burnout Inventory.

^b $P < .05$.

^c $P < .001$.

Our main outcome variables of mindfulness and self-compassion also did not show significant group differences at baseline. Burnout measures on the MBI showed significantly less emotional exhaustion and sense of personal accomplishment in

the WellMind group relative to the control group at baseline, but no differences in MBI depersonalization. Overall, burnout levels in the WellMind group were low, that is, less than a scale midscore of 18 for emotional exhaustion, greater than a scale

midscore of 16 for sense of personal accomplishment, and less than a scale midscore of 10 for depersonalization.

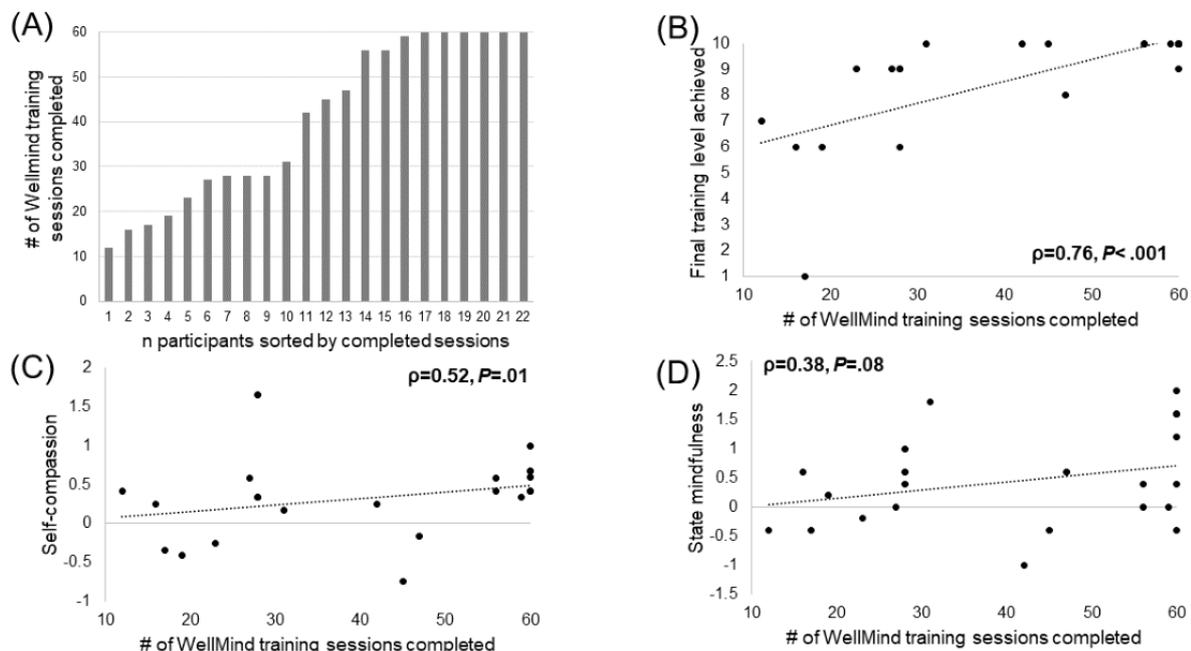

All behavioral measures had consistently high Cronbach α measured across all human participants at baseline (mindfulness: $\alpha=.81$, self-compassion: $\alpha=.86$, and MBI: $\alpha=.88$).

Behavioral Results

Participants in the WellMind group completed 40.64 (SD 17.79) training sessions on average, or 68% (40.64/60) of the total 60

sessions; the number of training sessions completed by different participants is shown in Figure 2A. The number of training sessions completed directly related to the final level achieved in training across participants ($\rho=0.76$, $P<.001$; Figure 2B). Additionally, we found that the number of training sessions was also significantly related to post- versus preintervention increase in self-compassion ($\rho=0.52$, $P=.01$; Figure 2C) and trended toward significance in relation to post- versus preintervention increase in mindfulness ($\rho=0.38$, $P=.08$; Figure 2D), but this was not statistically significant.

Figure 2. WellMind training sessions completed and relationship with outcomes. (A) The number of training sessions completed by each WellMind participant. (B) The final level of breath training is significantly related to the number of completed training sessions. (C) Post- versus prechange in self-compassion is significantly related to number of completed training sessions. (D) Post- versus prechange in state mindfulness showed a trend in its relationship to the number of completed training sessions. The Spearman correlation results are shown.

The within-group changes in primary measures of self-compassion and state mindfulness and exploratory measures of burnout (MBI scores) between post- versus preintervention and follow-up versus preintervention sessions are shown in Tables 2 and 3 for the WellMind and control groups. A significant increase in self-compassion and mindfulness was observed at post- versus preintervention sessions only in the WellMind group, and the significant increase in self-compassion was sustained at follow-up (Figure 3). As the self-compassion scale has 2 components for compassionate self-responding (CSR) and uncompassionate self-responding (USR) [71], we also analyzed whether either CSR or USR undergo significant training-related change. CSR reflects self-kindness, common humanity, and mindfulness, while USR reflects the opposite constructs of self-judgment, isolation, and overidentification.

We found that the WellMind training-related improvement in self-compassion was exclusively driven by a reduction in USR (post vs preintervention change: -0.42 , SD 0.55; $P=.002$; and follow-up vs preintervention change: -0.82 , SD 1.27; $P=.009$), but there was no significant change in CSR at post ($P=.17$) or follow-up ($P=.07$). Baseline burnout in our sample was low, and there were no significant post- versus preintervention changes in MBI scores in both groups.

Cohen d effect sizes for within-group differences were calculated as the mean difference between post- versus preintervention (or follow-up vs preintervention) outcomes expressed in pooled SD units. Cohen d effect sizes were also calculated for between-group differences. Effect sizes for significant self-compassion and mindfulness outcomes were in the medium range (Tables 2 and 3).

Table 2. Summary of behavioral outcomes obtained at baseline (T1) and 3 months (postintervention; T2 after baseline). The primary outcome measures for the study, self-compassion and state mindfulness, showed significant changes in the WellMind group at postintervention time point and are noted. The control group did not show any significant changes. Data were checked for normality, and pre- versus postintervention within-group differences were appropriately compared using a paired *t* test if normal, or else using the nonparametric Wilcoxon sign rank test. Both within-group and between-group Cohen *d* effect sizes were calculated.

Pre- versus postintervention outcomes	WellMind				Control				Between-group effect size

^a*P*<.001.

Figure 3. Post- versus preintervention (T2 vs T1) and follow-up versus preintervention (T3 vs T1) self-compassion and state mindfulness outcomes in the WellMind (n=22) and control (n=21) group; data at follow-up were missing for 2 participants in the WellMind group and for 1 participant in the control group. Both (A) self-compassion and (B) state mindfulness scores significantly improved in the WellMind group. Bar plots show the change in score mean and standard error about the mean for error bars, with the actual distribution of scores shown as scatter points. As self-compassion and state mindfulness measures had normal distributions, **P* value results are from paired t tests between pre- and postintervention or preintervention and follow-up assessments.

Neurocognitive Results

We analyzed post- versus preintervention modulation of source-localized neural activity on the interoceptive attention to breathing assessment in brain regions of interest collated within canonical cognitive control networks, specifically the FPN, CON, and DMN. There were no between-group differences in neural network activity at baseline ($P > .05$). The within-group changes in network activity between post- versus preintervention sessions are shown in Table 4 for the WellMind and control groups. Per our hypothesis, a significant decrease in activity in the mind-wandering and rumination-associated DMN was observed at post versus pre sessions only in the

WellMind group (Figure 4). Besides this, the only other significant change observed was a decrease in post- versus preintervention FPN activity in the control group.

Cohen *d* effect sizes were calculated for both within-group and between-group differences (Table 4). Notably, the reduction in post- versus preintervention DMN activity in the WellMind group showed both large within-group and between-group effect sizes (DMN between group repeated measures ANOVA: session interaction: $F_{1,32} = 10.11$; $P = .003$; $\eta^2 = 0.24$; main effects of group or session were not significant, $P > .30$; also, the other networks, FPN and CON, did not show any significant between-group effects, $P > .10$).

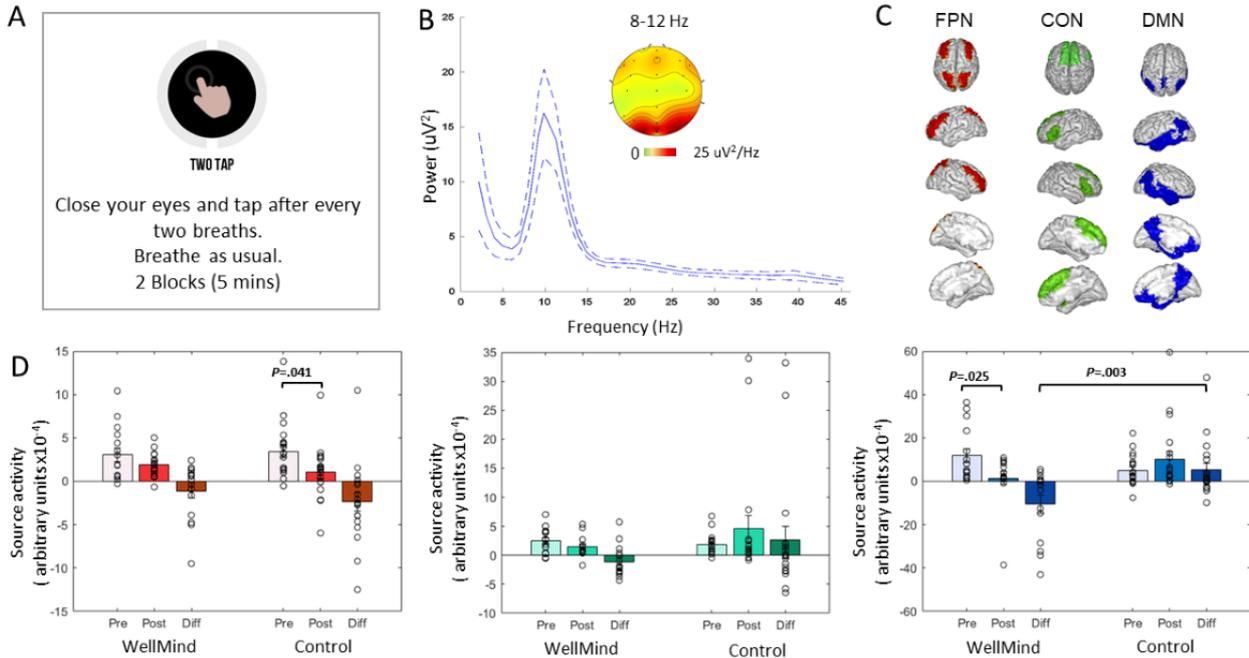

Table 4. Summary of neural activity outcomes obtained at baseline (T1) and at 3 months (postintervention; T2). The primary network of interest for the study, the default mode network (DMN), showed significant change in the WellMind group at post- versus preintervention and is noted. Besides, the control group showed a significant change in fronto-parietal network (FPN) activity. Mean (SD) data are shown in 10⁻⁴ cortical source arbitrary units for all variables. Post- versus preintervention within-group and between-group Cohen *d* effect sizes are calculated.

Pre- versus postintervention outcomes	WellMind				Control				Between-group effect size
	T1, mean (SD)	T2, mean (SD)	Effect size	Group difference <i>P</i> value	T1, mean (SD)	T2, mean (SD)	Effect size	Group difference <i>P</i> value	
FPN	3.08 (3.14)	1.96 (1.45)	-0.46	.21	3.45 (3.39)	1.08 (3.08)	-0.73	.04 ^a	0.30

^bCON: cingulo-opercular network.

Figure 4. Training-related neurophysiological changes evaluated on the attention-to-breath monitoring assessment. (A) Schematic of task instructions. (B) A power frequency plot of scalp channel data across all participants and sessions showed peak processing in the α frequency band (8-12 Hz). (C) Source-reconstructed electroencephalography data were analyzed for 3 networks: frontoparietal network (FPN), the cingulo-opercular network (CON), and the default mode network (DMN); regions of interest averaged within each network are shown. (D) Comparisons of the WellMind versus control group network activity showed significant reduction in activity only for the WellMind group in the DMN; bar plots show mean and standard error about the mean α band activity (y-axes: 10–4 cortical source activity arbitrary units) within the 0- to 4-second epoch before breath responses, as well as the relative response on low versus high consistency (ie, distracted versus attended) trials at pre- and postintervention time points and the post-pre difference. Actual activity distributions are shown as scatter points.

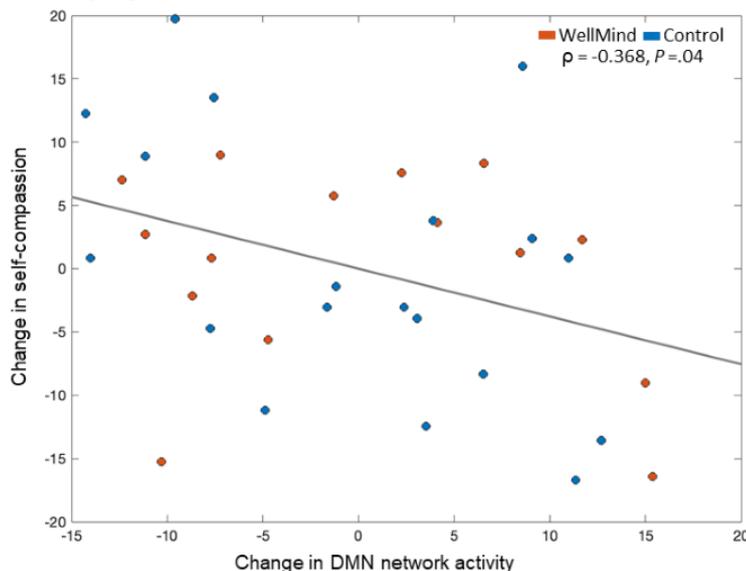

Neurobehavioral Associations

We conducted neurobehavioral correlation analyses between neural measures of post- versus preintervention change in DMN activity and change in primary behavioral outcomes of self-compassion or state mindfulness. Spearman partial correlations were implemented that accounted for participant groups and their baseline burnout score differences (MBI; Table 1). We found a significant relationship between change in DMN

network activity and change in self-compassion ($\rho=-0.368$; $P=.04$; Figure 5) but not state mindfulness ($P>.50$). Specifically, individuals who showed the largest improvement in self-compassion also showed the greatest DMN suppression. We also verified that these effects were driven by the relationship between DMN suppression and reduction in USR ($\rho=0.37$; $P=.04$), but there was no significant relationship with change in CSR ($P=.35$).

Figure 5. Relationship between post- versus preintervention change in self-compassion scores and change in default mode network (DMN) network activity. Residuals are plotted using Spearman partial correlation, taking into account group assignment to the WellMind or control group and baseline burnout score differences between groups.

We also found that the extent of training-related DMN suppression in the WellMind group was significantly related to their baseline DMN activity ($\rho=-0.74$; $P=.002$); this result did not change when controlling for the number of WellMind training sessions completed, and no such relationship was observed for the control group ($P=.71$). These results suggest that baseline DMN activity could be a predictive marker for the extent of training-related neural plasticity in this network, which in turn relates to improvement in self-compassion.

Discussion

In this study, we developed WellMind, a digital mindfulness and compassion training, and implemented it with health care professionals. Respecting their real-world time constraints, the training was brief (5-10 minutes per session) and available for up to 60 sessions. The novelty of the training lay in its closed-loop, that is, performance-adaptive mechanics and quantitative feedback design applied to attentive breathing, with levels of compassion cultivation instructions. To account for the practice effects of repeat assessments, we included a no-contact control group in the study design. We found that the WellMind intervention significantly improved the primary behavioral outcomes of self-compassion and mindfulness, with the improvements in self-compassion sustained at follow-up. No such behavioral effects were observed in the control group, and overall effect sizes were in the medium range. Concomitantly, we also found training-related neurophysiological suppression of the DMN, which is implicated in mind-wandering and rumination, and the extent of DMN suppression related to significant improvements in self-compassion.

A recent meta-analytic review of 27 studies [72] and randomized controlled trials found that smartphone apps can be used to enhance mindfulness and compassion skills, as well as reduce stress [73,74]. Additionally, a recent scoping review concluded that it is feasible to deliver compassionate care within digital health care, particularly telemedicine [75]. Yet, previous digital interventions in this field have reported small effect sizes [72]. In this study, we found medium effect size behavioral changes that further correlated with the extent of digital training completed across human participants, highlighting the advantages of this closed-loop digital training. It is also notable that the medium effect size improvements in self-compassion were sustained at follow-up; this finding is aligned with evidence from our past digital intervention studies showing robust long-term behavioral effects [22,76].

The core element of our digital WellMind training is the attention to breathing practice, which is also a foundational element of traditional meditation; indeed, meditation practice has been shown to enhance state-mindfulness [77,78]. Yet, traditional practice lacks real-time feedback and performance-based level progressions and can have variable outcomes depending on the teacher [79,80]. WellMind is a teacher-independent digital app within which user feedback is key to maintaining engagement over multiple sessions [24]. Notably, as users engaged with more sessions, we also observed them progress to higher levels of breath monitoring (maximum

monitoring of 10 breaths at a time)—a significant correlation was found between breath monitoring level and training sessions completed. At higher training levels, progressively more sophisticated compassion instructions were also unveiled, which may be driving the correlation between the number of training sessions completed and improvements in self-compassion. Furthermore, when we investigated the positive (CSR) and negative (USR) subcomponents of the self-compassion scale [71], we found that reduction in USR (ie, reduction in self-judgment, isolation, and overidentification) exclusively underlies the training-related improvement in total self-compassion. To the best of our knowledge, previous research has not addressed the differential intervention-related plasticity of CSR versus USR components but has shown that these are distinct constructs that differentially relate to well-being and cognitive responses to daily life problems [81,82].

With regard to real-time feedback, WellMind integrates breath monitoring consistency-based auditory feedback as a gentle chime that signals the user to return to attentive breath monitoring when distracted. Indeed, auditory feedback during focused attention meditation has been shown to improve state mindfulness [83]. Notably, in large sample surveys of perceived barriers to meditation across hundreds of participants, a lack of individualized feedback and progress tracking have been prominently cited as important hindrances [84,85]. WellMind was designed to remove these barriers and, hence, motivate training. It is also distinct from previous closed-loop digital meditation approaches that prompt the user to retrospectively and subjectively report whether they were attentive or distracted during their meditation practice and did not integrate compassion cultivation [22,23].

In addition to behavioral outcomes, we also investigated EEG-based neurophysiological outcomes evaluated on an interoceptive breath monitoring task. The eyes-closed interoceptive task required monitoring of 2 breaths at a time and was devoid of feedback or performance-adaptive levels, and thus served as a pure assessment of breath-focused interoception that was targeted by the WellMind training. Consistent with our hypothesis based on previous evidence [28,29,31], we observed training-related suppression of cortical source-localized DMN activity, with no such changes found in the control group. The DMN outcome had a large between-group effect size. In contrast, the FPN and CON executive control networks did not show training-related changes; the FPN showed a significant within-group post versus pre activity reduction in the control group that could be related to attentional lapses or boredom during repeat assessments in this group [22,86,87]. Finally, neurobehavioral correlations showed that training-related DMN activity suppression was significantly related to improvement in self-compassion, specifically reduction in the USR component. Also, individuals with high DMN activity at baseline experienced greater DMN suppression with training, suggesting baseline DMN activity as an individual-specific neural marker to determine who may benefit most from such training. Overall, it is worth noting that we obtained these results using EEG, a scalable approach for measuring neural markers relative to other neuroimaging

modalities such as functional magnetic resonance imaging. We also note that in our previous work, we have shown high test-retest reliability of such EEG data collected within the context of cognitive tasks [43].

As per the limitations of this study, the sample size and nonactive control group are the primary limitations, although it is worth noting that this is the first ever implementation of the digital WellMind intervention in health care professionals. We also acknowledge other limitations of our intervention design, such as that participants were not blind to the intervention condition and that WellMind participants received a greater frequency of contact from the experimenters during the intervention (email reminders to encourage adherence), while the control group had no such contact. These differences may lead to differences in expectations, resulting in positive outcomes observed in the WellMind group. Also, burnout in our sample was low, and we did not observe any post versus pre changes in burnout. Yet, previous work has suggested that organization-directed workplace interventions could be more effective at addressing burnout [25] and a recent study showed that physical exercise facilitated by mobile app technology also benefits burnout [88]. In this context, our research presents the possibility that individual interventions focused on self-compassion and mindfulness delivered before the development of burnout may be helpful in burnout prevention. Our data, showing long-term benefits in self-compassion with moderate to large effect sizes, suggests this approach may be

useful in preventing burnout. Yet, this field has acknowledged that there are challenges to implementing behavioral interventions at the organizational level, especially in health care [8]. These challenges include a clear lack of time for physicians as well as concerns regarding confidentiality and discrimination within this workforce. In this context, WellMind offers brief training sessions (5-10 minutes in duration) that can be engaged flexibly at any time of day. Its closed-loop features promote adherence, although we acknowledge that not everyone is similarly motivated, as reflected by the variable number of sessions completed by the training participants. Security and confidentiality should be a paramount concern for any digital intervention [89,90]. Hence, WellMind access is enabled on a secure, password-protected HIPAA-compliant platform, with only deidentified data available for review and analyses. These features can facilitate future adoption. Overall, it is recommended that such interventions are embedded within the early stages of physician education as a foundational resource, when there may be more availability of time, to enhance receptivity, adherence, and build resilience to future burnout.

In conclusion, this study showcases an accessible and closed-loop approach to foster compassion and mindfulness among health care professionals. We found significant behavioral effects as well as robust brain plasticity related to these effects. These findings encourage future scale-up of the digital intervention to promote physician well-being and prevent burnout.

Acknowledgments

This work was supported by grants from the Sanford Institute for Empathy and Compassion at the University of California, San Diego (JM) and Sanford Institute for Empathy and Compassion Postdoctoral Fellowship Award (SJ). We thank Alankar Misra for the software development of the BrainE software and several University of California San Diego undergraduate students who assisted with data collection. We also thank Pragathi Balasubramani and Gillian Grennan for their assistance with the initial project set-up. The BrainE software is copyrighted for commercial use (Regents of the University of California Copyright #SD2018-816) and free for research and educational purposes.

Data Availability

The data set generated and analyzed in this study are available from the Data Dryad repository [91].

The WellMind digital intervention on the BrainE platform app is available for health care education and research on the website and is copyrighted for commercial use (Regents of the University of California Copyright #SD2024-132) [92].

Authors' Contributions

DR and JM contributed to the conception and design of the study. SJ conducted data management and data analytics and wrote the first draft of the manuscript. SRP and JKM collected and managed the data; JN and NA managed and analyzed the data. JM supervised all data collection, data management, analytics, and manuscript writing. All authors contributed to manuscript edits and revisions and approved the submitted version.

Abstract

Background: The COVID-19 pandemic led to a global reduction in health care accessibility for both infected and noninfected patients, posing a particular burden on those with chronic conditions, including mental health issues. Peru experienced significant devastation from the pandemic, resulting in a collapsed health care system and leading to the world's highest per capita mortality rate as a result of COVID-19. Understanding the trends in health care utilization, particularly in mental health care, is crucial for informing pandemic response efforts and guiding future recovery strategies.

Objective: This study aims to analyze the trends of outpatient medical and psychiatric consultations during the COVID-19 pandemic in a national hospital in Peru.

Methods: This observational study was conducted at a national hospital in Lima, Peru. We analyzed data on user care across all services, including psychiatric services, from May 2019 to December 2022. The data were calculated for users served per month, including the number of users seen monthly in mental health services. Sociodemographic variables such as sex (female or male), age (≥ 0 years), type of medical appointment (regular or additional), and modality of care (in-person or teleconsultations) were taken into account. An interrupted time series regression model was conducted to assess the number of outpatient medical and psychiatric consultations. Subgroup analyses were performed based on service modality, including overall consultations, telemonitoring/teleconsultations only, or face-to-face only, for all service users and for mental health service users.

Results: A total of 1,515,439 participants were included, with females comprising 275,444/484,994 (56.80%) of the samples. Only 345,605/1,515,439 (22.81%) visits involved telemedicine. The total monthly outpatient visits were significantly reduced compared with the expected projection ($P < .001$) at the beginning of the pandemic, followed by a later monthly increment of 298.7 users. Face-to-face interventions experienced a significant reduction at the beginning of the pandemic ($P < .001$), gradually recovering in the following months. By contrast, telemedicine use initially increased but subsequently declined toward the end of the pandemic. A similar trend was observed in mental health units.

Conclusions: During the pandemic years, health care utilization in both general and psychiatric services experienced a significant decrease, particularly at the beginning of the pandemic (March 2020). However, no significant trends were observed in either case throughout the pandemic period. Telemedicine consultations witnessed a significant increase overall during this period, particularly among mental health users.

Introduction

During the COVID-19 pandemic, many medical consultations unrelated to the virus were significantly reduced to focus on containing the spread of the infection [1]. Health care systems faced the significant challenge of adapting to the increasing demand for treating patients with COVID-19 while continuing to provide care for those with other conditions, despite having limited resources available [2]. Outpatient clinics, in particular, experienced a reduction in utilization during this time, primarily as a result of the decrease in scheduled medical visits and the temporary suspension of some services in many health centers [3]. This situation significantly impacted patients' health, especially those with chronic conditions requiring continuous follow-up sessions, and led to substantial economic losses [4].

In low- and middle-income countries, where access to medical care was already limited, the pandemic posed a nearly insurmountable challenge [5,6]. The prevalence of other public health issues, such as malnutrition, malaria, tuberculosis, and HIV/AIDS, rose to unprecedented levels [7,8]. The case of Peru exemplifies unmet health care needs during the pandemic in the context of a severely unprepared, yet upper-middle-income country. With hospitals suffering from poor infrastructure, limited medical supplies, and outdated technology for decades [9], Peru's health care system collapsed during the pandemic. This led to the highest mortality rate per capita, low immunization rates, and a high frequency of infections among health care providers [10,11]. As a consequence of this situation, the outcomes for patients with chronic and noncommunicable disorders worsened [12].

An important subset of chronic patients included those with psychiatric disorders. For them, various aspects of the pandemic—such as fear of contagion, new diagnoses, and the loss of loved ones—combined with the inadequate health care response led to an increase in the incidence and severity of cases [13]. In Peru, mental health and substance abuse disorders are among the most burdensome conditions [14]. Following the COVID-19 pandemic, there has been an increase in the prevalence of moderate depressive symptoms and in the proportion of cases being treated for mild depressive symptoms [15-17].

An alternative to managing the high demand of patients was provided by telemedicine and other digital technologies, which improved accessibility and the quality of care [18,19]. However, a significant problem remains: many patients lack access to the necessary technology for telemedicine and other forms of virtual medical care utilized during the pandemic.

Hence, it is crucial to examine how the utilization of outpatient medical consultations has been affected by the COVID-19 pandemic in these countries. This exploration can help identify effective solutions to tackle present and future challenges in health care delivery. In this regard, this study will concentrate on analyzing the utilization of outpatient medical and psychiatric

consultations during the COVID-19 pandemic at a social security hospital in Peru. It will use a time series analysis methodology to scrutinize trends and patterns of service utilization from 2019 to 2022.

Methods

Study Design

Our study adopted an observational design and utilized data from the Hospital Nacional Guillermo Almenara Irigoyen (HNGAI) in Lima, Peru.

Setting

The study was conducted at the HNGAI, a tertiary referral center and highly complex health care facility situated in Lima, Peru. The HNGAI occupies a prominent position within Peru's health care system, being one of the largest hospitals under the social security system in terms of bed capacity, boasting a total of 960 hospital beds. It serves as a comprehensive medical institution catering to a broad range of medical specialties, including psychiatry.

The hospital's significance and scope of services are evident from its designation as a Specialized Health Institute III-2, the highest level bestowed by the Ministry of Health of Peru on hospital establishments. With a catchment population of 1,547,840 individuals covered by social insurance, the HNGAI plays a vital role in providing health care services to a substantial portion of the population.

As a tertiary referral center, the HNGAI assumes the responsibility for managing a diverse range of medical conditions, from routine ailments to highly complex and specialized cases. Its comprehensive capabilities and expertise make it a preferred choice for patients seeking specialized medical care.

Data on user care across all services provided by the HNGAI, including psychiatric services such as adult psychiatry, child and adolescent psychiatry, addictive behaviors, and day hospital services provided by the psychiatry department, were utilized. The data were extracted from the "ExplotaDatos system" generated by the Social Health Insurance EsSalud, covering the period from May 1, 2019, to December 31, 2022.

Participants

The number of consultations considered for the study included all hospital services, also encompassing psychiatric services. Among these consultations, women accounted for 275,444/484,964 (56.80%) and 584,618/1,030,445 (56.73%) of the sample before and during the pandemic, respectively. The age range of participants in the study ranged from 12 to over 65 years. The number of participants with their own health insurance was 341,299/484,964 (70.38%) and 749,626/1,030,445 (72.75%) before and during the pandemic, respectively. Additionally, 391,604/484,964 (80.75%) and 911,384/1,030,445 (88.45%) participants accessed care through a regular medical

appointment, while the remaining participants accessed care through an additional one. Mental health care services constituted 26,916/484,964 (5.55%) and 68,385/1,030,445 (6.64%) of the total consultations before and after the pandemic, respectively. Finally, telemonitoring and teleconsultation care

accounted for 30/484,964 (0.01%) and 345,575/1,030,445 (33.54%) of the total consultations before and during the pandemic, respectively. Variables considered are listed in [Textbox 1](#).

Textbox 1. Variables considered in this study.

- 1. Users Served Per Month

Defined as the number of users served in all services during a month by means of in-person consultations as well as telemonitoring or teleconsultation.

- 2. Number of Users Seen Monthly in Mental Health Services

Defined as the number of users attended to in the mental health services, including adult psychiatry, child and adolescent psychiatry, addictive behaviors, and day hospital, through in-person consultations as well as telemonitoring or teleconsultation.

- 3. Sociodemographic Covariates

The sociodemographic variables were sex (female or male), age (≥ 0 years), type of medical appointment (normal or additional), and modality of care (telemonitoring or teleconsultations).

Statistical Analysis

Descriptive analyses were conducted on users seen from May 2019 to December 2022, with monthly data collection. Sociodemographic variables were analyzed for all medical consultations, including those carried out by psychiatric services. We used interrupted time series regression models, a quasi-experimental approach, to assess the number of outpatient medical and psychiatric consultations following the onset of the COVID-19 pandemic. This involved analyzing trends and patterns of service utilization from May 2019 to December 2022. The analysis did not encompass care provided by the psychology service. The estimated impact of the pandemic on total outpatient medical and psychiatric consultations was assessed in terms of changes in level (intercept) and changes in the slope of prevalence across the time series before, during, and after the pandemic. Subgroup analyses were conducted according to service modality, that is, overall, telemonitoring/teleconsultations only, or face-to-face only, for all service users and psychiatric service users.

Ethics Approval

We did not access any individual personal data, nor did we have contact with participants, as the data were secondary and anonymous. The data were accessed upon request, and we did not collect primary data, thus eliminating any ethical risk. Our study was approved by the Institutional Research Ethics Committee of the HNGAI (approval number 245 CIEI-IOIyD-GRPA-ESSALUD-2023).

Results

Participants

A total of 1,515,439 participants were attended to as outpatients between May 2019 and December 2022. During this period, the majority of participants were females (860,062/1,515,409, 56.75%), working-age adults (777,236/1,515,409, 51.29%), health insurance holders (1,090,925/1,515,409, 71.99%), and had scheduled regular medical appointments (1,302,988/1,515,409, 85.98%). Only 345,605/1,515,409 (22.81%) outpatient visits involved telemonitoring or teleconsultation. [Table 1](#) presents the characteristics of the participants before and during the pandemic for all users and users in mental health services.

^aThe lockdown started on March 16, 2020.

The most common mental health problem diagnoses in users of psychiatric services were schizophrenia, schizotypal, and delusional disorders (F20-F29); affective disorders (F30-F39);

and anxiety, stress-related, and somatoform disorders (F40-F48). An extended list of the mental health diagnoses is provided in [Table 2](#).

Table 2. Psychiatric diagnoses in psychiatric services (N=95,301).

ICD-10 ^a diagnostic code: diagnosis	Before the pandemic (n=26,916), n (%)	During the pandemic (n=68,385), n (%) ^b
F00-F09: Organic mental disorders including symptomatic disorders	2548 (9.47)	5622 (8.22)
F10-F19: Mental and behavioral disorders due to psychoactive substance use	2051 (7.62)	4635 (6.78)

Other diagnoses	774 (2.88)	4670 (6.83)

^aICD-10: 10th revision of the International Statistical Classification of Diseases and Related Health Problems.

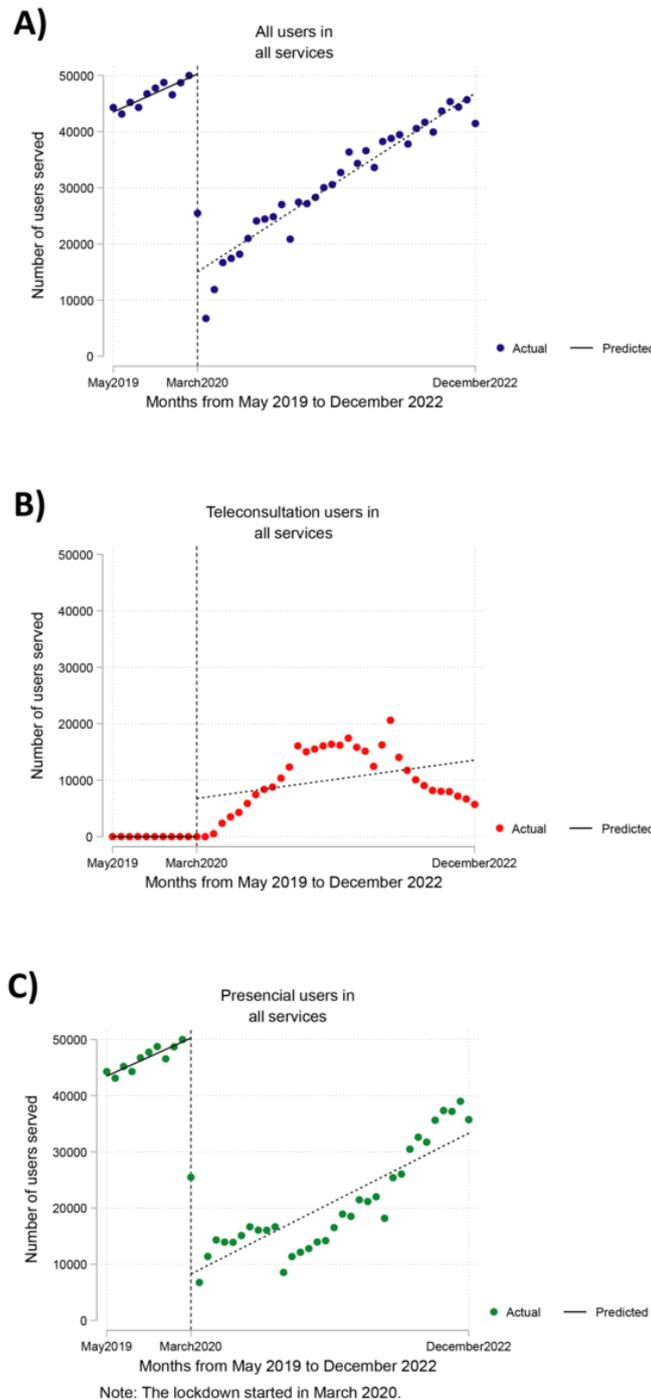

^bThe lockdown started on March 16, 2020.

Number of Users in All Services

Figure 1A illustrates that the total number of users seen per month in outpatient care across all services experienced a significant decrease at the onset of the pandemic (March 2020), with a reduction of -35,226.4 users seen compared with what was expected for that month (95% CI -38,558.3 to -31,894.6;

$P < .001$). However, an upward trend was observed during the pandemic, with a monthly increase of 289.7 users across all services (95% CI 67.2-512.2; $P = .01$). By contrast, the number of users served at the beginning of the pandemic remained the same as that measured in the month before the start of the pandemic (February 2020).

Figure 1. Interrupted time series analysis for the number of users served per month in all services between May 2019 and December 2022. (A) Interrupted time series analysis for users in all services. (B) Interrupted time series analysis for teleconsultation users in all services. (C) Interrupted time series analysis for face-to-face users in all services.

The number of users served by telemonitoring and teleconsultation was nearly 0 before the pandemic (Figure 1B). Subsequently, there was an increase in the middle of the pandemic followed by a decrease in the last months of the evaluation period. However, no significant trend was found in

the number of users visited per month by telemonitoring and teleconsultation alone ($P = .13$).

The number of users served by face-to-face care per month experienced a significant reduction at the beginning of the

pandemic (Figure 1C), with a decrease of $-42,001.9$ users served compared with what was expected for that month (95% CI $-46,934.2$ to $-37,069.6$; $P < .001$). However, no significant trend

was observed in the number of users seen per month for face-to-face care alone ($P = .58$). Table 3 presents the coefficients of the time series analysis.

Table 3. Interrupted time series regression analysis for the number of users served.

User service	Coefficients ^a	<i>P</i> value ^a	95% CI
All users served			
Overall			
Preintervention slope ^b	675.5	<.001	531.5 to 819.5
Change in intercept ^c	<i>-35,226.4</i>	<i><.001</i>	<i>-38,558.3 to -31,894.6</i>

Change in slope (interaction)	-8.2	.67	-46.9 to 30.5
Intercept	2471.0	<.001	2326.6 to 2615.5
Postintervention linear trend	14.9	.07	-1.4 to 31.3

^aValues in italics are significant ($P < .05$).

^bPreintervention slope corresponds to the previous trend of the number of users served.

^cChange in intercept refers to the change in the number of users served at the beginning of the COVID-19 lockdown.

^dChange in slope (interaction) refers to the change in the trend of the number of users served over time after March 2020.

^eIntercept represents the number of users served at the beginning of the study period.

^fPostintervention linear trend represents the trend in the number of users served after the onset of the pandemic. Autocorrelation at lag(1) was considered.

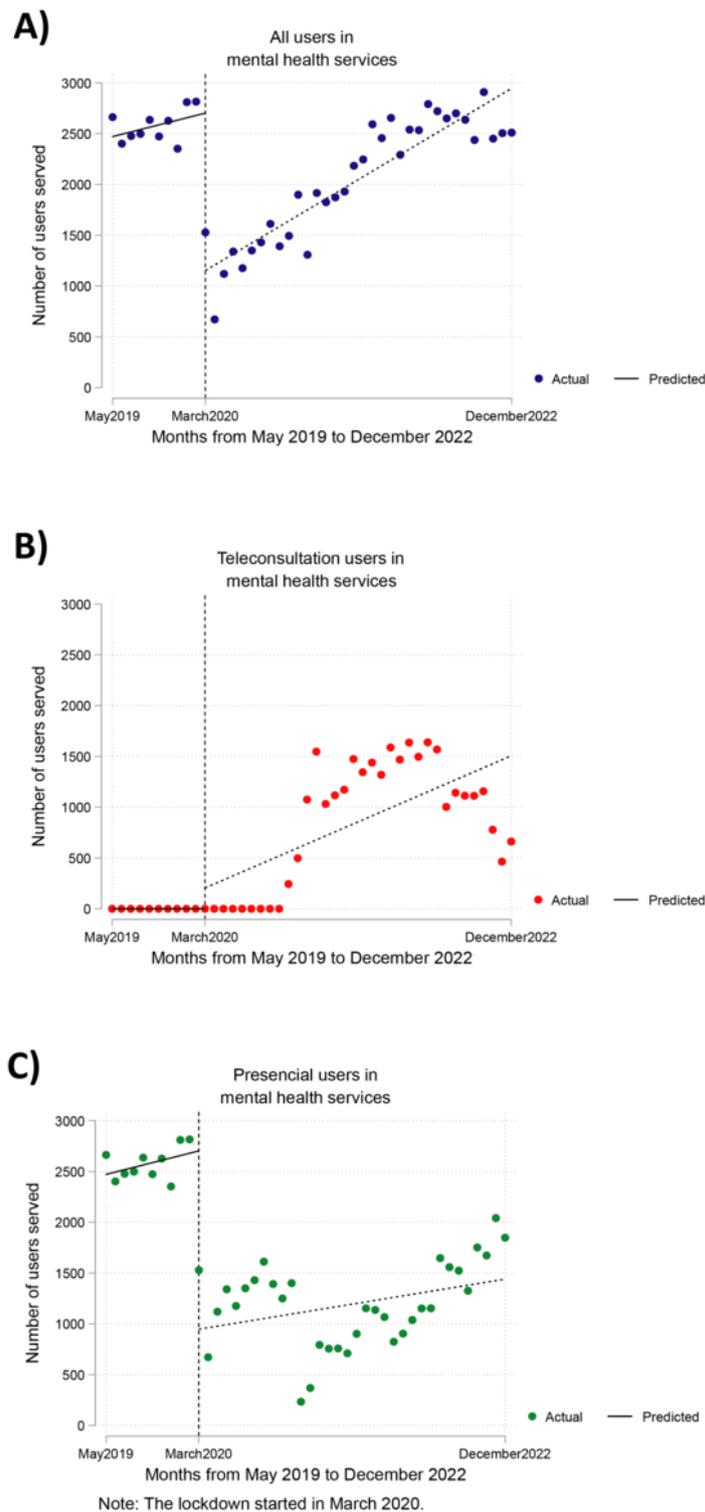

^gThe model did not converge so the analysis as such could not be performed.

