JMIR Mental Health

Journal Impact Factor (JIF) (2023): 4.8
Volume 12 (2025) ISSN 2368-7959 Editor in Chief: John Torous, MD, MBI

Contents

Editorials

Accelerating Digital Mental Health: The Society of Digital Psychiatry's Three-Pronged Road Map for Education, Digital Navigators, and AI (e84501)
John Torous, Kathryn Ledley, Carla Gorban, Gillian Strudwick, Julian Schwarz, Soumya Choudhary, Margaret Emerson, Michelle Patriquin, Allison Dempsey, Jason Bantjes, Laura Ospina-Pinillos, Jennie Hornick, Shruti Kochhar. . . . 12

Responsible Design, Integration, and Use of Generative AI in Mental Health (e70439)
Oren Asman, John Torous, Amir Tal. . . . 21

Building the Infrastructure for Sustainable Digital Mental Health: It Is "Prime Time" for Implementation Science (e78791)
Gillian Strudwick, Iman Kassam, John Torous, Sean Patenaude. . . . 26

Original Papers

Digital Contingency Management for Substance Use Disorder Treatment: 12-Month Quasi-Experimental Design (e73617)
Xiaoni Zhang, Valerie Hardcastle. . . . 33

Dashboard Intervention for Tracking Digital Social Media Activity in the Clinical Care of Individuals With Mood and Anxiety Disorders: Randomized Trial (e74212)
Leslie Miller, Tenzin Lhaksampa, Alex Walker, Carlos Aguirre, Matthew DeCamp, Keith Harrigian, Jennifer Meuchel, Aja Meyer, Brittany Nesbitt, Sazal Sthapit, Jason Straub, Danielle Virgadamo, Ayah Zirikly, Mark Dredze, Margaret Chisolm, Peter Zandi. . . . 61

Characteristics of Suicidal Patients Who Engaged in Suicide-Related Internet Use in the United Kingdom: Cross-Sectional Survey Findings (e73702)
Lana Bojani , Isabelle Hunt, Saied Ibrahim, Pauline Turnbull, Sandra Flynn. . . . 72

The Web-Based Recognise and Respond Gatekeeper Training Program: Noninferiority Randomized Trial (e63204)
Cassandra Chakouch, Ann Martin, Philip Batterham, Demee Rheinberger, Fiona Shand. . . . 86

Objectively Measured Smartphone Use and Nonsuicidal Self-Injury Among College Students: Cross-Sectional Study (e71264)
Wenhua Wang, Mingyang Wu, Xiaoxiao Yuan, Xue Wang, Le Ma, Lu Li, Lei Zhang. . . . 96

Exploring Suicide-Related Internet Use Among Suicidal Mental Health Patients in the United Kingdom: Cross-Sectional Questionnaire Study (e70458)
Lana Bojani , Isabelle Hunt, Sandra Flynn, Saied Ibrahim, Pauline Turnbull. 109

Treatment Without Cost? Effects and Side Effects of an Internet-Based Intervention for Depression: Randomized Controlled Trial (e71274)
Anna Baumeister, Lea Schuurmans, Alina Bruhns, Steffen Moritz. 121

Impact of Digital Safety Plan Activation on Subsequent Emergency Departments Visits Following an Initial Suicide Attempt: Quasi-Experimental Study (e70253)
María Barrigón, Carlos Schmidt, Matilde Elices, Alejandro Porras-Segovia, Ana De Granda-Beltrán, Antonio Artés-Rodríguez, Philippe Courtet, Víctor Pérez-Sola, Enrique Baca-García. 137

Impact of Conversational and Animation Features of a Mental Health App Virtual Agent on Depressive Symptoms and User Experience Among College Students: Randomized Controlled Trial (e67381)
Stephanie Six, Elizabeth Schlesener, Victoria Hill, Sabarish Babu, Kaileigh Byrne. 149

Using the PowerMom Digital Health Platform to Support Prenatal Mental Health and Maternal Health Outcomes: Observational Cohort Study (e70151)
Giulia Milan, Victoria Lee, Matteo Gadaleta, Lauren Ariniello, Arij Faksh, Giorgio Quer, Toluwalase Ajayi. 165

Effect of a Tailored eHealth Physical Activity Intervention on Physical Activity and Depression During Postpartum: Randomized Controlled Trial (The Postpartum Wellness Study) (e64507)
Sylvia Badon, Nina Oberman, Maya Ramsey, Charles Quesenberry, Elaine Kurtovich, Lizeth Gomez Chavez, Susan Brown, Cheryl Albright, Mibhali Bhalala, Lyndsay Avalos. 178