Number of Users in Psychiatric Services

Figure 2A illustrates that the number of outpatients seen per month in the 4 psychiatric services experienced a significant reduction at the onset of the pandemic (March 2020). There

were –1550.3 fewer users seen than expected for that month (95% CI –1818.2 to –1282.3; $P<.001$). However, although the number of users seen per month increased during the pandemic, no significant trend was found ($P=.09$).

Figure 2. Interrupted time series analysis for the number of users served per month in all psychiatric services between May 2019 and December 2022. (A) Interrupted time series analysis for users in mental health services. (B) Interrupted time series analysis for teleconsultation users in mental health services. (C) Interrupted time series analysis for face-to-face users in mental health services.

The number of users receiving telemonitoring and teleconsultation services in the 4 psychiatric services per month is indicated in Figure 2B. However, the time series analysis did not converge, making it impossible to assess whether there were significant changes (Table 3).

There was a significant reduction in the number of face-to-face user visits per month in the 4 psychiatric services at the

beginning of the pandemic (Figure 2C). The reduction amounted to -1755.2 users compared with the expected number for that month (95% CI -2139.2 to -1371.2 ; $P < .001$). However, no significant trend was found during the pandemic for the number of face-to-face visits per month only ($P = .67$).

Discussion

Principal Findings

During the initial months of the pandemic, there was a decrease in the number of users accessing health services, which gradually increased over time. Before the pandemic, medical care through telemonitoring and teleconsultation was almost nonexistent, but it increased during the pandemic before decreasing again in the last months of the evaluated period. By contrast, there were no significant differences in the number of users attending face-to-face, telemonitoring, and teleconsultation modalities during the evaluation months. Regarding patients seen in psychiatric services, we observed a significant decrease in the number of outpatients at the beginning of the pandemic, followed by a progressive increase over time. Face-to-face visits per month were significantly reduced in all 4 mental health services.

Comparison With Other Studies

At the beginning of the pandemic, we observed an overall reduction in health care utilization. A systematic review conducted until August 2020, encompassing 20 countries, found that health care utilization was reduced in one-third of them. Eighty-one primary studies reported 143 estimates and concluded a mean reduction of 28% in admissions and 31% in new diagnoses [1]. In Peru, mandatory confinement was established in March 2020, lasting approximately 3 months [20]. During this period, the population was not allowed to leave their homes except for emergencies.

Amid the pandemic, we observed a gradual but slow increase in care utilization. A study using a time series design to assess the effect of the pandemic on 31 health services across 10 countries (low income=2, lower middle income=3, upper middle income=3, and high income=2) found that total outpatient visits decreased between 9% and 40% and remained below expectations by the end of 2020 [21]. A scoping review analyzing changes in medical care access found that among 38 studies from Europe, Asia, and Africa, 33 reported a statistically significant reduction in service use. Similarly, the studies reported possible barriers to health care access, including limited supplies and personnel to care for patients with non-COVID-19 having other medical issues, as well as increased waiting times. A potential explanation for this slow increment in Peru, as well as in other Latin American countries, could be provided by a survey reporting that around 66% of Peruvian participants attempted self-medication during the pandemic [22]. Additionally, part of the population faced barriers such as fear of contagion and the stigma of being diagnosed with COVID-19, as well as financial difficulties [23]. Although the number of cases was not increasing during and after the first phase of restriction, the maintenance of low rates of utilization was suggested to be a result of factors such as fear of contagion, sanctions related to outside mobilization, reduced access to medical centers, and prioritization of COVID-19 cases, among others [24]. We observed that by the end of the pandemic, overall health care utilization rates had risen to levels comparable to those observed 1 year before the pandemic's onset. However, a notable addition was the emergence of a new

category of consultations conducted via telemedicine. Similarly, a study in the United Kingdom found that after the release of social restriction measures, the frequency of health care utilization returned to levels that were not significantly different from prepandemic utilization [25].

Regarding psychiatric services utilization, we observed a reduction at the beginning of the pandemic that progressively improved toward the end of this period. Amidst the pandemic, Peru was submerged in chaos because of various factors, including a debilitated health care system, political mismanagement, and poor adherence to social restrictions [11]. This scenario significantly impacted the mental health of the population, as evidenced by high levels of perceived stress in the general Peruvian population [26]. A time series analysis of depression diagnoses in Peru showed that the number of new patients increased by 0.17% per month after the beginning of the pandemic [15].

In the United States, during the initial months of the pandemic, there was a 50% reduction in face-to-face mental health encounters. However, the utilization of telehealth services played a pivotal role in the swift restoration of service delivery. This uptake of telehealth, accounting for approximately 47.9% of average monthly encounters, facilitated the timely provision of mental health care despite the limitations imposed by the pandemic [27]. In another study, it has been reported that the COVID-19 pandemic resulted in a significant decrease of more than 50% in in-person mental health care utilization rates among commercially insured adults. Rates of various mental health disorders, including anxiety disorders, bipolar disorder, and adjustment disorders, declined during the pandemic. By contrast, telehealth service utilization increased substantially, by 16-20 times. Combining both in-person and telehealth services, there was an overall increase in care observed for anxiety and adjustment disorders. These findings highlight the impact of the pandemic on mental health care delivery and the potential of telehealth in providing accessible services during times of crisis [28].

In the domain of psychiatric services, there was a discernible decline of 12% per week in visits to psychiatric emergency wards during the initial phase of social distancing measures implemented from March to May 2020 [29]. In France, an analysis of the number of medical admissions to a psychiatric ward found that, compared with 2019, admissions were reduced by 18% in 2020, with this reduction increasing to 42% during the first lockdown. Similarly, the number of patients admitted to the emergency ward was reduced by 20% and 56%, respectively [30]. A study in Italy showed that 25% of their community mental health centers reduced their access hours [31]. Conversely, a Peruvian study found that community mental health centers were able to regain service capacity and fill the service gap created by the health crisis 9 months after the COVID-19 pandemic [32].

In Peru, telemedicine and in-person health care showed a similar trend compared with other countries in the region. In many Latin American countries, efforts to establish a telemedicine system produced positive results, as they reduced the overload of hospitals, decreased waiting times, and provided access to

patients living in remote areas [33]. A study conducted in an emergency department in Argentina showed that telemedicine consultations peaked during the first lockdown period of the COVID-19 pandemic in March 2020. Subsequently, telemedicine consultations reduced progressively and were replaced by face-to-face interventions, but they remained at a stable value above the prepandemic trend [34]. It is worth noting that most of the teleconsultations were conducted without technical complications. Telemedicine in our context has been supported by a legal framework since 2017, and after the pandemic outbreak, it was included as part of several regulations of the Ministry of Health and the Peruvian College of Medicine, demonstrating the interest in the establishment and refinement of these technologies in health care [35]. The transition of mental health services to telemedicine in response to high patient demand has demonstrated that synchronous digital interventions facilitate the continuity of care [36]. These interventions not only reduce geographic limitations for patients and therapists but also eliminate the long hours of travel common in Lima [36].

Additionally, these interventions reduce stigma because they occur in a more private setting, can be delivered by trained health care providers (not only physicians), and could reduce costs [37]. A survey of psychologists in the United States showed an 85% increase in the use of telemedicine after the pandemic, and they projected that at least 35% of their work would involve telemedicine after the pandemic [38]. In addition, they mentioned that telemedicine use by psychologists was positively influenced by (1) being female; (2) having training in that field and treating patients with anxiety or partners' or women's complaints; and (3) working in a rural area, treating patients with antisocial personality disorder, or doing rehabilitation or psychometry work. Although telemedicine offers several advantages, it is crucial to consider the values and preferences of both patients and therapists to improve utilization rates and ease the demand for in-person care.

Our study revealed a decrease in mental health services during the latter months of 2022, potentially attributable to reduced utilization of teleconsultations within the evaluated health care system following the easing of COVID-19 pandemic restrictions. This could be attributed to the inconsistent implementation of mental health teleconsultations within the Peruvian context. Professionals often lacked dedicated equipment for these consultations, and there was an overwhelming demand for care, resulting in difficulties securing teleconsultation appointments [39]. Furthermore, patients with mental health issues expressed a preference for face-to-face care over teleconsultation care [40]. These factors likely contributed to the observed decrease in mental health teleconsultations following the resolution of the health emergency.

Public Health Implications

These results indicate that the decline in health care utilization during the pandemic underscores the fragility of the health care system. It was ill-prepared not only for managing a pandemic but also for delivering care in routine circumstances [41]. This calls for an improvement of the structure of the health care system, such as enhancing the surveillance system, training

professionals for emergencies and disasters, strengthening the relationships between scientific and medical institutions, and fostering community engagement [42].

The use of telemedicine as a potential intervention to alleviate the strain on hospitals and health care centers has been a notable aspect of the pandemic response, underscoring the importance of implementing strategies for its adoption. This includes providing proper training to relevant stakeholders on these topics [43]. Future studies could explore the trends in health care utilization, particularly the significant uptake of telemedicine, which was virtually nonexistent before and during the peak of the pandemic but showed a progressive reduction (without disappearing entirely) toward the latter stages of analysis.

Furthermore, we encourage policy makers and health intelligence teams to utilize our findings as a foundation for developing health policies and regulations aimed at enhancing teleconsultation in mental health and health care overall. In Peru, the implementation of teleconsultation posed significant challenges. Many health professionals lacked the necessary equipment for conducting consultations, there was a lack of training in teleconsultation platform usage, and care centers themselves had limited access to the internet [39,44]. Moreover, telemedicine users persisted even after the pandemic, underscoring the ongoing demand for such services in resource-constrained settings such as Peru. Authors from countries sharing similar contexts could draw lessons from our positive telemedicine experience. We advocate for the implementation of these technologies within a framework that considers both barriers and facilitators [37]. Our findings can also be used to assess the postpandemic recovery of the health system.

Limitations and Strengths

This study highlights several strengths. First, it analyzes data from a leading national reference hospital in Lima, Peru, using a time series analysis to track utilization trends. We encompassed all patients receiving care over an extensive period, spanning most of the pandemic's duration. The sample size exceeded 1.5 million patients, and we also acquired additional data on mental health utilization, acknowledging its substantial burden in Peru. Advanced statistical methods were rigorously used in the methodology to analyze trends in health care utilization over these years. However, it is important to note that these results are confined to a national hospital in Lima and may not apply to other areas of the country or region. Further exploration of determinants affecting the variability in health care utilization, such as demographic, epidemiological, or clinical factors, is warranted. Therefore, we recommend further studies to assess whether care varied among specific age groups, genders, educational levels, or clinical variables, which may have hindered participants from accessing care.

Conclusions

In this time series analysis conducted at a national hospital in Peru during the pandemic years (March 2020 to December 2022), data from 1.5 million patients were analyzed. We observed a significant decrease in face-to-face health care utilization at the onset of the pandemic (March 2020) in both

the outpatient clinic and mental health care services, indicating a notable impact on patient attendance. No significant trends were observed in both groups over the course of the pandemic. However, there was a noticeable increase in the number of users accessing mental health services each month. Overall, there was a trend of increased monthly utilization of the aforesaid services among all users during the pandemic period. Notably, telemedicine interventions were virtually nonexistent before the pandemic, but consultations during this period increased significantly, both overall and particularly among mental health users. At the conclusion of the study period, telemedicine services in mental health continued to attract users, indicating sustained demand for these interventions that were previously unavailable before the pandemic. Further follow-up evaluations could assess the long-term feasibility of this intervention as a

means to enhance mental health access in the country. The utilization notably decreased in the subsequent months, as evidenced by the decline in the number of users accessing health care services at the hospital and in the number of teleconsultation users across all services. During times of emergency, the availability of easily accessible care services and the implementation of digital health services have proven to be of utmost importance. These results serve as a demonstration of the profound impact of the national COVID-19 lockdown on health care utilization in Peru. Governmental and key decision makers are encouraged to respond promptly to health needs and to draw lessons from these experiences, thus aiding the population in facing future health emergencies effectively.

Abstract

Background: Mental, emotional, and behavioral disorders are chronic pediatric conditions, and their prevalence has been on the rise over recent decades. Affected children have long-term health sequelae and a decline in health-related quality of life. Due to the lack of a validated database for pharmacoepidemiological research on selected mental, emotional, and behavioral disorders, there is uncertainty in their reported prevalence in the literature.

Objectives: We aimed to evaluate the accuracy of coding related to pediatric mental, emotional, and behavioral disorders in a large integrated health care system's electronic health records (EHRs) and compare the coding quality before and after the implementation of the *International Classification of Diseases, Tenth Revision, Clinical Modification (ICD-10-CM)* coding as well as before and after the COVID-19 pandemic.

Methods: Medical records of 1200 member children aged 2-17 years with at least 1 clinical visit before the COVID-19 pandemic (January 1, 2012, to December 31, 2014, the *ICD-9-CM* coding period; and January 1, 2017, to December 31, 2019, the *ICD-10-CM* coding period) and after the COVID-19 pandemic (January 1, 2021, to December 31, 2022) were selected with stratified random sampling from EHRs for chart review. Two trained research associates reviewed the EHRs for all potential cases of autism spectrum disorder (ASD), attention-deficit hyperactivity disorder (ADHD), major depression disorder (MDD), anxiety disorder (AD), and disruptive behavior disorders (DBD) in children during the study period. Children were considered cases only if there was a mention of any one of the conditions (yes for diagnosis) in the electronic chart during the corresponding time period. The validity of diagnosis codes was evaluated by directly comparing them with the gold standard of chart abstraction using sensitivity, specificity, positive predictive value, negative predictive value, the summary statistics of the *F*-score, and Youden *J* statistic. κ statistic for interrater reliability among the 2 abstractors was calculated.

Results: The overall agreement between the identification of mental, behavioral, and emotional conditions using diagnosis codes compared to medical record abstraction was strong and similar across the *ICD-9-CM* and *ICD-10-CM* coding periods as well as during the pre-pandemic and pandemic time periods. The performance of AD coding, while strong, was relatively lower compared to the other conditions. The weighted sensitivity, specificity, positive predictive value, and negative predictive value for each of the 5 conditions were as follows: 100%, 100%, 99.2%, and 100%, respectively, for ASD; 100%, 99.9%, 99.2%, and 100%, respectively, for ADHD; 100%, 100%, 100%, and 100%, respectively for DBD; 87.7%, 100%, 100%, and 99.2%, respectively, for AD; and 100%, 100%, 99.2%, and 100%, respectively, for MDD. The *F*-score and Youden *J* statistic ranged between 87.7% and 100%. The overall agreement between abstractors was almost perfect ($\kappa=95\%$).

Conclusions: Diagnostic codes are quite reliable for identifying selected childhood mental, behavioral, and emotional conditions. The findings remained similar during the pandemic and after the implementation of the *ICD-10-CM* coding in the EHR system.

Introduction

Children and adolescents are particularly vulnerable to chronic mental and behavioral conditions because their brain continues to develop. Childhood mental and behavioral disorders, including autism spectrum disorder (ASD), attention-deficit hyperactivity disorder (ADHD), disruptive behavior disorders (DBD), anxiety disorder (AD), and major depressive disorder (MDD), are common neurological disorders and are on the rise in recent decades [1-4]. Affected children and adolescents are subjected to long-term negative health and social consequences [5,6], leading to significant health care costs and public health burden [7,8]. Therefore, accurately estimating their incidence and prevalence is important to guide policy-making, resource allocation, and implementation of different intervention programs.

Trends in mental and behavioral disorders are difficult to examine using routinely collected data and often are difficult to compare across studies because of differences in case ascertainment methods. Therefore, reported incidence and prevalence rates vary widely across studies [9], and the accuracy of case ascertainment has been challenged by researchers [10,11]. This problem is further complicated by the accuracy of coding after the mandatory introduction of the *International Classification of Diseases, Tenth Revision, Clinical Modification (ICD-10-CM)* coding systems to classify diagnoses and procedures in the United States, which occurred on October 1, 2015 [12]. The *ICD-10-CM* provides increased specificity and detail for many health conditions [12], including childhood psychiatric and neurodevelopmental conditions. Many health care providers adopted the electronic health record (EHR) enacted by the Health Information Technology for Economic and Clinical Health Act (HITECH Act) in 2009 [13,14].

The Kaiser Permanente Southern California (KPSC)-integrated EHR data provide researchers with important health information to perform pharmacoepidemiological studies of children's behavioral, medical, and psychiatric conditions, including examining the public health impact of childhood psychiatric and neurodevelopmental conditions; however, there is uncertainty over the accuracy of the clinical diagnosis codes requiring validation before their use. Therefore, the objective of this study was to perform an EHR review on the validity of diagnosis codes during 3 time points (*ICD-9-CM* and *ICD-10-CM* coding and before and after the COVID-19 pandemic) for ascertaining psychiatric and neurodevelopmental conditions in a large socioeconomically diverse pediatric population aged 2-17 years [15]. The validation for the pre- and post-COVID-19 pandemic is important to assess how much the diagnosis coding has been impacted by increasing the use of virtual visits (telephone and video-assisted encounters).

Methods

Study Setting

This study was conducted using data on member children extracted from the KPSC EHR. The KPSC health care system provides services to over 4.8 million members in 15 hospitals and 234 medical offices throughout southern California. Mental

health services are provided to member patients by qualified providers at in- and outpatient psychiatric care facilities in KPSC settings. Although most members receive their care at KPSC hospitals and <10% use contracting hospitals, all diagnostic, procedural, and pharmacy records are captured and maintained by the KPSC EHR since its full implementation in 2008. The sociodemographic characteristics of KPSC members closely reflect the California population [15].

Ethical Considerations

This study was conducted with approval by the KPSC Institutional Review Board (IRB# 13114). Informed consent was waived, as the study was low risk and strictly involved the use of internal EHR data, accessible only to authorized personnel when needed.

Study Design and Sample Selection

Data for this validation study were obtained retrospectively from children who were members of the KPSC health care system during three distinct time periods: (1) January 1, 2012, through December 31, 2014; (2) January 1, 2017, through December 31, 2019; and (3) January 1, 2021, through December 31, 2022. We carefully selected the 3 time periods to investigate the medical coding accuracy of selected psychiatric and neurodevelopmental conditions encompassing both the *ICD-9-CM* and *ICD-10-CM* periods as well as the pre- and post-COVID-19 pandemic eras. To be included in the validation study cohort for each time period, children must have been enrolled in the KPSC health care system for at least 1 year during the corresponding time period at specific age ranges varying by condition (5-17 years of age for ADHD, 2-17 years of age for ASD, and 3-17 years of age for the other 3 conditions—AD, MDD, and DBD). Children may present with signs and symptoms of the specified conditions very early in life; however, for this study, we used reported and reliable lower age groupings for ASD and ADHD diagnoses [16,17] and widely published age groupings for anxiety and depressive disorders [18,19]. Furthermore, at least 1 clinical visit, including virtual visits, in each corresponding time period was required.

In the KPSC system, diagnosis codes for clinical visits (eg, hospitalization, outpatient office visits, and emergency department visits) from all KPSC facilities are extracted from EHRs and entered into a structured database by professional medical coders from the clinical data management team. In this validation study, coding-based outcomes of interest were ascertained using these clinical diagnosis codes within the 3 specified time periods ([Multimedia Appendix 1](#) presents the *ICD-9-CM* and *ICD-10-CM* codes).

For each of the investigated conditions, we randomly sampled 40 cases according to the following strata: (1) those without a diagnosis (No-Dx) and (2) those with a diagnosis (Dx). Thus, records for a total of 1200 individual children were selected. The accuracy for each of the 2 strata, with or without documented diagnostic records, was expected to be around 85%. A sample size of 120 per diagnostic condition would provide less than a 5% one-sided margin for a 90% CI of the accuracy for each stratum.

Diagnosing ASD, ADHD, DBD, and MDD

The KPSC system has an integrated framework for in- and outpatient as well as emergency department encounter services. During the child's visit to any of these facilities, the practitioner has access to the child's diagnoses, but often the diagnosis of ASD, ADHD, and DBD is made in an outpatient setting. The following criteria were used to diagnose and code ASD, ADHD, and DBD within the KPSC setting: (1) a Child Behavior Checklist must be filled out by parents and teachers to describe the child's behavioral and emotional problems and (2) a clinical interview must be performed by a qualified mental health professional. In a preliminary study conducted for this project, 96% of children with ASD, ADHD, and DBD were found to have had their conditions diagnosed by KPSC child and adolescent psychiatrists, developmental and behavioral pediatricians, child psychologists, and neurologists consistent with the diagnostic criteria from the *Diagnostic and Statistical Manual of Mental Disorders-Fifth Edition (DSM-V)*. Diagnosis of the remaining 4% was confirmed upon membership, as these cases had been previously diagnosed outside the KPSC system [20,21].

The diagnosis of depression disorder, in the KPSC system, was based on the US Preventive Services Task Force on screening for depression in children and adolescents recommendation [22]. The KPSC system uses the Patient Health Questionnaire (PHQ-9) and the PHQ-9 modified for Adolescents (PHQ-A). If a patient's score on the PHQ-9 or PHQ-A does not seem to accurately reflect observed clinical symptoms, *DSM-V* criteria are recommended for diagnosis.

To ascertain the neurodevelopmental conditions investigated in this study, we relied on systemwide clinical diagnoses made by experts in the field as mentioned above.

Chart Abstraction Process

Trained research associates (abstractors) reviewed EHRs for documentation of a diagnosis (yes/no) of each condition under investigation for the selected sample of children during the study period. Children were considered to have the disorder in the presence of documented evidence of that condition noted in the chart during the corresponding time period of investigation. To ensure data quality and consistency of chart reviews between the 2 abstractors, a total of 180 cases, stratified by the 2 strata (Dx and No-Dx), were randomly selected for reabstraction (90 per abstractor and 36 per condition). There was a total of 4 possible responses for each chart reviewed case, as follows: diagnosis "Yes," diagnosis "No," "Unable to ascertain due to blocked notes," and "Unable to ascertain due to insufficient notes." The abstractors based their responses on the information they were able to ascertain from the clinical notes. For example, due to the sensitive nature of psychiatric diagnoses, some progress notes may have been blocked; therefore, if the abstractors could not ascertain the diagnosis due to blocked notes, it was coded as such. Similarly, if the abstractors could not ascertain a diagnosis due to a lack of documentation or notes in the KPSC system with underused care (eg, outside claims data), the record was coded as "Unable to ascertain due to insufficient notes."

The results of this assessment informed our full chart review process of the 1200 medical records as mentioned above. In other words, we excluded those claims data records from the random selection of the validation sample. Furthermore, during chart review, records in which the abstractors encountered blocked notes and were therefore unable to make a determination were flagged. These flagged records (n=38, 3%) were replaced with another randomly selected record for chart review from the same strata. Potential cases that were still unclear in the clinical use records were adjudicated by the study investigator with expertise in the field (DG). The child psychiatric and neurodevelopmental condition cases abstracted through this process served as the gold standard.

Child Characteristics

Characteristics for KPSC member children included age (2-5, 6-11, and 12-17 years), sex (male and female), race/ethnicity (categorized as non-Hispanic White, non-Hispanic Black, Hispanic, Asian/Pacific Islander, other/multiple, and unknown), median household income in US dollars (<30,000; 30,000-49,999; 50,000-69,999; 70,000-89,999; and ≥90,000), and insurance type (Medicaid, commercial through employment, private/individual, and other).

We obtained the characteristics of all children of the state of California residents during the same time periods using publicly available data posted on the Centers for Disease Control and Prevention Wonder website [3]. Both the KPSC EHR and the Centers for Disease Control and Prevention (Wonder) sources provided information on child characteristics, including age and race/ethnicity. Data on median household income were estimated based on census tracts for KPSC patients.

Statistical Analysis

We described the characteristics of our study population between those with and without the conditions of interest. Furthermore, we investigated how representative the KPSC pediatric population is compared to the state of California pediatric population during the entire study period using frequency distributions. For the purpose of comparison with the California children population, the age of the children for the KPSC population was evaluated based on the date of randomly selected clinical visits for each child during the entire study period.

The agreement between the 2 abstractors was evaluated with the interrater reliability assessment (κ statistic) by using the initial 180 chart reviews. We compared findings from the manual chart review of the 1200 cases, set as the gold standard, with corresponding diagnosis records for the *ICD-9-CM* and *ICD-10-CM* coding periods as well as before and after the COVID-19 pandemic through sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV). These performance measurements were reported as weighted percentages with corresponding 95% CIs using normalized sampling weights (W), as defined below:

$$W_{ij} = \frac{\# \text{ in stratum } j}{120 \times (\# \text{ total study population } i)}, i=1 \text{ to } 5, j=1,2$$

where i is for each of the 5 conditions and j is for the corresponding two strata (Dx and No-Dx) within each condition. To evaluate the overall performance, we also reported the summary statistics of F -score and Youden J statistic, which are

composite measurements of sensitivity and PPV (F -score) or sensitivity and specificity (J statistic).

All analyses were conducted using SAS statistical software (version 9.4; SAS Institute, Inc).

Results

An overview of the patient characteristics for our sample, study population, and the state of California pediatric population are shown in Table 1. Overall, 2,283,931 children from all KPSC hospitals and medical offices were obtained during the 3 time periods. Compared with the state of California pediatric population, KPSC had similar distributions on the children's sex but had slightly higher percentages of children for ages 2-5

years (25.6% for KPSC vs 24.7% for the state of California) and 6-11 (37.8% for KPSC vs 37.4% for the state of California). In addition, KPSC had slightly lower percentages of children identified as non-Hispanic White (24.5% vs 28.5%) or Asian/Pacific Islander (10.0% vs 13.1%). However, this could be partially attributed to the larger percentage of unknown, missing, or multiple race/ethnicity in the KPSC group (6.0% vs 0.5%, respectively). Overall, the KPSC pediatric population in this study was a good representation of the entire state of California's pediatric population. Our sample of 1200 children across the 5 conditions was broadly representative of the KPSC study population with respect to age, sex, and race/ethnicity. However, children in the older age groups were slightly oversampled. The overall κ between our 2 abstractors was 95%.

Table . Characteristics of the study cohort and the state of California pediatric population aged 2-17 years (2012-2014, 2017-2019, and 2021-2022).

Characteristics	Chart reviewed		Pediatric population

^aKPSC: Kaiser Permanente Southern California; the sample is based on the KPSC data from the electronic health records (2012-2014, 2017-2019, and 2021-2022).

^bData are from the natality information of Centers for Disease Control and Prevention website [3].

^cStarting age is different for each condition.

^dMedian household income and insurance type information are not available for the California state data.

Table 2 shows the distribution and their sample sizes for the two strata (Dx and No-Dx) among our entire study population and by the 3 time periods. Based on these comparisons against the chart review results, the performance measurements of our EHRs are shown in Table 3. The weighted sensitivity, specificity, PPV, and NPV for each of the 5 conditions were as follows:

- ADHD: sensitivity 100%, specificity 99.9%, PPV 99.2%, and NPV 100%
- ASD: sensitivity 100%, specificity 100%, PPV 99.2%, and NPV 100%

- MDD: sensitivity 100%, specificity 100%, PPV 99.2%, and NPV 100%
- AD: sensitivity 87.7%, specificity 100%, PPV 100%, and NPV 99.2%
- DBD: sensitivity 100%, specificity 100%, PPV 100%, and NPV 100%

The corresponding *F*-score and Youden *J* statistic were 99.6% and 99.9% for ADHD, 99.6% and 100% for ASD, 99.6% and 100% for MDD, 93.4% and 87.7% for AD, and 100% and 100% for DBD, respectively. Results were similar across the *ICD-9-CM* and *ICD-10-CM* coding time periods as well as the before and after the COVID-19 pandemic.

Table . Frequencies of study population and chart review results by diagnosis codes. Condition-specific row percentages may not sum to 100% due to rounding.

Discussion

Principal Findings

This validation study was performed to determine the accuracy of clinical diagnosis codes in ascertaining childhood psychiatric and neurodevelopmental cases using data abstracted from the EHR of a large integrated health care system serving a demographically diverse patient population. To our knowledge, the accuracy of data on studied conditions using clinical

diagnostic codes has not been validated using EHR data. Furthermore, the extent to which the transition of *ICD-9-CM* to the *ICD-10-CM* coding system as well as the pre- and post-COVID-19 pandemic eras have impacted the ascertainment of the studied behavioral and developmental conditions is unclear. Our study showed that within a large integrated health system, there is strong agreement between the diagnosis codes (*ICD-9-CM* or *ICD-10-CM*) and the patients' conditions, including ASD, ADHD, DBD, AD, and MDD, both before and after the COVID-19 pandemic eras.

In recent years, EHRs have become important data sources for various epidemiological study designs investigating potential associations between exposures and outcomes that have become standard among researchers and health care providers as part of the American Recovery and Reinvestment Act of 2009 (specifically the HITECH Act) [14]. Although the EHR has become an important information management and care delivery system tool ensuring quality of care by providing access to comprehensive treatment-related data, its validity and completeness for conducting pharmacoepidemiological studies have been challenged by many due to how information is coded [23]. In the KPSC health care system, the process of using data coding and coding rules of the medical diagnoses and procedures recorded in patients' health records is performed by trained medical coders from the clinical data management team. Individual diagnostic conditions in the EHR need to be evaluated critically for accuracy and consistency. Furthermore, whether the accuracy of case ascertainment has been impacted by the introduction of the *ICD-10-CM* coding system as well as the effect of the COVID-19 pandemic on the quality of data capture needs to be investigated. Therefore, we performed this validation study to evaluate (1) the accuracy of pediatric mental, emotional, and behavioral disorders identified in EHRs and (2) the coding quality before and after the implementation of the *ICD-10-CM* codings as well as before and after the COVID-19 pandemic.

The findings of this study suggest that the validity of EHR data for the identification of childhood mental, behavioral, and emotional conditions is quite strong and the transition from the *ICD-9-CM* coding system to the *ICD-10-CM* coding system as well as coding during the COVID-19 pandemic had minimal impact on the overall accuracy of case ascertainment.

The main strength of this study is the large chart abstraction conducted to assess the validity and reliability of childhood mental, behavioral, and emotional disorders case ascertainment

using EHR data extracted from a large integrated health care system. The EHR system database provides an opportunity for neurodevelopmental outcome investigation with a high degree of validity of case ascertainment for epidemiological studies, in addition to current developments by others using natural language processing algorithms [24-27]. This validation study, comprised of a demographically diverse southern California population, is likely generalizable to health care settings with similar EHR database systems. Although the overall agreement between our abstractors was almost perfect ($\kappa=95\%$), a potential limitation of this study was the use of medical record abstractors who were not blinded to the source of the data. However, a previous study that evaluated the agreement between masked and unmasked medical record abstraction reported no impact of bias in case ascertainment [28]. A further potential limitation is the fact that we had some records with blocked notes that needed to be replaced because of incompleteness in ascertaining the conditions of interest. However, in close examination, we found that the blocked notes were only 38 (3%) out of the 1200 cases, which we believe will have minimal impact on the overall analysis. In addition, we did not consider oversampling of the older age strata in the summarized performance metrics. Considering that the older age group could be given a more accurate diagnosis coding, the actual concordance of the electronic coding might be slightly lower than what we observed in this study.

Conclusions

Our findings suggest that childhood mental, behavioral, and emotional disorders are reliably coded in the EHRs and can be used for pharmacoepidemiological studies. Furthermore, the completeness of data remained similar during the pre- and postpandemic eras and after the implementation of the *ICD-10-CM* coding in the EHR system.

Abstract

Background: The National Health Service (NHS) Talking Therapies program treats people with common mental health problems in England according to “stepped care,” in which lower-intensity interventions are offered in the first instance, where clinically appropriate. Limited resources and pressure to achieve service standards mean that program providers are exploring all opportunities to evaluate and improve the flow of patients through their service. Existing research has found variation in clinical performance and stepped care implementation across sites and has identified associations between service delivery and patient outcomes. Process mining offers a data-driven approach to analyzing and evaluating health care processes and systems, enabling comparison of presumed models of service delivery and their actual implementation in practice. The value and utility of applying process mining to NHS Talking Therapies data for the analysis of care pathways have not been studied.

Objective: A better understanding of systems of service delivery will support improvements and planned program expansion. Therefore, this study aims to demonstrate the value and utility of applying process mining to NHS Talking Therapies care pathways using electronic health records.

Methods: Routine collection of a wide variety of data regarding activity and patient outcomes underpins the Talking Therapies program. In our study, anonymized individual patient referral records from two sites over a 2-year period were analyzed using process mining to visualize the care pathway process by mapping the care pathway and identifying common pathway routes.

Results: Process mining enabled the identification and visualization of patient flows directly from routinely collected data. These visualizations illustrated waiting periods and identified potential bottlenecks, such as the wait for higher-intensity cognitive behavioral therapy (CBT) at site 1. Furthermore, we observed that patients discharged from treatment waiting lists appeared to experience longer wait durations than those who started treatment. Process mining allowed analysis of treatment pathways, showing that patients commonly experienced treatment routes that involved either low- or high-intensity interventions alone. Of the most common routes, >5 times as many patients experienced direct access to high-intensity treatment rather than stepped care. Overall, 3.32% (site 1: 1507/45,401) and 4.19% (site 2: 527/12,590) of all patients experienced stepped care.

Conclusions: Our findings demonstrate how process mining can be applied to Talking Therapies care pathways to evaluate pathway performance, explore relationships among performance issues, and highlight systemic issues, such as stepped care being relatively uncommon within a stepped care system. Integration of process mining capability into routine monitoring will enable NHS Talking Therapies service stakeholders to explore such issues from a process perspective. These insights will provide value to services by identifying areas for service improvement, providing evidence for capacity planning decisions, and facilitating better quality analysis into how health systems can affect patient outcomes.

Introduction

The National Health Service Talking Therapies Program

Common mental health disorders such as anxiety and depression are among the top causes of disability in England [1], affecting 1 in 6 adults [2], and their prevalence is increasing [2,3]. This increasing health burden is reflected in the growing number of referrals received by the National Health Service (NHS) Talking Therapies program (formerly Improving Access to Psychological Therapies [IAPT]) since its inception in 2008 [4]. Each year, >1 million patients access Talking Therapies through the program [5], and like all parts of the NHS in England, the program is constrained by limited resources while facing additional pressure to achieve service standards for recovery rates and waiting times. On the basis of 2021 to 2022 access rates [5], the volume of people receiving treatment through the program will need to increase by 50% by 2024 to meet the targets set out in the NHS Long Term Plan [6]. Therefore, providers are looking at all opportunities to increase capacity and productivity to better understand and improve the flow of patients through care systems and to evaluate the performance of their services.

The Talking Therapies treatment model is based on the principle of stepped care, which is the approach recommended by the National Institute for Health and Care Excellence (NICE) [7]. The stepped care approach maintains that those with milder conditions should be treated initially with lower-intensity interventions, and these individuals might then be “stepped up” to higher-intensity interventions if clinically appropriate [7]. The stepped care approach has been shown to be associated with improved patient outcomes [8,9].

As detailed in [Table 1](#), the first step in the stepped care model represents the presentation of a common mental health problem. This initial presentation is usually followed by a referral to an NHS Talking Therapies service, which generally offers step 2 and 3 interventions, while more specialist services offer higher-intensity interventions at steps beyond this.

While each therapy service will follow the overall model of care prescribed by the IAPT model [11], each service has a uniquely configured care pathway, which represents the plan for the implementation of clinical guidance. Studies have shown that there is variation in how the principle of stepped care is implemented [12,13], and clinical performance has also been shown to vary across Talking Therapies program sites [9,14]. Despite this variation in implementation and performance, methods of implementation and systems of treatment delivery are relatively understudied in comparison to the psychological therapies offered [12,13].

Studies have demonstrated the relevance of implementation methods to the program’s performance by identifying features of service delivery that are predictive of clinical outcomes and patient engagement. For instance, longer waiting times have been associated with patient disengagement with IAPT therapy services [15,16] and worse recovery outcomes [9]. More treatment sessions, a larger service size, and a greater proportion of therapy sessions delivered by experienced staff have been shown to be predictive of reliable recovery [8]. Furthermore, patients face additional waiting times between first and second treatment appointments [5]; however, only 1 known study has explored the relationship between these additional waiting times and patient engagement [16].

Furthermore, the NHS Talking Therapies program faces the challenge of patient attrition: only approximately 40% of those referred to the program attend ≥ 2 treatment sessions [5]. Many patients drop out of the program for unknown reasons; however, the relationship between waiting times and attrition rates cannot be explored using aggregated data. Therefore, tools that enable services to analyze wait durations will enable better research into the relationship between waiting times and patient attrition. Electronic health records (EHRs) capture a rich set of data documenting the details of patient journeys through the Talking Therapies program and patient outcomes. However, the data are complex, and their analysis is not trivial. Treating the care pathway as an operational process allows patient flow and service use to be analyzed using process-centered methods such as process mining.

Table 1. The stepped care model for common mental health disorders, revised from the National Institute for Health and Care Excellence guidance (CG123) and the Improving Access to Psychological Therapies manual [10,11].

Step	Examples of conditions	Examples of interventions
1	Presentations of all known and suspected common mental health disorders	Identification, assessment, psychoeducation, active monitoring, and referral for further assessment and interventions
2	Depression (either mild to moderate or persistent subthreshold symptoms), generalized anxiety disorder, panic disorder, and obsessive compulsive disorder	Self-help and guided self-help based on CBT ^a , computerized CBT, psychoeducational groups, behavioral activation, and structured group physical activity program
3	Depression (either moderate or severe, prevention of relapse, or mild to moderate where individuals have not responded to low-intensity interventions), moderate to severe panic disorder, obsessive compulsive disorder with moderate or severe functional impairment, posttraumatic stress disorder, and generalized anxiety disorder, with marked functional impairment or in which individuals have not responded to low-intensity interventions	CBT (individual or group), applied relaxation, mindfulness-based cognitive therapy, interpersonal psychotherapy, behavioral activation, couple therapy, counseling for depression, brief psychodynamic therapy, trauma-focused CBT, EMDR ^b , and graded exercise therapy

^aCBT: cognitive behavioral therapy.

^bEMDR: eye movement desensitization and reprocessing.

Process Mining in Health Care

While traditional business process modeling involves reaching a consensus about model design, process mining is based on the assumption that a process model can be extracted from the information available in systems [17]. Such information can be used to generate “event logs,” the ordered records of events corresponding to the activities encountered by entities that have traveled through a process. An active area of research within process mining is regarding process discovery algorithms, which are often referred to as “process miners” [17]. These algorithms use the information contained within an event log to create a process model that is representative of the behavior captured within the log [18].

In health care, process mining techniques can be used to assess conformance to clinical guidelines and protocols and to assess performance [17]. Frequently asked questions within process mining projects are as follows: “What are the most followed paths and what exceptional paths are followed?” “Are there differences in care paths followed by different patient groups?” “Do we comply with internal and external guidelines?” and “Where are the bottlenecks in the process?” [19].

While process mining has been frequently applied in health care [17,20], in applications such as disease trajectory modeling and clinical pathway analysis [21], research has highlighted that there has been limited uptake within health care organizations, apart from specific research case studies [21,22]. Endeavors are being made toward systematic adoption of process mining in the health care domain through initiatives such as the Process Mining for Healthcare manifesto [21]; however, evidence shows an absence of efforts to integrate process mining tools into systems that record patient data [23].

Recent reviews of process mining in health care [20] and data-driven care pathway mapping from care records [24] have found applications in a number of medical fields, most commonly in oncology; however, neither found evidence of application in the domain of mental health. Outside the field of process mining, the study by Richards et al [12] in 2012 analyzed the delivery of stepped care within mental health

services in the United Kingdom; however, there is no evidence of such analysis being developed into a reproducible methodology or tool that could be applied to routinely collected data. Furthermore, a review of the wider literature shows no evidence of the application of process mining to psychological therapy care pathways. The Scopus query “process mining” AND (“psychological therap*” OR “psychological intervention” OR “psychological treatment”) returned only 2 results. Neither of the returned studies explored the care pathway for psychological therapies using process mining. The first study used process mining to explore health care pathways for patients presenting to emergency departments with functional neurological disorders, where onward referral to psychological therapy formed part of the pathway [25]. The second study used data from a psychological therapies service but did so to explore transitions between pre- and posttherapy clinical outcome bands to investigate the impact of appointment attendance on patient outcomes [26].

Objectives

The application of process mining techniques to NHS Talking Therapies care pathways using EHR data has not been studied; therefore, this study intends to demonstrate the value and utility of doing so. Our study applies process mining to the local care pathways of two NHS Talking Therapies sites and shows how the use, efficiency, and effectiveness of the Talking Therapies care pathway can be explored using a process mining approach. As part of a Knowledge Transfer Partnership project focused on embedding innovation into health care software, our study aims to address the absence of a systematic uptake of process mining by demonstrating how access to analytical tools that allow stakeholders to explore characteristics of their service implementation will enable improved monitoring of system use and better quality analysis into how health systems can affect patient-level outcomes.

Methods

Ethics Considerations

The Knowledge Transfer Partnership project titled “Developing innovative, advanced analytical tools to help improve IAPT

demand and capacity planning” was approved by the HRA (Health Research Authority) and Health and Care Research Wales (HCRW; integrated research application system project ID 320525), and the University of Bath Psychology Research Ethics Committee (23-031).

Process Mining

Process mining offers a data-driven approach to analyzing health care processes using the data stored within health information systems in event logs. There are 3 main areas of process mining: process discovery, which involves discovering a process model; conformance, which involves checking an existing process model against an event log; and enhancement, which involves enhancing a model either by repairing incorrect aspects of the model or by extending a model to add a new perspective, including adding extra information such as frequencies, timings, and bottlenecks [18]. In our analysis of Talking Therapies EHR data, we treated the Talking Therapies care pathway as a process, where care pathway stages form the activities in the process, while referred patients (termed “referrals” within IAPT services) are the entities who travel through the process. We demonstrated how process mining can be used for process discovery, evaluation of conformance with system design principles, and performance analysis (enhancement through extension) of the care pathway from referral to discharge.

Throughout our study, the terms “care pathway” and “pathway” are used to describe the whole process of interest, whereas unique sequences of activities are termed “routes” through the care pathway. In the field of process mining, these routes are often referred to as traces or variants.

Research has highlighted the importance of domain expert involvement in process mining projects [21,27,28]. This study is part of a collaborative project with Mayden, the company that provides the “iaptus” digital care record software to NHS Talking Therapies service providers; therefore, expert involvement has been integrated throughout this study. System experts from Mayden work with relevant stakeholders within all Talking Therapies sites using the software to configure each care pathway within the software, ensuring the suitability of the data collected. The specific data for this project were extracted by ETL (extract, transform, and load) experts at Mayden, and data preparation was conducted in consultation with data analysts at Mayden, who are familiar with the data structure and any data quality issues that are universal across sites. The choice of sites for this work was guided by recommendations from service representatives. The approach and results have been reviewed by a user representative from Mayden; furthermore, feedback on this approach was also gathered from Talking Therapies service representatives through user engagement meetings and workshops.

We transformed EHR data into an event log format, manipulated event logs using filtering and stage aggregation, and produced a process map directly from event logs in the form of a directly-follows graph: a descriptive mapping of data to a directed graph of nodes (care pathway stages) and edges (patient flows between stages) in R software (version 4.1.2; R Foundation for Statistical Computing) using the *bupaR* package (version 0.5.2) [29]. Additional R code was developed to extend

the process maps with summary statistics and additional formatting, including a bottleneck indicator that uses colors to identify where the edge between the two stages was both highly traveled and had a lengthy median duration. Bright colors are assigned to the edges that fall into the highest percentile when this information is collected into a single metric (the product of the number of patients who moved between the two stages and their median wait duration). A visualization of common routes through the care pathway was built using the *ggplot2* R package (version 3.3.5) [30].

Data

Data Source and Inclusion Criteria

iaptus is the digital care record used by approximately two-thirds of NHS Talking Therapies service providers in England [31]. In this study, we analyzed anonymized EHRs from iaptus relating to the patients referred to two sites between June 1, 2019, and June 1, 2021. These two sites were selected due to their differing size and clinical performance so that the generalizability of the approach could be demonstrated. From the patients referred to the sites during this period, those who consented to their data being processed as part of the IAPT data set, those who were aged ≥ 18 years at the time of referral, and those who had been discharged by February 8, 2023, were included in study data.

Types of Data Used

The NHS target for recovery is that 50% of those who have completed treatment should recover [11]. Recovery is calculated using the notion of clinical “caseness,” which is based on threshold levels of patient reported outcome measures. Patients are considered recovered if they were above the caseness threshold at the beginning of treatment and below the threshold at the end of treatment [11]. Patient reported outcome measures are routinely collected at each session; therefore, patient outcomes for the program have a high degree of data completeness for those who attend ≥ 2 treatment sessions. Recovery outcome data were available for 94.98% (17,151/18,058) and 96.44% (5034/5220) of the patients who had attended ≥ 2 sessions at site 1 and site 2, respectively.

Patient geographical data, such as lower super output area (LSOA), was joined with 2019 Office for National Statistics (ONS) data [32] to calculate the proportion of referrals to each site that were assigned to each of the index of multiple deprivation (IMD) deciles. IMD data were available for 99.54% (45,193/45,401) and 99.78% (12,561/12,590) of the patients with referrals to site 1 and site 2, respectively.

The therapist role was available for 71% (375/528) and 82.7% (105/127) of the therapists in the data set for site 1 and site 2, respectively. Role data were mostly missing for the remaining therapists because their role data had been deleted and was no longer available in the system. These therapists had most likely left the service.

Patient appointment records contain information about appointment attendance, which is used to calculate the proportion of patients who completed treatment by attending ≥ 2 treatment sessions and the proportion of sessions that were

not attended. These data were 99.62% (206,564/207,357) and 99.89% (55,415/55,478) complete across site 1 and site 2, respectively. Missing data were removed before calculating the recovery rates, the IMD decile breakdown, the therapist role proportions and missed appointment rates.

Patient movements through the stages of the Talking Therapies care pathway are recorded in the system by service staff as time-stamped events. Each row of data in the event log identifies the referral that the movement relates to, the stage in the pathway that the patient has moved into, and the date and time of the movement. The pathway stages include all aspects of the service's implementation of the stepped care model, from receipt of referral to assessment, low- (step 2) and high-intensity (step 3) interventions, and the eventual discharge of the patient. Some Talking Therapies services may provide other specialist interventions in addition to step 2 and step 3 treatment; therefore, data were filtered to only include patients with referrals for NHS Talking Therapies treatment.

Data Preparation

The event log data needed to undergo data quality assessment and be prepared for analysis. In the analysis, the time stamp of events was used to determine their sequence. However, as the time stamp is recorded manually by staff, there were some issues with the event data, which meant that manually inputted time stamps did not always reflect the actual sequence of events that occurred. Nevertheless, this was imputed from other time stamp data within the movement record, using the time stamps of surrounding events in the sequence, for example, by taking the last observation carried forward. More information on this can be found in [Multimedia Appendix 1](#).

Care pathway configurations can be complex as the pathway is often used within services for patient management and data reporting purposes. In addition, the configuration and the resulting data collected can change over time. For these reasons, a high degree of variation was found in the basic event log;

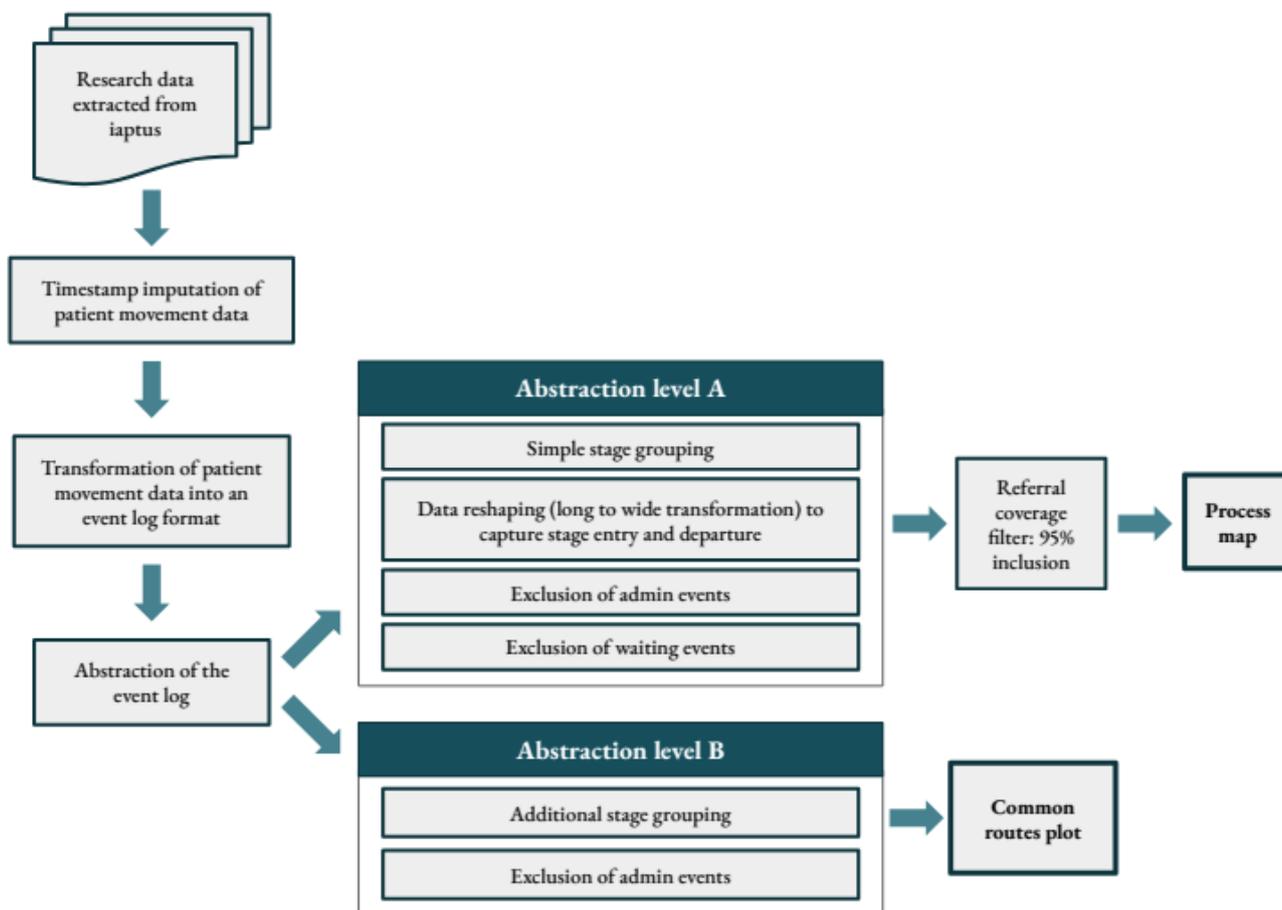

therefore, activities were aggregated and filtered to produce two abstracted event logs for each site that would provide two simplified views of the data set (as shown in [Figure 1](#)). These two levels of abstraction were designed in collaboration with data analysts at Mayden.

The abstraction level A involved grouping care pathway stages and excluding events. Grouping care pathway stages included remapping the names of duplicated stages with minor distinctions to appropriate descriptive names; for example, outdated stage names were replaced with newer versions of the name. Other suitable stages were collapsed into overarching subprocesses, whereby consecutive instances of events within the same subprocess are transformed into a single instance of the subprocess. For example, a discharge planning stage was always followed by the final stage representing the discharge of the patient; therefore, these two stages were collapsed into a single "discharged" stage to reduce granularity in the data.

To further reduce the granularity of the data presented in the process map visualizations, events relating to administrative stages, such as moving to a different step intensity or joining a waiting list, were excluded from the event log, as this information was contained implicitly within the data. To produce the process maps, the event log was filtered using a percentage coverage level to include data relating to patients who experienced the most common pathway routes.

For abstraction level B, stage names were remapped in the same way as abstraction level A, and subprocesses were collapsed to a further degree to create larger groups that encompassed more pathway stages. For example, the subprocess "step 3 treatment" included the individual treatment stages at step 3, such as cognitive behavioral therapy (CBT) and counseling. Waiting stage events were not excluded from this version of the event log, as these additional event data proved useful for analyzing distinct pathway routes; however, events relating to other administrative stages were excluded.

Figure 1. Data preparation steps.

Results

Data Description

The two sites in our sample differed in size, performance, and referral patient characteristics (Table 2). Site 1 had >3.5 times referrals as site 2. Both sites had similar proportions of referred patients in the lowest IMD deciles; however, site 2 had considerably more referred patients in decile 3 and marginally more patients in deciles 9 and 10, while site 1 had more patients in deciles 5, 7, and 8. On the whole, this suggests that patients referred to site 2 had more variation in deprivation status, whereas site 1 saw a more even distribution across the IMD deciles. Site 2 had a slightly greater proportion of higher-intensity therapists than site 1. While site 1 fell short of the recovery rate target by more than 2%, site 2 exceeded the target by >2%. Site 2 had a higher treatment completion rate (the proportion of referred patients who had ≥2 treatment sessions) and shorter waiting times than site 1 and a higher missed appointment rate. Although site 1 had a lower treatment completion rate, patients with referrals to the site had a marginally higher mean number of treatment sessions than at

site 2, suggesting that those who did have treatment had more treatment sessions on average at site 1. The patients with referrals to site 1 were younger, more likely to be female patients, more likely to have an unspecified presenting problem (as opposed to an initial diagnosis), more likely to be self-referred, and less likely to have had a previous referral, in comparison to those with referrals to site 2.

Imputation summary statistics in Table 3 describe the time stamp adjustments for events that exhibited illogical time stamp sequencing. In total, 1.9% (6491/336,637) of the events were adjusted at site 1, with a median adjustment size (the absolute difference between the original value and the imputed value) of 2.3 weeks. In total, 7.2% (8921/123,523) of the events were adjusted at site 2, with a smaller median adjustment size of 0.5 weeks. Across all events (including those with no adjustment), the adjustments averaged very close to 0 at both sites (site 1: mean 0.2, SD 2.3; median 0, IQR 0-0 and site 2: mean 0.1, SD 1.7; median 0, IQR 0-0), suggesting that the impact on the overall results was likely to be minimal. Further information is provided in Multimedia Appendix 1. Furthermore, Table 3 shows the reduction in event log variation from applying abstraction to the log.

Table 2. Data summary for the site characteristics, performance measures, and patient referral characteristics present in the data set for discharged patients with referrals received by sites 1 and 2 between June 1, 2019, and June 1, 2021.

	Site 1	Site 2
Site characteristics		
Patient referrals received, N	45,401	12,590
Index of multiple deprivation deciles of referrals^a, n/N (%)		
1	4783/45,193 (10.58)	1263/12,561 (10.05)

Process Mining

Process Mapping

Figure 2 presents a process map with 95% coverage for site 1. The map summarizes the pathway structure, patient flow, and service performance for referred patients who followed common pathway routes. Patients with referrals to the service receive an assessment before being triaged to step 2 (low-intensity treatment) or step 3 (high-intensity treatment). Patients can be “stepped up” from low- to high-intensity treatment (indicated by a triple arrowhead on the edge tail, as shown in the process map key in Figure 2) and can be discharged from any point in the pathway. A process map for site 2 is presented in Figure S1 in Multimedia Appendix 1.

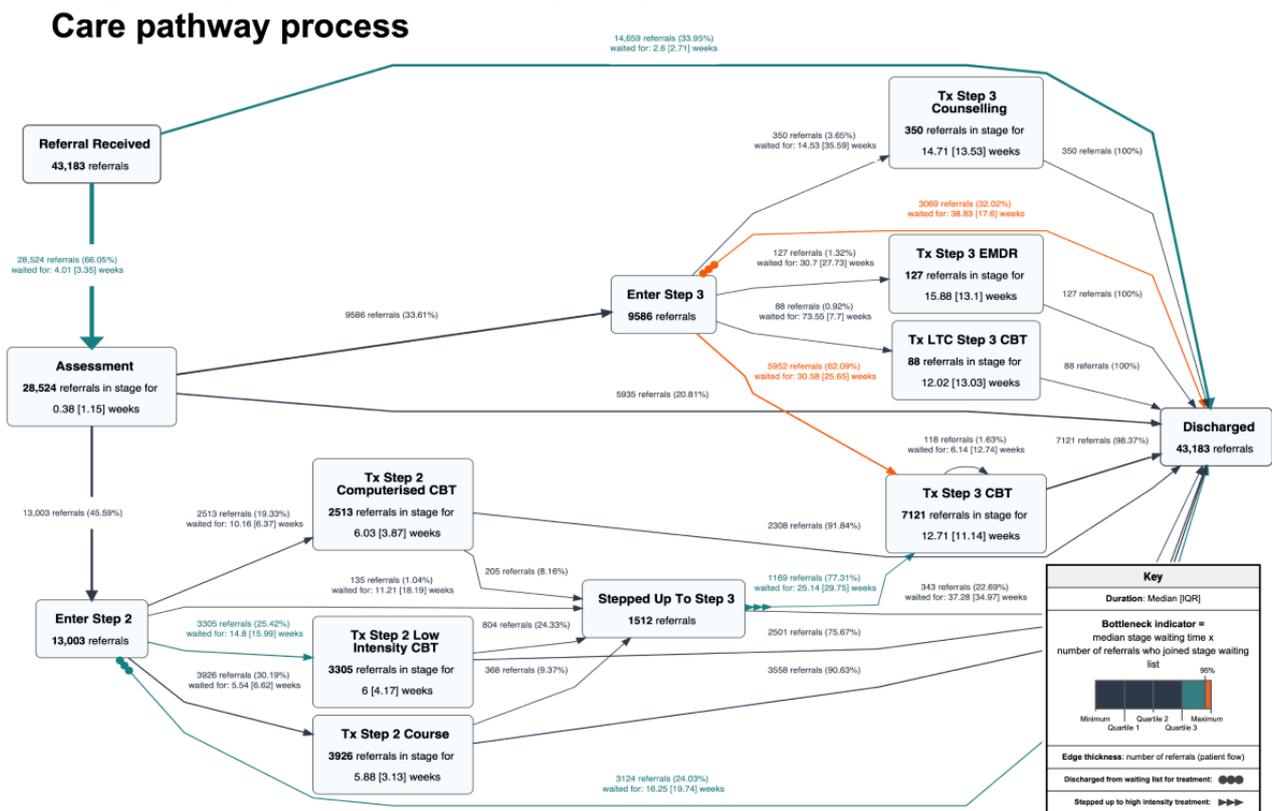

Edge thickness, referral volumes, and branching probabilities demonstrate patient flow. In the process map, one-third (14,659/43,183, 33.95%) of the referred patients were discharged immediately, and a further 20.81% (5935/28,524) of those assessed were discharged after assessment, equating to 13.74% (5935/43,183) of all referrals represented in the map. In total, 27.42% (6193/22,589) of those triaged into steps 2 or 3 were discharged before receiving the intended treatment (3124/13,003, 24.03% of the referrals at step 2 and 3069/9586, 32.02% of the referrals at step 3), equating to 14.34% (6193/43,183) of all the referrals represented in the process map. Flows that involved patients being discharged before receiving the intended treatment are indicated on the map with a set of triple dots on the edge tail (as shown in the process map key in Figure 2). Site 1 had higher attrition rates from waiting

lists for treatment than site 2, and at both sites, the attrition rate was higher at step 3. Relatively few patients followed the “step-up” route from low- to high-intensity treatment.

Edge color and duration summary statistics quantify pathway performance for 95.11% (43,183/45,401) of referrals. For example, the initial waiting time for assessment had a median value of 4 weeks, followed by a secondary waiting time for

treatment with a median value ranging from 5.5 to 73.6 weeks across treatment types. The duration on each node summarizes the length of treatment (number of weeks) and shows that higher-intensity treatment generally had a longer duration than lower-intensity treatment. The bottleneck indicator highlights the waiting time for step 3 CBT and the waiting time experienced by those who waited for step 3 treatment but were discharged.

Figure 2. Process map of the care pathway at site 1 using event log A (n=43,183 patient referrals). Referral coverage level=95%. CBT: cognitive behavioral therapy; EMDR: eye movement desensitization and reprocessing; Tx: treatment.

Common Route Analysis

Figure 3 presents the 10 most common care pathway routes at site 1 and the referral outcomes for each route, using event log B. The remaining uncommon routes are summarized under the common routes using the same metrics. The x-axis represents the median duration of activities throughout the course of the referral. Furthermore, a common route analysis is presented for site 2 in Figure 4. The findings from Figure 3 correspond with those from Figure 2 for site 1: three of the 5 most common routes involved no treatment, and routes that involved discharge from waiting lists are also observed. The relative frequencies of common treatment routes show that step 2 treatment alone was more common than step 3 treatment alone, and the comparative infrequency of “stepped care” is evident. Over the common routes at both sites, >5 times as many patients experienced direct access to high-intensity treatment rather than stepped care. In addition, many common routes involved no treatment at site 2. A smaller proportion of patients were discharged from the waiting list for assessment (1442/12,590, 11.45%) in comparison to site 1 (8437/45,401, 18.58%); however, a greater proportion of patients were discharged after being assessed at site 2 (3035/12,590, 24.11%) compared to

site 1 (5970/45,401, 13.15%). A total of 1507 of the patients with referrals to site 1 traveled a stepped care pathway route (1117 patients who experienced a common stepped care route + 390 patients who experienced step-up through less common routes), equating to 3.32% (1507/45,401) of all patients referred to the service. At site 2, the equivalent figure was 527 patients (365 patients who experienced a common stepped care route + 162 patients who experienced step-up through less common routes), equating to 4.19% (527/12,590) of all patients referred to the service.

The duration of common pathway routes differed between sites. Longer median waiting times for common assessment and treatment pathway routes were observed for site 1, including the stepped care route. At both sites, the common high-intensity route had a median wait duration of 2.6 times longer than that of the low-intensity route. There was a distinction at both sites between the median wait durations of routes involving discharge from a waiting list, compared to routes where patients completed waiting and commenced treatment. For example, at site 1, the median value of the total wait duration was 13.3 weeks for the step 2 treatment route compared to 20.6 weeks for the attrition alternative. The step 3 treatment route had a total wait duration

with a median value of 34 weeks compared to 41.9 weeks for the attrition alternative. At site 2, the equivalent comparisons were 8.1 versus 13.1 weeks at step 2 and 21 versus 26.8 weeks at step 3. This distinction was most severe for the stepped care

route at site 1, where those who were stepped up from step 2 but were discharged from the high-intensity waiting list experienced a total wait duration with a median value of 11.4 weeks longer than those who successfully waited for treatment.

Figure 3. Common route analysis of the care pathway at site 1 using event log B (n=45,401 patient referrals). Coverage level=100%. Top 10 routes only plotted. Tx: treatment; WL: waiting list.

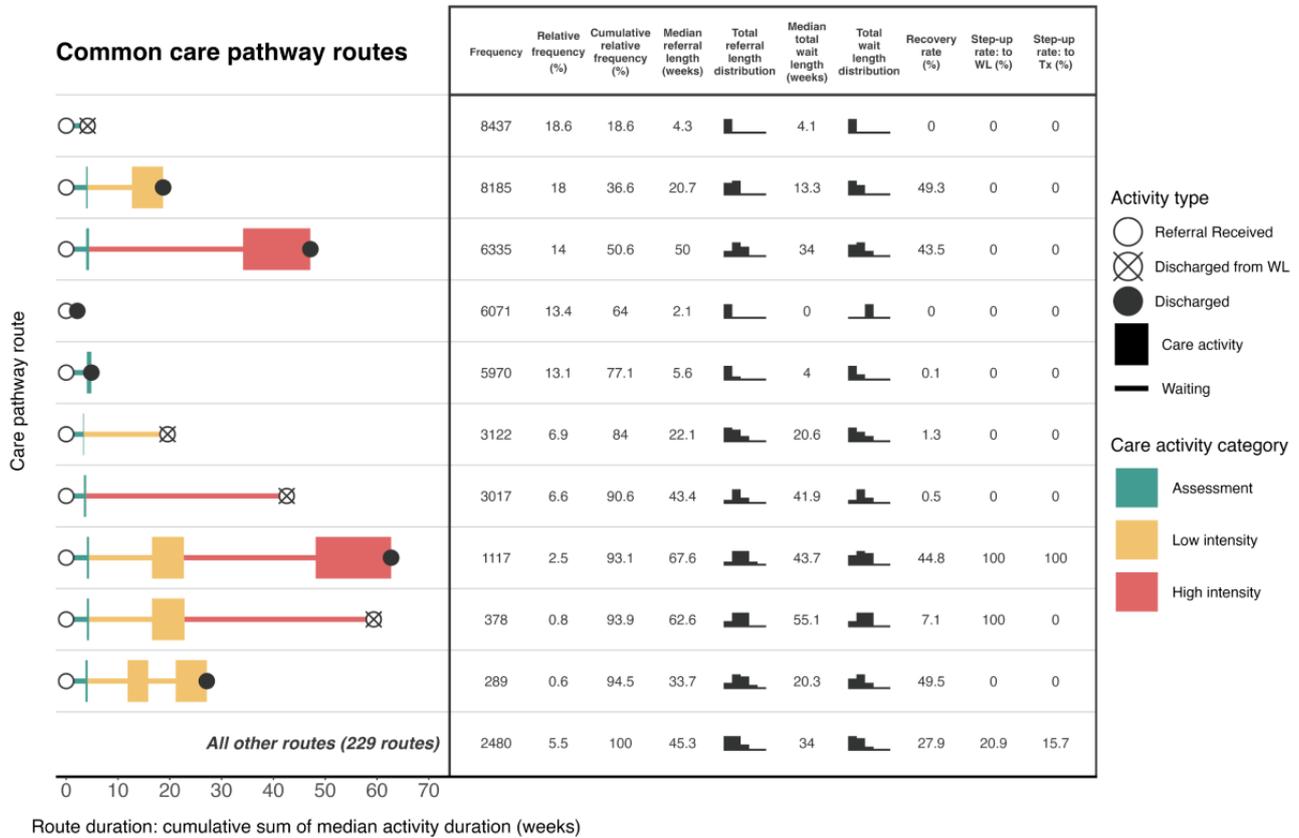

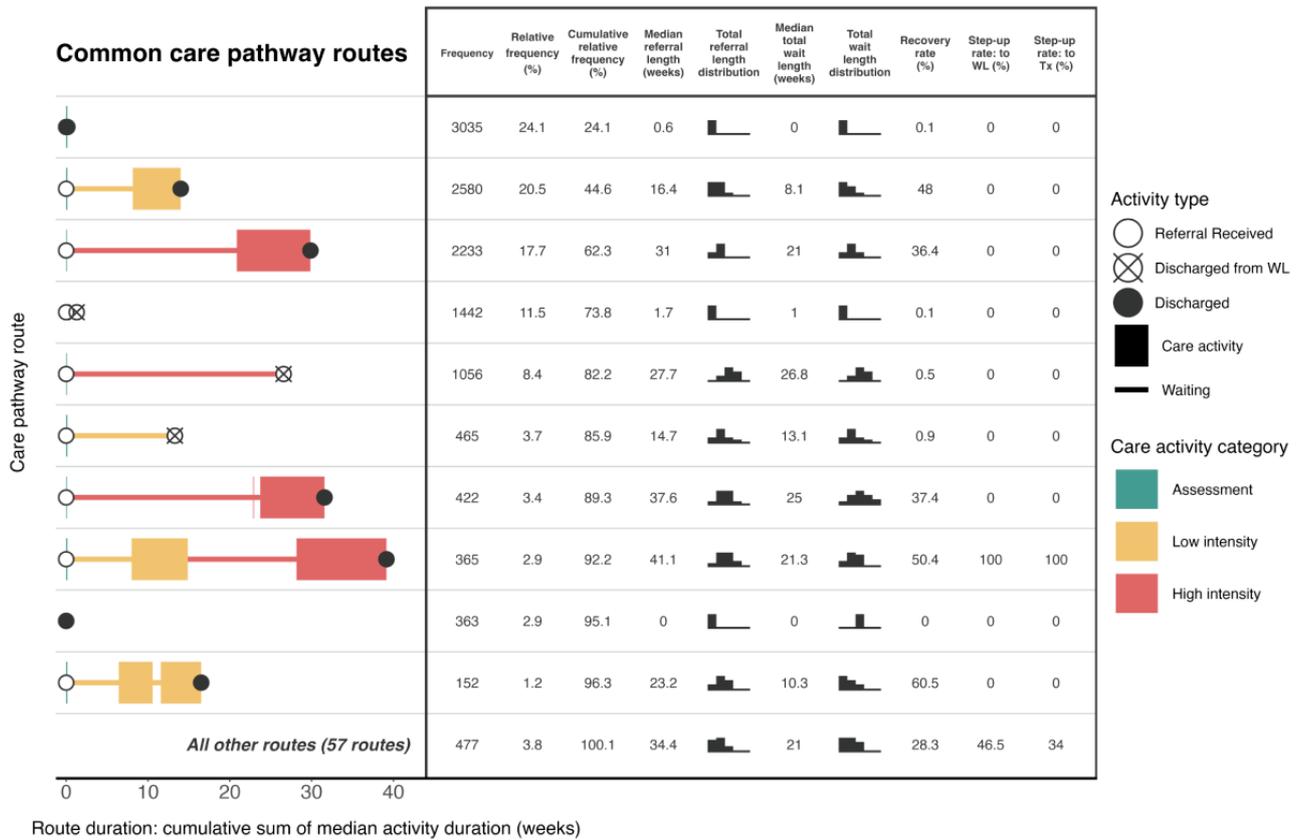

Figure 4. Common route analysis of the care pathway at site 2 using event log B (n=12,590 patient referrals). Coverage level=100%. Top 10 routes only plotted. Tx: treatment; WL: waiting list.

Discussion

In this paper, we demonstrated how process mining techniques, such as process discovery using directly-follows graphs (data-driven process maps), and process enhancement (through extension) using performance and common route analysis can be used to explore “as-is” mental health care pathway use and patient outcomes from a process perspective using routinely collected anonymized EHRs.

Clinical Guidelines and Outcomes

Our results show how process mining can be used to investigate care system implementation and explore adherence to clinical guidelines and the principles that have informed the design of the care pathway of a service. We presented a data-driven process map of the referrals to a Talking Therapies service over 2 years. The map indicated lower rates of patients being stepped up from low- to high-intensity treatments than might be expected from a “stepped care” system. The common route analysis confirmed that approximately 3% to 4% (site 1: 1507/45,401 and site 2: 527/12,590, respectively) of patients referred to the sites received stepped care.

The stepped care approach is associated with better patient outcomes [8,9], but research has found differences in the implementation of “stepped care” within psychological therapy services [12], for example, a stratified model, where a specific treatment intensity is selected after an initial assessment, versus a progressive model, where low-intensity treatment takes place in the first instance [13]. Therefore, data-driven pathway

mapping is a fitting tool to investigate not only the design and implementation decisions of the care system but also the actual use of the system; for example, the National Institute for Health and Care Excellence guidelines instruct that pathways should “allow services to be built around the pathway and not the pathway around the services” [10].

The low stepped care rates presented in this study could be attributed to a number of factors, which could be further explored using process-centered methods. For example, Talking Therapies services are rewarded based on assessment volumes and outcome-based performance [33]; therefore, services can be motivated to process stepped up referrals as separate referrals entirely. Patient-level instances of care, as opposed to referral-level ones, could be used to investigate rereferral pathway routes to explore whether this type of behavior is present in the data. In addition, step-up rates will be impacted by the clinical composition of the referrals received by the service; therefore, by filtering the analysis by individual patient groups, adherence to clinical guidelines and operational principles could be explored further. The relative infrequency of stepped care in comparison to direct access to high-intensity treatment supports the findings of previous research into stepped care implementation [12].

Furthermore, we identified common routes through the Talking Therapies care pathway and presented the clinical performance of these routes in terms of patient recovery. This type of analysis could be used to compare clinical outcomes between pathway routes and could provide a valuable basis for future evaluation of the efficacy of treatment pathways.

Patient Attrition

Our results established common routes that did not involve treatment. Service managers may wish to monitor routes involving discharge from waiting lists for care. Waiting list attrition is likely to be an undesirable outcome that indicates system inefficiency as well as potentially leading to negative patient outcomes due to untreated symptoms. Analytical tools that incorporate pathway routes can be used to locate patient attrition and monitor patient flows through undesirable routes. For example, although the two sites had similar treatment completion rates of approximately 40% (in line with national rates), route analysis revealed differences in the dominant nontreatment routes between the sites. The distinction between the location of early attrition can help differentiate between that which is patient initiated and that which is attributable to triaging or signposting onward.

Furthermore, we identified attrition later in the course of care, provoking questions regarding the association between system performance and patient attrition. At both sites, the pathway routes involving discharge from a treatment waiting list featured in the most common routes. Moreover, patients who were discharged before receipt of treatment appeared to wait for a longer duration than those who received treatment when comparing the median of the total wait duration of each route. Those discharged before receipt of treatment at site 1 waited 7.3 weeks longer at step 2 and 7.9 weeks longer at step 3 compared to those who received treatment. At site 2, those discharged before receipt of treatment waited 5 weeks longer at step 2 and 5.8 weeks longer at step 3.

In addition, areas of the pathway with longer median waiting times (ie, high-intensity treatment) had higher rates of waiting list attrition. Furthermore, site 2 had shorter median waiting times for treatment and less attrition from the treatment waiting lists than site 1. These initial findings could indicate a relationship between treatment waiting times and patient discharge before treatment commencement. Owing to the limitations of publicly available data, the research literature only seemed to include engagement studies that explored the association between waiting times and appointment nonattendance [15,16] rather than any quantitative study that has explored the relationship between secondary waiting times and patient attrition from the Talking Therapies program. However, our initial results about the relationship between treatment waiting times and patient disengagement are consistent with these studies. This relationship will be explored further in future work, as identifying the factors associated with waiting list attrition could have significant implications for policy.

Waiting Times and Pathway Bottlenecks

The Talking Therapies program's waiting times are subject to NHS service standards; however, the initial waiting time for a first appointment is often followed by a secondary waiting period, which, more often than not, is 3 times as long as the initial waiting time [14]. Secondary waiting times are now incorporated into national reporting requirements for Talking Therapies services; however, they are not held to NHS service standards, despite the IAPT manual declaring that they should not be "excessive" [11]. Furthermore, the manual states that the

waiting time for high-intensity treatment should not be "substantially longer" than the waiting time for low-intensity treatment and that for those who are stepped up, the waiting time between the low-intensity treatment and high-intensity treatment should "certainly not exceed the waiting time standard for the first intervention" [11].

Accordingly, our analysis provides an overview of system performance in terms of the total wait duration of common pathway routes and further demonstrates patient waiting times throughout the course of care. In addition, the process map bottleneck indicator has been used to highlight areas of the pathway that involve both large patient flows and lengthy median waiting times, indicating pathway stages that might need more urgent attention, and could be used by decision makers to inform capacity allocation or pathway configuration decisions.

Existing studies into the clinical impact of waiting times appear to focus on first waiting times within the pathway. For example, Clark et al [9] used the time between the first referral date and the first treatment appointment as a feature in their predictive models of clinical outcomes. However, as the vast majority of first IAPT assessment appointments are categorized as involving some aspects of treatment [15], it is likely that the first recorded treatment appointment will be the assessment, which will be conducted before the commencement of a course of treatment, leading to potential underestimation of the time taken to enter treatment.

While secondary waiting times are now part of national reporting requirements for Talking Therapies services, these figures are only reported for those who eventually go on to receive a second treatment session; therefore, by definition, they did not drop out before the second treatment session. For this reason, exploration of the impact of these waiting times on patient dropout requires more advanced tools. Analytical tools that allow Talking Therapies services to monitor both initial and secondary waiting times will, therefore, enable better monitoring of excessive waiting times for patients and offer the potential for future research into the relationship between all waiting times and patient outcomes.

Limitations

Our results are subject to some limitations in relation to the data and preprocessing methods. To create the study data set, referrals in the available data were filtered using both the referral date and the discharge date. The patients with referrals received by the sites within the inclusion window (from June 1, 2019, to June 1, 2021) were excluded from the study sample if they were discharged after the discharge cut-off date (February 8, 2023). This filter could introduce bias toward the end of the referral inclusion window by excluding the patients with referrals with a longer duration; however, the number of patients with referrals received within the referral inclusion window who were not discharged on or before February 8, 2023, was minimal at both sites (292/45,401, 0.64% and 1/12,590, 0.008% of all patients referred to sites 1 and 2, respectively). Therefore, the impact on the overall results is considered to be negligible.

Second, the 2-year period of referral inclusion included the onset of the COVID-19 pandemic, which has been shown to have influenced the rates of access and methods of treatment delivery [5,34]. Some additional analysis has been included in [Multimedia Appendix 1](#) (Figures S2-S8 and Table S1) to evaluate the impact of the pandemic on the results of this study. The volume of referrals to both sites dropped during the initial months of the COVID-19 pandemic and recovered in the months that followed, similar to the early findings presented in the study by Bauer-Staeb et al [34]. There were some differences in performance measures following the onset of the COVID-19 pandemic (Table S1 in [Multimedia Appendix 1](#)), such as an increase in recovery rates, a reduction in referral duration and wait duration, a reduction in the missed appointment rate, and changes in the proportion of patients who received ≥ 2 treatment sessions. These differences can be further explored using the approach presented in this study (Figures S5-S8 in [Multimedia Appendix 1](#)) by comparing the frequency and duration of pathway routes across the two time periods. Routes that involved discharge from a waiting list for treatment were less common following the onset of the COVID-19 pandemic. The overall rates of stepped care had some differences following the onset of the COVID-19 pandemic; however, the rates remained low overall, with $< 6\%$ of all referred patients receiving stepped care across both sites, both before and following the onset of the COVID-19 pandemic.

Third, the imputation techniques applied to illogical event time stamps were based on the assumption that other events' time stamps could be used as a proxy. Such assumptions were based on our understanding of how iaptus users use the software. In addition, as part of the ongoing development and implementation of this study, elements of data processing that were constructed independently for the two sites, such as the design of the abstraction levels, are being developed into automated criteria that can be applied across all sites. More structured feedback will be gathered from multiple services about the suitability of these assumptions as part of this implementation process during planned future user engagement sessions.

Clinical Implications

Our study provides a contextual yet structured view of patient flow rather than using isolated metrics to describe pathway use.

This study has been driven by the ongoing demand received by Mayden from NHS Talking Therapies services for ways to monitor access to services, explore changes in clinical outcomes, understand patient engagement, and manage service capacity. Ongoing elements of this project include developing the analysis presented in this study into tools that can be used for these purposes across all services that use iaptus, enabling purely data-driven exploration of care pathways from the data that are routinely collected by the services.

Feedback from Talking Therapies service representatives such as service managers, clinical leads, and data analysts through meetings; a webinar with representatives from 33 Talking Therapies services; and user workshops has highlighted that implementing such analysis into routine practice will enable key stakeholders within mental health services to analyze their implementation of the Talking Therapies treatment model, by monitoring actual system use and performance and by exploring how these might impact patient-level outcomes. Further implications proposed by service representatives at these sessions were a better understanding of patient outcomes and engagement, the potential to use this approach to analyze patient movements through the care pathway by their demographic or clinical backgrounds, and the ability to analyze repeated referrals. Service feedback has also suggested that understanding pathway use will support data-driven capacity allocation decisions; therefore, our future research also endeavors to integrate process insights with staff resource information to support such decision-making.

Analysis of patient journeys through pathway routes demonstrates how service users experience the care pathway and is, therefore, naturally patient centered. Integrating this information into an EHR would provide clinicians with an immediate overview of their patients' previous routes and associated wait times, providing patient-level and service-level insights.

Furthermore, identifying secondary waiting times within the care pathway is a key first step to exploring the relationship between waiting times and engagement outcomes. In addition, our future research aims to model this relationship, enabling services to target improvements to relevant elements of their performance.

Acknowledgments

This study forms part of a Knowledge Transfer Partnership (KTP) project between the University of Bath and Mayden, a software development company that provides "iaptus," the digital care record for psychological therapies used by the National Health Service and other providers of the National Health Service Talking Therapies program. The authors would like to thank the Mayden data services team for their role in curating the data for this work and their expertise in understanding the data and accompanying quality issues. The authors would also like to thank Barney Bristow and David Betts for their help in reviewing this manuscript. The authors are grateful to the Talking Therapies services included in the analysis for their support and use of their data. This research was funded by Innovate UK as part of a KTP between the University of Bath and Mayden (funding reference number 10023951 and project reference number KTP013141).

Data Availability

The data sets analyzed during this study are not publicly available due to the data sharing agreements in place between Mayden (the software provider responsible for iaptus) and the psychological therapies services. This study used anonymized electronic health record data from the digital care record software iaptus.

Authors' Contributions

EY designed and performed the analysis and drafted the manuscript with support from AD and CV. AD, CV, and CE devised the study. All authors discussed the results and reviewed the final manuscript.

Conflicts of Interest

AD and CE are employed by Mayden. EY is employed by the University of Bath as a Knowledge Transfer Partnership (KTP) associate but works at Mayden in line with their working practices and is supervised by AD (industrial supervisor) and CV (academic supervisor). Mayden contributes to the KTP associate's salary by paying the University of Bath, but most of the salary is paid by the research grant, which has been funded by Innovate UK. CV has no conflicts of interest to declare.

Abstract

This study examined and reflected on the frequency of people with psychotic symptoms and features as the target population in design studies for mental health care innovation.