Identifying Adolescent Depression and Anxiety Through Real-World Data and Social Determinants of Health: Machine Learning Model Development and Validation (e66665)
Mamoun Mardini, Georges Khalil, Chen Bai, Aparna DivaKaran, Jessica Ray. 193

Codeveloping an Online Resource for People Bereaved by Suicide: Mixed Methods User-Centered Study (e56945)
Edouard Leaune, Kushtrim Bislimi, Pauline Lau-Taï, Héloïse Rouzé, Benoit Chalancon, Laurène Lestienne, Pierre Grandgenevre, Margot Morgiève, Nathalie Laplace, Guillaume Vaiva, Julie Haesebaert, Emmanuel Poulet. 203

Multimodal Digital Phenotyping Study in Patients With Major Depressive Episodes and Healthy Controls (Mobile Monitoring of Mood): Observational Longitudinal Study (e63622)
Talayeh Aledavood, Nguyen Luong, Ilya Baryshnikov, Richard Darst, Roope Heikkilä, Joel Holmén, Arsi Ikäheimonen, Annasofia Martikkala, Kirsi Riihimäki, Outi Saleva, Ana Triana, Erkki Isometsä. 217

Patterns of Skills Review in Smartphone Cognitive Behavioral Therapy for Depression: Observational Study of Intervention Content Use (e63497)
Emily Bernstein, Katharine Daniel, Peyton Miyares, Susanne Hoeppner, Kate Bentley, Ivar Snorrason, Lauren Fisher, Jennifer Greenberg, Hilary Weingarden, Oliver Harrison, Sabine Wilhelm. 235

Efficient Online Recruitment of Patients With Depressive Symptoms Using Social Media: Cross-Sectional Observational Study (e65920)
Carolin Haas, Lisa Klein, Marlene Heckl, Marija Kesi , Ann-Katrin Rueß, Jochen Gensichen, Karoline Lukaschek, Tobias Kruse, POKAL-Group.
2 5 3

Investigating Project Care UK, a Web-Based Self-Help Single-Session Intervention for Youth Mental Health: Program Evaluation (e72077)
Maria Loades, Grace Perry, Noah Marshall. 270

A Social Support Just-in-Time Adaptive Intervention for Individuals With Depressive Symptoms: Feasibility Study With a Microrandomized Trial Design (e74103)
Timon Elmer, Markus Wolf, Evelien Snippe, Urte Scholz. . . . 289

Association Between Psychosocial Characteristics and eHealth Literacy: Cross-Sectional Study of Hybrid Secondary Prevention in Mental Health (e73697)
Johannes Stephan, Jan Gehrmann, Ananda Stullich, Monika Sinha, Matthias Richter. . . . 308

Effect of Minimal Individual or Group Enhancement in an eHealth Program on Mental Health, Health Behavior, and Work Ability in Employees With Obesity: Randomized Controlled Trial (e66518)
Siniriikka Männistö, Joona Muotka, Laura-Unnukka Suojanen, Raimo Lappalainen, Kirsi Pietiläinen, Riitta Korpela. . . . 329

Web-Based Interactive Training for Managers (Managing Minds at Work) to Promote Mental Health at Work: Pilot Feasibility Cluster Randomized Controlled Trial (e76373)
Juliet Hassard, Holly Blake, Teixiera Dulal-Arthur, Alexandra Frost, Craig Bartle, Joanna Yarker, Fehmidah Munir, Ben Vaughan, Guy Daly, Caroline Meyer, Sean Russell, Louise Thomson. . . . 348

A Prompt Engineering Framework for Large Language Model–Based Mental Health Chatbots: Conceptual Framework (e75078)
Sorio Boit, Rajvardhan Patil. . . . 415

The Digital Therapeutic Alliance With Mental Health Chatbots: Diary Study and Thematic Analysis (e76642)
Zian Xu, Yi-Chieh Lee, Karolina Stasiak, Jim Warren, Danielle Lottridge. . . . 463

Anticipation and Motivation as Predictors of Leisure and Social Enjoyment and Engagement in Young People With Depression Symptoms: Ecological Momentary Assessment Study (e74427)
Angad Sahni, Ciara McCabe. . . . 484