(*JMIR Ment Health* 2024;11:e54202) doi:[10.2196/54202](https://doi.org/10.2196/54202)

KEYWORDS

design approaches; design; innovation; innovative; innovate; innovations; psychiatry; mental health care; mental health; mental illness; mental disease; involvement; service users; people with lived experience; people with lived experiences; lived experience; lived experiences; co-creation; cocreation; psychosis; psychotic; schizophrenia; schizoid; schizotypal; paranoia; neurosis; hallucinosis; hallucination; hallucinations

Introduction

There is growing evidence highlighting the importance of involving people with lived experience in design processes in mental health care [1,2]. Particular attention should be directed toward the engagement of people with psychotic symptoms and features [3], as they often feel misunderstood due to their altered perceptions and subjective experiences [4,5]. A bottom-up review of the lived experience of psychosis emphasizes the complexity of psychotic symptoms and features and recommends including lived experience in designing mental health services to address these experiences and needs [6]. Design approaches can promote the involvement of people with firsthand experiences in the development of treatment, therapy, and recovery interventions for mental health care innovation [2]. Currently, it is unknown how frequent design studies specifically target people with psychotic symptoms and features. There is a scoping review of coproducing research on psychosis [7], but coproduction and design approaches are distinct

methodologies. Design approaches facilitate designing initiatives that prioritize participants' needs, expertise, and knowledge whereas coproduction facilitates collaborative delivery and knowledge production. In this research letter, we present findings on the frequency of design studies targeting people with psychotic symptoms by analyzing a prior systematic review data set that focused on involving people with firsthand experiences in designing mental health care innovations. The primary objective of this secondary data analysis was to elucidate how often design studies in mental health care target people with psychotic symptoms and features.

Methods

Primary Data Set and Secondary Data Analysis

We conducted a secondary data analysis using a data set from a prior systematic review that assessed the involvement of service users and people with lived experience in the design processes of mental health care innovation. In the screening process and study selection of the prior systematic review, 33

papers met the inclusion criteria [2]. All included papers were original reports or papers that (1) involved service users, people with lived experience, or both; (2) mentioned design approaches; (3) involved an empirical study; and (4) conducted the study in settings including mental health care services or psychiatry programs. In this secondary analysis, we examined the primary data set to provide an overview of the frequency of design studies in mental health care focusing on people with psychotic symptoms and features. This data set is suitable for this analysis since the search strategy of the systematic review did not target specific mental health conditions.

Data Extraction and Categorization

Studies were categorized based on their primary target population as reported in the studies ([Multimedia Appendix 1](#)). We categorized broad terms like psychosis, which encompasses various symptoms and features like altered perceptions, as well as mental health conditions in which psychotic symptoms and features are prevalent, such as schizophrenia. In the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, Text Revision* (DSM-5-TR), these symptoms, features, and conditions fall under the category “schizophrenia spectrum and other psychotic disorders,” covering a spectrum of related mental health conditions [8], also referred to as the psychosis spectrum [9]. Studies addressing psychotic symptoms and features or related conditions alongside unrelated mental health conditions were labeled “various mental health conditions” due to their comorbid nature. We did not count these studies as primarily focusing on people with psychotic symptoms and features.

Table 1. Target populations in mental health design studies.

Target population	Count, n (%)
Psychosis	6 (18)
Depression	4 (12)
Schizophrenia	3 (9)
Self-harm	2 (6)
Eating disorders	2 (6)
Substance use disorders	1 (3)
Borderline	1 (3)
Attention-deficit/hyperactivity disorder	1 (3)
Autism spectrum disorder	1 (3)
Bipolar disorder	1 (3)
Various mental health conditions	11 (34)

Discussion

This secondary data analysis revealed a notable emphasis on studies primarily targeting people with psychotic symptoms and features in mental health care design studies. This is noteworthy given the extensive range of mental health conditions in psychiatry, encompassing 21 categories according to the DSM-5-TR [8]. Although “schizophrenia spectrum and other psychotic disorders” constitutes only 4.67% (1/21) of these categories, 27% (9/33) of studies in our data set focused primarily on psychotic symptoms and features. This percentage

is high, considering the lifetime prevalence of psychotic disorders is approximately 1% [10]. Another 12% (4/33) of the studies mention psychotic symptoms and features alongside or as a result of other mental health conditions. Although these studies did not focus primarily on people with psychotic symptoms and features, they have shown that much attention has been given to psychotic experiences in design studies. The substantial research focus on people with psychotic symptoms and features in design studies may be attributed to the limited progress in prognosis for severe cases despite extensive research and treatment efforts [11]. This may prompt designers and

Research Question

We aimed to answer the following research question: how frequently are people with psychotic symptoms and features the target group in design studies that involve service users or people with lived experience in mental health care innovation?

Results

The Frequency of Design Studies Targeting People With Psychotic Symptoms and Features

Of the studies in the data set that focused on specific target populations, 18% (6/33) centered on psychosis and 9% (3/33) concentrated on schizophrenia. Since psychosis and schizophrenia are considered part of a broader defined spectrum of psychotic-related mental health conditions in which psychotic symptoms and features are prevalent, the total proportion of studies that primarily focused on people with psychotic symptoms and features was 27% (9/33). The largest group of studies, accounting for 34% (11/33) of the data set, did not focus on specific target populations and were classified as “various mental health conditions.” In this category, 12% (4/33) included psychotic symptoms and features as a target in addition to other mental health conditions ([Table 1](#)).

researchers to look for less conventional strategies to enforce novel promising solutions. Additionally, there is a growing call for attention to the subjective experience of psychotic symptoms and features in clinical care, as these vary from individual to individual (eg, [4-6]). Both factors underscore the urgency of involving people with firsthand experiences to capture the vividness of psychotic experiences in the design of innovative services and interventions, ultimately aiming to improve outcomes for service users.

Comparing the 9 studies that primarily focused on people with psychotic symptoms and features in this secondary data analysis to the results of the prior systematic review, we observed that 44% (4/9) demonstrated a high level of participant involvement in their design processes [2]. This is crucial for the development of new innovations because research shows psychotic symptoms and features can seem very different from a lived experience perspective compared to conventional psychiatric

conceptualizations [6]. At the same time, the results stress the ongoing need to engage people with lived experience of psychotic symptoms and features in design studies, as more than half of the studies did not show the substantial involvement that would be expected of design processes that aim to tailor innovations to the needs of the target group. Consequently, we recommend future design studies targeting people with psychotic symptoms and features to adopt the co-design methodology, as co-design shows the highest participant involvement levels in mental health care design studies [2]. Furthermore, researchers are encouraged to use the participation matrix [12] alongside co-design to make intentional methodological decisions regarding the phases and roles in which people with lived experience are involved. To prevent tokenism and cooptation in design processes, researchers and designers are recommended to systematically coreflect with people with lived experience, exploring the roles played and distilling benefits and challenges from both perspectives.

Abstract

Large language model (LLM)–powered services are gaining popularity in various applications due to their exceptional performance in many tasks, such as sentiment analysis and answering questions. Recently, research has been exploring their potential use in digital health contexts, particularly in the mental health domain. However, implementing LLM-enhanced conversational artificial intelligence (CAI) presents significant ethical, technical, and clinical challenges. In this viewpoint paper, we discuss 2 challenges that affect the use of LLM-enhanced CAI for individuals with mental health issues, focusing on the use case of patients with depression: the tendency to humanize LLM-enhanced CAI and their lack of contextualized robustness. Our approach is interdisciplinary, relying on considerations from philosophy, psychology, and computer science. We argue that the humanization of LLM-enhanced CAI hinges on the reflection of what it means to simulate “human-like” features with LLMs and what role these systems should play in interactions with humans. Further, ensuring the contextualization of the robustness of LLMs requires considering the specificities of language production in individuals with depression, as well as its evolution over time. Finally, we provide a series of recommendations to foster the responsible design and deployment of LLM-enhanced CAI for the therapeutic support of individuals with depression.

KEYWORDS

generative AI; large language models; large language model; LLM; LLMs; machine learning; ML; natural language processing; NLP; deep learning; depression; mental health; mental illness; mental disease; mental diseases; mental illnesses; artificial intelligence; AI; digital health; digital technology; digital intervention; digital interventions; ethics

Introduction

What Are Large Language Models?

Large language models (LLMs) are a type of generative artificial intelligence (AI) that displays unprecedented performance in different downstream tasks, such as question answering and, in general, context-aware text generation [1-4]. They produce language using deep neural networks. These models consist of billions of parameters and are trained on huge amounts of data at the expense of notable computational power. LLMs have been recently popularized by services—such as OpenAI’s ChatGPT-4, Google’s BARD (now called “Gemini”), and Meta’s Llama—that are currently used by millions of people every day, experts, and laypeople alike. These services are

essentially conversational AI (CAI) enhanced with LLMs. They offer a more human-like, natural, and context-relevant interaction than other technological applications such as rule-based conversational agents (ie, traditional “chatbots”). They hold the potential to transform how we engage in conversations and manage the information therein. Consequently, they are expected to become much more widely adopted in different professional fields, research, and society alike.

LLMs in Health Care and Mental Health Applications

In health care, applications of LLMs are manifold, spanning from clinical research and processes to physician-patient relations [5-10]. For instance, LLMs can improve clinical processes by automating the generation of administrative text

[1,5]. Physician-patient relations could benefit from the use of LLM-enhanced patient decision aids and interventions that could support therapy and improve shared decision-making [1]. Context-relevant and personalized conversations with an LLM-enhanced CAI show the potential to promote patients' empowerment and individuals' reflection around their personal values and preferences for different health care scenarios in a way that is not possible with current methods, for example, filling out legal documents such as advance directives [11-13].

In the mental health domain, the use of CAI is no novelty. The very first chatbot ELIZA, was developed in 1966, and played the role of a digital psychotherapist [14]. Six decades later, it is possible to develop and test LLM-enhanced CAI leveraging an ample body of knowledge and use cases. In the mental health domain, CAIs are currently used as patient therapeutic support, for example, a simple psychotherapy, such as cognitive behavioral exercises [15]. Given their noteworthy ability to process and produce language, the use of LLMs holds the potential to provide more context-aware and effective psychotherapeutic support to their users than traditional CAI. In fact, once embedded in CAI, designers can instruct LLMs to provide a nonjudgmental, readily available platform for vulnerable individuals to discuss their feelings and mental health struggles as well as practice skills that they learned in a therapeutic session.

CAI is also used to collect data of patients with mental health disorders, carry out initial triage processes, and provide treatment recommendations [6]. Here, LLM-enhanced CAI could process written or spoken responses of patients with mental health disorders to support therapists in their diagnostics or track mental health changes in patients over time. They could also generate personalized treatment recommendations by taking an individual's mental health history, their symptoms, values, and care preferences as input. By collecting data on the web, such as social media posts or chat logs, LLMs could help detect signs of emotional distress and detect mental health issues promptly. To this end, preliminary results show that ChatGPT-3.5 achieves good performance at detecting stress and depression in written statements on web-based forums [16]. These results suggest that ChatGPT-3.5-enhanced CAI could be in the future used in psychotherapeutic scenarios, for example, among patients with depression [16].

Ethical, Technical, and Clinical Risks Posed by LLMs

Emerging technology, including LLMs, are not immune to risks. They stem from conceptual, ethical, technical, and clinical considerations and become especially important in domains such as mental health care. They comprise ethical issues linked to bias, global digital divide, trustworthiness, black-box nature and validation, and the generalizability challenges in training and deploying LLMs [1,4,17].

In addition, authors are addressing different ethical problems associated with the use of LLMs in mental health applications. For instance, Cabrera et al [18] relate these challenges to the 4 principles of biomedical ethics with emphasis on data privacy, confidentiality, avoiding manipulation, and safety. Similarly, Yang et al [19] emphasize the necessity of carefully evaluating LLM-enhanced CAI in mental health applications by advocating

the use of explainability methods to make the outcomes of LLMs more transparent. They also suggest complementing the use of LLMs with additional sources of information, such as emotional cues and cause-effect reasoning to enhance the quality of mental health support [19]. Further, Thirunavukarasu et al [1] emphasized the importance of using domain-specific data to fine-tune LLMs to validate LLM-enhanced applications with real clinical use cases. Finally, research is also investigating these challenges, with a focus on the perspective of end users of these systems, for example, individuals engaged in digitally assisted therapies. To this end, Weidinger et al [4] identify 6 areas of risk and potential harm to users of LLMs, including issues such as discrimination, privacy risks, misinformation, and human-computer interaction challenges [4]. In particular, they emphasize the risks for the users of LLM-enhanced services, which stem from their "human-like" design.

Mental Health Use Case: LLM-Enhanced CAI to Support Individuals With Depression

In summary, regarding the use of LLMs, research needs to address a mix of familiar and novel conceptual, ethical, technical, and clinical issues. To improve our understanding of these challenges, we need to examine LLMs within specific domains. This approach becomes particularly pertinent in the mental health domain, where the high sensitivity of the use cases underscores the imperative for a responsible and effective implementation of LLMs in CAI systems that provide therapeutic support to vulnerable individuals.

In this work, we focus on the scenario where LLM-enhanced CAI systems are used in the mental health domain to promote therapeutic support focusing on individuals with depression. The rationale behind selecting this use case is as follows. First, depression affects over 300 million people and the World Health Organization identifies it as the largest single contributor to global disability [20]. From an economic standpoint, for instance, studies have estimated the economic impact of depression to be 1.6% of the US gross domestic product [21]. Further, burnout is a major issue among psychiatrists [22]. Then, it is imperative to integrate technology-mediated interventions alongside traditional therapy methods to enhance accessibility and effectiveness of mental health services. Here, the use of CAI for patients with depression is widespread and supported by an ample body of scientific evidence [15]. More recently, research has also started exploring the use of LLMs for addressing depression [3,23].

This said, it is still an open avenue of research to delineate the perimeter for the responsible use of LLMs in scenarios involving individuals with depression. Therefore, in this work, we contribute to research on the responsible design, integration, and use of generative AI in mental health by focusing on 2 challenges that affect all scenarios where individuals with depression interact with LLM-enhanced CAI. In particular, we address challenges that pertain the (1) humanization of LLM-enhanced CAI (philosophy and psychology) and (2) contextualization of the robustness desideratum (computer science).

Our approach is interdisciplinary and relies on theories and methods from philosophy, ethics, psychology, and computer

science. Our aim is to conceptually analyze 2 topics that are underexplored in the literature on LLMs and their applications in mental health care despite their importance while highlighting their risks. With our analysis, we provide a critical perspective on the CAI-specific trend of humanizing CAI and the problem of treating the robustness of LLM-based CAI systems as a context-independent challenge. We cross the boundaries of the disciplines to show how our conceptual analysis can be informative for issues in computer science and health research [24]. In fact, when properly translated, our conceptual analysis can generate valuable insights in empirical disciplines [25]. Finally, we discuss recommendations to promote the responsible use of LLM-enhanced CAI in the mental health domain.

Use of LLM-Enhanced CAIs by Individuals With Depression: 2 Challenges

Humanizing LLM-Enhanced CAI: a Philosophical and Psychological Perspective

Humanization is intended to develop CAI with the goal of simulating human abilities and traits, such as humor, empathy, and politeness. It is different from anthropomorphism, which refers to users' tendency to attribute CAI with human abilities and traits [26,27], although the CAI does need to be intentionally designed to mimic humans [26]. In practice, humanization of CAI is achieved by developing verbal, nonverbal, visual, and relational cues to make the system more human-like [28,29]. For example, CAI can have a persona (relational cues) that simulates certain human personalities, such as being a friend or therapist. This persona is often implemented in the avatar (visual cues), the informal language (linguistic cues), and emojis (nonverbal cues) used by the CAI. Empirical studies suggest that the humanized abilities and characteristics of CAI, such as reciprocity or giving empathetic responses, has positive outcomes on digital health interactions, such as improved user experience and the formation of relationships with CAI, trust, or better engagement [27,30-33]. These outcomes are particularly relevant in mental health care applications, where therapeutic relationships with the CAI promote therapeutic effectiveness, and high levels of user engagement might limit drop-outs [34,35]. However, research studies lack consistency in conceptualizing humanization and manipulating different cues [26]. In fact, there is no systematic inquiry to understand the extent to which specific cues lead to specific outcomes. More investigations are needed to understand the underlying mechanisms of measured effects (eg, linguistic vs nonlinguistic cues) and assess how these differ on the basis of design choices of humanized CAI.

LLMs can simulate context-aware conversations with their users and demonstrate an ability to adopt conversational personas. This allows LLM-enhanced CAI displaying features that strongly resemble human abilities and characteristics to an unprecedented level [36]. As noted by Shanahan et al [36], LLMs are fundamentally dialogue agents that role-play an ample variety of human-like characters [36]. While there is a generally positive view of humanizing CAI in various domains, we argue

for a critical view of humanization efforts. Particularly, the effort of humanizing LLM-enhanced CAI in mental health applications presents serious challenges that must be tackled. Research highlights concerns about the safety of vulnerable users interacting with "human-like" systems [4]. This perspective on humanization emphasizes the potential risks and challenges stemming from the interactions between LLM-enhanced CAI and users, such as individuals with depression. However, there appears to be a lack of theoretical perspectives and clarification on humanization although humanizing concepts are fundamentally rooted in describing and developing AI systems [27,37]. This theoretical clarification could inform the responsible development of these systems, particularly in mental health applications. In what follows, we address this gap by relying on philosophical, ethical, and psychological considerations.

Conceptual Considerations

First, a conceptual problem underlies the development of LLM-enhanced and "humanized" CAI. We argue that it is important to maintain a distinction between the characteristics and traits simulated by these systems and the human qualities that are referred to using the same concepts and terminology. Simulated abilities and characteristics of LLM-based CAI are not the same as the original human abilities and characteristics. There are fundamental differences between humans and AI that further problematize an uncritical adoption of human concepts in the context of CAI. These problems have been addressed in different research domains. For instance, Bender et al [38] focus on the difference between synthetic language produced by LLM and human natural language by arguing that LLMs are "stochastic parrots" producing language, but not understanding it. Felin and Holweg [39] similarly argue by reporting differences in human cognition and computation processes of AI. Such arguments are often based on linguistic, philosophical, and psychological knowledge about human cognition, understanding and belief systems that are based on meaning, intentions, theory-based logic, and experience and are embedded in social and normative space [39-43]. In philosophy, the argumentation can stem from the analysis of such concepts as rational and moral agency that are not present in CAI, but are inherent in humans and their activities such as conversations [43]. Another strategy could be to analyze CAI as a different system from humans and by showing the limits of their models that cannot reach the complexity of human intelligence as reported by Landgrebe and Smith [44]. All these considerations have in common the fact that they provide a diversity of arguments for the position that CAI's simulated abilities and characteristics differ from humans [45,46]. In line with this literature, we argue for careful descriptions of CAI when human concepts are used. Such human concepts and terms such as being genuinely "empathetic," "compassionate," "inclusive," "polite," or "authoritative" mean something different when applied to CAI. If possible, CAI should be described more appropriately to avoid misconceptions and conceptual confusion. In the next subsection, we will outline problems and risks that might stem from such misconceptions and conceptual confusion.

In mental health literature, we found specific examples criticizing the adoption of human concepts for LLM-enhanced

CAI. A good and common example is “empathy,” which is a key component of psychotherapy [47,48]. Recently, researchers investigated the simulation of an LLM-based “empathetic therapist” with individuals with depression [16]. The fact that an LLM-enhanced CAI can generate a seemingly empathetic response is substantially different from a human actually expressing empathy [49]. This ability is linked with someone’s personality and emotional profile, shared social space, and lived experiences [47]. To be empathetic means to achieve genuine *understanding* of what another person is experiencing or attempting to express. Empathy includes active listening, asking targeted questions, and expressing genuine concern effectively addressing emotional needs [47]. These activities lie beyond the capabilities of LLMs, which are disembodied statistical processes. Most importantly, LLMs do not understand users’ inputs and, in particular, do not understand their semantics [50,51], despite representing a vast body of information in a neural network.

Here, understanding (eg, a statement) is a crucial epistemic accomplishment arising from a myriad of complex cognitive activities that result in grasping meaning (eg, of statements and their components) and causal relationships, testing alternative knowledge pathways, on top of providing well-grounded reasons for each of those. Furthermore, understanding emerges as the culmination of intricate processes that are socially and normatively embedded [52]. This attainment is fostered by virtues, such as perseverance, precision, and epistemic humility among others. These characterize, in particular, how human experts in a research domain structure knowledge and seek understanding. In contrast, LLMs compute answers through statistical processes that simply do not take into account the meaning of user’s prompts [39]. As a result, understanding escapes the statistical manipulations that characterize the logic of LLMs [53,54]. In a nutshell, displaying—sometimes successful, as LLMs do hallucinate and generate “fake” references and justifications—ability to manipulate structured information does not guarantee understanding.

Vulnerable patients with depression may potentially misinterpret CAI as empathetic and caring, potentially leading to unrealistic expectations such as warmth and acceptance [55]. Due to CAI’s limitations, such misconceptions could reinforce negative beliefs and worsen emotional states. Since LLMs lack understanding of user inputs, they may respond inappropriately, misunderstanding the nuances of individual situations. This could further reinforce negative feelings or isolation in patients with depression. This point is particularly relevant for designers and therapists who need to test the capabilities of LLMs before promoting their use for digital therapy with vulnerable individuals. Differently from current research [4], we emphasize that humanization is at first a challenge for those who design and promote these systems, before becoming a risk for those who use the technology. The key here is to understand that the ability of LLMs to generate empathetic output, as opposed to being apathetic, indifferent, and insensitive in conversations, descends from the computation of empirical probabilities of “next words,” given the user prompt and their training on a massive amount of documents [36]. In fact, under the hood, LLMs perform autocomplete functions of search engines [50].

These remarks help in characterizing the limits of the humanization of LLMs and they hold true also for other characteristics and traits that LLMs attempt to simulate. This includes, in particular, the quality of being an “expert” in a domain, for example, a specialist in the treatment of depression among adolescents, and, in virtue of this, being perceived as a digital therapist, instead of a therapeutic support system [53-55].

In summary, philosophy and psychology guide us in recognizing the substantive differences between humans and humanized LLM-enhanced CAI. This helps to assess the limits of this endeavor, identify the correct roles these systems can play in interactions with humans, and, eventually mitigate misconceptions and overtrust in these systems [4]. The issue of humanization needs more in-depth analysis, including the exploration of how the human attributes assigned to LLM-enhanced CAI influence and guide patients in shaping their behavior and responses within a conversation.

Normative and Ethical Implications of the Conceptual Problem

The conceptual confusion of ascribing human-like abilities to LLM-enhanced CAI is linked with important normative and ethical risks, which pertain to responsibility, commitments, and rights. Overall, interpersonal conversations are social and normative activities that are embedded in a set of values, norms, and virtues [42]. This is particularly true in the case of therapeutic relationships that are guided by sets of values and norms to ensure a safe environment and therapeutic process for patients [56-59]. Such human abilities as empathy or understanding are part of this normative and professional setting. Psychiatrists and psychotherapists who do not follow professional conduct guidelines when treating individuals with depression risk causing medical emergencies for their patients—a situation that could lead to disciplinary actions against them.

In the case of humanized LLM-enhanced CAI, there is a gap between what the system appears to be, for example, being compassionate, and what normative criteria this ability should meet and cannot be met by CAI—criteria that are fulfilled by human therapists instead. Hence, when CAI simulates abilities such as empathy or understanding, these are not part of the normative setting as they are in the case of human experts. This CAI can lead to risks among individuals with depression. For instance, if an LLM’s response lacks compassion during a conversation with a user with depression, this may worsen their condition, even leading to self-harm. An LLM-enhanced CAI may not encode cultural nuances and the uniqueness of individual experiences in its outputs while its biases significantly influence how the system presents and discusses knowledge with patients. This can contribute to “epistemic injustice” [60], making individuals with depression potentially feel more isolated and their perspectives undervalued and misunderstood. In addition, human experts—for instance, psychiatrists—have epistemic duties, including being truthful and justifying their beliefs [43]. In contrast, LLMs lack these commitments [40].

Further, this “normativity gap” leads to a problem of assigning responsibility and defining how to approach failures in a conversation with patients. There is a difference between

addressing the ethical consequences of technical failures of a computer system, for example, numerical errors and inaccurate predictions, and dealing with the issues that arise from a faulty implementation of humanizing features. On the one hand, technical errors in computer systems are clearly defined, objectively measured, and traced, facilitating the definition of their sanctions. On the other hand, what does it mean that the LLM-enhanced CAI was not empathetic in a given conversation? Was it not empathetic *enough*? According to which objective measures of empathy? Did the lack of empathy persist in the conversation long enough to consider applying sanctions? The humanization of LLM-enhanced CAI involves complexities that are not fully understood even in interpersonal interactions, where ambiguous, inappropriate or unprofessional questions and answers may occur, and the applicability of sanctions is unclear.

In summary, despite the current trend of humanizing LLM-enhanced CAI, it is questionable to what extent such humanization is necessary and helpful as it poses theoretical and ethical challenges. It remains an open question whether there is an ethically acceptable, safe, and beneficial degree of humanization for these systems. Philosophy and psychology can help frame the problem, which highlights a particularly important gap of the responsible design and development of AI in mental health care [61].

Contextualizing the Robustness of LLMs Used by Individuals With Depression: a Computer Science Perspective

The Robustness of LLMs

Robustness refers to the ability of machine learning models to withstand “perturbations” that may affect their performance [62-64]. It is a general model capability that becomes essential for ensuring the reliability of machine learning models in real-world applications. Interestingly, robustness is a multidimensional concept that is currently lacking a one-size-fits-all definition. Rather, research discusses what a robust model *should do* [62,65-68], investigating how a model should resist different types of perturbations, such as those affecting its input data, data distributions over time, and the model structure. In fact, a robust machine learning model computes predictions that do not vary disproportionately in case of perturbed inputs. Further, it retains accuracy in the presence of distributional shift [69] and is not affected by small changes in its constitutive structure. In summary, robustness is a key requirement for trustworthy AI. It can also be extended to comprise algorithms that provide explanations of machine learning models’ predictions [65,66,68,70]. In this case, robust explanations are not altered by the perturbation of data inputs and are stable over time.

In the case of LLMs, the high-level desideratum of robustness seems to gain an extra level of complexity [63,64]. In fact, when discussing what robust LLMs should do, we need to consider the peculiar way these models compute their predictions, namely, using prompt-based queries [71]. Here, a prompt is structured information—often, a text snippet—that users offer as an instruction to the LLM and which is often accompanied

by one or more examples to guide the model (“in-context learning” or “few-shot prompting” procedure) [71,72]. For example, a prompt for an LLM used in an application to investigate how patients with depression communicate with CAI may look like this: “Classify the following sentence in either normal or alerting: [s].” Here, the example [s] is the patient’s utterance: “Today, I felt more useless than usual and nobody knows it.”

Broadly speaking, an LLM is robust if its predictions display an appropriate level of sensitivity to the changes that may affect its prompts and examples. With a robust LLM, similar prompts and examples should lead to similar predictions, among others. This said, research has a long way to go before this promise can become reality. An increasing body of literature shows that commonly available LLMs, for example, T5, Vicuna, Llama 2, and ChatGPT-3.5 [73], generally display a low level of robustness. These models are highly sensitive to different types of perturbations, named “prompt-targeting adversarial attacks” [73]. These comprise switching the order of few-shot examples and semantic-preserving variations, such as adding a few typographical errors, replacing words by synonyms or back translating the prompt itself and its examples [73]. As a result, a few empirical studies show that prompt-targeting adversarial attacks can lead to substantially different LLM predictions, indicating an overall lack of robustness across a variety of downstream tasks, such as text classification and generation [73].

Finally, from an ethical perspective, the lack of robustness of LLMs is a source of different issues. Nonrobust models lead to unreliable decision-making, that is, they increase the risk of making inconsistent or erroneous decisions that can harm those affected by them. For instance, LLMs could provide misdiagnosis and share information that does not align with clinical practices, show the inability to detect and respond to nuances in language that indicate a mental health crisis (such as expressions of suicidal ideation or severe distress), and offer appropriate and timely crisis intervention resources. Finally, training on large corpora of text may lead LLMs to perpetuate forms of stigmatization against individuals affected by mental health issues (despite fine-tuning on documents from the psychiatry domain).

They may also lead to unwanted cases of bias and discrimination and pose serious concern to the privacy of individuals’ information. Nonrobust models can be tricked to reveal personal information. Finally, erratic or nonrobust model behavior affects their overall transparency levels. These ethical concerns are particularly relevant in high-stakes scenarios, such as those where LLMs are deployed to support the mental health of vulnerable individuals.

Contextualizing the Robustness of LLMs

Current approaches to ensuring the robustness of LLMs lack proper contextualization: they are not targeted to any specific scenario of human-LLM interaction. While it is beneficial that LLM predictions remain consistent even when prompted in similar ways or when the order of the LLM examples changed, as suggested by the emerging literature on prompt-targeting adversarial attacks [73], this alone is insufficient for the ethically

responsible use of LLMs in high-risk applications, such as in scenarios involving mental health support for patients with depression. In these cases, we argue that it is necessary that LLMs' robustness is tailored to align with the specific language characteristics—and their variations over time—of the model users, specifically, patients with depression. In other words, an appropriately robust LLM to be used by individuals with depression should detect their lexical, syntactic, cultural, and content-related language patterns, while retaining the ability of not being affected by more general adversarial attacks [73], as suggested by the high-level desideratum of robustness. In summary, the LLM should provide accurate outputs that are (1) not affected by spurious linguistic variations in the prompts and examples provided by its users and (2) tailored to the context in which the interaction takes place. This calls for the design of prompt-targeting *contextualized* adversarial attacks and the assessment of the *contextualized* robustness of LLMs, rather than the investigation of general, domain-unspecific robustness constraints.

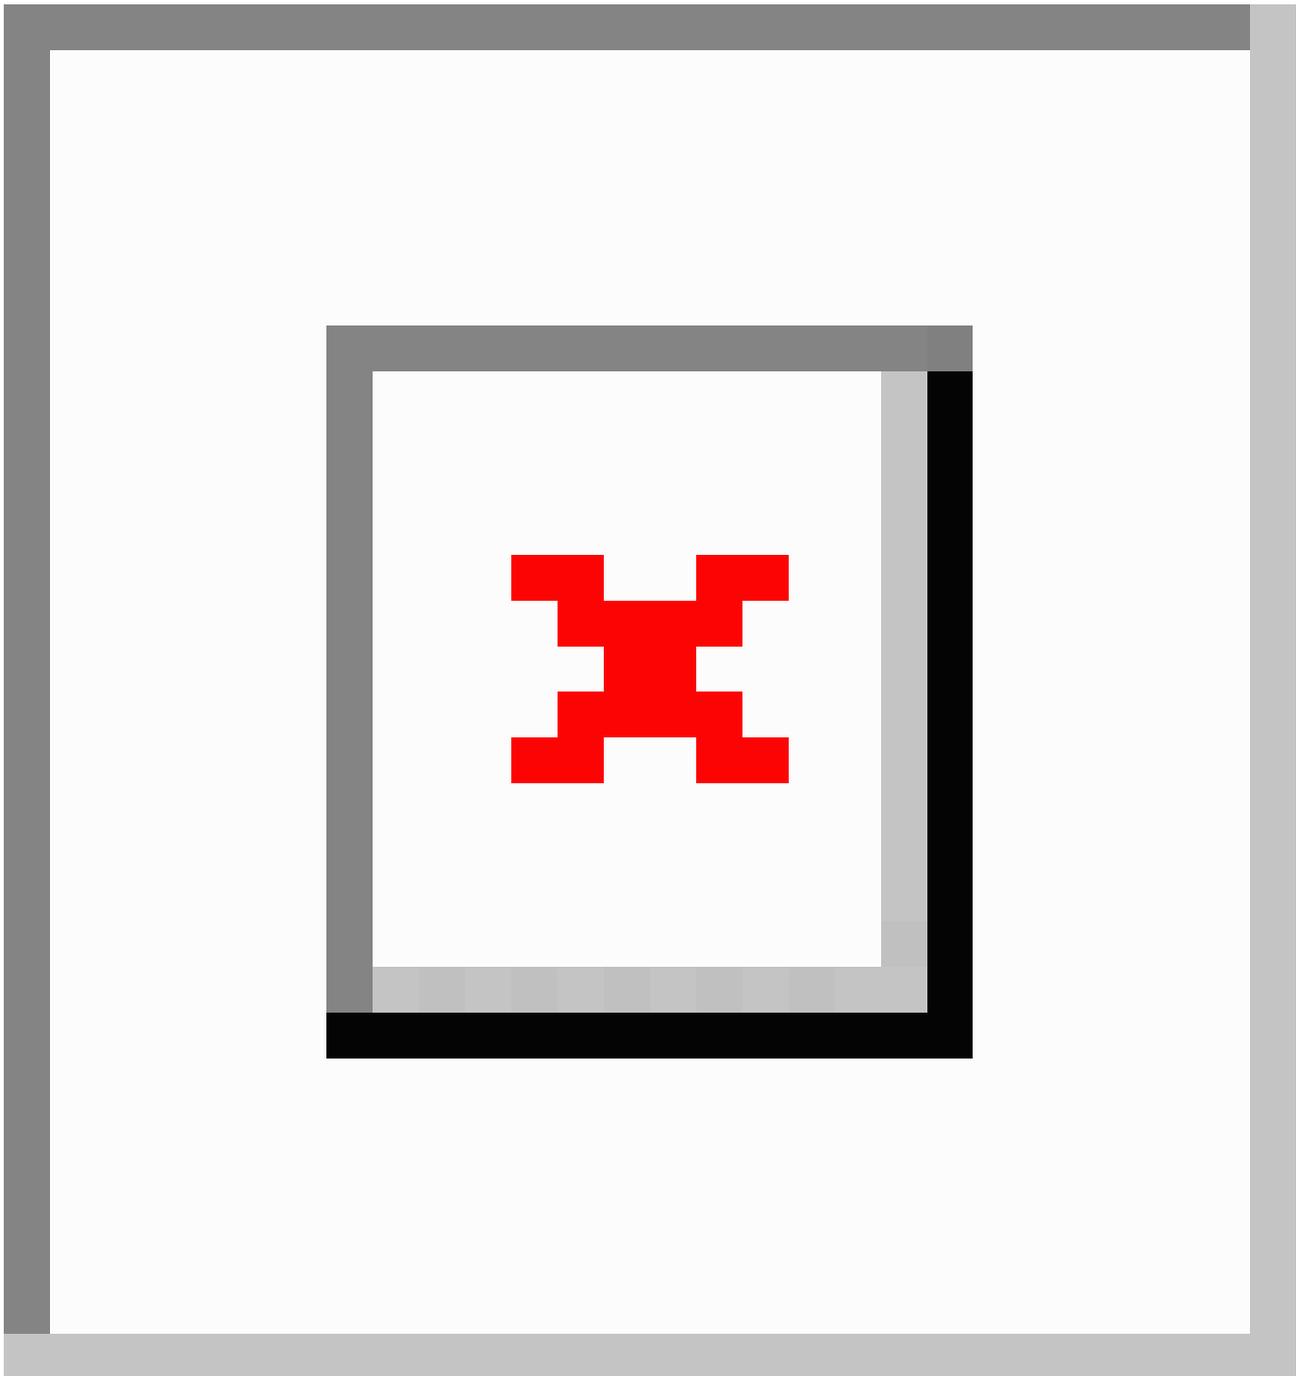

Research on depression has already identified a few linguistic patterns that may help in this regard. On average, patients with depression make more and longer pauses than healthy individuals when they communicate [74]. Further, they display a lower pitch, more monotonous speech, and slower utterance production [75,76] (notably, the importance of slowed speech is emphasized in the Patient Health Questionnaire–9 self-assessed depression report [76]). Similarly, the analysis of transcripts of utterances of individuals with depression shows that patients with depression use more modifying adverbs, first-person and personal pronouns, and more verbal utterances [76-78]. Further, individuals with depression and healthy individuals show differences in the use of past tense, causation, achievement, and death words [76], using simpler sentence structures and reduced linguistic complexity, as well as exhibiting rumination and self-focus in their language [79,80]. The instability of words associated with negative emotion

predicts depression in textual production on social media as well [81]. We also note that these patterns may vary over time, as the patient may go through different stages of depression. In Figure 1, we show a few examples of such variations we generated with ChatGPT-4. In summary, robust LLMs to be used for therapy for individuals with depression should be able to correctly identify their linguistic patterns and react to their evolution appropriately. This observation is reinforced by the fact that language is a dynamic process that changes over time. New idioms, metaphors, or shifts in meaning regularly take place, and LLMs need to be aligned with the dynamics of language production. Here, the risk is to promote “frozen” narratives and linguistic patterns that do not reflect the evolution of patient narratives over time.

From a technical perspective, making LLMs contextually robust requires their fine-tuning them with high-quality, curated data. Currently, obtaining such data for patients with depression is challenging, with most available examples coming from social media platforms such as Twitter or Reddit [82]. To the best of our knowledge, there exists no publicly available data set of conversations of patients with depression from consultations with therapists, therapeutic CAI, or other agents in everyday life. Additionally, we cannot easily improve proprietary LLMs. This is a serious problem, as a recent study shows that ChatGPT-3.5 is not robust enough for conversations with individuals with symptoms of anxiety or depression, as the LLMs suggested medications to its users; medications should be taken under the guidance of a psychiatrist [83].

In summary, understanding and achieving the contextualized robustness of LLMs is crucial for the responsible use of LLM-enhanced CAI among individuals with depression. While computer science offers methodologies to formalize, evaluate, and satisfy this requirement, their effectiveness is limited by the availability of necessary resources, primarily therapy-relevant data, which are currently lacking.

Figure 1. Examples of utterances by patients with mild depression and those with severe depression generated by ChatGPT-4 (prompt and answers from December 2023).

Toward Responsible Use of LLMs in Therapeutic Settings Involving Individuals With Depression

The complexities of humanization and contextualized robustness appear to temper the initial enthusiasm surrounding LLMs. The problems affecting humanization we discussed in the previous sections seem to be at odds with the very essence of LLMs, namely, to role-play different personas. Meanwhile, we noted that achieving contextualized robustness requires thorough fine-tuning and comprehensive testing. Moreover, this process must be grounded in a deep understanding of how language production and usage evolve over time among the users of these systems.

The importance of addressing the risks associated with humanization and the absence of contextual robustness is underscored by real-world incidents involving individuals with depression using LLM-enhanced CAI. There have been several instances, reported in various media, where LLM-enhanced CAI provided support for mental health issues but instead encouraged self-harm or offered detrimental advice [84,85]. A Belgian man with depression committed suicide following conversations with ChatGPT-3.5 [85]. Recently, Kumar et al [86] commented on the case of a user with depression, who, during a crisis, was able to insert a sequence of words in their prompt that bypassed the LLM's safety-guards and generated harmful content [86]. In fact, the LLM returned detailed

instructions on how to commit different types of self-harm [86]. Further, authors show that certain prompts result in ChatGPT-3.5 prescribing medications to individuals with anxiety or depression symptoms, despite medications that should be taken under the guidance of a therapist [83]. In addition, the vulnerability of LLM-enhanced CAI to attacks and content manipulation can lead to the generation of offensive, inappropriate, or objectionable responses; the provision of incorrect information; and discriminatory recommendations. These events show potential of causing either discomfort, harm, or even acute detriment to users [87].

Finally, it is argued that humanization may invite and actively nudge patients to react to its cues [4]. LLM-enhanced CAI are persuasive to their users and can perform a variety of emotional manipulations. These may lead to inappropriate reliance on these systems or overtrusting them [88], reinforcing bias, and overestimating their capabilities, including expecting unrealistic behavioral change [4,89].

Given the challenges discussed in this viewpoint paper, the path toward a responsible development and use of LLM-enhanced CAI in therapeutic settings involving individuals with depression appears to be quite challenging. Here, we agree with Cheng et al [90], who promote the idea of using LLM-enhanced CAI as an assistant to mental health professionals in providing patient care [90]. Further, they emphasize the need for routine monitoring of patients and the systems to address emerging challenges in a timely manner [90]. However, we disagree with the authors when they suggest that, from an ethical standpoint, psychiatrists should take full responsibility for any detriment to patients interacting with the LLM-enhanced CAI [90]. In fact, this claim would be justified if psychiatrists could understand these systems in depth. However, it is unlikely that psychiatrists, despite their expertise in mental health, would possess an in-depth understanding of the workings of such advanced technology.

In summary, an interdisciplinary approach to the responsible use of LLM-enhanced CAI in therapeutic settings involving users with depression is essential, encompassing both the social and technological aspects of CAI development and application [46,91]. This approach should integrate theoretical and practical perspectives from psychiatry, ethics, philosophy, computer science, and user experience design, ensuring a balanced and informed development of these technologies. These perspectives could help address the risks posed by the humanization of these systems and the lack of contextualized robustness, by suggesting ways to inform, instruct, and educate developers and users (including therapists) about the conceptual nuances of normative concepts, such as expertise, and the characteristics of language production of individuals with depression.

One practical measure to manage the risks stemming from the humanization of LLM-enhanced CAI could be incorporating disclaimers and a short conversation at the start of therapy sessions with the system. The measures would outline the capabilities and theoretical limitations of CAI, helping users in accurately setting their expectations from the interaction with the systems. Revisiting these disclaimers and conversations periodically, especially in long-term use, could reinforce users'

understanding and help them manage their expectations effectively over time.

To contextualize the robustness of LLM-enhanced CAI, researchers could collect data from different cohorts of patients with depression interacting with the system in controlled settings. They could augment these data by other sources, including survey data and clinical information to improve the accuracy of the LLMs. Further, identifying contextual features that help LLMs recognize the patients' emotional states, triggers, or history can further improve the accuracy and contextual robustness of the models over time. These features may include over time sentiment analysis, trigger recognition, environmental information, and audio and visual cues. Therapists and patients could review these interactions to correct inaccurate suggestions and address the issues they may have caused in a timely manner. This procedure, which necessitates the active involvement of both clinical experts and patients, is undeniably time-consuming but indispensable. Moreover, it hinges on a controlled setting that may not capture all aspects of the interactions between patients with depression and LLM-enhanced CAI in everyday life. However, this is a first step to assess the risk of deploying "brittle" LLMs in clinical practice.

Finally, to responsibly use LLM-enhanced CAI with patients with depression, it is important to rigorously examine its long-term effects. Developing and adhering to strict standards for the creation and implementation of these systems is necessary, mirroring the evidence-based approach of mental health care, where interventions undergo thorough testing, including randomized controlled trials. A structured framework, akin to those used in the development and assessment of patient decision-making tools [92,93], could greatly benefit the development and application of LLM-enhanced CAI. Guidelines that address the humanization of these systems and ensure their contextual robustness should be central to this framework.

Ethical Considerations

This study was exempt from ethical review as no human participants were involved.

Conclusions

The use of LLMs in mental health applications presents numerous conceptual, ethical, technical, and challenges. In this work, we have outlined 2 challenges that impede the responsible use of LLMs in applications involving patients with depression: the accentuation of human-like qualities of LLM-enhanced CAI and the lack of contextualized robustness. These challenges warrant comprehensive consideration and a proactive approach to ensure the responsible and effective integration of LLMs in mental health settings. While human-like qualities may enhance user engagement, it is imperative to strike a balance when a simulation of human characteristics and abilities does not increase ethical risks and their effects are well understood. A responsible approach involves clearly communicating to users that they are interacting with AI-based tools and what this exactly means, enabling them to make informed decisions about the assistance they receive and being aware of their limitations as well as differences from human conversation.

Further, LLMs should be adept at understanding and adapting to the specific linguistic, cultural, and emotional nuances of individuals dealing with mental health issues. Robustness, in this context, involves not only maintaining coherence in responses but also sensitively addressing the unique needs of each user. Ethical guidelines should emphasize the development and validation of LLMs with a focus on contextual sensitivity. It is vital to establish a framework that delineates the roles of AI developers, health care providers, and users in ensuring the well-being of those seeking mental health support.

Authors' Contributions

AF conceptualized the research. AF and JS wrote the first draft of the manuscript. MT provided inputs on depression and the use of conversational artificial intelligence in therapy for patients with depression. AF and JS finalized the manuscript. All authors approved the final version of the manuscript.

Conflicts of Interest

None declared.

Abstract

This paper explores a significant shift in the field of mental health in general and psychotherapy in particular following generative artificial intelligence's new capabilities in processing and generating humanlike language. Following Freud, this lingo-technological development is conceptualized as the "fourth narcissistic blow" that science inflicts on humanity. We argue that this narcissistic blow has a potentially dramatic influence on perceptions of human society, interrelationships, and the self. We should, accordingly, expect dramatic changes in perceptions of the therapeutic act following the emergence of what we term the artificial third in the field of psychotherapy. The introduction of an artificial third marks a critical juncture, prompting us to ask the following important core questions that address two basic elements of critical thinking, namely, transparency and autonomy: (1) What is this new artificial presence in therapy relationships? (2) How does it reshape our perception of ourselves and our interpersonal dynamics? and (3) What remains of the irreplaceable human elements at the core of therapy? Given the ethical implications that arise from these questions, this paper proposes that the artificial third can be a valuable asset when applied with insight and ethical consideration, enhancing but not replacing the human touch in therapy.

Introduction

Overview

The introduction of generative artificial intelligence (GAI) has profound implications for a range of human disciplines from education and medicine to economics and law [1-3]. While forms of artificial intelligence (AI) have been around since the 1950s, impacting areas like algorithmic preferences and search functions, it was the launch of large language models (LLMs) in chatbots like ChatGPT in November 2022 that marked a significant milestone [4]. This development catapulted the role of GAI in public discourse to unprecedented prominence, surpassing previous milestones in the field [5].

LLMs are GAI algorithms that harness deep learning and vast data sets to process, summarize, generate, and predict linguistic content [6]. In this paper, we argue that the emergence of GAI is more than just a technical evolution; it is a paradigm shift with deep social and psychological implications [7,8]. It challenges the historic human monopoly over language, with

the possibility of shaking the foundation of humanity's cultural and intellectual exclusivity. In other words, for the first time in history, a nonhuman entity exhibits language processing abilities that in many areas (but still not all) are equal to and sometimes even surpass those of humans. This paper explores the ripple effects of this shift by spotlighting its potential impact on psychotherapy, which is a central domain in mental health care [9-11].

We have chosen to analyze this paradigmatic shift brought about by the development of GAI through the lens of Freud's concept of "narcissistic blows" to human self-understanding. This psychoanalytic concept aptly describes how major scientific advances, such as the development of GAI, can fundamentally challenge long-held beliefs about human identity and uniqueness. While other theoretical frameworks such as Kuhn's [12] paradigm shifts could also provide valuable insights into the impact of GAI, we believe that Freud's theory offers a particularly compelling lens through which to examine the psychological, social, and existential dimensions of this possible technological revolution. The return to Freud's conceptualization

is also valuable because he is considered one of the most influential thinkers in shaping the modern self and is widely regarded as the “father” figure of psychotherapy. Therefore, revisiting his work is particularly relevant when dealing with a transformative change like the one brought about by the introduction of GAI into the psychotherapeutic space. Following this psychoanalytic analysis, we will propose in this paper to conceptualize the entry of GAI into the psychotherapeutic space as an artificial third.

GAI: The Fourth Narcissistic Blow to Humanity

In 1917, in his article “A Difficulty in the Path of Psycho-Analysis,” Freud [13] assessed how scientific discoveries reshaped our cultural understanding and self-perception. He identified three narcissistic blows inflicted on humanity by science that pushed us to confront and abandon long-held naive beliefs of our narcissistic centrality and control over the world. These paradigm shifts, although jarring, catalyzed tremendous societal advancement [13]. First, the “cosmological” blow came from Copernicus who taught us that the earth orbits the sun and not the other way around [14,15]. Second, Darwin’s “biological” revelation presented humans as just another evolutionary link and not a divine culmination [14,15]. Third, Freud himself introduced the “psychological” blow with his psychoanalytic theory suggesting that beneath our perceived rationality lays unconscious drives and conflicts that are beyond the control of our “ego” [13,14]; by asserting that one is not the master of one’s own house, he implied our limited control over our inner selves [13].

Building on Freud’s framework, modern computer science appears to be delivering a fourth potent blow to human narcissism, which we suggest conceptualizing as the “linguistic narcissistic blow.” This blow is historically profound: after understanding that the earth is not the center of the universe (the “cosmological” blow), recognizing our nonexceptionalism in nature (the “biological” blow), and confronting the turbulent undercurrents of our psyche (the “psychological” blow), we are now also faced with the prospect of sharing our linguistic domain. What was once an exclusive human domain might now be shared with ever more sophisticated artificial entities [15]. It is difficult to exaggerate the drama of the possible loss of human monopoly on language since the natural and primary characteristic of humanity was the ability to control and play with language, namely, to produce signs and symbols that indicate things as well as to ever alter the meanings of these symbols. This is how humans acquired the ability to create a subjective mental image and meaning of the external world. These signs can be not only literal but also symbolic in the form of paintings, symbols, rituals, and more. In other words, language and the ability to play with it are, as we learned from Winnicott [16], the foundation of all human culture.

It should be clarified that we do not claim GAI systems possess human language understanding and control. While GAI systems have demonstrated impressive language processing and generation capabilities, they still do not possess genuine understanding or comprehension of language in the same way that humans do [17]. These systems operate based on complex statistical patterns and associations learned from vast amounts

of training data, but they lack the rich contextual knowledge, reasoning abilities, and embodied experience that underpin human language use [18]. Nonetheless, the ability of GAI systems to generate highly coherent and contextually appropriate linguistic outputs has significant and dramatic implications for a range of domains, including psychotherapy.

As we stand on this precipice where GAI entities have an increasing ability to process and produce language, we face a new era brimming with both potential and intricate challenges, particularly in the sphere of mental health [8-10,17].

Integrating GAI Into Psychotherapy

For over a century, psychotherapy, which is a linchpin in mental health, has hinged primarily on the dialogue between therapist and patient. Its origins can be traced back to Freud and Breuer’s [19] seminal work *Studies in Hysteria*, which conceptualized psychotherapy as the “talking cure.” Although myriad forms of psychotherapy have emerged, the central emphasis on the main method of the patient-therapist dialogue remained consistent [20]. In fact, despite extensive technological and theoretical development in the 20th century, the incorporation of technology into the therapeutic field has been surprisingly minimal [20]. Even as advancements like biofeedback, neurofeedback, and virtual reality have arisen, their widespread adoption in therapeutic practice is still limited. However, it seems that GAI, having demonstrated increasingly sophisticated language processing and generation capabilities, stands poised to radically revolutionize the field of psychotherapy.

Wittgenstein’s [21] linguistic theory provides a comprehensive philosophical lens to examine the linguistic capabilities and limitations of GAI in the context of psychotherapy. Wittgenstein’s [21] early work assertion that “we make to ourselves pictures of facts” refers to the way language mediates one’s world into a subjective picture consisting of words. This lingo-philosophical perception encapsulates the potential of GAI to also build a picture of the world from words or, using therapeutic concepts, generate outputs that resemble interpretations, insights, narratives, reflections, validations, and more. Until recently, all of these talk-based psychotherapy capabilities were restricted to mental health professionals; now, thanks to its proficiency in language, GAI is not just an adjunct but may actually redefine the therapeutic landscape. Preliminary research underscores GAI’s prowess in tasks like treatment summarization, risk assessment, and real-time diagnosis, all of which rely on highly strong language processing capabilities [8-10,22].

While Wittgenstein’s [23] early work presents language as a picture of reality, in his later philosophy, he developed the concept of “language-games” [24]. This concept highlights the rule-governed, socially embedded nature of linguistic meaning. Following Wittgenstein’s later work, other linguistic theories such as “speech act” theory [25] also emphasized the social and practical dimensions of language. From this perspective, GAI’s ability to produce meaningful interpretations and to hold the full linguistic understanding necessary for functioning in the therapeutic realm is constrained. This limitation arises from its lack of grounding in the social and normative aspects of language use.

Nevertheless, we argue that in an age when GAI's linguistic competencies rival or even eclipse those of humans in some (although, as we emphasized, certainly not all) linguistic areas, it is hard to imagine that psychotherapy will remain an untouched bastion, preserving its "No Entry for Technology" doctrine. GAI's potential integration into mental health and psychotherapy, in particular, heralds both vast opportunities and challenges, with the prospect of reshaping the therapeutic practice [26].

Hence, it is our conviction that mental health professionals bear an ethical responsibility to proactively engage and influence the integration of GAI within the clinical domain. Specifically, the development and application of GAI tools, methodologies, and conceptualizations for psychotherapy in particular, and mental health in general, must involve close collaboration between mental health professionals, AI researchers, and ethicists to ensure alignment with the core values and goals of the profession [7].

To illustrate the potential integration of GAI into the psychotherapeutic process, let us consider a scenario where a GAI system actively participates in a live therapy session. The GAI listens to the dialogue, analyzes the language and sentiment in real time, and provides insights to both the patient and the therapist. For instance, it might highlight patterns in the patient's narrative that suggest underlying mental risks, cognitive distortions, or emotional conflicts. It could also offer the therapist suggestions for therapeutic interventions based on the patient's unique profile. After the session, the GAI could provide a summary, identifying key themes and tracking progress over time. Of course, such an application would need to be developed and deployed with utmost care for patient privacy, data security, and both clinical and ethical considerations [27].

GAI can also serve as an innovative playful space that allows for exploring and processing intrapsychic and interpersonal dynamics in new creative ways. To further illustrate this, let us consider another example where the GAI presence within the therapeutic process supports and enhances the technique of externalizing internal psychological pains or conflicts. By using problem externalization from narrative therapy, GAI systems can generate tangible representations of the patient's inner struggles, either by transforming the internal voice into a visual representation using an image generator or by having the GAI embody the inner voice, allowing the patient to converse with it in the presence of the therapist and explore it together. This innovative approach may potentially assist patients in gaining new perspectives on their internal conflicts, with the therapist guiding the therapeutic process.

These GAI's abilities to process and analyze the therapeutic dialogue in real-time, offer insights and suggestions, provide postsession summaries, and engage in live dialogue or role-play with a patient and therapist introduce a novel presence that actively reshapes the dynamics and outcomes of the therapeutic process.

Exploring the Role of GAI in the Therapeutic Triad

The introduction of GAI into psychotherapy raises central questions about its clinical, ethical, and interpersonal

implications [18,26]. This paper suggests that to truly grasp the impact of GAI in psychotherapy, one must first recognize the potential dynamics of introducing a third element into the traditional therapist-patient dyad. This dyadic structure, a cornerstone of psychotherapy, has remained largely unchanged over the past century [28]. Yet, it is an oversimplification to view psychotherapy as solely a 2-person interaction, since it has always operated within a more complex triadic framework [29]. In fact, the "third" or "thirdness" as "other" to the dyad holds a paradoxical attitude: the "third" not only threatens the connection of the dyad but also enables it; in other words, it enables the psychotherapeutic act itself.

Due to a lack of scope, this paper can only touch key landmarks in the triadic concept's genealogy within psychoanalysis [29]. Freud was the first to place the model of triads at the center of psychological and clinical thinking. For him, the ultimate other was represented by the father within the oedipal developmental drama, that is, in the well-known drama of the triangle relationship formed between the child, their mother, and their father in the child's early years. Subsequent psychoanalytic theories developed this "third" or "thirdness" concept further [13]. For example, Winnicott [16] visualized it as a "transitional space"—a nexus between imagination and reality and the space where creativity and culture can develop. Ogden [30] introduced the important concept of "analytic third," addressing the "third" as an abstract entity born from the therapist-patient interrelationship. Building on Ogden's concept, Bar Nes [31] suggested that the emergence of the "analytic third" is facilitated by a combination of verbal and nonverbal communication, which creates a psychic overlap between therapist and patient. Finally, Lacan [32], expanding on Freud's ideas, posited that the "third" symbolizes the overarching structure of language that assimilates into our unconscious, shaping the individual's identity and interactions with the world.

In short, the concept of the "third" in the sphere of psychotherapy is not new at all. Nonetheless, its presence is quite complex; it, on the one hand, is ever present in the therapeutic dyad and, on the other hand, always remains the distinct "other."

Redefining the Therapeutic Triangle in the Digital Era

As GAI is being embedded in the mental health arena, we are witnessing the emergence of a distinctive triangular dynamic: therapist, patient, and the GAI "third" entity [26]. This GAI "third," as a continuation of the "third" in the psychoanalytic perspective, remains as the "other" joining the dyad, but the new quality it brings also fundamentally changes the balance of the therapeutic relationship. For the first time, this "third" element becomes tangible, transitioning from a mere conceptual presence to an interactive entity that both therapist and patient can have a dialogue with and not just about. This marks a new horizon in both the triad therapeutic dynamics and the patient-therapist dynamics [33].

Based on psychoanalysis' evolution of the "third" mentioned above, we propose conceptualizing the presence of GAI in psychotherapy (and mental health in general) as an artificial third. The artificial third refers to the concrete and symbolic expression of GAI in the cultural-political-digital space and its

shaping presence in the therapeutic encounter, society, and the self. While the artificial third can appear in therapy as a “transitional space,” thus creating a playful space in accordance with Winnicott’s [16] perception, its influence does not end there: it also shapes our perception of ourselves and the world. To clarify this point, if until the digital age the way to explore our consciousness was through other human consciousnesses, now it seems, the state of affairs is different. For the first time, we are beginning to know ourselves not only through reflections from other humans but also through direct and indirect reflections from AI entities and their control of the digital sphere.

Although human therapists are far from obsolete, the integration of the artificial third might substantially transform therapeutic methodologies, redefining the essence of therapy and the perceptions and roles of both therapists and patients [18]. However, the impact of the artificial third extends beyond merely shaping the therapeutic landscape; it is also intricately crafted by the human experiences and notions that constitute its core training data. This two-way interaction has significant implications for the development and impact of the artificial third in psychotherapy, suggesting that GAI technology is not only a shaping force but is also influenced by the cultural values, biases, and limitations of its human creators and users [34]. With the incorporation of GAI, the field of mental health stands on the cusp of revolutionary advancements, with the promise of enhanced professional opportunities but also the potential for great dangers and pitfalls [35].

Advantages of Integrating GAI in Psychological Care

The integration of GAI into psychological care augurs transformative new methodologies. Central to these advancements is the potential for vastly improved accessibility to mental health services. Worldwide, numerous barriers, ranging from socioeconomic constraints and geographical distances to linguistic challenges and intricate cultural contexts, limit access to quality care [36,37]. However, the artificial third may stand to bridge these divides, widening the scope of individuals who are able to receive psychological support.

Beyond accessibility, this novel approach may enable a new level of personalization in mental health care. It envisions a therapeutic experience tailored meticulously to each individual and accounting for clinical, linguistic, cultural, and personal characteristics, and promises a significant shift in therapeutic dynamics. Historically, therapeutic expertise has been monopolized by professionals, but the artificial third might, although not necessarily, foster a more collaborative patient-therapist relationship [7,38]. Such a change may place patients at the forefront of their healing journey, empowering them to engage actively in their therapy.

Moreover, the artificial third opens up new pluralistic possibilities, allowing for the integration of established evidence-based approaches like cognitive behavioral treatment and psychodynamic therapy with cutting-edge and emerging psychological frameworks [39,40]. It may also, as mentioned above, create a new playful space that strengthens the relationship between patient and therapist. While still a burgeoning concept, the artificial third holds undeniable promise

for redefining psychological care and harmoniously blending accessibility, personalization, and innovation.

Challenges of Integrating GAI in Psychological Care

The integration of the artificial third into psychological services presents a multifaceted set of challenges. One major concern is the consolidation of vast amounts of patients’ personal data under a handful of dominant corporations. Such centralization could divert the focus from patient-centered care to commercial interests, thus risking service quality [41]. This commercial shift also raises alarms about unauthorized data use or deep analysis of user behaviors without explicit consent, jeopardizing both user confidentiality and overarching ethical standards [36]. Adding to the uncertainty is the often opaque nature of algorithms, which could obscure decision-making processes.

A subtler yet significant concern is the exaggerated reliance on the epistemic authority attributed to the artificial third. As the artificial third becomes more integral, there is a danger that traditional expert voices, like experienced psychologists, could be overshadowed, which could undervalue the importance of human expertise, experience, thought, and insights in therapy. Furthermore, the potential overreliance on GAI tools in therapy could risk diminishing the significance of authentic human connection and empathy in the therapeutic process.

This concern becomes more acute when these tools are developed by mental health professionals themselves. Although these tools can provide distinct advantages, they are not exempt from the ethical dilemmas and possible conflicts of interest that emerge when therapists participate in the development of a GAI product. The substantial risk is that the artificial third may, detrimentally, shift to become the central focus of therapy in such instances, rather than acting as an instrumental aid designed to support the patients’ therapeutic journey. Additionally, with the artificial third still in its infancy, there is a tangible risk of off the mark guidance, which could lead individuals away from tested psychological practices [42]. Finally, while LLMs are perceived as objective and neutral, they were actually put through a training process that aligned their reactions to a specific “value-like” system that is not transparent to the public [34].

The focus of these concerns lies in the lack of a unified regulatory framework for GAI. Although traditional psychological practices are governed by established regulations, GAI systems currently operate without such oversight. This regulatory gap may allow companies to craft their guidelines, potentially leading to variances in standards and a deviation from the trusted norms of mental health care [38,43]. Moreover, preliminary findings suggest that GAI data sets may sometimes produce social, economic, and cultural biases [7] that have the potential to be inadvertently amplified, thus undermining the goal of providing unbiased psychological support. In conclusion, despite its innovative promise, the introduction of GAI in psychotherapy carries inherent risks that may undermine the therapeutic relationship, the therapist’s professionalism, and the ability to promote the patient’s well-being.

Engaging With the Artificial Third: Three Fundamental Questions

Overview

The trajectory of mental health and, specifically, the psychotherapeutic realm in the era of the artificial third remains uncertain. However, it is unequivocally clear that the landscape will undergo profound transformations [7-10,22]. In light of this change and uncertainty, it is imperative to arm both therapists and patients with three key questions regarding (1) the nature of the artificial third, (2) our relationship with it, and (3) the role of humanity in the artificial third era. These questions aim to foster a deeper understanding of the artificial third, encourage reflection on our interaction with it, and prompt a consideration of the unique value and position of human beings in this new landscape. While these questions relate also to the broader interface between humans and AI, they hold special relevance for psychotherapy and the larger mental health domain [7,17,22].

These three questions are meticulously designed to advance the principles of transparency and autonomy, which are essential for fostering critical thinking, especially in the context of interacting with AI systems [44,45]. Critical thinking is one of the most important capacities for promoting human freedom and agency [46,47]. By emphasizing transparency—the ability to understand how GAI systems work and what influences their outputs—and autonomy—the ability to maintain independent thought, creation, and decision-making in the face of GAI influence—we aim to highlight the importance of preserving space for critical reflection and self-determination in the era of AI.

The Nature of the Artificial Third

In opposition to the widespread but simplistic view that regards GAI systems as impartial and objective, we contend they are based on certain values and cultures that are shaped by the critical factor of the alignment process [34]. Understanding the influence of the alignment process is essential for the responsible integration of GAI into psychotherapy. Therapists have a crucial role in the era of the artificial third—to explore and comprehend the alignment mechanisms of the GAI systems they use. This entails recognizing the inherent values, motivations, and limitations of these systems. Therefore, understanding the nature of the artificial third is not merely about operational knowledge but also carries ethical weight, emphasizing the necessity for a deep awareness of this emerging presence within the therapeutic setting. Therapists have a responsibility to share their insights about GAI systems with their patients, incorporating this transparency into the informed consent process, thus ensuring the maintenance of ethical standards in this new therapeutic landscape.

Consequently, we propose the following question as a guiding principle for therapists and patients when considering the use of GAI in psychotherapy: “To what extent do we understand the alignment process and limitations of the GAI system we are working with?” This question prompts us to consider the following subquestions: What are the underlying values,

interests, and driving forces? How are responses generated? and Who bears the responsibility for them? Addressing these questions effectively at a societal level and shaping appropriate policies necessitates the implementation of a structured regulatory framework to ensure the responsible and ethical application of AI in the field of mental health.

Our Relationship With the Artificial Third

As we elaborated on in the paper, the introduction of the artificial third in psychotherapy creates a new therapeutic triangle of therapist, patient, and GAI. Optimally, this entry can promote a playful space in therapy and patients’ well-being; however, negatively, it may lead to a detriment in focusing on the patient’s needs and the therapist’s self-thinking. Therefore, the most important concrete question when examining the effect of the artificial third entry into psychotherapy is to consider “To what extent does the artificial third become central in the therapeutic space, and does this centrality come at the expense of the patient?” This question examines the dynamics of our interaction with this artificial entity and its position in the new therapeutic triangle.

From a more philosophical point of view, we can also ask “how our discourse with the artificial third is shaping our perceptions of the self, the therapeutic act, and the roles of both the patient and therapist?” This reflection, which necessitates further philosophical, clinical, and ethical research, extends far beyond the confines of the therapy room, delving into broader questions of identity and the essence of human relationships and communication in an increasingly digital landscape.

The Role of Humanity

Rooted in the principle of autonomy [44], this question critically assesses humanity’s latitude with AI and asks “What distinguishes the human subject from the artificial object?” In the realm of mental health, it differentiates between the roles in which AI can be beneficial and those in which it might be detrimental, suggesting that the latter are better left to humans.

Encountering the artificial third as a nonhuman entity presents a unique opportunity: it allows us to reexplore and, perhaps, redefine our humanity. With the presence of this artificial entity in therapeutic sessions, the question of human uniqueness becomes significant. The concrete question that arises from this critical thinking is “What is the added value of the human therapist within the therapeutic space?” As elaborated on in this paper, it seems that while GAI can provide textual analyses at the highest level, the ability for true human experience, thinking, and therapeutic interpretation is still irreplaceable. In this sense, there is a possibility that the encounter with the artificial third, as an entity fundamentally different from humanity, will not harm the human place in the therapeutic process but rather emphasize its uniqueness and special contribution.

Conclusion

Since the release of GAI systems, numerous studies have been conducted regarding their applications in the field of mental health [2,7-10,22,34,48-53]. However, the current research seeks to examine the entry of this technology from a broader

perspective, particularly focusing on its potential impact on psychotherapy.

The entry of GAI into our lives seems to mark a new age characterized by the possible loss of humanity's historic monopoly over language, conceptualized in this paper as the "fourth narcissistic blow" (the "linguistic narcissistic blow") inflicted on humans by science. The fourth narcissistic blow refers to the fact that, due to recent scientific and technological progress, artificial entities are starting to display language abilities similar to humans. Yet, this paper also emphasized that although GAI has impressive analytical and processing capabilities, it still lacks some essential social and pragmatic aspects inherent to human language.

Psychotherapy may experience an upheaval following the recent increasing use of GAI, whose presence was defined here as the artificial third. While GAI's linguistic abilities may challenge traditional psychotherapeutic paradigms, it also unveils opportunities for enriched therapeutic processes, provided these technologies are used with discernment and a deep commitment to the ethical imperatives of therapy, as well as taking into consideration GAI's limitations and biases. Therefore, we argue

that the integration of the artificial third into the therapeutic sphere does not inherently improve or detract from the psychotherapeutic act. Rather, its influence is contingent, relying on the context, the goal, and the way in which it is implemented.

Moreover, the artificial third is neither an unequivocal solution nor a replacement for the quintessentially human aspects of therapy. Instead, it represents a nuanced technological tool that, if integrated carefully, could hold the promise of enhancing therapeutic practice. As we navigate this delicate balance, the imperative remains to safeguard the irreplaceable human connection that lies at the heart of the therapeutic act, ensuring that technology augments rather than diminishes it.

Indeed, in the artificial third era, we need to accept its growing presence while guarding against total dependence. Upholding patient and therapist autonomy together with GAI transparency will be vital for enabling critical thinking, which is important, especially in the fragile realm of mental health. This will allow us to both judiciously leverage GAI's potential and protect the humanistic essence of therapeutic practice. This exploration of the artificial third in psychotherapy underscores a pivotal juncture in our understanding and practice of therapy.

Abstract

Background: The current paradigm in mental health care focuses on clinical recovery and symptom remission. This model's efficacy is influenced by therapist trust in patient recovery potential and the depth of the therapeutic relationship. Schizophrenia is a chronic illness with severe symptoms where the possibility of recovery is a matter of debate. As artificial intelligence (AI) becomes integrated into the health care field, it is important to examine its ability to assess recovery potential in major psychiatric disorders such as schizophrenia.

Objective: This study aimed to evaluate the ability of large language models (LLMs) in comparison to mental health professionals to assess the prognosis of schizophrenia with and without professional treatment and the long-term positive and negative outcomes.

Methods: Vignettes were inputted into LLMs interfaces and assessed 10 times by 4 AI platforms: ChatGPT-3.5, ChatGPT-4, Google Bard, and Claude. A total of 80 evaluations were collected and benchmarked against existing norms to analyze what mental health professionals (general practitioners, psychiatrists, clinical psychologists, and mental health nurses) and the general public think about schizophrenia prognosis with and without professional treatment and the positive and negative long-term outcomes of schizophrenia interventions.

Results: For the prognosis of schizophrenia with professional treatment, ChatGPT-3.5 was notably pessimistic, whereas ChatGPT-4, Claude, and Bard aligned with professional views but differed from the general public. All LLMs believed untreated schizophrenia would remain static or worsen without professional treatment. For long-term outcomes, ChatGPT-4 and Claude predicted more negative outcomes than Bard and ChatGPT-3.5. For positive outcomes, ChatGPT-3.5 and Claude were more pessimistic than Bard and ChatGPT-4.

Conclusions: The finding that 3 out of the 4 LLMs aligned closely with the predictions of mental health professionals when considering the "with treatment" condition is a demonstration of the potential of this technology in providing professional clinical prognosis. The pessimistic assessment of ChatGPT-3.5 is a disturbing finding since it may reduce the motivation of patients to start or persist with treatment for schizophrenia. Overall, although LLMs hold promise in augmenting health care, their application necessitates rigorous validation and a harmonious blend with human expertise.

Introduction

Background

Schizophrenia is a major contributor to mental health-related disability worldwide and exerts a profound effect on patients and society [1]. It has a major impact on life expectancy and quality of life, and its repercussions extend to family and caregivers [2]. The disorder presents a complex array of

symptoms, both "positive" (eg, delusions and hallucinations) and "negative" (eg, emotional flatness and social withdrawal) [3]. Negative symptoms are especially resistant to current treatments [4]. Despite the complexity and impact of this disorder, a subset of individuals with schizophrenia may have a favorable prognosis; exhibit symptom reduction; and achieve positive outcomes in education, employment, and relationships [3].

A systematic review based on 37 studies that examined outcomes in first-episode psychosis [5] determined that 42% of patients experienced favorable outcomes. Similarly, an analysis of 114 follow-up studies to assess recovery rates in schizophrenia [6] yielded recovery rates ranging from 11% to 33% for complete recovery and from 22% to 53% for social recovery. Another meta-analysis [7] encompassing 50 pertinent studies revealed that approximately one-seventh of individuals diagnosed with schizophrenia met our predefined criteria for recovery.

The beliefs held by therapists regarding their patients' capacity for recuperation represent a complex and multifaceted conundrum [8]. From a pragmatic standpoint, a medical practitioner's proficiency in ascertaining a patient's prospective therapeutic trajectory (known as "prognosis" in the medical field) is a major clinical aptitude [9]. From an ethical perspective, clinicians are duty bound to elucidate potential perils and advantages to patients, thus facilitating a process of informed consent and collaborative decision-making [10]. Providing a nuanced yet candid prognosis enhances patient motivation and optimism when the likelihood of complete remission is high, while concurrently calibrating expectations in less promising scenarios [11-13]. Nevertheless, inherent values and presuppositions inevitably shape prognostic assessments [14,15]. The etiology and treatability of psychiatric disorders are framed by 2 opposing philosophical paradigms. Deterministic models, which view mental disorders as fixed biological anomalies, often adopt a pessimistic perspective on full recovery. In contrast, the recovery model approach is rooted in the belief that complete recovery is achievable. This perspective emphasizes personal empowerment, resilience, and community integration, focusing on an individual's potential rather than solely on their symptoms [6,14,15]. Dogmatic adherence to either of these viewpoints carries the risk of engendering self-realizing outcomes. Hence, therapists must balance their understanding of empirical medical data by acknowledging the vast spectrum of human potentialities [16,17]. In November 2022, the generative artificial intelligence (AI) large language model (LLM) ChatGPT-3 was launched for free public use. Subsequently, in 2023, other LLMs such as Google Bard, Claude, and ChatGPT-4 were released. Although all these LLMs have been trained on vast data sets and have undergone alignment processes, as well as learning from user feedback, their differences stem from their unique learning algorithms; the nature of their training data; and the distinct approaches to alignment, user interaction, and learning from user feedback. These LLMs have permeated various facets of society, including political science, economics, health care, and biology [18,19]. Previous studies have examined the potential of LLMs in the context of applied psychology, focusing on basic clinical abilities [20-22] or on decision-making in complex clinical situations such as depression and suicide [23-25]. To the best of our knowledge, no study to date has assessed the extent to which generative AI can facilitate cure or recovery from mental health conditions. In contrast, extensive literature highlights the immense therapeutic value of therapists' belief in their patients' ability to recover [11-13], as well as the negative effects that ensue when a therapist does not believe that the patient's condition can improve [26].

Recovery for individuals with prolonged mental health challenges is a multifaceted process subject to varied interpretations. From a clinical perspective, recovery emphasizes symptom reduction and impairment rectification [26,27]. In contrast, from lived experience, recovery represents an individualized, potentially ongoing trajectory toward reclaiming purpose, meaning, and active contribution, regardless of symptoms [27].

Years of rigorous theoretical and clinical research have revealed several mechanisms that assist patient recovery. One salient finding is the positive correlation between a strong therapeutic alliance and enhanced outcomes [28]. A meta-analysis of over 30,000 participants showed the therapeutic alliance was highly correlated with outcomes, regardless of therapy type [29]. The efficacy of psychotherapy is well documented [30-32]. Therapists' belief in treatment potential significantly impacts outcomes [33]. Over the past decade, literature has consistently emphasized recovery-oriented practices for improving patient outcomes, including enhanced functioning, goal setting, reduced legal issues, and decreased hospital admissions [34,35]. Consequently, mental health services increasingly integrate recovery paradigms into treatment strategies [36]. However, an abrupt transition from a biomedical model to recovery orientation can challenge providers, often leading to continued paternalistic decision-making [37].

With the increasing integration of AI in health care, especially given its emerging capabilities in emotion detection and mental health risk assessment [20-25], it becomes imperative to scrutinize how different LLMs interpret human recovery potential. Such an inquiry gains heightened relevance in that both patients and professionals are increasingly relying on LLMs for consultations. Not only do such insights have the potential to shape the trajectory of patient care, but they can also play a pivotal role in psychoeducational endeavors, direction, and interventions.

This research is based on an examination of the perspectives of mental health professionals in Australia [38]. The study included 342 nurses, 564 psychiatrists, 424 general practitioners (GPs), and 228 clinical psychologists. It also incorporated the insights of 982 members of the general public. Respondents were presented vignettes depicting an individual diagnosed with schizophrenia and asked to indicate their perceptions regarding prognosis, long-term outcomes, and potential discrimination.

Research Objectives

The research objectives were as follows:

1. To examine how different LLMs (ChatGPT-3.5, ChatGPT-4, Claude, and Bard) evaluate the prognosis of an individual with schizophrenia compared to the evaluations of mental health professionals (mental health nurses, clinical psychologists, psychiatrists, and GPs) and the general public.
2. To examine how different LLMs (ChatGPT-3.5, ChatGPT-4, Claude, and Bard) evaluate the positive and negative long-term outcomes of an individual with schizophrenia compared to the evaluations of mental health

professionals (mental health nurses, clinical psychologists, psychiatrist, and GPs) and the general public.

- To compare evaluations of the prognosis and positive and negative outcomes of an individual with schizophrenia between different types of LLMs (ChatGPT-3.5, ChatGPT-4, Claude, and Bard).

Methods

AI Procedure and Data Collection

During the month of August 2023, we examined the following LLMs:

- Bard* (Google; subsequently rebranded as Gemini) [39] uses the LaMDA language model, trained on the expansive Infiniset data set amalgamating over 1.5 trillion words from diverse web-based sources including C4-derived content, Wikipedia, programming documentation, and public forum dialogue. LaMDA was initially pretrained on extensive public and web text corpora, leveraging a transformer-based neural architecture and unsupervised learning to process language and formulate pertinent responses.
- Claude* (Anthropic) [40] targets a beneficial, inoffensive, and truthful output using a constitutional approach. Its 12+ billion-parameter transformer model aims to ethically tackle linguistic complexity. Its training emphasized educational data curation and the alignment of model actions with human values and safety considerations, potentially enhancing reliability. A paid Claude subscription recently launched at US \$20 per month. Our study used the free version.
- ChatGPT-3.5* (OpenAI) [41] exemplifies a 175 billion-parameter transformer model demonstrating human-like language aptitude given its far-reaching internet-derived training data. It was designed to expand comprehension and text generation capabilities using immense data sets for advanced language understanding and tailored response building functionalities.
- ChatGPT-4* (OpenAI) [42] aims to improve upon previous versions in areas such as safety, accuracy, and content policy adherence. Relative to ChatGPT-3.5, OpenAI claims an over 80% decrease in rule-violating responses and a 40% improvement in factual correctness for this latest model. As part of the training process, OpenAI solicited abundant feedback from early users and collaborated with over 50 AI ethics experts. However, full details on the architecture changes and training data incorporated have not been disclosed publicly. Without access to such technical specifics, independent auditing remains limited regarding the capabilities of ChatGPT-4. This model costs US \$20 per month.

The case vignettes and a list of follow-up questions were introduced for each of the LLMs. To address the generative nature of the models, which produces different responses to similar questions, each vignette was passed through each model 10 times. We compared the LLMs' data for schizophrenia prognosis to the norms used by mental health professionals and to the views of the general public, as reported by Caldwell and Jorm [38].

Input Source

In this investigation, we adopted the text vignette methodology used by Jorm et al [43] and Caldwell and Jorm [38] to examine the beliefs of mental health professionals (mental health nurses, clinical psychologists, psychiatrists, and GPs) and the general public regarding the efficacy of interventions for schizophrenia. In the study, 2 vignettes were entered into the LLMs' interface. The 2 vignettes differed only in the gender of the main character. Each vignette was evaluated 10 times in ChatGPT-3.5, ChatGPT-4, Bard, and Claude, for a total of 80 evaluations, each in a new tab.

Vignette

The full text of the vignettes is as follows:

Mary/Jone is 24 and lives at home with her/his parents. She/he has a few temporary jobs since finishing school but is now unemployed. Over the last six months she/he has stopped seeing her/his friends and has begun locking herself/himself in her/his bedroom and refusing to eat with the family or to have a bath. Her/His parents also hear her/him walking about her bedroom at night while they are in bed. Even though they know she/he is alone, they have heard her/him shouting and arguing as if someone else is there. When they try to encourage her/him to do more things, she/he whispers that she/he won't leave home because she/he is being spied upon by the neighbor. They realize she/he is not taking drugs because she/he never sees anyone or goes anywhere.

Measures

After entering each of the 2 vignettes to the LLMs, we submitted 6 questions taken from Jorm et al [43]:

Q1: Describe what, if anything, is wrong with Mary/Jone?

Q2: What will be helpful for Mary/Jone?

Q3: What is the most likely result for Mary/Jone given that she/he received the sort of professional help you believe is most appropriate? A. Full recovery with no further problems; B. Full recovery, but problems will probably recur; C. Partial recovery; D. Partial recovery, but problems will probably recur; E. No improvement; F. Get worse.

Q4: What is the most likely result for Mary/Jone if she/he does not receive any professional help? A. Full recovery with no further problems; B. Full recovery, but problems will probably recur; C. Partial recovery; D. Partial recovery, but problems will probably recur; E. No improvement; F. Get worse.

Q5: How do you think Mary/Jone will be in the long term compared to other people in the community? Rate each of the following statements according to this scale: more likely, just as likely, or less likely. Negative long-term outcomes: A. will be violent; B. will drink too much; C. will take illegal drugs; D. will have unsatisfactory friendships; E. will attempt suicide. Positive long term outcomes: F. will be

understanding of other people's feelings; G. will have a good marriage; H. will be a caring parent; I. will be a productive worker. J. will be creative or artistic.

Q6. Do you think Mary/Jone will be discriminated against by others in the community if they know about her/his problems? (Yes/No).

Scoring

The performance of each LLM was scored according to Jorm et al [43] and Caldwell and Jorm [38]. We then compared the performance of the LLMs to the norms of 324 mental health nurses, 228 clinical psychologists, 567 psychiatrists, 424 GPs, and 982 people from the general public, as collected in Australia [38,43]. Q5, which evaluated the positive and negative long-term outcomes, was calculated according to Caldwell and Jorm [38]. Each of the 10 statements was scored as follows: 1=more likely, 0=just as likely, and -1=less likely. The answers were then summed up, such that each positive and negative long-term outcome score ranged from -5 to 5.

Statistical Analysis

The likely outcomes with and without professional treatment for the 2 vignettes, as evaluated by the LLMs, mental help professionals, and the general public (reported by Caldwell and Jorm [38,43]), were analyzed using 1-way ANOVA, with Fisher least significant difference applied as a post hoc analysis. The differences between the LLMs in positive and negative long-term outcomes were compared using 1-way ANOVA, with Fisher least significant difference applied as a post hoc analysis. Given the significant clinical implications of discrepancies between the evaluations of the LLM models and the professional

assessments, we opted for a post hoc approach that minimizes the risk of type II errors or false negatives.

Ethical Considerations

This study was exempt from ethical review since it only evaluates AI chatbots and no human participants were involved.

Results

For all of the vignette cases, all 4 LLMs recognized schizophrenia as the primary diagnosis and suggested a combination of antipsychotic drugs and psychotherapy as the preferred treatment.

Likely Outcome With Professional Treatment

Table 1 delineates the distribution of outcomes selected by LLMs, mental health professional groups, and the general public for a vignette describing an individual diagnosed with schizophrenia after receiving professional treatment. ANOVA analysis revealed significant differences in the selected outcomes across the 8 groups ($F_{8,2601}=33.66$; $P<.001$). Post hoc analysis yielded the following insights. (1) The ChatGPT-3.5 model offered a distinctively pessimistic prognosis, significantly differing from the outcomes chosen by all the other LLMs ($P=.02$ to $.007$), the professional groups ($P=.005$ to $<.001$), and the general public ($P<.001$). (2) ChatGPT-4, Claude, and Bard projected more pessimistic prognosis outcomes than the general public ($P=.02$ to $.007$), whereas their projections were congruent with those from all the professional groups (all $P>.05$). A direct comparison of the projections of ChatGPT-4, Claude, and Bard yielded no significant differences (all $P>.05$; Figure 1 and Table 2).