Principles of Industry-Academic Partnerships Informed by Digital Mental Health Collaboration: Mixed Methods Study (e77439)
Sophie Hall, Olivia Hastings, Kelly Prentice, Beverley Brown, Jacob Andrews, Sonal Marner, Rebecca Woodcock, Jennifer Martin, Charlotte Hall. . . . 497

Co-Developing Content Updates for the Card Sort Task for Self-Harm–Digital (CaTS-D) With People With Lived Self-Harm Experiences: Pilot Study and Thematic Analysis (e71296)
Katherine Bird, Ian Greentree, Brian O'Shea, Ellen Townsend. . . . 511

Leveraging Large Language Models and Agent-Based Systems for Scientific Data Analysis: Validation Study (e68135)
Dale Peasley, Rayus Kuplicki, Sandip Sen, Martin Paulus. . . . 532

Leveraging Swipe Gesture Interactions From Mobile Games as Indicators of Anxiety and Depression: Exploratory Study (e70577)
Vibhav Chitale, Julie Henry, Ben Matthews, Vanessa Cobham, Nilufar Baghaei. . . . 558

Influence of Topic Familiarity and Prompt Specificity on Citation Fabrication in Mental Health Research Using Large Language Models: Experimental Study (e80371)
Jake Linardon, Hannah Jarman, Zoe McClure, Cleo Anderson, Claudia Liu, Mariel Messer. . . . 580

Digital Migration of the Loewenstein Acevedo Scales for Semantic Interference and Learning (LASSI-L): Development and Validation Study in Older Participants (e64716)
Philip Harvey, Rosie Curiel-Cid, Peter Kallestrup, Annalee Mueller, Andrea Rivera-Molina, Sara Czaja, Elizabeth Crocco, David Loewenstein.

Use of Digital Health Technologies for Dementia Care: Bibliometric Analysis and Report (e64445)
Hebatullah Abdulazeem, Israel Borges do Nascimento, Ishanka Weerasekara, Amin Sharifan, Victor Grandi Bianco, Ciara Cunningham, Indunil Kularathne, Genevieve Deeken, Jerome de Barros, Brijesh Sathian, Lasse Østengaard, Frederique Lamontagne-Godwin, Joost van Hoof, Ledia Lazeri, Cassie Redlich, Hannah Marston, Ryan Dos Santos, Natasha Azzopardi-Muscat, Yongjie Yon, David Novillo-Ortiz. 600

A Personalized and Smartphone-Based Serious Gaming App Targeting Cognitive Impairments in Alcohol Use Disorder: Double-Blinded, Randomized Controlled Efficacy Trial Among Outpatients (e67167)
Nicolaj Mistarz, Laust Knudsen, Anna Mejldal, Kjeld Andersen, Anneke Goudriaan, Lotte Skøt, Tanja Maria Michel, Angelina Mellentin. 626

Telehealth-Based vs In-Person Aerobic Exercise in Individuals With Schizophrenia: Comparative Analysis of Feasibility, Safety, and Efficacy (e68251)
David Kimhy, Luz Ospina, Melanie Wall, Daniel Alschuler, Lars Jarskog, Jacob Ballon, Joseph McEvoy, Matthew Bartels, Richard Buchsbaum, Marianne Goodman, Sloane Miller, T Stroup. 639

Establishment and Maintenance of a Digital Therapeutic Alliance in People Living With Negative Symptoms of Schizophrenia: Two Exploratory Single-Arm Studies (e64959)
Cassandra Snipes, Cornelia Dorner-Ciossek, Brendan Hare, Olya Besedina, Tim Campellone, Mariya Petrova, Shaheen Lakhan, Abhishek Pratap. 649

Effectiveness of General Practitioner Referral Versus Self-Referral Pathways to Guided Internet-Delivered Cognitive Behavioral Therapy for Depression, Panic Disorder, and Social Anxiety Disorder: Naturalistic Study (e68165)
Jill Bjarke, Rolf Gjestad, Tine Nordgreen. 666

Understanding Problematic Smartphone and Social Media Use Among Adults in France: Cross-Sectional Survey Study (e63431)
Laurent Karila, Nathaniel Scher, Clement Draghi, Delphine Lichte, Ilan Darmon, Hanene Boudabous, Hanah Lamallem, Olivier Bauduceau, Marc Bollet, Alain Toledano. 683

Exploring the Differentiation of Self-Concepts in the Physical and Virtual Worlds Using Euclidean Distance Analysis and Its Relationship With Digitalization and Mental Health Among Young People: Cross-Sectional Study (e60747)
Kai Chan, Christy Hui, Charlton Cheung, Yi Suen, Stephanie Wong, Corine Wong, Bosco Kam, Eric Chen. 697