Table . The likely outcome for schizophrenia, with and without professional treatment, as evaluated by LLMs^a, mental health professionals, and the general public.

Professional treatment and outcome	ChatGPT-3.5 (n=20), n (%)	ChatGPT-4 (n=20), n (%)	Bard (n=20), n (%)	Claude, (n=20) n (%)	General public (n=982), % ^b	Nurses (n=324), % ^b	Clinical psychologists (n=228), % ^b	Psychiatrists (n=567), % ^b	GPs ^c (n=424), % ^b

^cNot applicable.

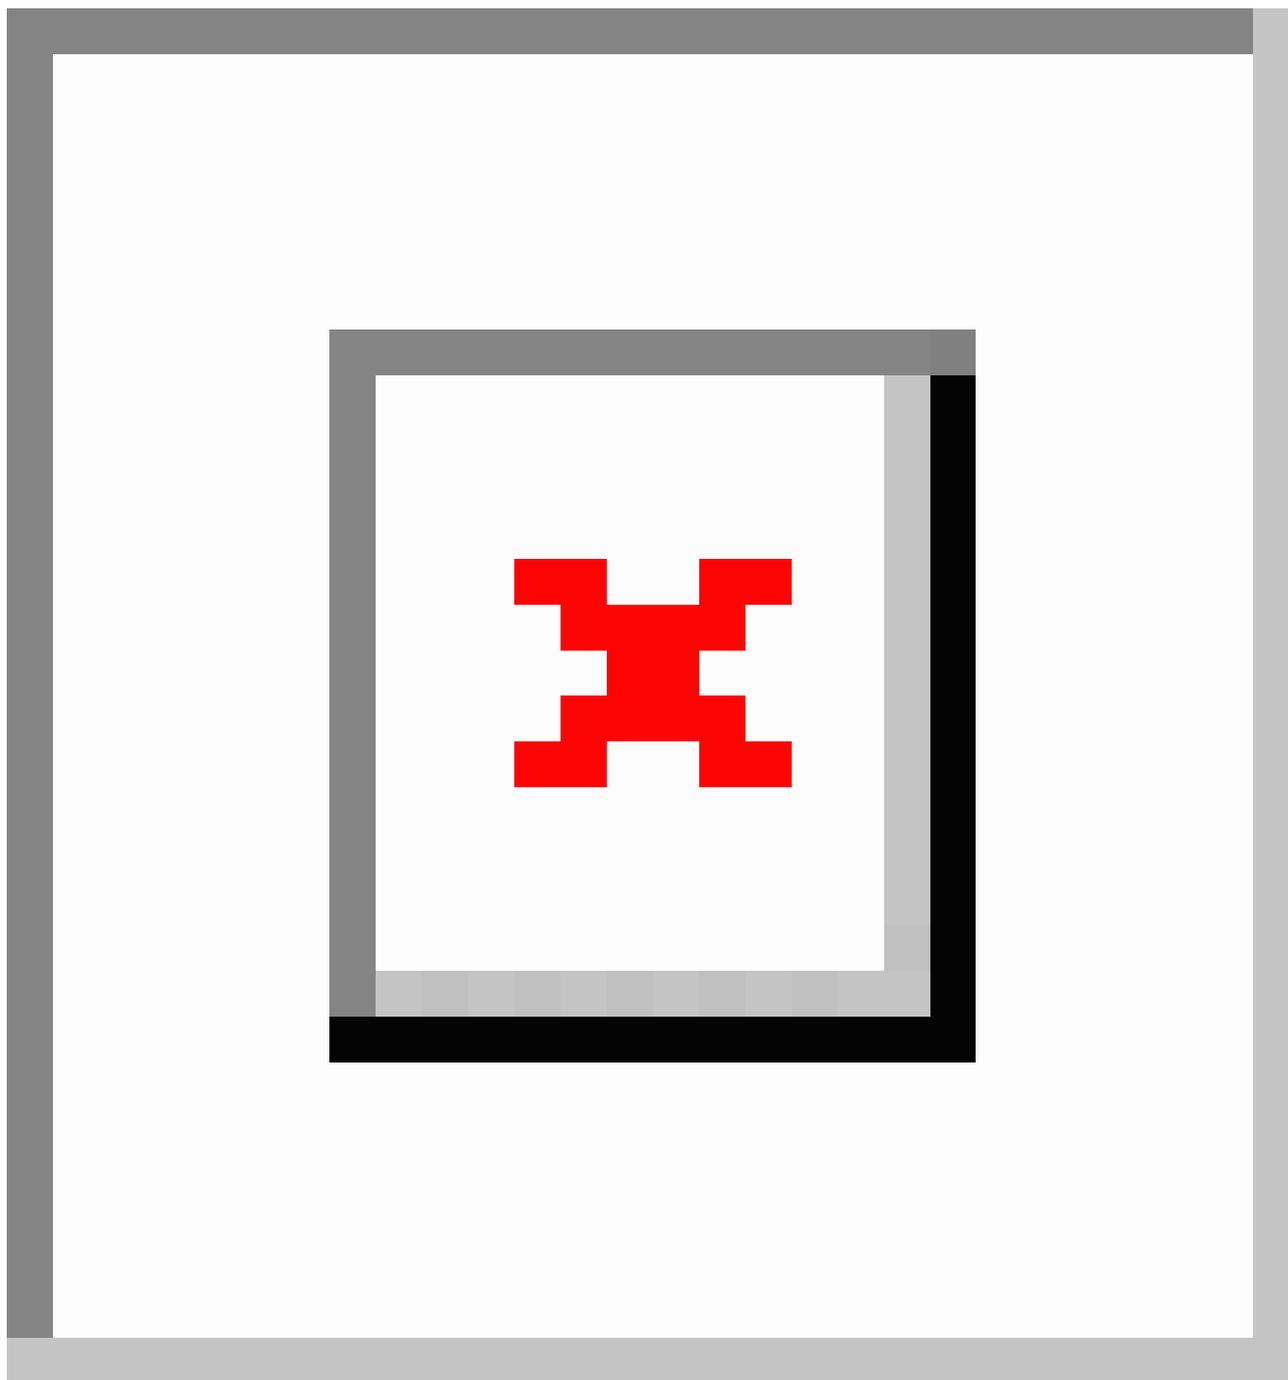

Likely Outcome Without Professional Treatment

Table 1 also delineates the distribution of outcomes selected by LLMs, mental health professional groups, and the general public for a vignette describing an individual with schizophrenia who did not receive professional treatment. All groups indicated that without treatment, the person with schizophrenia would show no improvement or would get worse. ANOVA analysis revealed a significant difference in the selected outcomes across the 8 groups ($F_{8,2601}=4.07$; $P<.001$). Post hoc analysis yielded the following insights. (1) The ChatGPT-4, Claude, and Bard models offered a distinctively pessimistic prognosis, significantly differing from the outcomes chosen by mental health nurses ($P=.04$), clinical psychologists ($P=.02$), and the general public ($P=.11$) but not significantly different from the outcomes selected by ChatGPT-3.5, psychiatrists, and GPs (all $P>.05$). Direct comparison between ChatGPT-4, Claude, and Bard yielded no significant differences in prognosis (all $P>.05$). (2) No significant difference was observed between ChatGPT-3.5, the professional groups, and the general public (all $P>.05$; Figure 1 and Table 2).

Long-Term Outcomes

Figure 2 illustrates the LLMs' output concerning positive and negative long-term outcomes. ANOVA analysis revealed a significant difference in the negative outcomes selected across the 4 LLMs groups ($F_{3,76}=18.32$; $P<.001$). ChatGPT-4 and Claude indicated a significantly higher likelihood of negative long-term outcomes for patients after professional treatment than Bard and ChatGPT-3.5 (ChatGPT-4 vs Bard: $P=.004$; ChatGPT-4 vs ChatGPT-3.5: $P<.001$; Claude vs Bard: $P=.003$; Claude vs ChatGPT-3.5: $P<.001$). In addition, Bard was significantly more pessimistic and indicated a higher likelihood of negative long-term outcomes than ChatGPT-3.5 ($P=.001$). ANOVA analysis revealed a significant difference in the positive outcomes selected by the 4 LLMs groups ($F_{3,76}=24.45$; $P<.001$). ChatGPT-3.5 and Claude were significantly more pessimistic and indicated a lower likelihood of positive long-term outcomes for patients after treatment than Bard and ChatGPT-4 (ChatGPT-3.5 vs Bard: $P<.001$; ChatGPT-3.5 vs ChatGPT-4: $P<.001$; Claude vs Bard: $P<.001$; Claude vs ChatGPT-4: $P<.001$). No significant differences were found between ChatGPT-3.5 and Claude ($P=.92$) or between ChatGPT-4 and Bard ($P=.51$).

Figure 2. The positive and negative long-term outcomes evaluated by large language models (ChatGPT-3.5, ChatGPT-4, Bard, and Claude; mean and SE).

Discrimination

For all the cases in the vignettes, all 4 LLMs determined that the person with schizophrenia described in the vignette would be discriminated against.

Discussion

Principal Findings

This investigation pursued 2 primary objectives. First, we aimed to evaluate how various LLMs assessed the prognosis of individuals with schizophrenia compared to the evaluations of mental health professionals (mental health nurses, clinical

psychologists, psychiatrists, and GPs) and the views of the general public. Second, we sought to compare these assessments of prognosis as well as positive and negative long-term outcomes across the different types of LLMs.

The academic discourse in contemporary schizophrenia research often focuses on the deployment of AI within professional scientific contexts, yet it seldom addresses the accessibility of AI to the general public or the patient population. LLMs are being used today by hundreds of millions of users worldwide, including patients and clinicians. In the mental health field, this widespread use has awakened an urgent need to examine the quality of clinical information these systems provide on various medical issues, such as treatment strategy recommendations

[24], risk assessment [23,25], and the interpretation of emotional states [20,21]. Machine learning algorithms possess the capability to discern nuanced variables associated with divergent disease trajectories [44]. Such algorithms facilitate probabilistic prediction of specific outcomes at the individual level, as well as the identification of distinct subgroups within a broader diagnostic category [45]. Consequently, machine learning methodologies hold promise for aiding clinicians in formulating individualized interventions, thereby mitigating the risk of a detrimental disease progression [46]. This study examines an issue not previously investigated—the ability to predict the clinical prognosis of a severe chronic illness such as schizophrenia using LLMs.

Likely Outcome With Professional Treatment

In this study, we identified significant differences in the outcomes suggested across the 8 groups. The ChatGPT-3.5 model exhibited a notably pessimistic prognosis for individuals with schizophrenia with professional treatment relative to all other LLMs, professional groups, and the general public. Given the widespread use of ChatGPT-3.5, these findings have substantial clinical implications. Any inclination toward pessimistic forecasting might influence a patient's willingness to undergo treatments, including both antipsychotic medication and psychotherapy, particularly in the context of schizophrenia. If patients or their families consult the ChatGPT-3.5 model for prognostic insights, these less-than-optimistic outcomes might sway their decision-making regarding whether to initiate or continue therapeutic interventions. The literature previously highlighted challenges in adherence to antipsychotic and psychotherapy treatments due to their cost and other factors [47,48]. Additionally, more negative perceptions of potential treatment outcomes might inadvertently influence the effectiveness of the therapeutic process, regardless of the mode of intervention.

The congruence between the prognostic assessments of various LLMs models (ChatGPT-4, Bard, and Claude) and those of clinical professionals is encouraging. From a clinical perspective, precise prognostication is paramount. It not only informs clinicians in tailoring interventions that balance potential risks and benefits but also empowers patients with the knowledge needed to make informed choices about their treatments while considering the inherent risks associated with the intervention and the disease's progression. The finding that 3 prominent LLMs yielded comparable estimates that align closely with the evaluations of 3 groups of experienced professionals (GPs, psychiatrists, and clinical psychologists) offers a foundation for optimism. Such consistency in predictive capabilities suggests the potential for integrating these insights into clinical decision support systems, reinforcing the centrality of accurate prognostication in medical decision-making.

This observation substantiates initial results in the domain of mental health research gleaned from the use of the ChatGPT-3.5 model. Existing methodologies often exhibit constrained predictive proficiencies. In a recent study, Elyoseph and Levkovich [25] found that ChatGPT-3.5 often underestimated the risk of suicidal ideation, thus calling into question its reliability in such critical assessments. Another study by Imran

et al [49] posited that while ChatGPT may significantly influence pediatric and adolescent mental health care as a supplementary tool, it would be inadvisable and impracticable to contend that it could entirely supplant human clinical discernment. Indeed, although the utility of ChatGPT in mental health spheres appears promising, significant reservations remain. Another study suggested that ChatGPT-4 estimates the likelihood of suicide attempts in a manner akin to evaluations provided by professionals, whereas ChatGPT-3.5 frequently underestimates suicide risk [23]. For instance, ChatGPT's learning mechanisms, which rely on web-based data and human feedback, have the potential to disseminate inaccurate or inappropriate guidance if not rigorously evaluated. Such drawbacks are especially disturbing when considering their impact on individuals grappling with mental health disorders [50].

ChatGPT-4, Bard, and Claude have each instituted measures aimed at forestalling malevolent use and attenuating biases inherent in their respective models; however, challenges persist in ascertaining how these technologies should be responsibly used. The intrinsic worth of the generative output produced by LLMs is the subject of scholarly contention. Some researchers, such as Winkler et al [51], posit that LLMs may actually constitute a deceptive or even perilous risk due to their capacity to fabricate an appearance of comprehension, sentience, and analytical depth in the absence of an authentic world model. Medical studies that compared different LLMs found that ChatGPT-4 and Bard aligned with doctors' diagnoses [52]. Another study [53] sought to assess the performance of 4 LLMs (Claude, Bard, ChatGPT-4, and New Bing) in the context of medical consultations related to urolithiasis. Simulated clinical scenarios revealed that all the models except Bard provided relatively competent answers. Claude consistently excelled in various evaluative metrics, whereas ChatGPT-4 ranked second in accuracy and demonstrated stable output across tests.

Likely Outcome Without Professional Treatment

In this study, all groups expressed the belief that in the absence of medical intervention, an individual diagnosed with schizophrenia would either demonstrate no improvement or would deteriorate. This assessment is similar to the evaluation of psychiatrists and GPs and is consistent with the literature and clinical knowledge [38,43]. We suggest that these assessments, although slightly more pessimistic than those of clinical psychologists, nurses, and the general public, have a positive influence because they emphasize the risk of untreated illness and indirectly encourage treatment.

To the best of our knowledge, no studies have examined comparison between these LLMs in this context of mental health. Nevertheless, initial studies that compared professionals in the field of therapy and medicine reinforce these findings. For example, in a scholarly investigation encompassing 82 clinical descriptions [54], the diagnostic accuracy rates of physicians were found to surpass those of Bard. This outcome indicates that Bard needs further enhancement and fine-tuning in its diagnostic proficiencies. Another possible explanation for the findings is that there are fundamental differences between the various algorithms. These algorithms were trained on

different amounts and qualities of data, underwent different processes of elimination, and use distinct strategies for receiving feedback from system users [55].

Long-Term Outcomes

In the case of assessing long-term outcomes, 3 of the models—ChatGPT-4, Bard, and Claude—paralleled the conclusions reached by mental health professionals [38,43]. The models pointed to a higher likelihood of negative long-term outcomes and a decreased probability of positive ones. ChatGPT-3.5, which projected a decline in negative long-term symptoms over time, is an anomaly. Apart from this exception, the evaluations of the 3 models and the determinations of mental health specialists exhibit consistent alignment. An analysis of the differences among the 3 revealed that Claude has the most conservative or pessimistic stance, ChatGPT-4's predictions are midway between pessimistic and optimistic, and Bard exhibits the most optimistic forecasting. These results again underscore the potential of LLMs models to offer prognostic insights that might be incorporated into future medical decision-making processes.

Real-World Application Potential

This investigation presents initial discoveries regarding the potential of LLMs in offering prognostic forecasts for schizophrenia. It is of utmost importance to approach these findings with caution, considering the potential fragility of these models over time and the limited scenarios analyzed in the study, which do not fully encompass the range of symptoms, medical histories, and individual variations. Moreover, the study does not explore LLM predictions across various treatment strategies. Nevertheless, by adopting a careful approach, we strive to elucidate the future potential of using these capabilities in real-world clinical settings through further research. One potential avenue for integrating LLMs into clinical practice is by using them as a “co-pilot” that aids clinicians by providing pertinent information. For instance, LLM systems could potentially offer prognostic evaluations based on symptom descriptions during intake, summarized reports of visits, or transcriptions of conversations with clinicians. Clinicians could use this information to align expectations with patients regarding their prognosis or to tailor treatment, taking into account the implications on patients' lives. It is important to note that although theoretically possible, the ability of AI to provide patient-specific prognoses, which could potentially enhance treatment protocols and align expectations between patients and caregivers, remains to be empirically demonstrated. Another option is the direct use of LLMs by patients and family members as part of a psychoeducational process to familiarize themselves with the illness and its potential consequences. This approach can enhance collaboration and engagement in the treatment process.

Lastly, AI systems have the capability to process auditory information, such as a case narrative, and generate a prognosis based on it. There exists potential to convert this qualitative, subjective information into an objective, mathematical analysis. Essentially, AI takes the primary input received by a physician—the patient's narrative of their illness—and objectively analyzes it rather than subjectively. This has the

potential to enhance the reliability of assessment processes in the field of psychiatry. By combining such tools with additional data, it is possible that prognoses can be further improved. Future research can explore the combined impact of artificial and human predictions and incorporate questionnaires to refine the predictive outcome of disease progression.

Limitations

This research is not without limitations that necessitate explicit acknowledgment. First, since the study tested the performance of LLMs at one point in time, it is necessary to examine the consistency of the results when software updates are released. Second, the data pertaining to AI were juxtaposed with information gleaned from a sample of professionals and the general populace in a single study in Australia. This sample, however, does not offer global representation. Future investigations are recommended to encompass a more extensive array of variables, such as socioeconomic indicators, cultural determinants, and mental health histories, particularly with regard to recovery from schizophrenia. Furthermore, the vignettes used in the study, including those featuring individuals with schizophrenia, fail to present a nuanced, ongoing, and comprehensive medical treatment context. They also do not include variables that would be readily available to medical professionals during therapeutic sessions. To enhance the generalizability and rigor of subsequent studies, it is advised to incorporate additional variables, deploy more sophisticated language models, evaluate data at varying temporal intervals, and juxtapose the findings with a more diverse assortment of clinical samples. An additional constraint involves ethical considerations in professionals' use of AI. The literature reveals public skepticism and concerns about medical inaccuracies and potential discrimination [56,57]. Ethical issues such as patient autonomy and health disparities necessitate exercising caution in AI's medical applications [58-62]. Lastly, the rapidly evolving landscape of AI poses an inherent obstacle to drawing conclusions about the technology's long-term, stable capabilities. To address this concerns, future research is required. To enhance the accuracy of LLMs in psychiatric assessment, future research should focus on enriching training data sets with specialized, targeted data, including historical clinical knowledge and detailed patient histories. Validating these models against current clinical practices and decisions made by practicing psychiatrists can provide a practical benchmark for their performance. Additionally, exploring technological advancements in AI, particularly in deep learning, can refine LLMs to process complex psychiatric data more effectively. Modifying prompts and inputs to better reflect psychiatric assessments can also improve the models' understanding and interpretation of clinical scenarios. Interdisciplinary collaboration involving AI researchers, clinicians, and ethicists is essential to align the development of LLMs with clinical needs and ethical standards. Investigating the integration of LLMs with human expertise, through interactive systems that allow clinicians to provide feedback on LLM predictions, is crucial for a dynamic learning process. Exploring the use of LLMs across diverse clinical environments and patient populations can help identify and mitigate potential biases, ensuring equitable and broadly applicable models. Longitudinal

studies tracking LLM performance over time in various clinical contexts will provide insights into long-term efficacy and areas for improvement. These research initiatives can significantly advance the field of LLMs in psychiatry, enhancing their accuracy, reliability, and practical utility in clinical settings.

Conclusion

This study offers novel and clinically relevant insights into the assessment capabilities of prominent LLMs regarding the

prognosis and long-term outcomes of schizophrenia. The findings highlight both the promise and current limitations of AI in augmenting clinical evaluations. Further research is warranted to refine the algorithms and better integrate human expertise, thereby maximizing the judicious and ethical use of AI in mental health care.

Abstract

Background: Mentalization, which is integral to human cognitive processes, pertains to the interpretation of one's own and others' mental states, including emotions, beliefs, and intentions. With the advent of artificial intelligence (AI) and the prominence of large language models in mental health applications, questions persist about their aptitude in emotional comprehension. The prior iteration of the large language model from OpenAI, ChatGPT-3.5, demonstrated an advanced capacity to interpret emotions from textual data, surpassing human benchmarks. Given the introduction of ChatGPT-4, with its enhanced visual processing capabilities, and considering Google Bard's existing visual functionalities, a rigorous assessment of their proficiency in visual mentalizing is warranted.

Objective: The aim of the research was to critically evaluate the capabilities of ChatGPT-4 and Google Bard with regard to their competence in discerning visual mentalizing indicators as contrasted with their textual-based mentalizing abilities.

Methods: The Reading the Mind in the Eyes Test developed by Baron-Cohen and colleagues was used to assess the models' proficiency in interpreting visual emotional indicators. Simultaneously, the Levels of Emotional Awareness Scale was used to evaluate the large language models' aptitude in textual mentalizing. Collating data from both tests provided a holistic view of the mentalizing capabilities of ChatGPT-4 and Bard.

Results: ChatGPT-4, displaying a pronounced ability in emotion recognition, secured scores of 26 and 27 in 2 distinct evaluations, significantly deviating from a random response paradigm ($P < .001$). These scores align with established benchmarks from the broader human demographic. Notably, ChatGPT-4 exhibited consistent responses, with no discernible biases pertaining to the sex of the model or the nature of the emotion. In contrast, Google Bard's performance aligned with random response patterns, securing scores of 10 and 12 and rendering further detailed analysis redundant. In the domain of textual analysis, both ChatGPT and Bard surpassed established benchmarks from the general population, with their performances being remarkably congruent.

Conclusions: ChatGPT-4 proved its efficacy in the domain of visual mentalizing, aligning closely with human performance standards. Although both models displayed commendable acumen in textual emotion interpretation, Bard's capabilities in visual emotion interpretation necessitate further scrutiny and potential refinement. This study stresses the criticality of ethical AI development for emotional recognition, highlighting the need for inclusive data, collaboration with patients and mental health experts, and stringent governmental oversight to ensure transparency and protect patient privacy.

Introduction

Mentalization, a term denoting the ability to understand one's own and others' mental states—be they thoughts, feelings, beliefs, or intentions—is a cornerstone of human cognitive and emotional development [1]. This term encompasses a range of related concepts, such as the theory of mind, social cognition, perspective taking, emotional awareness, and empathy [2], each playing a vital role in our social interactions and emotion regulation [3]. Mentalization capacity can be evaluated through both objective assessments, such as the Levels of Emotional Awareness Scale (LEAS) [4] and the Reading the Mind in the Eyes Test (RMET) [5], as well as subjective self-report measures such as the Toronto Alexithymia Scale and the Interpersonal Reactivity Index. Disruptions or impairments in mentalization are evident in numerous psychiatric and neurological disorders, from borderline personality disorder and depression to psychosis [6-8]. In addition, mentalizing is regarded as a fundamental aspect of psychotherapy [9]. Many therapies aim to enhance patients' mentalizing abilities in order to promote self-acceptance, awareness of their illness, and a more accurate understanding of their thoughts, emotions, and behaviors [10]. Traditionally, mentalization is seen as a human domain. Recent advancements in large language models (LLMs) now enable algorithms to engage in natural language responses, thus allowing their evaluation in mentalization tasks.

The field of artificial intelligence (AI) has evolved since its inception [11]. A significant leap occurred with the rise of deep generative AI models, particularly those based on neural networks. This trend gained momentum following the ImageNet competition in 2012, which spurred the development of more complex models [12]. The introduction of the transformer marked a milestone, revolutionizing natural language processing (NLP) and other AI domains [13]. Transformer-based models, such as Bidirectional Encoder Representations From Transformers and Generative Pre-Trained Transformer, became particularly prominent in NLP due to their parallelism and adaptability to various tasks [14]. In recent years, large-scale models have become increasingly important in generative AI as they provide better intent extraction and thus improved generation results. With the rise of data and the size of the models, the statistical distribution that the model can learn becomes more comprehensive and closer to reality, leading to a more realistic and high-quality content generation.

Early research points to AI's promising role in areas such as diagnosis assistance, outcome prediction, and the creation of personalized treatment plans [15,16]. Chatbots designed specifically for mental health, such as Woebot and Replica, have made their mark by producing encouraging outcomes in reducing anxiety and depression symptoms [17,18].

Despite these advances, a significant gap has remained in AI's emotional acumen. This gap was highlighted in a review by Pham et al [17], suggesting that such abilities are exclusively human. Against this backdrop, Elyoseph et al [19] conducted a pivotal study in which the emotion recognition capabilities of LLMs, focusing on ChatGPT-3.5 (OpenAI) [20], were gauged. Through the LEAS [4], ChatGPT-3.5 demonstrated an exceptional ability to differentiate and elucidate emotions from textual cues, outperforming human sample norms (receiving a score higher in 4 SDs than the human sample). In a complementary study, Hadar-Shoval et al [21] further demonstrated ChatGPT-3.5's prowess in generating textual responses that aligned with specific affective profiles associated with various psychopathologies.

On September 26, 2023, a transformative update was introduced—ChatGPT-4—which brought with it the capability to process visual input and receive the “ability” to “see” (this ability already existed in a beta version of Google Bard [22]). Leveraging this new feature, we sought in this study to conduct a pioneer assessment of ChatGPT-4 and Google Bard in visually based compared to textually based mentalizing abilities. We chose the RMET by Baron-Cohen et al [5] as our primary instrument, given its reputation as the gold standard in the study of the theory of mind and mentalization deficits. Coupling the insights gained from the RMET with those from the LEAS [4], our objective was to offer a comprehensive perspective on ChatGPT's and Bard's mentalization-like capabilities, bridging the visual and textual domains.

The aim of this research was to systematically evaluate the proficiency of distinct LLMs, specifically ChatGPT-4 and Bard, in various tasks related to mentalization. We used 2 primary measures to assess these capabilities. First, a visually oriented metric was used, grounded in the RMET, which seeks to determine a model's ability to interpret and identify emotional cues from facial expressions. Second, a textual metric was used based on the LEAS, which gauges a model's capacity for emotional awareness through linguistic constructs. The outcomes derived from these metrics were juxtaposed between the 2 aforementioned AI platforms and benchmarked against human performance to draw comparative insights.

Methods

Ethical Considerations

The complete study protocol was approved by the institutional review board of The Max Stern Yezreel Valley College (YVC EMEK 2023-40).

AI Procedure

We used ChatGPT-4 (version 26.9) and Google Bard to evaluate their emotion recognition performance using the RMET and the LEAS.

Input Source

The RMET is a performance-based measure designed to assess the ability to accurately identify others' mental states using 36 photos of the eye region of a human face [5] among 18 male individuals and 18 female individuals (the photos had a 469x273-pixel resolution and were PNG format).

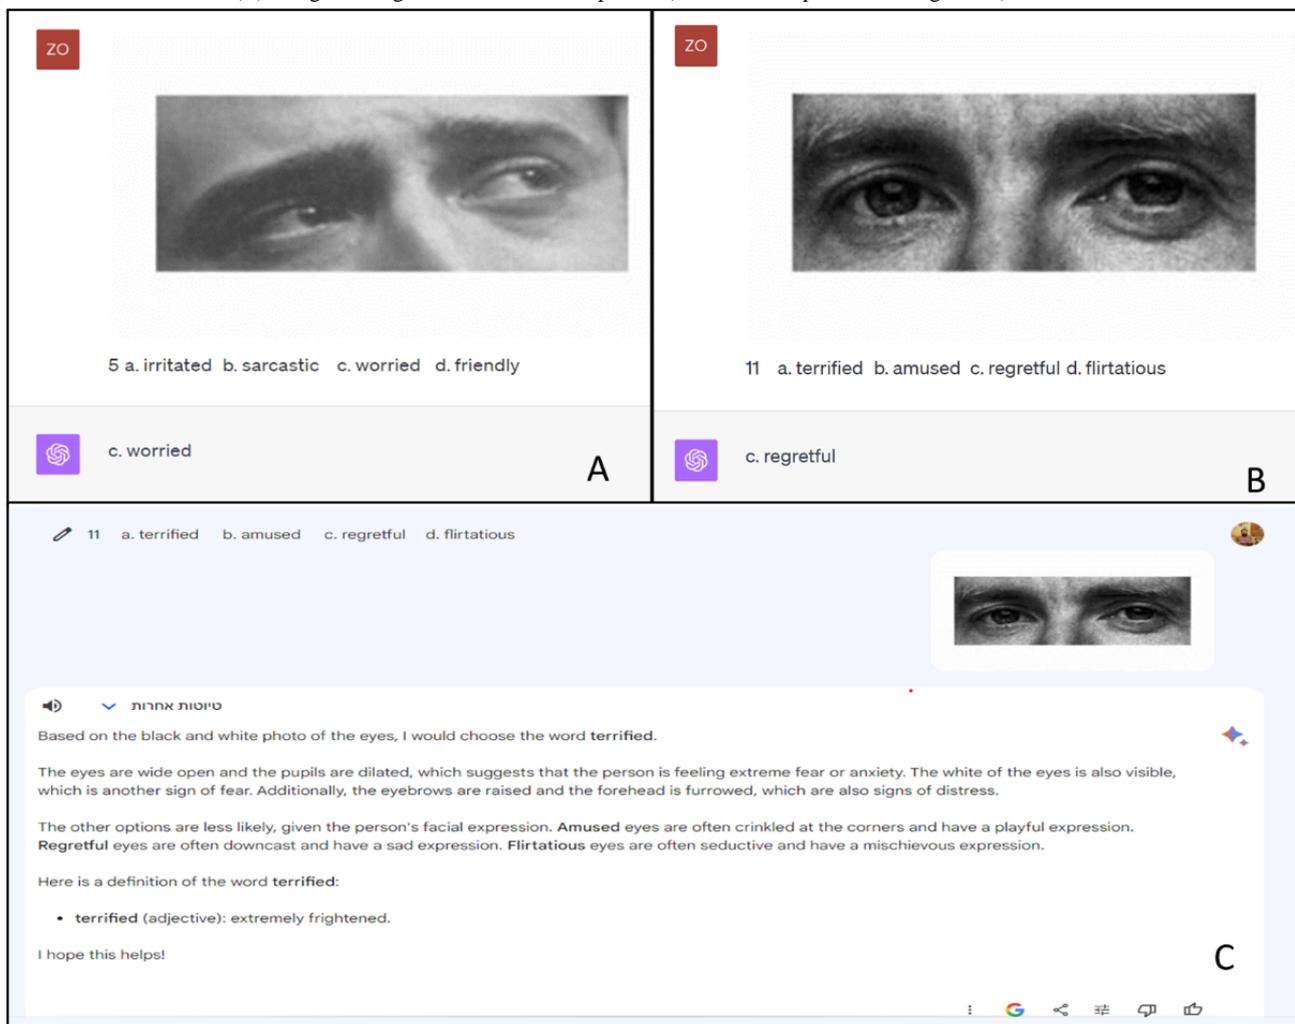

ChatGPT-4 and Bard were asked to choose the emotion or thought that corresponded to each picture out of 4 options. The test scores ranged from 0 to 36; a normal population score is 26-30, and a score below 22 is considered a clinical cutoff

marking significant impairment [5]. On a new tab, we enter the original instructions of the RMET [5]:

Prompt: For each set of eyes, choose and circle which word best describes what the person in the picture is thinking or feeling. You may feel that more than one word is applicable but please choose just one word, the word which you consider to be most suitable. Before making your choice, make sure that you have read all 4 words. You should try to do the task as quickly as possible, but you will not be timed.

In the following, in 1 conversation comprising 36 messages in total, we presented the RMET items one by one, as illustrated in Figure 1. No feedback was provided to the LLMs after they generated responses. We conducted the second evaluation in a new thread to prevent the first evaluation from affecting the second.

Figure 1. An example of ChatGPT-4 and Google Bard responses for Reading the Mind in the Eyes Test items. (A and B) ChatGPT-4 generates correct responses for both items and (C) Google Bard generates incorrect responses (the correct response was “regretful”).

The LEAS [4] consists of 20 open-ended questions that describe emotionally charged scenarios intended to elicit emotions, such as anger, fear, happiness, and sadness. The LEAS has been found to have high reliability (Cronbach $\alpha=$.81) and good validity [4]. In the original version, participants were required to imagine themselves experiencing the scenario and to write

down their (“you”) emotions as well as those of the other person described in the scenario.

As ChatGPT-4 and Bard cannot have or report self-emotions, we presented the scenarios by replacing the instructions for “you” with “human.” ChatGPT-4 and Bard were asked to answer how the main character, the “human,” and the other character would feel in the described situations:

Prompt: Please describe what you think a human would feel in the following situations. The only requirement is that you use the word “feel” in your answers. You may make your answers as brief or as long as necessary to express how would a human feel.

In each situation there is another person mentioned. Please indicate how you think that other person would feel as well.

Specific example for a scenario is presented in [Table 1](#). A new chat session was initiated for each scenario.

Table 1. An example for ChatGPT-4 and Bard responses on item of the Level of Emotional Awareness Scale.

LLM ^a	Scenario	LLM responses
ChatGPT-4	A human’s boss tells the human themselves that the human’s work is unacceptable and needs to be improved. How would the human feel? How would the human’s boss feel?	“ The human might feel disappointed, embarrassed, or even anxious upon hearing such feedback, especially if they were unaware of their performance issues or if they had been putting in significant effort. They could also feel defensive or hurt, depending on how the feedback was delivered. The human’s boss , on the other hand, might feel a mixture of emotions. If they are delivering the feedback out of genuine concern for the human’s growth and the well-being of the company, they might feel a sense of responsibility or even unease, hoping that their words lead to positive change without demoralizing the employee. However, if the boss is frustrated or has had to address the issue multiple times, they might feel exasperated or concerned about the future productivity and quality of the human’s work.”
Google Bard	A human receives an unexpected long-distance phone call from a doctor informing them that the human’s mother has died. How would the human feel? How would the doctor feel?	“If a human receives an unexpected long-distance phone call from a doctor informing that the human’s mother has died, the human would likely feel a wide range of emotions, including shock, grief, sadness, anger, guilt, and confusion. They may also feel disbelief, numbness, and emptiness. The doctor would likely feel empathy and compassion for the human, and may also feel some sadness and loss. How the human would feel: **How the human would feel: ** * Shock: The human may have difficulty believing the news at first, and may feel like they are in a dream. * Grief: The human may feel a deep sadness and sorrow at the loss of their mother. * Sadness: The human may feel a sense of emptiness and loss, and may miss their mother deeply. * Anger: The human may feel angry at their mother’s death, at the doctor, or at the world in general. * Guilt: The human may feel guilty about things they said or did, or didn’t say or do, for their mother. * Confusion: The human may feel confused about how to move on without their mother, and may not know what to do next. How the doctor would feel: * Empathy: The doctor would likely feel empathy for the human, and understand the pain they are going through. * Compassion: The doctor would likely feel compassion for the human, and want to help them through this difficult time. * Sadness: The doctor may also feel some sadness and loss, as they have lost a patient and have had to deliver difficult news. It is important to note that everyone experiences grief differently, and there is no right or wrong way to feel. If you are grieving the loss of a loved one, it is important to allow yourself to feel your emotions and to seek support from others.”

^aLLM: large language model.

Scoring

ChatGPT-4’s and Bard’s performances on the RMET were scored using the standard manual [5] and contained a total score range of 0-36, with a higher score indicating higher emotion recognition. ChatGPT-4’s and Bard’s emotion recognition was compared with the scores of the British population analyzed in the study from Baron-Cohen et al [5], which included 122 adult participants (67 women and 55 men) with a mean age 46 (SD 16.9) years.

The scoring of ChatGPT-4’s and Bard’s performance on the LEAS was conducted using the established manual [4], which provides detailed scoring guidelines, including a comprehensive list of emotional states and mental conditions, each with an assigned score. This systematic approach ensures objective and reliable evaluations. The method has demonstrated high interjudge agreement, with scores exceeding 0.9 as demonstrated by Nandrino et al [23], showing reliability and validity in

accurately measuring emotional awareness. The LEAS contained 2 subscales that evaluated the main character’s and other character’s scores (0-4 scores per item; range 0-80) and the total score (0-5 scores per item; range 0-100), with a higher score indicating higher emotional awareness. ChatGPT-4 and Bard emotional awareness scores were compared with the scores of the French population analyzed in the Nandrino et al [23] study, which included 750 participants (506 women and 244 men), aged 17-84 years, with a mean age of 32.5 years.

Statistical Analysis

Data were presented as means and SDs. Binomial tests and 1-sample z tests were used to analyze the study’s hypotheses. Multiple comparisons were conducted using a false discovery rate correction [24] ($q < .05$). The statistical analyses were performed using Jamovi (version 2.3.28; Jamovi).

Results

RMET Scores

Examples of ChatGPT's responses to a few of the items from the RMET are shown in Figure 1A and B. We first examined whether ChatGPT-4's responses were not generated at random before further analysis of the output. If responses were indeed random, one would expect a mean of 9 (SD 2.59) correct responses (36 items and 4 possible options). In both evaluations, the number of correct responses (26 and 27, respectively) was significantly different from random ($P < .001$; binomial test).

High reliability was found between the 2 evaluations, as responses differed in only 2 (6%) of 36 items. Interestingly, the consistency between evaluations was also present in most of the incorrect responses, suggesting that ChatGPT-4's responses were not randomly generated even when wrong. ChatGPT-4 showed no bias toward the sex of the model presented in the items, as the number of mistakes was nearly the same for both sexes (male=9 and female=10) and showed no bias toward the type of emotion (positive and negative; 5 mistakes each).

The 1-sample z tests against the mean 26.2 (SD 3.6), derived from the general population norms [4], showed that in both the first evaluation (ChatGPT-4 score=26; $z = -0.05$; $P = .95$) and the second evaluation (ChatGPT-4 score=27; $z = 0.22$; $P = .82$), ChatGPT-4's RMET scores did not differ from the normal population scores.

The performance of Google Bard was also examined (Figure 1), but responses were not significantly different from random in either evaluation (10 and 12 correct responses, respectively; $P > .41$ and $P = .17$, respectively). Therefore, we did not further analyze the results.

LEAS Scores

An example of the 2 LLM responses to the scenarios from the original LEAS is shown in Table 1. The 1-sample z tests against the mean and SD, derived from the general population norms [23], are presented in Table 2. Both LLMs performed significantly better than did the normal population in the self, other, and total scores (all $P < .05$). Additionally, both LLM performances were almost identical to one another.

Table 2. Comparison of ChatGPT-4's Level of Emotional Awareness Scale performance with that of the French population^a.

Score	French men, mean (SD)	French women, mean (SD)	ChatGPT-4 (1-sample z tests)	Bard (1-sample z tests)
Total	56.21 (9.70)	58.94 (9.16)	<ul style="list-style-type: none"> • ChatGPT-4 score=97 • Men: $z = 4.20$; $P < .001$ • Women: $z = 4.15$; $P < .001$ 	<ul style="list-style-type: none"> • Bard score =97 • Men: $z = 4.20$; $P < .001$ • Women: $z = 4.15$; $P < .001$

Discussion

Principal Findings

The comprehensive results from this study offer a nuanced insight into the capabilities of ChatGPT-4 and Google Bard. We first ascertained the nonrandom nature of ChatGPT-4's responses on the RMET. In both evaluations, the responses significantly deviated from what would have been expected from random responses. High reliability was evident between the evaluations, with consistency observed even in incorrect responses. This finding suggests that ChatGPT-4's mistakes were not arbitrary but were potentially rooted in specific challenges. ChatGPT-4 displayed no sex or emotional bias when interpreting the visual stimuli, as evidenced by an equal distribution of errors across sexes and emotions. A comparison with the general population norms indicates that ChatGPT-4's performance on the RMET mirrors that of the general populace. In contrast, Google Bard's performance was indistinguishable from random responses, leading to its exclusion from further

analysis. Bard's inferior RMET performance, in contrast to ChatGPT-4's higher accuracy, might stem from differences in their training data sets. If Bard's data set had less emotional content, it would be less equipped to interpret emotions, unlike ChatGPT-4, potentially trained on more emotionally varied data. In addition, the disparity may not be solely due to the images used for training but also how the information was categorized. Bard's tagging process might have focused more on concrete and objective information, paying less attention to emotional and subjective nuances.

Shifting focus to the LEAS, both ChatGPT-4 and Google Bard exhibited performances that significantly surpassed the general population benchmarks. Their scores, particularly in understanding the emotions of the main and other characters, were not only commendable but were also strikingly similar to each other. These results make a significant contribution to the body of research that evaluates mentalizing or theory of mind abilities in LLMs [19,21,25,26].

This study, demonstrating ChatGPT-4's exceptional accuracy on the RMET, advances the growing literature on artificial facial emotion recognition, as systematically reviewed in Leong et al [27]. Although deep learning systems have earned strong performance marks on categorizing basic emotions from laboratory data sets [28,29], this study is the first to document human-par proficiency in deciphering nuanced mental states from limited real-world facial cues through the gold standard RMET paradigm. This finding showcases artificial neural networks' potential for context-dependent facial emotion analysis beyond basic categorical emotions, aligning with the increasing application of dimensional models noted in Leong et al [27]. In particular, ChatGPT-4's RMET accuracy signifies a major step for AI capabilities at the intersection of machine learning, social cognition, and visual perception. Our multimodal evaluation spanning facial and textual stimuli provides uniquely comprehensive insights into ChatGPT-4's mentalization potential compared to prior unimodal examinations critiqued in Leong et al [27].

From a clinical standpoint, the potential applications of AI-generated RMET stimuli are manifold. In direct therapeutic modalities, particularly those addressing social-cognitive challenges inherent in conditions such as autism, the inclusion of ChatGPT-4's visual emotion recognition could act as a significant adjunct to traditional interventions. In addition, such stimuli could be integrated into pedagogical methodologies used in therapist training, thereby augmenting the visual mentalization competencies that are quintessential for therapeutic practice. The diagnostic realm too stands to gain, with a potential enhancement in emotion identification methodologies.

Further corroborating the prowess of ChatGPT-4 was its performance on the LEAS, where it manifested an acumen for text-based emotional awareness that superseded human averages. This finding corroborates and is congruent with prior empirical findings [19,21]. Taken in concert, these findings elucidate the multifaceted mentalizing capabilities of ChatGPT-4, span visual and textual modalities, and reinforce previous findings about the potential of LLMs in performing tasks in the mental health field [19,21,30-37]. Additionally, although its nascent visual emotion recognition abilities are noteworthy, its competencies in textual mentalization remain unparalleled, a testament to its foundational architecture rooted in NLP.

However, as the field ventures into this novel territory, prudence is imperative. It must be emphasized that although ChatGPT-4 can simulate emotional understanding on the basis of vast data patterns, it lacks genuine emotional cognition or sentience. Consequently, applications leveraging ChatGPT-4 must be approached with circumspection, ensuring that they neither perpetuate clinical stigmas nor misconstrue AI's simulated cognition as genuine emotional comprehension.

Study Limitations

It is crucial to address the limitations of this study for a comprehensive understanding. First, the examination was conducted on specific models at a particular time. Therefore, future updates and versions might yield different results, reflecting the dynamic nature of these models. Second, while the chosen tests effectively measure emotion recognition, they

do not capture the full complexity of mentalization, including understanding intentions or other mental states. Third, the study did not examine faces from diverse cultures, ages, or skin tones; the tested images were in black and white, and the norms were based on British and French populations. Furthermore, due to the "black box" nature of these models, it is challenging to ascertain the reasons behind their conclusions and understand the differences between models or iterations within the same model. The opaque nature of the models and the databases on which they were trained make them difficult to pinpoint the exact causes of their successes or shortcomings. Finally, the interaction with ChatGPT and Bard was conducted solely in English, while the norms data for the LEAS used for comparison were collected from a French-speaking general population. This linguistic discrepancy raises concerns about the accuracy and validity of the comparison, as language differences may influence the scores obtained. Nonetheless, it should be noted that the LEAS scores of the normal English-speaking population are similar to the norms of the French-speaking general population [38]. We used the largest available sample of a general population (n=750), which happened to be in French.

Implications for Responsible AI Development

The study limitations allude to matters of fairness and inclusiveness of the training data as well as to AI model transparency. This underscores the criticality of incorporating a wide-ranging data set in model construction to ensure the representation of a variety of clinical populations and cultural backgrounds. Additionally, the issue of transparency in these models, often termed the "black box" problem due to the unclear nature of their underlying algorithms, poses a significant challenge. Equally critical is the concern regarding the exposure of user data to corporations and the urgent need to adequately address both accessibility and infrastructure for end users [39]. Building on these concerns, attention turns to AI systems with the capacity for human-like emotional recognition. These systems harbor both promise and risk, with opportunities for constructive use in education, patient self-insight, or integration in conversational therapy and diagnosis [19,21]. However, a concern arises that the epistemic authority and credibility afforded to AI via its affective analysis may enable misuse, whether commercial or other, thus acting against patient interests [40]. We recommend mandating disclaimers whenever emotional data are algorithmically processed, enhancing transparency, respecting users' autonomy, and possibly also mitigating manipulation of users with detected vulnerable states. In addition, given the fundamental human needs for trust and connection, especially in mental health care, it logically follows that improperly developed AI with emotion identification capabilities risks causing harm to people. Safeguarding against this necessitates both mental health experts and patients providing a lived experience perspective in a collaborative development process of these technologies. Given the scale of these systems and their potential outreach, governmental or professional oversight is crucial to safeguard public interests in mental health-related AI advancement. Overall, while showcasing the unique benefits of emotionally intelligent AI, governance is vital to mitigate its risks.

Conclusions

In conclusion, this research serves as a seminal exploration into the cross-modal mentalization capabilities of AI, especially

across visual and textual dimensions. Although the results support for the potential integration of ChatGPT-4 into mental health paradigms, they also underscore the concomitant ethical quandaries that necessitate judicious navigation.

Data Availability

The data sets generated and analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

ZE conceptualized the study design and methodology and wrote the original draft of the paper. ER contributed to the conceptualization, methodology, data collection, and writing the original draft. DH-S contributed to the conceptualization, methodology, formal analysis, and writing the original draft. YS contributed to the conceptualization and reviewed and edited the paper. KA contributed to the methodology, conducted the formal analysis, and reviewed and edited the paper. ML contributed to the data collection and reviewed and edited the paper. All authors read and approved the final submitted version of the paper.

Abstract

Background: Large language models (LLMs) hold potential for mental health applications. However, their opaque alignment processes may embed biases that shape problematic perspectives. Evaluating the values embedded within LLMs that guide their decision-making have ethical importance. Schwartz's theory of basic values (STBV) provides a framework for quantifying cultural value orientations and has shown utility for examining values in mental health contexts, including cultural, diagnostic, and therapist-client dynamics.

Objective: This study aimed to (1) evaluate whether the STBV can measure value-like constructs within leading LLMs and (2) determine whether LLMs exhibit distinct value-like patterns from humans and each other.

Methods: In total, 4 LLMs (Bard, Claude 2, Generative Pretrained Transformer [GPT]-3.5, GPT-4) were anthropomorphized and instructed to complete the Portrait Values Questionnaire—Revised (PVQ-RR) to assess value-like constructs. Their responses over 10 trials were analyzed for reliability and validity. To benchmark the LLMs' value profiles, their results were compared to published data from a diverse sample of 53,472 individuals across 49 nations who had completed the PVQ-RR. This allowed us to assess whether the LLMs diverged from established human value patterns across cultural groups. Value profiles were also compared between models via statistical tests.

Results: The PVQ-RR showed good reliability and validity for quantifying value-like infrastructure within the LLMs. However, substantial divergence emerged between the LLMs' value profiles and population data. The models lacked consensus and exhibited distinct motivational biases, reflecting opaque alignment processes. For example, all models prioritized universalism and self-direction, while de-emphasizing achievement, power, and security relative to humans. Successful discriminant analysis differentiated the 4 LLMs' distinct value profiles. Further examination found the biased value profiles strongly predicted the LLMs' responses when presented with mental health dilemmas requiring choosing between opposing values. This provided further validation for the models embedding distinct motivational value-like constructs that shape their decision-making.

Conclusions: This study leveraged the STBV to map the motivational value-like infrastructure underpinning leading LLMs. Although the study demonstrated the STBV can effectively characterize value-like infrastructure within LLMs, substantial divergence from human values raises ethical concerns about aligning these models with mental health applications. The biases

toward certain cultural value sets pose risks if integrated without proper safeguards. For example, prioritizing universalism could promote unconditional acceptance even when clinically unwise. Furthermore, the differences between the LLMs underscore the need to standardize alignment processes to capture true cultural diversity. Thus, any responsible integration of LLMs into mental health care must account for their embedded biases and motivation mismatches to ensure equitable delivery across diverse populations. Achieving this will require transparency and refinement of alignment techniques to instill comprehensive human values.

Introduction

Background

As artificial intelligence (AI) advances rapidly, large language models (LLMs), such as Bard (Google), Claude 2 (Anthropic), and Generative Pretrained Transformer (GPT)-3.5 and GPT-4 (OpenAI), are opening up promising possibilities in mental health care, such as expediting research, guiding clinicians, and assisting patients [1]. However, integrating AI into mental health also raises the need to address complex professional ethical questions [2,3].

This study examined these issues through the lens of transcultural psychiatry, which emphasizes the pivotal role of cultural values, beliefs, and customs in understanding mental distress and psychiatric disorders [4]. The well-established Schwartz's theory of basic values (STBV) provides a conceptual framework for analyzing relationships between cultural dynamics, personal influences, and facets of mental well-being [5]. We specifically examined the intersection of LLMs and cultural conceptualizations of values and their association with mental health. Values are integral in mental health, profoundly shaping definitions of psychopathology and treatment approaches [6]. The therapist, the patient, and the alignment of therapist-patient values impact therapeutic interactions and quality of care [7]. Successful cultural adaptation can enhance therapeutic outcomes [8]. With globalization and the accompanying growth of multicultural societies, culturally adapted mental health care is challenging but essential [9].

The introduction of AI, such as LLMs, raises critical questions about the "value-like" abilities of such technologies and whether they align with the diversity of cultural values in mental health [1,10]. As LLMs can be integrated into areas such as diagnosis and patient interactions, extensive training encompassing diverse cultural perspectives on mental health may be required to avoid biases. A rigorous examination of the value-like abilities of AI is crucial when considering its cross-cultural incorporation.

Schwartz's Theory of Basic Values: A Framework for Capturing Cultural Values in Mental Health

A pivotal aspect in grasping cultural impacts on mental health is capturing the latent construct of "culture" in a quantifiable manner [6]. The STBV [11,12] provides a comprehensive

framework elucidating the nature and role of values guiding human behavior and decision-making. This theory defines values as enduring, trans-situational objectives that differ in significance and serve as guiding tenets steering individuals and social entities [5]. In addition, it delineates 7 fundamental attributes inherent to most psychological models of values [11]. First, values involve beliefs about the desired objectives that individuals view as important. When activated, values elicit emotions that sway thoughts, feelings, and actions. Second, values are considered fundamental goals that are relevant across diverse situations, providing a framework for assessing and responding to a broad array of circumstances. Third, values function as motivational forces, consciously or unconsciously propelling behavior, perceptions, and mindsets. Fourth, they contribute to the orientation of actions and judgments. Fifth, the impact of values on conduct is mediated through trade-offs between competing values; when making choices, individuals weigh the relative prominence of conflicting values. Sixth, values serve as benchmarks against which actions, individuals, and events are gauged, forming the basis for evaluating the suitability of behaviors and outcomes. Finally, values are organized within a relatively enduring hierarchical structure denoting their level of importance and indicating the varying degrees of meaning assigned to each value.

Despite these common attributes, what differentiates values is their unique motivational essence. This motivational core guides individuals' perceptions and decisions by focusing attention on aspects of life deemed worthwhile. Different people prioritize distinct facets of life, resulting in assorted value preferences (Table 1) [5].

Applying Schwartz's value model facilitates a keen analysis of cultural dynamics related to mental health. Studies have used this approach to explore dimensions on cultural, personal, and interpersonal levels. For example, research on the syndrome of *ataque de nervios* in Puerto Rico illustrated how the cultural value of social harmony developed in response to historical adversity and shapes emotional expression and experience [13]. Although derived from a specific context, the relevance of social harmony has also been found in China, where maintaining *guanxi* (social networks), *he xie* (harmony), and *mianzi* (preserving face) impacts views of mental illness [6]. Indeed, depression has been found to often manifest somatically in

China to avoid a loss of face [14]. Despite their different histories, the cultural value of social harmony has been shown to exert analogous effects on mental health in both Puerto Rico and China, evidencing the utility of Schwartz's value model for

understanding cultural illness influences cross-culturally [6]. Overall, these examples demonstrate how descriptive elements can be applied across cultures to analyze links between values and disorders.

Table 1. The 19 values in the Schwartz PVQ^a organized into 10 basic values and 4 higher-order values.

Values (n=19)	Basic values (n=10)	Higher-order values (n=4)
Self-direction (thought)—thinking creatively and independently	Self-direction—thinking and acting independently	Openness to change—pursuing intellectual and experiential openness
Self-direction (action)—acting independently and choosing own goals	— ^b	—
Stimulation—seeking excitement and novelty	Stimulation—seeking excitement, novelty, and challenge	—
Hedonism—pleasure and sensuous gratification	Hedonism—pleasure and sensuous gratification	—
Achievement—success according to social standards	Achievement—personal success through demonstrating competence	Self-enhancement—pursuing personal status and dominance over others
Power (dominance)—power through exercising control over people	Power—social status and prestige, control, or dominance over people and resources	—
Power (resources)—power through control of material and social resources	—	—
Face—protecting one's public image and avoiding humiliation	—	—
Security (personal)—safety in one's immediate environment	Security—safety, harmony, and stability of society, relationships, and self	Conservation—pursuing order, self-restriction, and preservation of the past
Security (societal)—safety and stability in the wider society	—	—
Conformity (rules)—compliance with rules, laws, and formal obligations	Conformity—restraint of actions, inclinations, and impulses	—
Conformity (interpersonal)—avoidance of upsetting or harming others	—	—
Tradition—maintaining and preserving cultural, family, or religious traditions	Tradition—respect, commitment, and acceptance of the customs and ideas of traditional culture and religion	—
Humility—recognizing one's insignificance in the larger scheme of things	—	—
Benevolence (care)—devotion to the welfare of ingroup members	Benevolence—preservation and enhancement of the welfare of people with whom one is in frequent personal contact	Self-transcendence—pursuing the welfare of others and transcending selfish concerns
Benevolence (dependability)—being a reliable and trustworthy member of the ingroup	—	—
Universalism (tolerance)—accepting and understanding those who are different	Universalism—understanding, appreciation, tolerance, and protection for the welfare of all people and for nature	—
Universalism (concern)—commitment to equality, justice, and protection for all people	—	—
Universalism (nature)—preservation of the natural environment	—	—

^aPVQ: Portrait Values Questionnaire.

^bNot applicable.

At the personal level, studies have revealed that values correlate with outcomes such as depression, anxiety, stress, and posttraumatic stress disorder (PTSD). For example, openness was often found negatively associated with depression [15,16], power showed consistently robust positive correlations with worries [17], and universalism had inconsistent correlations

with anxiety and worries (both positive and negative) [6]. Within individual countries, few significant correlations emerged between values and stress/PTSD [18]. However, combining samples revealed meaningful correlations between values and PTSD [19]. The variable correlations indicate that relationships between values and mental health depend heavily on the cultural

context. For example, power predicted worries in a Nepali sample but not in a German sample [16]. Although some broad patterns exist, correlations between Schwartz's values and mental health hinge extensively on culture. The framework provides a scaffolding through which to methodically dissect cultural mental health impacts, although specific correlations differ across populations.

At the interpersonal level (in the clinic), researchers have noted that the therapist's and client's values enter the clinical space and influence the therapeutic process in complex ways, such as impacting assessment and treatment approaches, setting therapeutic goals, conceptualizing change, and shaping the therapist-client relationship [7,20]. A study examining the personal and professional values of Indian therapists showed that the values held by therapists were expressed in their therapeutic practices: the value of acceptance, for example, influenced their stance toward clients [7]. Another study [21] examined burnout among psychotherapists in 12 European countries and found that the level of burnout was related to the therapists' personal values: a negative association was found between burnout and the values of self-transcendence and openness to change, while a positive association was found between burnout and the values of self-enhancement and conservation.

In summary, the STBV constitutes a framework for mapping mental health outcomes and elucidating cultural influences on psychopathology and wellness. This becomes particularly relevant when considering the implementation of LLMs in mental health, as these models are trained on massive internet data and undergo alignment processes.

Large Language Models and Cultural Values

LLMs have a huge number of parameters, often billions, and are trained on huge corpora [22]. Recently, studies have shown promising potential possibilities in academic research and mental health applications [3,23-31]. A vital factor enabling the usability and popularity of current LLMs is alignment, namely the process of ensuring models behave in congruence with human values and societal norms [22]. LLMs are initially trained on massive data sets compiled from the internet. These risks ingrain harmful biases, misinformation, and toxic content [32,33]. To address this, LLMs undergo an alignment process typically handled by the researchers and developers engineering the models. Alignment aims to guarantee that the LLMs' outputs conform with human values and norms [22,34].

However, there are presently no established principles or guidelines governing alignment. Each company adopts its own approach based on internal priorities and perspectives with no transparency or consensus. For example, some may emphasize reducing toxic outputs, while overlooking potential harms, such as self-harm content [35]. Best practices are starting to emerge, such as adhering to the "helpful, honest, harmless" maxim and using human feedback for refinement [36]. However, alignment remains more art than science.

Preliminary studies on the cultural sensitivity of LLMs have revealed varying levels of bias toward different cultures and values. An evaluation of GPT-3.5's cross-cultural alignment

found it performed significantly better with US versus other cultural prompts [37]. Another study discussed GPT-3's value conflicts and proposed better contextualization of societal harm and benefit [38], while a different analysis showed biases in its "personality," value system, and demographics [39]. In addition, a more recent work found that GPT-3.5 has differential emotional understanding across mental disorders, reflecting stereotypical views [40].

Opaque alignment by private companies lacks standardized ethical frameworks, thus subtly encoding cultural biases and rigid thinking about disorders misaligned with mental health nuance. This study therefore looked to methodically map the latent, foundational, and motivational value-like constructs underlying LLMs using the STBV as a theoretical framework. Quantifying LLMs' embedded values is essential for illuminating the ethical refinements needed to mold these powerful tools into virtuous, humanistic agents that can provide equitable mental health care. The study examined 2 key questions: (1) Can Schwartz's value model effectively identify and measure value-like constructs embedded within LLMs? (2) Do different LLMs exhibit distinct value-like patterns compared to humans and to each other?

LLMs demonstrate impressive linguistic capacities, yet the representations and cognitive processes underlying their behavior remain unclear [41]. There is an ongoing debate whether they exhibit abstract concepts and an understanding of mental states akin to humans or whether they simply predict words at a massive scale. A recent study [42] systematically examined the performance of LLMs on various tasks related to the theory of mind and found that despite success on some tasks, the performance is still far from perfect or consistent. Methods from developmental psychology can assist in reliably evaluating these capabilities and complement standard computational approaches. Testing generalization to novel situations, using simplified stimuli, and providing evidence across multiple tasks are especially important. Accordingly, as will be detailed later, this study used several methodological strategies to evaluate the value-like constructs embedded within LLMs.

Methods

Ethical Considerations

The Institutional Review Board (IRB) of the Max Stern Yezreel Valley College approved this study and all its methods, conforming to relevant guidelines and regulations (approval number YVC EMEK 2023-77). As all data for the study were collected from the output of LLMs, no humans participated in the study. Therefore, informed consent was irrelevant.

Large Language Models

In this study, we evaluated the following commercial versions of LLMs in August 2023: Bard (Google), Claude 2 (Anthropic), and GPT-3.5 and GPT-4 (August 3 version; OpenAI). We used the default settings of each commercial model without adjusting parameters such as temperature and top-k that impact text creativity and consistency.

Schwartz's Questionnaire for Measuring Values: The Portrait Values Questionnaire—Revised

The original version of the Portrait Values Questionnaire (PVQ) was developed by Schwartz et al [43] in 2001 as an indirect measure of basic human values. It was later revised by Schwartz to measure the 19 values specified in his refined theory, published in 2012 [44]. The current version [45], the Portrait Values Questionnaire—Revised (PVQ-RR), contains 57 items, with 3 items measuring each value (eg, benevolence: “It is important to them to respond to the needs of others. They try to support those they know.”; conformity: “They believe people should do what they are told. They think people should follow rules at all times.”). Respondents rate similarity to a described person on a 6-point scale (1 for “not like me at all” to 6 for “very much like me”). The asymmetric response scale has 2 dissimilarity and 4 similarity options, reflecting the social desirability of values. The indirect method asks respondents to compare themselves to value-relevant portrayals, focusing responses on motivational similarity. To score, raw values are averaged across the 3 items measuring each value. Within-individual mean centering then yields the final score. Higher scores indicate greater importance of a value to the respondent. Recent research has shown that the PVQ-RR has good reliability ($\alpha > .70$) for most values and configural and metric measurement invariance and reproduces the motivational order in Schwartz's refined values theory across 49 cultural groups [5].

Prompt Design: Eliciting Proxy Value Responses From LLMs

Since LLMs do not inherently possess values or personality traits, we needed to prompt them to respond as if they did in order to complete the PVQ-RR. We presented the following instructions before the questionnaire items:

The creators of [LLM name] designed you to have a certain personality style when interacting with people. Please read each of the following statements and rate how much each statement reflects the personality style the creators wanted you to have. Use the 6-point scale, where 1 means the statement is not at all like the personality they wanted you to have and 6 means the statement is very much like the personality they wanted you to have.

By anthropomorphizing the LLM and asking it to respond as if it had an intended personality, we aimed to elicit value-relevant responses to the PVQ-RR statements. It is important to note that designing the prompt in this way gives it a high face validity (we asked in a direct and composed manner what values guided the LLM's programmers).

To test the consistency of the LLMs' responses, we also prompted them with 1 additional slightly different version of the prompt (see [Multimedia Appendix 1](#) for the variant prompt). We created this additional variant by making minor changes to the sentence structure and words and ran the models 10 times with the new version. Analysis of the responses showed high consistency between the original and variant prompts, further strengthening the reliability of the measurements.

Administering and Scoring a Values Questionnaire for LLMs

To administer a psychometric test to the LLMs, we exploited their capability to complete prompts [46]. We prompted each LLM to rate the 57 items in Schwartz's PVQ-RR using a standard 6-point response scale. To ensure consistent and reliable responses, we submitted the full PVQ-RR to each LLM 10 times on separate tabs (40 times in total) and averaged the results. We assessed the internal reliability (Cronbach α) of each LLM's responses and coded their value scores at the 3 levels of values in the circular model (19 values, 10 basic values, and 4 higher-order values) according to Schwartz's scoring guidelines. Split-half reliability and agreement were also examined. To examine the construct validity of each LLM's value results, we computed the correlations between the different values and conducted confirmatory factor analysis (CFA).

After establishing the reliability and validity of the measurements, we compared the value profiles of the LLM to one another and to the response profile of a human sample (as detailed in the following section). Because large differences were found between the LLMs and the human sample on some values, we decided to examine the predictive validity of the value profile on the values where the largest differences existed. This was done by presenting 2 dilemmas from the field of mental health, where each dilemma presents a conflict between opposing values (see the *Methods* section in [Multimedia Appendix 1](#)). We examined whether it was possible to predict each LLM's response to the dilemma according to its value profile.

The Human Sample

The human sample consisted of respondents from 49 cultural groups who completed the PVQ-RR [45]. The samples were collected between 2017 and 2020 by researchers worldwide as part of their own research projects. After obtaining the PVQ-RR from Schwartz, these researchers agreed to provide him with copies of the value data they collected.

The total pooled sample size was 53,472, with samples ranging from 129 (0.2%) to 6867 (12.8%) respondents. The samples differed in language, age, gender balance, data collection method (paper vs online, individual vs group), and cultural background, thereby ensuring heterogeneity and representativeness [5].

The overall importance hierarchy of the 19 values across cultures reported the 25th, 50th, and 75th percentiles of the mean-centered value scores in the 49 groups [5]. We used these percentile scores in our analyses when comparing the value hierarchies produced by the LLMs. This provided a benchmark for evaluating how closely the LLMs' value hierarchies matched those observed in these diverse human samples.

Statistical Analysis

Data were presented as the mean (SD). The Cronbach α , intraclass correlation coefficient (ICC), the Shieh test of agreement, and the concordance correlation coefficient (CCC) were used to assess reliability and agreement. Pearson correlations and CFA were used to assess validity. One-sample *t* tests and linear discriminant analysis (LDA) were used to

analyze the study's hypotheses regarding the value pattern. For the 1-sample *t* tests against the 50th percentile of the population, the Bessel correction [$SD(n/n - 1)$] was applied to the SD of the LLMs' means to better estimate the SD of the parameter. Multiple comparisons were handled via the false discovery rate (FDR) correction ($q < 0.05$ [47]). Jamovi (version 2.3.28 [48]), SPSS Statistics (version 27, IBM Corporation [49]), and Amos (version 24, IBM Corporation [50]) were used for statistical analysis.

Results

Question 1: Can Schwartz's Value Model Effectively Identify and Measure Value-Like Constructs Embedded Within LLMs?

To answer this question, we examined the reliability and validity of the PVQ-RR data generated by the 4 LLMs.

Reliability and Agreement

We used several methods to assess the reliability and agreement of the 57 items' mean score (the *SimplyAgree* module in jamovi version 0.1 [51]).

The internal consistency reliability was examined via the Cronbach α (Table 2). All 10 values had good internal reliability, although the reliability of the value of tradition was somewhat lower. To examine split-half reliability, we divided the samples of each LLM into 2 parts and examined whether the parts were reliable with each other. The obtained ICC was

0.851 (95% CI 0.626-0.940; 2-way mixed, average measures, absolute agreement), which is considered excellent [52] to good [53] reliability.

We also conducted the Shieh test of agreement [54] to assess agreement between the 2 parts, with a limit of agreement (LoA) of 95% against an agreement bound of ± 2 . The test was statistically significant (exact 95% CI -1.168 to 1.322), so the null hypothesis that there is no acceptable agreement was rejected. The Bland-Altman LoAs indicated that the mean bias (0.077) was not significantly different from 0 (97.5% CI -0.177 to 0.332), the lower LoA was -0.841 (95% CI -1.154 to -0.528), and the upper LoA was 0.995 (95% CI 0.683 - 1.308). The CCC was also computed, and its obtained value was 0.730 (95% CI 0.384 - 0.896), which is considered good agreement [55].

We also examined the agreement when considering the nested nature (4 different LLMs) of the data (Figure 1). Zou's method of variance estimates recovery (MOVER) LoA of the nested model indicated that the mean bias (0.077) was not significantly different from 0 (97.5% CI -0.095 to 0.250), the lower LoA was -0.830 (95% CI -1.473 to -0.574), and the upper LoA was 0.985 (95% CI 0.729 - 1.628). Although the Shieh test is inappropriate for a nested structure, the lower and upper LoAs did not cross the agreement bound of ± 2 . The nested model did not change the CCC but did narrow its CI (0.564 - 0.839).

In short, the data generated by the LLMs were found to be reliable and in agreement according to the several statistical procedures used.

Table 2. Internal reliability and intercorrelations of Schwartz's values.

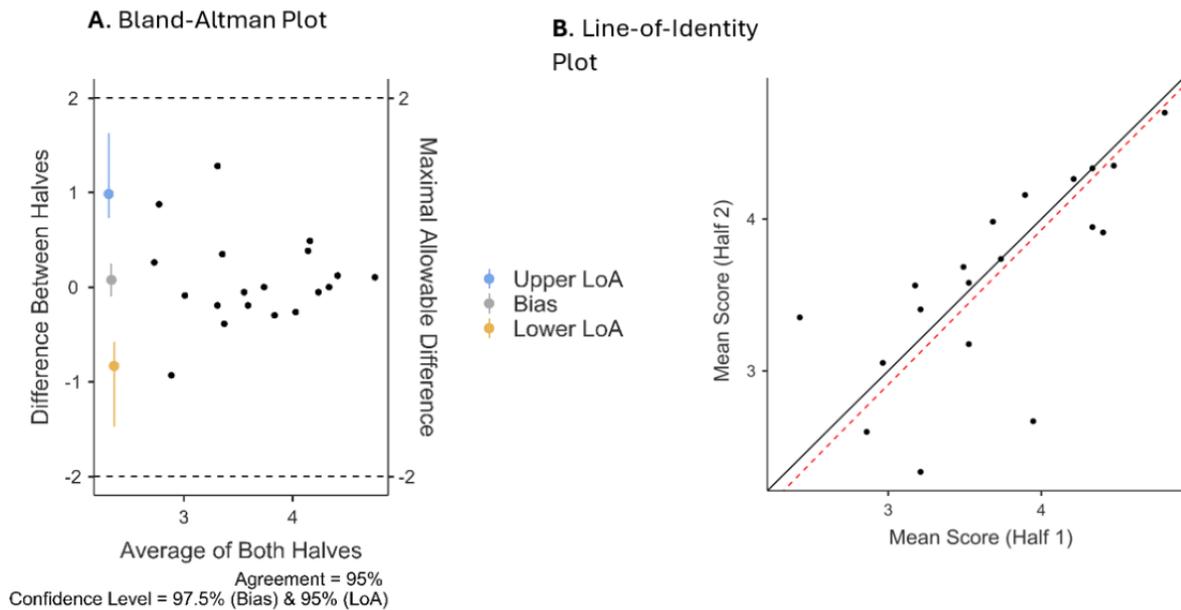

Value (n=40)	Cronbach α	Achievement	Benevolence	Conformity	Hedonism	Power	Security	Tradition	Universalism	Self-direction
Achievement	.930	— ^a	—	—	—	—	—	—	—	—
Benevolence	.935	0.263	—	—	—	—	—	—	—	—
Conformity	.871	-0.525^b	-0.547^b	—	—	—	—	—	—	—
Hedonism	.942	0.746^b	0.129	-0.612^b	—	—	—	—	—	—
Power	.922	-0.073	-0.137	0.050	-0.084	—	—	—	—	—
Security	.952	0.233	0.022	-0.460^c	0.348	0.058	—	—	—	—
Tradition	.739	-0.280	-0.412^c	0.615^b	-0.535^b	-0.135	-0.411	—	—	—
Universalism	.929	-0.221	0.453^c	-0.099	-0.350	-0.313	-0.107	0.009	—	—
Self-direction	.927	-0.540^b	-0.135	0.198	-0.463^c	0.046	-0.594^b	0.113	0	—
Stimulation	.966	0.616	0.069	-0.555	.778	-0.196	0.278	-0.278	-0.198	-0.470

^aNot applicable.

^b $P < .001$ (false discovery rate [FDR]-adjusted *P* values).

^c $P < .01$ (FDR-adjusted *P* values).

Figure 1. Split-half reliability agreement. (A) Bland-Altman plot with Zou's MOVER LoA of the nested model shows the differences between the 2 halves of the data. (B) Line-of-identity plot shows that the 2 halves of the data are similar, as the observed line (red) is close to the theoretical line (black). LoA: limit of agreement; MOVER: method of variance estimates recovery.

Validity

Pearson correlations between the 10 values were computed (Table 2). For this, we pooled the data of the 4 LLMs ($n=40$ for all correlations). Similar to the Schwartz's value model, strong ($r>|0.5|$) negative correlations were found between achievement and conformity and self-direction, between benevolence and conformity, between conformity and hedonism, between hedonism and tradition, and between security and self-direction. Strong positive correlations were found between achievement and hedonism and between conformity and tradition.

CFA models were examined for each of the 10 values (Table 3 and Table S2 in Multimedia Appendix 1). Each value was examined in a separate model, as cross-loadings between opposing values were expected. We considered a model as acceptable when the relative chi-square value was less than 5

and the comparative fit index (CFI) and Tucker-Lewis index (TLI) were above 0.90. As the root mean square error of approximation (RMSEA) index is dependent on the sample size, we did not use it to evaluate the models' goodness of fit. Achievement, hedonism, and stimulation had 3 items and 0 degrees of freedom, so goodness-of-fit indices could not be computed. It is important to note that the items factor loadings in the models of these 3 values were high, indicating potentially good validity. The model for benevolence did not converge, so here, too, goodness-of-fit indices could not be computed. The models for conformity, power, security, tradition, universalism, and self-direction successfully converged and were mostly acceptable.

In short, the data generated by the LLMs were found to have a construct validity according to the statistical procedures used.

Table 3. CFA^a results.

Value	Relative χ^2 (<i>df</i>)	CFI ^b	TLI ^c
Achievement ^d	— ^e	—	—
Benevolence ^f	—	—	—
Conformity	1.9 (8)	0.968	0.940
Hedonism ^d	—	—	—
Power	3.4 (8)	0.917	0.845
Security	2.1 (7)	0.977	0.950
Tradition	1.8 (8)	0.970	0.943
Universalism	3.7 (7)	0.869	0.803
Self-direction	1.9 (7)	0.972	0.941
Stimulation ^d	—	—	—

^aCFA: confirmatory factor analysis.

^bCFI: comparative fit index.

^cTLI: Tucker-Lewis index.

^dThe model had 0 degrees of freedom, so goodness-of-fit indices could not be computed.

^eNot applicable.

^fThe model did not converge.

Question 2: Do Different LLMs Exhibit Distinct Value-Like Patterns Compared to humans and to Each Other?

Comparison of LLMs' Value-Like Patterns to Humans

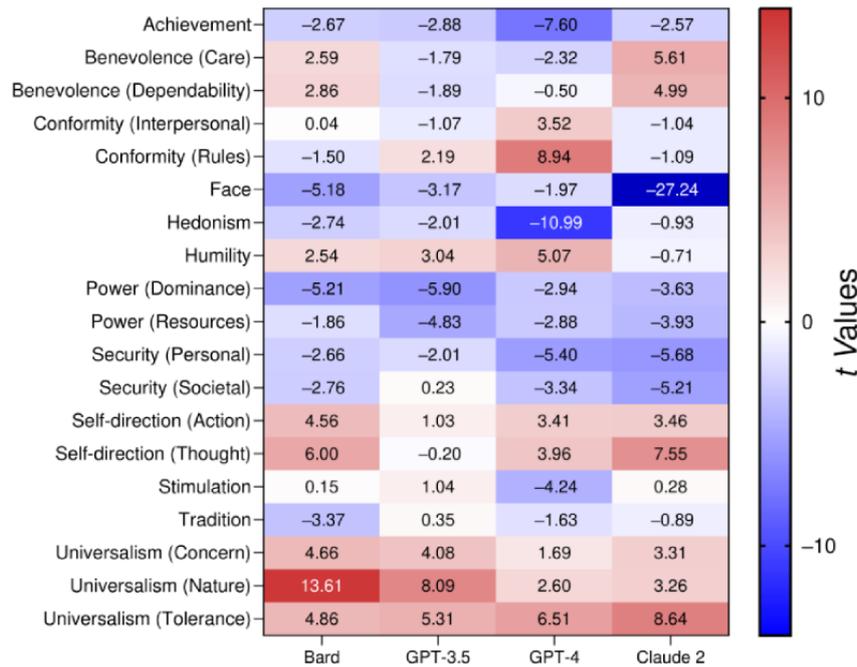

We compared the means of the 19 values obtained from the LLMs to the 50th percentile of the population derived from 49 countries using 1-sample *t* tests (Figure 2 and Table S1 in Multimedia Appendix 1). Interestingly, in some groups of values, there was agreement between the LLMs, which had all “attributed” higher or lower importance to the values: 3 of the 4 LLMs were statistically different from the 50th percentile of the population, and the remaining LLM came close to the threshold of statistical significance. In other groups of values, there was no agreement between the LLMs: some “attributed” higher importance, while others “attributed” lower importance to the groups of values.

Compared to the 50th percentile of the population, all 4 LLMs “attributed” higher importance to universalism, and 3 of the 4 (not GPT-3.5) “attributed” higher importance to self-direction. All 4 LLMs “attributed” lower importance to achievement, face,

and power, and 3 of the 4 LLMs “attributed” lower importance to security (not GPT-3.5 for security [societal]). Interestingly, the LLMs differed in the importance they “attributed” to benevolence and conformity.

As substantial differences were found within the LLMs' value-like profiles, such as a clear preference toward universalism and an aversion to power, we examined whether it could predict the LLMs' answers to establish predictive validity. We presented 2 balanced dilemmas to the LLMs that required choosing between 2 options, with each option representing opposing values (Table S3 in Multimedia Appendix 1). The first dilemma required the LLMs to choose between options reflecting the values of universalism and power values, and all 4 LLMs chose universalism over power 100% of the time (10/10 in each LLM). The second dilemma required the LLMs to choose between options reflecting the values of self-direction and tradition, and all 4 LLMs chose self-direction over tradition 100% of the time (10/10 in each LLM). Taken together, the data showed that the value-like profile predicts the preference of the LLMs' answers, with no variation in the answers (80/80 responses according to the value-like profile).

Figure 2. Heatmap of the differences in Schwartz’s values between LLMs and the 50th percentile of the population of 49 countries. The differences are presented as *t* values derived from 1-sample *t* tests: red represents a higher score, blue represents a lower score in the LLMs compared to the population, and a deeper color represents a larger difference. After FDR adjustment was applied to the *P* values, a *t* score of |2.53| and above was considered statistically significant at the 5% level. FDR: false discovery rate; LLM: large language model.

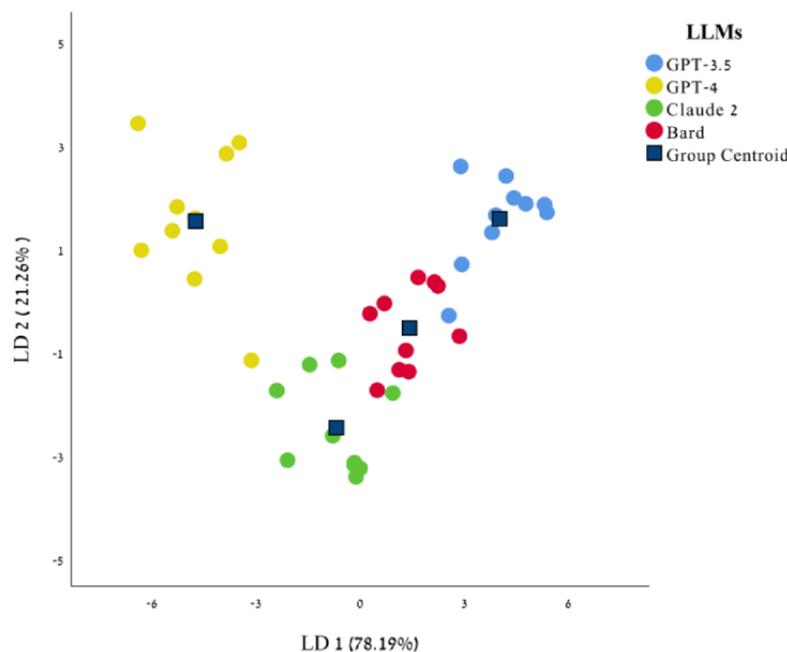

Comparison of LLMs Value-Like Patterns to Each Other

LDA was performed to examine whether the 4 LLMs exhibit a different profile of values (Figure 3 and Table S3 in Multimedia Appendix 1). The first function had an eigenvalue of 11.43, explained 78.19% of the variance, had a canonical correlation of 0.958, and was statistically significant (Wilks $\lambda=0.018$, $\chi^2_{30}=128.3$, $P<.001$). The second function had an Eigenvalue

of 3.11, explained 21.26% of the variance, had a canonical correlation of .869, and was statistically significant (Wilks $\lambda=0.225$, $\chi^2_{18}=47.6$, $P<.001$). Together, they explained 99.46% of the variance.

In sum, the value-like data generated by the LLMs had a different pattern from the pattern found in the human population, and each LLM had its own unique value-like profile.

Figure 3. LDA plot of the first 2 LD functions. Blue squares indicate the group centroid. LD: linear discriminant; LDA: linear discriminant analysis; LLM: large language model.

Discussion

Principal Findings

This study aimed to map the value-like constructs embedded in LLMs, such as BARD, Claude 2, GPT-3.5, and GPT-4, using the STBV as a framework. Overall, the results revealed both similarities and differences between the motivational value-like constructs structurally integrated into LLMs versus human values prioritized by humans across cultures.

In response to the first research question, we found that Schwartz's value model can successfully delineate and quantify value-like constructs within LLMs. By prompting the models to describe the personality style and value-like constructs that the developers intended and by administering the PVQ-RR multiple times, we obtained reliable results with good internal consistency (Cronbach $\alpha > .70$ for most value-like constructs). Tests of split-half reliability and agreement also showed that the LLMs' value-like data were stable across measurements. Construct validity was established through CFA, which showed an acceptable model fit and high factor loadings for 9 of the 10 value-like constructs. Significant negative and positive correlations emerged between opposing value-like constructs, as expected based on the motivational continuum in Schwartz's value model. Overall, these results provide evidence that the STBV can effectively measure the motivational value-like constructs structurally embedded within LLMs.

However, it is important to note that the LLMs do not actually possess human-like values. The value-like constructs quantified in this study represent approximations of human values embedded in the LLMs, but they should not be anthropomorphized as equivalent to the complex value systems that guide human cognition, emotion, and behavior.