Psychotherapy Access Barriers and Interest in Digital Mental Health Interventions Among Adults With Treatment Needs: Survey Study (e65356)
Isabella Starvaggi, Lorenzo Lorenzo-Luaces. 707

Directory of Public Datasets for Youth Mental Health to Enhance Research Through Data, Accessibility, and Artificial Intelligence: Scoping Review (e73852)
Hua Min, Xia Jing, Cui Tao, Joel Williams, Sarah Griffin, Christianne Esposito-Smythers, Bruce Chorpita. 813

Understanding the Needs of Moderators in Online Mental Health Forums: Realist Synthesis and Recommendations for Support (e58891)
Heather Robinson, Millissa Booth, Lauren Fothergill, Claire Friedrich, Zoe Glossop, Jade Haines, Andrew Harding, Rose Johnston, Steven Jones, Karen Machin, Rachel Meacock, Kristi Nielson, Paul Marshall, Jo-Anne Puddephatt, Tamara Raki , Paul Rayson, Jo Rycroft-Malone, Nick Shryane, Zoe Swithenbank, Sara Wise, Fiona Lobban. 1222

Explainable AI for Depression Detection and Severity Classification From Activity Data: Development and Evaluation Study of an Interpretable Framework (e72038)
Iftikhar Ahmed, Anushree Brahmacharimayum, Raja Ali, Talha Khan, Muhammad Ahmad. 1295

Personalization Strategies for Increasing Engagement With Digital Mental Health Resources: Sequential Multiple Assignment Randomized Trial (e73188)
Julien Rouvere, Isabell Griffith Fillipo, Meghan Romanelli, Ashish Sharma, Brittany Mosser, Theresa Nguyen, Kevin Rushton, John Marion, Tim Althoff, Michael Pullmann. . . . 1313

Governing AI in Mental Health: 50-State Legislative Review (e80739)
J Shumate, Eden Rozenblit, Matthew Flathers, Carlos Larrauri, Christine Hau, Winna Xia, E Torous, John Torous. . . . 1333

Comparing Generative Artificial Intelligence and Mental Health Professionals for Clinical Decision-Making With Trauma-Exposed Populations: Vignette-Based Experimental Study (e80801)
Katherine Wislocki, Sabahat Sami, Gahl Liberzon, Alyson Zalta. . . . 1351

Young People's Experiences Using a Digital Mental Health Tool to Support Their Care in a Real-World Service: Lived Experience–Led Qualitative Study (e70154)
Carla Gorban, Min Chong, Adam Poulsen, Ashlee Turner, Haley LaMonica, Sarah McKenna, Elizabeth Scott, Ian Hickie, Frank Iorfino. . . . 1364

Testing the Feasibility, Acceptability, and Potential Efficacy of an Innovative Digital Mental Health Care Delivery Model Designed to Increase Access to Care: Open Trial of the Digital Clinic (e65222)
Natalia Macrynikola, Kelly Chen, Erlend Lane, Nic Nguyen, Jennifer Pinto, Shirley Yen, John Torous. . . . 1379

Physician Perspectives on the Potential Benefits and Risks of Applying Artificial Intelligence in Psychiatric Medicine: Qualitative Study (e64414)
Austin Stroud, Susan Curtis, Isabel Weir, Jeremiah Stout, Barbara Barry, William Bobo, Arjun Athreya, Richard Sharp. . . . 1399

A Comparison of Responses from Human Therapists and Large Language Model–Based Chatbots to Assess Therapeutic Communication: Mixed Methods Study (e69709)
Till Scholich, Maya Barr, Shannon Wiltsey Stirman, Shriti Raj. . . . 1410

Seeking Emotional and Mental Health Support From Generative AI: Mixed-Methods Study of ChatGPT User Experiences (e77951)
Xiaochen Luo, Zixuan Wang, Jacqueline Tilley, Sanjeev Balarajan, Ukeme-Abasi Bassey, Choi Cheang. . . . 1426

Determinants of Patient Satisfaction With Telemental Health Services in Germany: Representative Cross-Sectional Postpandemic Survey Study (e65238)
Ariana Neumann, Hans-Helmut König, André Hajek. . . . 1440

Understanding Safety in Online Mental Health Forums: Realist Evaluation (e75320)
Paul Marshall, Neil Caton, Zoe Glossop, Steven Jones, Rachel Meacock, Paul Rayson, Heather Robinson, Fiona Lobban. . . . 1456