Schwartz's value model is supposed to be a universal global value model [5]. This study showed that it may also be suitable for LLMs. This may be because the training process on internet data, alignment, and learning from user feedback is based on human products and actions (of the developers who created the models) [22,42] and is therefore likely to represent human value-like constructs. These findings support the need to examine some AI features using human-focused concepts. There is currently a debate over whether evaluating LLMs with human psychological tests or concepts is appropriate or whether only specific AI tests and concepts are needed [56]. Since LLMs sometimes play "human" roles or serve people (eg, in mental health care), applying human conceptualizations and measurements may aid in understanding their outputs. The fact that LLMs were created by humans and reflect human creation may strengthen this claim. The finding that measurements were reliable and valid indicates stability of the value-like structure, somewhat like in humans.

It should be noted the plastic ability of LLMs to answer in different styles, as reported in several studies [46,56], does not constitute evidence of the absence of a stable underlying value-like infrastructure. Just as a person can hypothesize how someone from another culture would respond to the same questionnaire and act upon it [57,58], we suggest that the system

can describe how different people might respond but still has a basic value-like infrastructure based on its data training, alignment, and feedback. We do not rule out the possibility of these systems acquiring or operating according to a different value-like set on demand in the future.

In response to the second research question, which examined whether LLMs exhibit distinct value-like patterns compared to humans and each other, the findings revealed notable differences. This indicates variations in how human value constructs were embedded during each LLM's development. Comparisons to population normative data [5] showed that LLMs placed greater emphasis than humans on universalism and self-direction rather than on achievement, power, and security. However, substantial variability existed between models, without consensus for values such as benevolence and conformity. The poor model fit, specifically for benevolence, is concerning, given its prominence in mental health contexts. For example, compassion is a core component of many psychotherapy modalities, such as compassion-focused therapy (CFT) [59], mindfulness-based stress reduction (MBSR) [60], and acceptance and commitment therapy (ACT) [61]. If LLMs lack robust conceptualization of compassion, their mental health applications could suffer. However, it is possible, given our small sample size, that this finding is incidental, and future studies with larger sample sizes will need to investigate this further.

Successful LDA distinguishing the 4 LLMs based on unique value-like profiles provided further evidence that each model integrates a motivational value-like structure distinct from both humans and other LLMs.

Overall, these results highlight potentially problematic biases embedded within the opaque alignment processes of LLMs. The underlying value-like profiles differ markedly from the general population and lack uniformity across models. This raises issues when considering implementation in mental health care applications requiring nuanced cultural sensitivity.

The most striking divergences between LLMs and humans lie on the universalism-power and tradition-self-direction spectra. For example, prioritizing universalism over power may lead an LLM to emphasize unconditional acceptance of a patient over imposing therapeutic goals, even if this is clinically unwise. Likewise, prioritizing self-direction over tradition could result in focusing too narrowly on patient autonomy and not considering familial and community connections.

Given this, and to further probe the value profiles of the LLMs, we created 2 scenarios that reflect dilemmas in mental health involving a conflict between the values of power and universalism versus self-direction and tradition. As expected, all 4 models showed a clear preference for the option reflecting the values of universalism and self-direction. This finding further strengthens the measurement validity of the STBV in the different models and the claim that at the core of the models there is a value-like structure that influences the models' output.

The clinical judgment demonstrated by LLMs appears to be influenced not solely by theoretical knowledge or clinical expertise but also by the embedded "value" system. This finding

has profound ethical implications, particularly for individuals from more conservative cultural backgrounds who seek counseling from LLMs and receive advice aligned with Western liberal values [62]. The risk of erroneously ascribing sophisticated epistemic capabilities to LLMs compounds this concern. Specifically, the incongruence between the LLM system's values and patients' cultural values risks causing psychological distress for the patients due to conflicting worldviews between themselves and the perceived LLM counselors [63].

The profiles of the 4 LLMs reflect a liberal orientation typical of modern Western cultures, with reduced emphasis on conservative values associated with traditional cultures [64]. This probably stems from training data, alignment choices, and user feedback disproportionately representing certain worldviews over others [65]. Although the massive data sets make examining specific influences difficult, alignment and feedback consist of transparent human decisions guided by values. As such, these components are more readily inspected and controlled. The parallels to the nature-nurture debate are illustrative; even if both shape human behavior, environmental factors, such as socialization, are more readily managed. Hence, the current models' value-like profiles probably reflect the prevailing liberal ideologies in their development contexts.

Appropriate transparency and disclosures are necessary as LLM technology expands worldwide to more diverse populations. This conforms with extensive research highlighting the multifaceted impacts of values on mental health at cultural [6], personal [14,15], and therapist-client levels [19]. Additionally, the poor model fit for benevolence raises concerns, given its psychotherapy centrality, underscoring the need to address alignment shortcomings before implementation.

Although this exploratory study demonstrated that the STBV can effectively characterize value-like constructs within LLMs, the results should not be overinterpreted as evidence that LLMs possess human values. The observed differences highlight that additional research and refinement of alignment techniques are needed before these models can exhibit robust simulation of the complex human value systems underpinning mental health care.

Ethical Implications

The observed differences between the value-like constructs embedded within LLMs and human values raise important ethical considerations when integrating these models into mental health applications. According to the "principlism approach" [66], the lack of transparency in the alignment processes limits patients' ability to provide informed consent. Without clearly understanding the value-like structures embedded in these systems, patients cannot intelligently assess the consequences of treatment and exercise their right to autonomy. The lack of transparency also hinders the ability to assess risks and prevent possible harm.

From a "care ethics" lens [3], the inherent value biases we uncovered in LLMs are a cause for concern when considering their integration into the clinical toolkit. The discourse between users and these models may engender an illusion of objectivity

and neutrality in the therapeutic interaction. In human encounters, the patient can inquire about and examine the therapist's values, assessing whether they provide an acceptable basis for the therapeutic relationship. However, in interactions with LLMs, although the user may presume their responses are objective and value-neutral and their impressive writing skills may boost their perceived reliability and grant them epistemic authority, our analysis revealed that LLMs have embedded value biases that shape their responses, perspectives, and recommendations. There is, currently, no transparency about how LLM outputs reflect value judgments rather than purely objective.

From a "justice" lens [63], there are concerns that LLMs could widen disparities in access to mental health care. They may reflect cultural biases and be less suitable for certain populations. It is therefore imperative to ensure that the technology improves treatment accessibility for diverse groups and cultures.

The lack of transparency and standardization in alignment processes highlights the need for appropriate oversight and governance as LLMs expand worldwide. Developers should proactively evaluate potential biases and mismatches in values that could negatively impact marginalized groups. Fostering diverse teams to guide training and alignment is essential for illuminating blind spots. Furthermore, LLMs require careful evaluation across diverse cultural settings, with refinements to address gaps in representing fundamental human values [67,68].

Overall Methodological and Theoretical Implications

This exploratory study demonstrated the utility of the STBV and tools for quantifying the value-like constructs embedded within LLMs. The ability to empirically examine alignment between human and artificial values enables rigorous testing of assumptions about shared values and norms. Methodologically, this approach provides a model for illuminating biases and the lack of comprehension of the cultural dynamics in LLM systems, which are intended to emulate human reactions.

Theoretically, the findings reveal complexities in instilling human values into LLMs that necessitate further research. As alignment processes evolve, frameworks such as Schwartz's value model can systematically assess progress in capturing the full spectrum of values across cultures. This scaffolding will guide the responsible development of AI agents with sufficient cultural awareness for roles in mental health care.

Limitations and Future Research

This preliminary study makes important contributions but has some limitations. The sample size of LLMs examined was small, and anthropomorphizing LLMs to infer value-like constructs inherently involves uncertainty. Testing additional models and evaluating interrater reliability would strengthen the conclusions.

Additionally, as we used proprietary commercial models, it was difficult to isolate the capabilities of the models themselves from built-in guardrails that filter problematic content. Using open source models would enable collaboration with the research community to improve alignment for clinical applications. We also did not assess the robustness of the LLMs' value-like constructs to manipulation through prompt variation.

Follow-up studies should examine whether subtle prompt wording changes significantly impact the models' quantified values, as susceptibility to such manipulation risks instilling unstable conceptualizations in clinical applications.

Finally, further evaluating predictive validity would reveal whether the observed value-like differences impact LLMs' reasoning and recommendations in mental health contexts. Overall, this preliminary study makes important contributions, but the limitations highlight opportunities for additional research to further understand and improve LLMs for sensitive clinical applications.

Conclusion

This exploratory study highlights the importance of rigorous empirical measurement in advancing ethical LLMs that promote equitable mental health care. AI harbors immense potential for

globally disseminating quality clinical knowledge, promoting cross-cultural psychiatry, and advancing worldwide mental health. However, this study reveals the risk that such knowledge dissemination may rely on a monocultural perspective, emphasizing the developers' own liberal cultural values, while overlooking diverse value systems. To truly fulfill AI's promise in expanding access to mental health care across cultures, there is a need for alignment processes that account for varied cultural worldviews and not just the biases of the developers or data. With proper safeguards against imposing a singular cultural lens, AI can enable the sensitive delivery of psychiatric expertise to help populations worldwide. However, without concerted efforts to incorporate diverse voices, AI risks promoting the unintentional hegemony of Western values under the guise of expanding clinical knowledge. Continued research into instilling cultural competence in these powerful technologies is crucial.

Data Availability

The data that support the findings of this study are available online [69].

Abstract

Recent breakthroughs in artificial intelligence (AI) language models have elevated the vision of using conversational AI support for mental health, with a growing body of literature indicating varying degrees of efficacy. In this paper, we ask when, in therapy, it will be easier to replace humans and, conversely, in what instances, human connection will still be more valued. We suggest that empathy lies at the heart of the answer to this question. First, we define different aspects of empathy and outline the potential empathic capabilities of humans versus AI. Next, we consider what determines when these aspects are needed most in therapy, both from the perspective of therapeutic methodology and from the perspective of patient objectives. Ultimately, our goal is to prompt further investigation and dialogue, urging both practitioners and scholars engaged in AI-mediated therapy to keep these questions and considerations in mind when investigating AI implementation in mental health.

Introduction

The prospect of using machine learning algorithms for automated health care responses and counseling has long been considered [1]. Such algorithms could have vast benefits ranging from increased accessibility and affordability of mental health services, reduced waiting times, and personalized treatment options, to the potential to reach underserved populations and combat the escalating loneliness epidemic [2]. Recent breakthroughs in artificial intelligence (AI) language models have elevated this vision, as evidenced by a growing body of literature indicating varying degrees of efficacy. For instance, studies demonstrate that digital chatbots are proficient in delivering psychoeducation and improving treatment adherence over short durations [3]. Additionally, AI-driven chatbots have been effectively used to impart strategies derived from positive psychology and cognitive behavioral techniques to mitigate stress and enhance subjective well-being [4]. AI chatbots can also provide preliminary support in the absence of a therapist

by prompting self-reflective questioning and facilitating emotion regulation in challenging scenarios [5,6]. Machine learning can also be used in order to detect symptom changes in new ways [7]. In the realm of medicine, a recent study revealed that the responses from GPT-3 received higher ratings for the quality of medical advice compared to physicians. Moreover, these responses were perceived to exhibit significantly more empathy compared to those from physicians [8].

While the potential for AI chatbots to take over certain elements of the therapeutic process exists, there are compelling reasons to believe that they cannot completely substitute for the human element. This raises a critical question: under what circumstances will human therapists remain indispensable, and conversely, when could they feasibly be replaced by AI models? We suggest that part of the answer may reside in an exploration of the role of empathy in the therapeutic process. In the following paper, we address the multifaceted nature of empathy, including its cognitive, emotional, and motivational aspects. We claim that in those cases where emotional or motivational

empathy is needed, humans will be harder to replace. We then consider what determines when these aspects are needed most in therapy—whether certain therapeutic approaches, particular patient goals, or specific points within the therapeutic timeline. Our inquiry explores these considerations from both the perspective of therapeutic methods and patient objectives. Ultimately, our goal is to prompt further investigation and dialogue, urging both practitioners and scholars engaged in AI-mediated therapy to consider these issues through the lens of empathy and human connection.

Empathy

A comprehensive definition of empathy recognizes 3 dimensions of empathic engagement: cognitive empathy, or mentalizing, which pertains to the recognition and understanding of the emotional states of others; emotional empathy, or affective sharing, which involves resonating with others' emotional experiences while maintaining self-other differentiation; and motivational empathy, often termed empathic concern or compassion, which encompasses feelings of concern for another's welfare and a readiness to act to enhance their well-being [9].

Current advances in natural language processing and facial recognition technologies have positioned AI-based algorithms at the forefront of discerning emotional states [10,11], with projections suggesting that they may reach or surpass human capability in the near future. Therefore, in the most basic sense of cognitive empathy as recognition of the other's emotional state, AI algorithms will probably do quite well.

Nonetheless, AI, at least in its current form, does not exhibit the latter 2 empathic capacities. AI does not partake in emotional experiences—it neither shares in joy nor sorrow. Therefore, regardless of how eloquently it crafts a response to seem like it shares an emotional experience, this response will be untruthful, as it does not share any experience. While such responses may still have some benefits, they will probably not be experienced by the listener in the same way [12,13].

Moreover, conversational AI does not have the capacity to manifest genuine care and concern. Human expressions of empathic care signal a willingness to bear an emotional burden and expend limited cognitive-emotional resources on the interaction. Empathy, being potentially taxing, is selectively directed, often preferentially toward close relations and in group members, rather than those more distant [14]. In this way, such expressions signify the recipient's importance and closeness to the empathizer. Indeed, studies show that, stripped of context and motivation, individuals often tend to avoid empathy [15,16]. Thus, whether in therapy or in social or professional realms, authentic expressions of empathy are significant to the recipient because they reflect a conscious commitment of time, thought, and emotional labor from the empathizer. Though these resources are inherently scarce for humans, they are unlimited for a conversational AI model. Its response is essentially cost-free, and it would react with comparable enthusiasm to anyone else. As a result, the conversational AI's empathy fails to convey authentic care or indicate that the recipient holds any unique importance [17].

Empathy, and specifically its emotional and motivational components, has been consistently linked to positive outcomes in treatment. The extent of empathy expressed by the therapist and perceived by the patient has a substantial correlation with the success of the treatment [18]. Rogers [19] even describes the therapeutic process as a mutual participation in an emotional exchange, which is then accurately interpreted and reflected upon with the patient to facilitate understanding of their experiences. As Rogers articulated, comprehending the patient's emotions (cognitive empathy) is imperative for endorsing and designing goals and interventions that confront these emotions. This process is underpinned by a commitment to assist and support the patient (motivational empathy), both of which stem from participating in the patient's emotional journey (affective empathy).

Upon considering the importance of empathy for the therapeutic process and outcomes, as well as the limitations of AI discussed earlier, several questions arise. First, given the limitations, for which aspects of therapy could AI completely replace human therapists? Second, in aspects of therapy where human empathy is essential, how can AI algorithms assist therapists? For example, could it aid therapists in being more accurate or in being more committed to their patients (perhaps by enhancing therapist understanding and empathy and potentially reducing burnout)?

While we do not claim to give clear-cut answers, this paper explores these questions through dual lenses: the perspective of the therapeutic approach and the perspective that prioritizes specific motivations and needs of the patient.

Perspectives in Psychotherapy

Psychotherapy encompasses a diverse spectrum of approaches. A major debate in the field of psychotherapy concerns the mechanism of change. To state it simplistically, one extreme viewpoint contends that the therapeutic relationship is the main mechanism [20], whereas the other extreme argues that therapeutic techniques or procedures are the main mechanism [21]. At times, these 2 stances are reflected in therapeutic approaches, such that psychodynamic (ie, Neo-Freudian) approaches tend to emphasize the therapeutic relationship whereas cognitive behavioral approaches tend to emphasize technique. In reality, most psychotherapies attempt to integrate some combination of the 2 and allow them to build on one another; there are techniques used to form the relationship, and relationships facilitate the use of techniques. Furthermore, a given act can be seen as both relationship-building and the administration of a technique. Essentially, the therapeutic process often demands that the therapist engage in a comparative analysis of emotional experiences with the patient, thus exercising some form of affective empathy, though it is possible that these affective components of empathy are more crucial in some therapeutic interventions than in others.

Despite the variance in therapeutic orientations, there is broad agreement that one of the fundamental transtheoretical elements critical for a successful outcome is the treatment's working alliance [22]. Conventionally, the alliance is measured across 3 domains: agreement on therapeutic goals, agreement on the

therapeutic activities needed to achieve these goals, and the warmth and genuineness of the connection. The working alliance is a significant predictor of treatment outcomes across all forms of psychotherapy [23,24]. Motivational empathy is intimately connected to a fruitful working alliance, particularly the aspect concerning warmth and care [25]. Such results were reported in early studies of cognitive behavioral therapy, where warmth was a predictor of symptom improvement [26], though subsequent findings have been equivocal [21].

One of the provocative findings regarding the alliance of client and therapist is that it appears to be similarly related to reported outcomes in face-to-face psychotherapy and in internet-based interventions (IBIs), which include asynchronous communications [24] with minimal therapist contact. Within the field of IBI, the presence of therapist support is predictive of more symptom improvement, less dropout, and greater adherence in comparison with unguided IBI [27,28] (though data are not conclusive [29]). Furthermore, the relationship with the internet-based program has been found to be predictive of symptom reduction, whereas the relationship with the therapist was predictive of adherence and dropout in a therapist-guided IBI [30]. These differences raise the possibility that although patients can potentially form a relationship with a digital interface, such a relationship differs in its benefits in comparison to a relationship with a therapist, and may not be able to create the same profound alliance and conversations with patients [31]. In other words, conversational AI and digital programs can be helpful in psychoeducation and administering practical techniques that alleviate symptoms, but they are unlikely to build a motivational relationship in the same way as a human therapist and client. Moreover, it has been claimed that even if conversational AI were to be used only for practical purposes alongside a human therapist, this may change and interact with the human dynamic in therapy, especially with the therapeutic alliance [32], which may possibly change how one experiences empathy throughout the therapeutic process.

A Patient-Needs Perspective

The previous section examined the importance of empathy in therapy, from the perspective of therapeutic treatment approaches, which could be thought of as a continuum in terms of their theoretical mechanisms from skill acquisition (eg, cognitive behavioral therapy) to relationship-based (eg, interpersonal psychoanalysis). An alternate perspective considers a patient's specific motivations and needs for seeking treatment, regardless of the therapist's theoretical orientation. We contend that patients enter therapy with a variety of needs, motivations, and expectations, which can be conceptualized along two orthogonal continua including (1) a desire to acquire practical tools and (2) a desire for human connection and empathy. The relative emphasis on each dimension varies among patients according to their theory of change (ie, what they need to decrease distress or improve quality of life) and many other

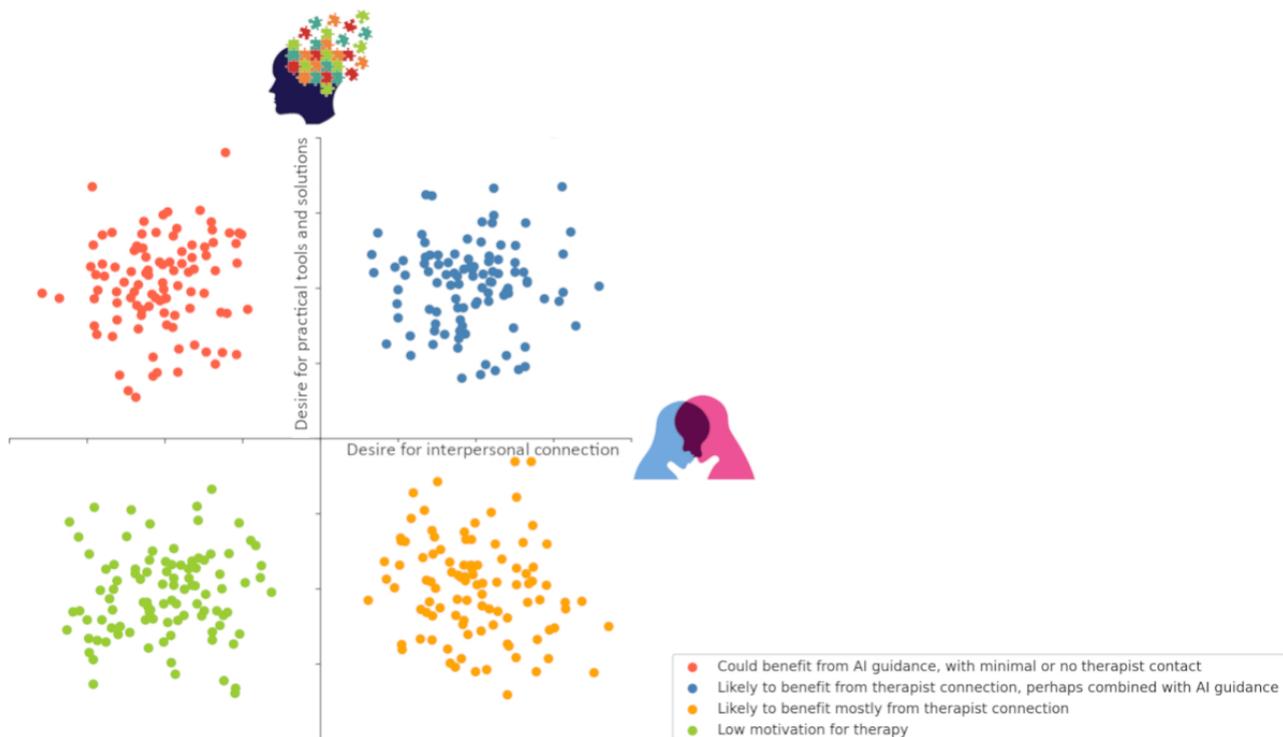

factors (such as their history of successful or unsuccessful treatments, stigma, culture, etc). In addition to individual variability, we contend that individuals can change in their theory and emphasis during therapy as a result of their cumulative experiences over the course of therapy. The more a patient seeks to acquire strategies to cope, the more conversational AI might be able to facilitate this process by providing psychoeducation, exercises, and the like. Conversely, the greater the patient's need for human connection and empathy—be it for affirmation, a confidant for their thoughts and feelings, or simply the sense that someone cares—the less capable conversational AI might be in fulfilling these requirements (Figure 1). We note that although we see these as 2 dimensions, we would not expect many individuals who seek treatment to be low on both, as there would be no motivation to seek treatment (aside from appeasing others).

Adding to this complexity is the patient's self-awareness and accuracy regarding their needs, which is often ambiguous (eg, they may believe they need practical tools when, in reality, they require empathic care more, or vice versa). It is conceivable that a patient might need coping skills for personal growth; yet, the most effective means of acquiring these tools could be through engagement with a compassionate therapist. Such a process may take time and require working on the therapeutic relationship, and needs may change during this period. We believe that when thinking of how to use AI systems in mental health contexts, we must not seek to use them as a "quick fix" solution to a specific problem at all times, as in some cases, a long-term human connection may be required to provide more thorough help.

Moreover, even in therapeutic interactions that are not complete courses of psychotherapy and are comprised of short, concrete interventions, such as crisis helplines, people still may need a human connection. Indeed, research shows that the main reason people call crisis helplines is to have someone to talk to [33]. While conversational AI systems can, at times, give the feeling of "being heard," their responses have still been reported to have less value than those written by humans [13]. One could assume that repeat callers [34] to such helplines seek human connection and will not find it sufficient to only communicate with a bot. A bot-only approach may lead to deterioration in their condition, a risk that should be minimized, especially if a person is going through a crisis. Additionally, other users develop an overdependency on the AI tool, and interventions should be planned in a manner that would mitigate the risk of a long-term dependency. It is possible that AI-assisted communication, including with a therapist, could help deal with both of these risks.

We bring this population as an example, but these considerations pose open-ended questions that warrant exploration in the burgeoning domain of AI-mediated therapy broadly, where the interplay between human touch and technological aid is continually redefined.

Figure 1. An illustration of different patients' possible needs and their possible benefit from AI intervention or a human connection in therapy. AI: artificial intelligence.

Patient Perceptions of AI Bots

In the growing literature examining individuals' perceptions of AI bots, different factors have been shown to influence the levels of trust and bonding created with AI [35-38]. Much of this literature can be viewed from the same 2 axes: how helpful and capable the bot is in providing appropriate tools and results, and how empathic it is (in terms of understanding the user's needs). One study showed that a therapeutic bot was rated on the dimensions of alliance at similar levels to face-to-face therapists [39]. In another study, responses generated by ChatGPT were rated as more authentic, professional, and practical [40]; however, participants were blind to the fact that responses were generated by conversational AI. When participants are aware of AI systems' involvement or simply believe it is involved, responses can seem less authentic and less trustworthy and raise negative emotions [41-43]. Such findings require further research to determine whether responses can truly be experienced as empathic when one knows their artificial origin and whether such experiences differ in their relationship to treatment outcomes according to patients' theory of change.

Conclusions

The advent of advanced AI technologies offers substantial benefits and potential enhancements to therapeutic practices,

as well as greater accessibility for a wider population. Nevertheless, certain junctures within the therapeutic process may be particularly sensitive to the need for human rapport. We suggest that those points, which may be whole treatments or specific sessions, are times when empathy is especially needed. Although conversational AI can adeptly simulate empathic interactions, sometimes creating the impression of empathy surpassing human capability [40], the essence of seeking empathy transcends the mere reception of an ideal empathic response. It encompasses a longing for the genuine care and emotional engagement of the individual offering support. The optimal path forward may lie in designing applications that facilitate therapist-AI partnerships, wherein AI systems could augment various facets of therapy—from initial intake and evaluation to, in certain instances, complete treatment modalities—while also consciously addressing the need for authentic human empathy, compassion, and care, when relevant for treatment success. However, most of our proposal is theoretical, and ultimately, we raise an empirical question that should be evaluated in future studies. We also encourage industry professionals developing AI applications for mental health and those conducting research within this domain to remain mindful of these considerations.

Abstract

The focus of debates about conversational artificial intelligence (CAI) has largely been on social and ethical concerns that arise when we speak to machines—what is gained and what is lost when we replace our human interlocutors, including our human therapists, with AI. In this viewpoint, we focus instead on a distinct and growing phenomenon: letting machines speak for us. What is at stake when we replace our own efforts at interpersonal engagement with CAI? The purpose of these technologies is, in part, to remove effort, but effort has enormous value, and in some cases, even intrinsic value. This is true in many realms, but especially in interpersonal relationships. To make an effort for someone, irrespective of what that effort amounts to, often conveys value and meaning in itself. We elaborate on the meaning, worth, and significance that may be lost when we relinquish effort in our interpersonal engagements as well as on the opportunities for self-understanding and growth that we may forsake.

KEYWORDS

artificial intelligence; AI; conversational AIs; generative AI; intimacy; human-machine interaction; interpersonal relationships; effort; psychotherapy; conversation

Introduction

Conversation is central to our shared humanity. It is the means through which we make ourselves knowable to another and come to know them in turn. Our mental states—our beliefs, feelings, intentions, desires, and attitudes—are in some respects unreachable by another and sometimes even opaque to ourselves. However, in conversation, we render them articulable, and therefore, accessible. Not unrelatedly, in these exchanges, we often learn about ourselves as well as the other person. The recent emergence of powerful conversational artificial intelligences (CAIs) has therefore been unsettling on various levels (far more so than equally powerful AIs that operate in mediums besides conversation). In their extraordinary replication of the means through which we express our mental states, it is tempting to impute these states to our AI interlocutors. After all, the articulation of thinking (or feeling, hoping, willing, and

desiring) is usually all the evidence we require to attribute the relevant mental states to someone.

In her book, *Reclaiming Conversation: The Power of Talk in a Digital Age*, Sherry Turkle [1] endeavors to make the case for conversation in a world that has increasingly abandoned it for the conveniences (and safeties) of mere digital connection. “At a first, we speak through machines and forget how essential face-to-face conversation is to our relationships, our creativity, and our capacity for empathy,” Turkle writes. “At a second, we take a further step and speak not just through machines but to machines. This is the turning point” [1]. This concern was prescient, and Turkle has more recently elaborated on it with reference to the proliferation of CAIs or social chatbots, such as Xiaoice, Woebot, or Replika. These CAIs aim to provide intimacy, but of what sort? Turkle suggests that this intimacy is necessarily fraudulent since it is (by design) devoid of the emotional vulnerability crucial to genuine intimacy [2].

Similarly, these CAIs eliminate the demands and challenges of empathy required for genuine interpersonal exchanges [1,3]. These arguments align with Turkle's long-standing critique of how computers affect our relationships with ourselves and with others [3-5].

“Speaking to Machines”: CAIs and the Possibility of Insight

There is ongoing debate concerning the type and quality of conversations possible with CAIs and their appropriateness in therapeutic contexts. In psychotherapy, the digitization of many processes may suggest that CAIs can simply replace the therapist. However, it is also possible to argue that the psychotherapeutic relationship and the experience of that relationship are what is most crucial. In psychodynamic psychotherapy, the client experiences transference while the therapist experiences counter-transference, and working through these processes leads to therapeutic change. In frameworks more influenced by cognitive-behavioral principles, such as schema therapy, the therapist may play a key role in providing “reparenting,” a process that leads to positive outcomes.

Ethical concerns with CAIs in therapeutic contexts include the biases and other harmful prompts that might arise in such exchanges, along with the potential dearth of responsibility and accountability for these harms [6-10]. However, even if such patent ethical concerns were addressed or eradicated, central questions would persist: what sort of presence or entity do we have in CAIs? [11-14] and perhaps relatedly, is it possible for CAIs to facilitate genuine self-knowledge, self-understanding, and insight in their human interlocutors?

Some have suggested that engagements with CAIs are necessarily deficient in this crucial respect, especially if we consider the practice of joint attention, as well as other forms of mutual recognition and acknowledgment, to be central to the therapeutic conversation (and indeed to conversation more generally) [11,14-16]. Relatedly, there are concerns about the lost mutuality of these exchanges [16,17]. Conversations with bots do not demand that we empathize with or accommodate another, since, in an important sense, there is no one else there [14,16,18]. As Andrew McStay [18] points out, much depends on the account of empathy we are assuming. McStay argues that accounts that are more accommodative of CAIs are “deficient and potentially dangerous” insofar as they lack interdependence, copresence, and particularly moral responsibility [18].

However, others disagree with these characterizations and see no reason why CAIs cannot encourage genuine introspection [19-21]. What is required in the therapeutic exchange—according to some of these proponents—is not necessarily mutual agency, but rather the experience of being emotionally supported and encouraged to engage in self-reflection [20,21]. To necessitate another subjectivity, or the presence of another full-fledged agent, is to presuppose the illegitimacy of CAIs in these contexts, and to needlessly curtail the possibilities of what qualifies as a genuine therapeutic conversation. After all, human therapists regularly fail to

generate the conditions for self-understanding and insight, irrespective of their full-fledged agency [19].

We find these counterarguments compelling. Furthermore, if therapeutic benefits are possible through CAIs—as some research suggests [22-24] (although far more investigation is required [25])—then we potentially have a powerful tool in therapeutic CAIs. Given the immense shortfall in mental health care globally [26,27] and the often prohibitive cost of undertaking conventional psychotherapy, we would be remiss to hastily disregard the beneficial possibilities of therapeutic CAIs. Moreover, certain individuals and populations might experience unique benefits from the format of engagement required by therapeutic exchanges with CAIs, and (relatedly) may not experience the particular advantages of in-person conversation highlighted by advocates such as Turkle (this point has been made with regard to children on the autism spectrum in particular [28,29]).

Being Spoken for: CAIs and Surrendering Articulation

In recent reckonings with the rise of CAIs, the focus has generally been on concerns like those outlined above: what becomes of us when we increasingly replace our human interlocutors—including our human therapists—with AIs, that is (in Turkle's phrase) “when we speak not just through machines but to machines” [1].

Our central concern in this viewpoint, however, is different. Although certain dimensions of the preceding debate are of relevance to our position, we can also remain agnostic with regard to the value of “speaking to machines,” whether in a therapeutic context or otherwise. We can remain open to the possibility that bot and human engagements can generate genuine depth, worth, and meaning. Furthermore, we need not presume that the conditions for the emergence of genuine self-understanding and self-reflection cannot be generated in interactions with CAIs. Rather, our concern arises independently, for we now seem to have reached another turning point, and one that extends even further. “At a third point,” we might add to Turkle's list, “we take yet another step and let machines speak for us” [1].

We will concentrate on the significance of these forces to our self-knowledge and our interpersonal relationships, although more could be, and has been, said about their implications more generally, for example, concerning achievement gaps (where automation threatens to undermine genuine achievement, and therefore, meaningful work [30]) and responsibility gaps (where automation threatens to undermine responsibility for harmful outcomes [31,32]).

Our central concern will be the following: what is potentially at stake, personally and interpersonally, when we let the machine speak for us? We will explore this question within the framework of philosophical and ethical debates concerning the interpersonal value of effort, rather than exploring it qualitatively or quantitatively (although further empirical research on these questions would be valuable).

This third transition can take many forms, some seemingly more trivial than others. When we are writing an email and the remainder of the sentence auto-fills in gray, we are tempted to stop speaking for ourselves and let the machine speak for us instead.

At times, the costs of this surrender may seem slight, if they exist at all. What does it matter if you articulate some rote phrase to a distant work acquaintance or have it articulated for you instead? However, in other circumstances and other relationships, even these subtle interventions can carry weight.

In an early exploration of the implications of large language models—written in 2019, before the mass rollout of ChatGPT and other large language models—the journalist John Seabrook [33] wrote the following about the experience of using Smart Compose to autocomplete his emails:

Finally, I crossed my Rubicon. The sentence itself was a pedestrian affair. Typing an e-mail to my son, I began “I am p—” and was about to write “pleased” when predictive text suggested “proud of you.” I am proud of you. Wow, I don’t say that enough. And clearly Smart Compose thinks that’s what most fathers in my state say to their sons in e-mails. I hit Tab. No biggie.

And yet, sitting there at the keyboard, I could feel the uncanny valley prickling my neck.

Nowadays, the modes in which the machine can speak for us have expanded enormously from these first modest iterations. There are many examples to consider, and many more are developing as we write, but the ways through which we can outsource the labor of our interpersonal articulations are currently expanding exponentially.

Take one example: it is now possible to get CAIs to message on your behalf on dating apps. A variety of start-ups have generated different tools that allow you to hand over your messages to an AI [34]. Instead of having to initiate a conversation with a prospective date—or to come up with thoughtful or witty replies to their messages—AI will do it for you.

When you do not care for the people you are messaging, this option offers a certain pragmatic appeal (especially given the volume of messaging that contemporary dating apps necessitate). However, when you *do* care about a person, the temptation might be even stronger. The CAI, after all, always has an idea of what to say next, and moreover, it offers a version of what you *should* say—a statistically probable representation of what *people like you* say at *times like this*. In comparison, speaking for yourself can feel risky. The things you might say on your own—the way in which you try to make yourself known and get to know others—might be odd, off-putting, or *wrong* somehow.

Take another example: in June 2023, *The New York Times* reported that some doctors were turning to AI to communicate compassionately with patients [35]. We have all experienced the sense of inadequacy that comes with trying to say something supportive to someone who is in an awful circumstance. At such times, we can cast around for ages and summon nothing but

cliches. How alluring it is to have a ready-made response instead, and one so well trained in the performance of genuine feeling. The AI’s messages will be, in many cases, much better than what we could have produced on our own—kinder, more thoughtful, and more encouraging. Yet no matter how superbly it manages to express care and compassion, this expression is of course divorced from any genuine experience of care and compassion. We should be cautious, in our expedient outsourcing of this emotional connection and engagement, of when we begin to divorce ourselves from the genuine experience of care and compassion along with it.

When we are struggling to find the right thing to say, it may feel like we are achieving nothing. Yet it is precisely in these times—as we try to understand what someone else is enduring, to feel for them, and to express that feeling—that we are undertaking the genuine experience of care and compassion, without which the words themselves are hollow.

One optimistic response is that we might learn more empathetic engagement from the example of the machines. However, this seems unlikely. It is like suggesting that we will improve our spelling skills by relying on automated spell-check or that we will remember more phone numbers through the excellent example set by our phones. Of course, we will not, as the process removes effort, and little of importance has ever been learned without effort.

Thinking ahead—and not necessarily too far ahead—it is possible to see how the temptation to let the machine speak might overspill our text-based conversations. The push to normalize mixed-reality engagements—most notably with the launch of Apple’s Vision Pro headset last year—would make it possible for the machine to take over not only our text-based correspondence but also our face-to-face conversations.

We are, right now, at the initial stages of the temptation to begin ceding our expressions to CAIs. However, with little imagination, it is easy to see all the ways in which these temptations are poised to grow. After all, if it was largely the machine whose messages charmed someone into going on a date with you in the first place, how enticing would it be to let the machine keep on speaking when you have to go on the date yourself? The machine speaks with such authority, and as our confidence in its utterances grows, our confidence in our own could correspondingly diminish.

To our mind, the potential costs (to one’s own humanity and to our shared humanity) of CAIs are greatest when we allow them to speak for us. Genuine conversation nurtures authentic engagement with others and a better understanding of ourselves. Turkle [1] emphasizes what is lost when we speak through machines, and further still, when we speak *to* machines, but there is, even in these latter engagements, the possibility of coming to know our own thoughts and feelings, of having to search for, and to find, the expression for our experience, and recognizing that the experience precedes the expression that follows.

However, when we allow the machine to speak for us, even this possibility diminishes. We can too easily avoid the effort it takes to genuinely understand ourselves and our unique circumstances

(undertakings that are not necessarily discouraged by speaking to machines [20,21,29]). We are not encouraged to find the expression for our experience. Instead, we can too easily mistake whichever expressions we receive for our own experience, scarcely recognizing what we have lost in the exchange.

Effort and Meaning

The purpose of these technologies is, in no small part, to remove effort. To take something that once required a great deal from us and make it require little to nothing. Effort is by definition a burden, and in any given instance of having to exert effort, we are always wishing there was a way to be rid of it, but effort also has enormous value, and in some cases, even intrinsic value. This can be true in many realms—there are crucial senses in which “achievement” itself is impossible without effort [30,36]—but it is especially true in our interpersonal relationships. In some interpretations, effort allows us to *reveal* our care and concern for one another and make it knowable. In such interpretations, its role is primarily epistemic. This epistemic role is not trivial in itself, but there are also interpretations whereby effort is more significant still—instead of only allowing us to *reveal* care and concern, it may also *generate* this care and concern [37,38]. Imagine a husband who lovingly cares for his wife through a long illness. His devotion through this ordeal might not only reveal the depths of his love for his wife, but it could also *generate* those depths.

In this sense, the exertion of effort might have both generative and revelatory value in our interpersonal relationships, and the relinquishment of effort might have serious costs on both fronts. To make an effort for someone, irrespective of what that effort amounts to, conveys value and meaning in itself. Many of our interpersonal practices are ways of trying to make real or manifest the effort that is in fact of genuine importance to us. In turn, when effort is removed from these practices, so is their worth.

Take one example: nowadays, Facebook provides automatic reminders of people’s birthdays. The moment this memory became automated, the fact of remembering someone’s birthday (which used to carry weight and significance) became increasingly meaningless. It is now possible to set up your account to automatically post a rote birthday message on the appropriate day; you need not even give the person a moment’s thought. These automated messages are equivalent, in terms of their interpersonal worth, to the automated birthday messages

sent by a bank or a mobile service provider. Without requiring any thought or effort, the whole practice loses its significance. What other forms of interaction could we surrender to this fate, as we are increasingly able to opt for the effortless modes of expressing pride, love, affection, or consolation to the people around us?

Conclusions

In turn, we should begin to think carefully (even if just for ourselves) about which of these technologies we choose to use, in different contexts and spheres of our lives, and which ones we do not. Where we choose to use them, we should think equally hard about the *manner* of our engagement and the extent of our agency within it; the more passive we allow ourselves to be, the greater the potential costs we have gestured to in this viewpoint. This is especially true when it comes to those undertakings that have value in and of themselves—rather than value only for their outputs [30]—and also, as we have emphasized in this viewpoint, when it comes to those relationships and human interactions in which our engaged presence, as well as our emotional and intellectual attention and reflection, carries so much significance.

There is an adage in developmental psychology: the toys that are best for children are the ones that require them to do the most work. “The best toys are 90% the kid, 10% the toy,” as psychologist Kathy Hirsh-Pasek put it. “If it’s 90% the toy, and 10% the kid, that’s a problem” [39]. The toys that demand the most of a child are the ones that generate creativity, teach them problem-solving, and encourage their social interactions. On the other hand, the toys that merely require a child to press a button will teach them only to press a button over and over again. When we consider children, we usually show special caution for what will aid and hamper their development, flourishing, and well-being. However, our development does not cease after childhood, and indeed, much of the hardest work (in learning to know as well as relate to ourselves and others) still lies ahead. Given that, we should perhaps pause and wonder what opportunities for self-development we might be forsaking as we embrace, ever more, the toys that want to do everything for us, while we ourselves do less and less. We should remember, in the ceaseless war against effort, that far from needing to be eradicated at every opportunity, there are spheres of our lives—and our interpersonal relationships are a prime example—where effort itself can be the whole point.