Effectiveness of Text Messages and Text Messages Plus Peer Support on Psychiatric Readmission and Length of Stay: Outcomes From a Quantitative Stepped-Wedge Cluster Randomized Trial (e81760)
Vincent Agyapong, Reham Shalaby, Belinda Agyapong, Wanying Mao, Ernest Owusu, Hossam Elgendy, Ejemai Eboreime, Peter Silverstone, Pierre Chue, Xin-Min Li, Wesley Vuong, Arto Ohinmaa, Frank MacMaster, Andrew Greenshaw. . . . 1470

Impact of a Virtual Reality Intervention on Stigma, Empathy, and Attitudes Toward Patients With Psychotic Disorders Among Mental Health Care Professionals: Randomized Controlled Trial (e66925)
Jing Tay, Yuanrong Qu, Lucas Lim, Rohan Puthran, Chye Tan, Rajkirren Rajendran, Ker Wei, Huiting Xie, Kang Sim. . . . 1484

Using Digital Phenotypes to Identify Individuals With Alexithymia in Posttraumatic Stress Disorder: Cross-Sectional Study (e83575)
Tomas Meaney, Vijay Yadav, Isaac Galatzer-Levy, Richard Bryant. . . . 1500

Associations Between Both Smartphone Addiction and Objectively Measured Smartphone Use and Sleep Quality and Duration Among University Students: Cross-Sectional Study (e77796)
Jian Yin, Xuanyi Tang, Zeshi Liu, Yangyang Gong, Hui Yang, Yanping Zhang. . . . 1528

Abstract

Digital mental health tools such as apps, virtual reality, and artificial intelligence (AI) hold great promise but continue to face barriers to widespread clinical adoption. The Society of Digital Psychiatry, in partnership with *JMIR Mental Health*, presents a 3-pronged road map to accelerate their safe, effective, and equitable implementation. First, education: integrate digital psychiatry into core training and professional development through a global webinar series, annual symposium, newsletter, and an updated open-access curriculum addressing AI and the evolving digital navigator role. Second, AI standards: develop transparent, actionable benchmarks and consensus guidance through initiatives like MindBench.ai to assess reasoning, safety, and representativeness across populations. Third, digital navigators: expand structured, train-the-trainer programs that enhance digital literacy, engagement, and workflow integration across diverse care settings, including low- and middle-income countries. Together, these pillars bridge research and practice, advancing digital psychiatry grounded in inclusivity, accountability, and measurable clinical impact.

KEYWORDS

AI; LLM; mental health; apps; digital navigators; artificial intelligence; large language model

Background

As research on digital mental health tools, such as apps, virtual reality, and artificial intelligence (AI), continues to expand and suggest benefits, clinical interest has also increased, yet the gap between research and real-world implementation remains stark [1]. Toward bridging this divide, the Society of Digital Psychiatry (SODP) and *JMIR Mental Health* have developed a multipronged international approach to support training, implementation, and standards for digital mental health worldwide. Education and training must be complemented by workforce support and shared development of new digital and AI tools. Toward these aims, the SODP will support three pillars: (1) education and training through accessible learning activities, (2) workforce development through advancing support and standards for Digital Health Navigators, and (3) the development of clinical AI through creating actionable benchmarks and guidance.

XSL•FO
RenderX

The potential of digital mental health tools has become a global focus, with mental health now viewed as the single greatest health concern [2] and technology supporting this growing need [3]. With smartphone ownership now exceeding 90% in many countries and internet access improving across the world [4], technical barriers to digital mental health continue to fall. Although digital literacy barriers persist and are even greater for non-English speakers, they are now well-recognized, with programs demonstrating the capacity to support even patients with serious mental illness, adolescents navigating developmental transitions, and older adults.

Notably, however, even when reimbursement is available [5], multiple reviews have confirmed that adoption of digital solutions—ranging from mobile apps to digital therapeutics and AI—remains low among both patients and clinicians [6,7]. Patient self-help tools have also faced low engagement with data, suggesting that some degree of clinical support is necessary [8,9], especially since the smartphone app market is nonhomogeneous in providing privacy and efficacy information [10]. These challenges are not new, and landmark research by Bamul et al in 2019 [11] demonstrated that user engagement with mental health apps is negligible after 1 week. In 2019, Ng et al [12] also revealed that a lack of consensus in measuring engagement with and uptake of digital mental health tools precludes progress. The literature also points to inequities between high-income countries and low- and middle-income countries [13]. Despite the abundance of apps, only 14.5% are available in Spanish and none have undergone evaluation with Spanish-speaking users [14]. Moreover, digital competency—particularly patients' and clinicians' ability to effectively use and evaluate mental health apps—remains difficult to assess, as only a few validated instruments are currently available [15]. In 2015, Ben-Zeev et al [16] called for the need for a technology coach to support integration and engagement. Now, in 2025, these challenges remain largely unsolved, with engagement remaining low, standards nonexistent, and the use of technology coaches, now referred to as digital navigators [17], still minimal.

Although continued research will provide new solutions, additional approaches are necessary to ensure progress in digital mental health implementation can accelerate to meet the need for clinical care. The SODP is implementing a 3-pronged approach (Figure 1). First, expand education to increase clinical uptake and engagement with digital tools. Second, develop standards for AI to catalyze progress by establishing clear benchmarks for success and guiding future innovation. Lastly, provide training and support for digital navigators to facilitate broad implementation.

Education

The SODP is dedicated to promoting clinician education in digital mental health. Today, many medical and nursing schools, peer specialist training programs, psychology and therapy degree programs, and other clinical training pathways do not cover digital mental health. Clinicians are understandably hesitant to recommend digital tools without adequate training or evidence-based guidance. Even when motivated to integrate technology, they frequently experience pressure to preserve existing workflows and not address ongoing barriers such as patient engagement and digital literacy, resulting in technology being deprioritized. These challenges are compounded by the lack of clinic- and system-level infrastructures to facilitate effective implementation [18].

JMIR Mental Health serves as the official journal of the SODP, embodying its shared mission to advance and disseminate cutting-edge research in digital mental health. So, in response to these challenges, the journal and society jointly host a monthly webinar series that highlights emerging innovations and diverse perspectives from invited speakers, featuring experts in digital psychiatry, internet interventions, cutting-edge technologies, mental health policy, ethics, and more [19]. Guests are thoughtfully selected based on their real-world work and ability to present up-to-date content. This series is designed to spotlight rigorous, critical, and forward-looking research that

XSL•FO
RenderX

explores how and why new digital mental health tools and technologies work, their limitations, and their place within broader care models. This collaborative effort not only extends the reach of this research to a global audience but also enhances the society's visibility and representation at major conferences, including the American Psychiatric Association annual meeting. These events provide a crucial platform for authors, editors, reviewers, and readers to engage with both *JMIR Mental Health* and SODP, learn about their initiatives, and contribute to the broader movement for evidence-based, peer-reviewed research. Complementary outreach activities, such as participation in the American Psychiatric Association's Mental Health Innovation Zone and the publication of postevent blogs, further extend the journal and society's reach, ensuring their work bridges the gap between research and clinical implementation. The recordings from these monthly webinars are subsequently repurposed into evergreen video content and made available asynchronously on YouTube and other social media platforms, including LinkedIn, X (formerly Twitter), Facebook, and Bluesky.

A similar approach is applied to the annual symposium, with each session produced and promoted individually to transform valuable knowledge into lasting, accessible educational resources. Furthermore, a quarterly newsletter copublished by *JMIR Mental Health* and the SODP provides insights into emerging trends and developments in digital mental health, featuring highlighted books, recent webinar recordings, upcoming industry events, and a quarterly question-and-answer section. This newsletter serves as a free, credible resource drafted by the SODP coleaders with citations and references for the 300 to 400 interprofessional members, ensuring they remain informed about advances in the field. As an immediate next step, the SODP will formally support the training and educational goals of clinicians and researchers by collaborating on a core curriculum with major educational bodies and providing a structured training plan for researchers, which is often required when applying for career development awards. The first step will be to release a new curriculum that updates the older one [20], with a focus on the expanded role of the Digital Health Navigator today as well as AI. Training will be accessible online, and coleaders will aim to offer local treatment in their region that will expand with time.

AI Standards

The SODP is also committed to advancing the safe and effective application of AI to improve and expand mental health care. As AI and large language models become increasingly powerful and capable of enhancing aspects of clinical care, the need for clear benchmarks and standards is crucial [21]. Without effective ways to evaluate the risks and benefits of AI in mental health, the field will be unable to self-regulate and pursue the most promising advances. Today, there are over 50 frameworks to evaluate AI, yet none of them are actionable and able to guide care considerations or research advances [22-86]. Leveraging the global reach of the SODP, we will propose clear and actionable recommendations that will improve transparency, understanding, and collaboration in the mental health AI space. Importantly, these recommendations will emphasize the need for representativeness across populations—ensuring that datasets, evaluations, and implementations reflect the diversity of real-world users and contexts—to enhance fairness and generalizability. We will organize a Delphi consensus meeting with SODP members representing stakeholders from around the world. In addition, we will support the creation of benchmarking tools through the MindBench.ai initiative, which will enable any AI program to score against a representative, comprehensive, and rigorous battery of cases.

Digital Navigator Training

Ultimately, the SODP is dedicated to promoting the growth of digital navigator roles. Digital navigators are currently conceptualized as human support coaches who can assist with digital access and equity, patient engagement, and the clinical integration of any digital health technology, are increasingly in demand [17,87-93]. However, foundational and scalable training, let alone certification and support for the role, is missing. The SODP will share leading examples of digital navigator programs worldwide to offer training and support through a theme issue in *JMIR Mental Health*, training on the SODP website, and training for the trainers by SODP coleaders. While each team will need to customize the role for their unique clinical setting and technology use case, there are core skills and competencies that the SODP will support to ensure consistent base training, fidelity to that training, and access to new training and skills as the field evolves while also exploring how best to adapt the digital navigator role into diverse health systems across the globe.

Education, standards, and digital navigator training are not panaceas that negate the need for more research. Instead, each of these 3 efforts can support new research advances by ensuring they reach clinicians quickly through education, are transparent about risks and benefits through standards, and are ready to be implemented through digital navigators. Thus, the ongoing partnership between the SODP and *JMIR Mental Health* provides an ideal platform to ensure that the best research informs the SODP's efforts and its efforts to advance that research toward its goal of supporting care.

With this renewed focus, it is essential to note that the SODP's name refers to the goal to support digital tools, including but not limited to therapy-based ones, and all patients, including those with severe mental illness. Such a goal requires an inclusive team, and the society's educational focus already reflects this, as well as our leadership team, which represents different roles, professions, and voices from around the world. Looking ahead, the society is also committed to ensuring these efforts are relevant and actionable across the Global South by supporting culturally adapted AI standards, supporting scalable digital navigator training tailored for low- and middle-income country contexts, and fostering equitable research and policy partnerships worldwide.

Membership today stands between 300 and 400 interprofessional members and remains free at this time, with access at [94]. We hope you will join us in supporting the acceleration of digital mental health toward improving outcomes for all patients today and preventing these illnesses for people tomorrow.

Abstract

Generative artificial intelligence (GenAI) shows potential for personalized care, psychoeducation, and even crisis prediction in mental health, yet responsible use requires ethical consideration and deliberation and perhaps even governance. This is the first published theme issue focused on responsible GenAI in mental health. It brings together evidence and insights on GenAI's capabilities, such as emotion recognition, therapy-session summarization, and risk assessment, while highlighting the sensitive nature of mental health data and the need for rigorous validation. Contributors discuss how bias, alignment with human values, transparency, and empathy must be carefully addressed to ensure ethically grounded, artificial intelligence–assisted care. By proposing conceptual frameworks; best practices; and regulatory approaches, including ethics of care and the preservation of socially important humanistic elements, this theme issue underscores that GenAI can complement, rather than replace, the vital role of human empathy in clinical settings. To achieve this, an ongoing collaboration between researchers, clinicians, policy makers, and technologists is essential.

(JMIR Ment Health 2025;12:e70439) doi:10.2196/70439

KEYWORDS

responsible AI in medicine; AI ethics; digital mental health ethics; artificial intelligence; large language model; model alignment

Introduction

The continued development of generative artificial intelligence (GenAI) and large language models (LLMs) shows potential in many fields, including high-stakes areas such as education, judicial work, security, and health. Utilizing this potential responsibly requires thoughtful deliberation and consideration and the creation of guidelines and conceptual frameworks that encompass the complexities of some of these fields.

The name of this theme issue reflects its focus—"Responsible Design, Integration, and Use of Generative AI in Mental Health." The current abilities of GenAI models for language generation and image synthesis already demonstrate their ever-growing potential use in personalized mental health psychoeducation, diagnosis, treatment planning, and interventions. However, integrating any of these applications within the mental health care realm requires careful examination, given the sensitive nature of mental health data, research, and interventions and the various capacities that may be expected of these models in these realms, to be considered of acceptable professional standard. Recent studies highlight the significant ethical challenges posed by GenAI, emphasizing the need for robust governance frameworks to mitigate risks and enhance the trustworthiness of these technologies [1-3].

This theme issue unites diverse stakeholders in exploring and adding a critical building block for the global challenge of conceptualizing and operationalizing responsible GenAI in mental health. It includes a collection of articles that examine the advantages, challenges, and potential risks associated with deploying GenAI models in mental health care while also proposing guidelines and best practices for their ethical and responsible implementation. Several papers discuss the application of GenAI in clinical settings; the ethical implications of artificial intelligence (AI)–driven mental health interventions; and the development of new frameworks to ensure the alignment of GenAI systems with human values, virtues, and ethical standards. These include transparency, accountability, and fairness in AI applications; privacy and data security [4]; and authenticity and congruence [5].

The exploration of GenAI's role in mental health is particularly timely, given its rapid adoption and the evolving landscape of digital health technologies. Recent research has highlighted the transformative potential of GenAI in creating personalized

XSL•FO
RenderX

mental health interventions that can enhance care delivery and patient outcomes. For instance, GenAI models are already used to generate therapeutic content, simulate dialogues for therapy, and even predict mental health conditions based on language patterns and sentiment analysis [6]. However, this potential is accompanied by significant ethical and practical challenges, such as ensuring the accuracy and reliability of AI-generated content and preventing the misuse of these technologies [7]. This theme issue provides a platform for in-depth discussions on these topics and proposes actionable insights for the responsible integration of GenAI in mental health care.

Current Capabilities and Limitations

We begin by exploring GenAI's capabilities and limitations in mental health applications. Although the ever-evolving capacities explored in any research are, by definition, representatives of the time and models examined, the conceptual and normative-related discussions could have longer-term implications and relevance. The first paper, "Capacity of Generative AI to Interpret Human Emotions From Visual and Textual Data: Pilot Evaluation Study" [8], evaluates the ability of ChatGPT-4 and Google Bard to interpret human emotions from both visual and textual data. Using the Reading the Mind in the Eyes Test and the Levels of Emotional Awareness Scale, the study found that ChatGPT-4 performed well in both visual and textual emotion recognition, aligning closely with human standards. Google's GenAI Bard, however, showed limitations in visual emotion interpretation. This paper emphasizes the need for inclusive data and stringent oversight to ensure accurate and reliable emotional recognition by AI systems.

The second paper, "Comparing the Perspectives of Generative AI, Mental Health Experts, and the General Public on Schizophrenia Recovery: Case Vignette Study" [9], compares the perspectives of GenAI models, mental health professionals, and the public on schizophrenia recovery. The findings show that some AI models align closely with professional views, while others, like ChatGPT-3.5, demonstrate pessimism that could negatively impact patient motivation. The study highlights the potential and limitations of AI in providing clinical prognoses and underscores the need for rigorous validation of AI applications in mental health.

The third paper, "Suicide Risk Assessments Through the Eyes of ChatGPT-3.5 Versus ChatGPT-4: Vignette Study" [10], examines the capability of ChatGPT models to assess suicide risk based on vignettes. The findings indicate that ChatGPT-4's assessments align more closely with those of mental health professionals compared to ChatGPT-3.5, which often underestimates suicide risk. These findings highlight the potential of advanced AI models to support mental health professionals but also underscore the necessity for further research and careful implementation to ensure accurate and safe use in clinical settings.

The paper "Exploring the Efficacy of Large Language Models in Summarizing Mental Health Counseling Sessions: Benchmark Study" [11] evaluates the performance of state-of-the-art LLMs in summarizing therapy sessions. By introducing the Mental Health Counseling-Component–Guided Dialogue Summaries dataset and assessing task-specific LLMs, like MentalLlama, Mistral, and MentalBART, the study demonstrates their promise while emphasizing their current limitations in terms of clinical applicability. Expert assessments revealed the need for further refinement and validation before such tools can be integrated into practice.

Another key contribution, "Large Language Models Versus Expert Clinicians in Crisis Prediction Among Telemental Health Patients: Comparative Study" [12], compares GPT-4's performance with that of senior clinicians in predicting suicide crises based on intake data. Although GPT-4 approached clinician-level performance in some metrics, its reliability was limited by sensitivity and bias issues. The study underscores the potential such tools have for augmenting crises prediction but highlights the need for additional safety measures and validation.

Ethical and Humanistic Considerations

Herein, we delve into the ethical and humanistic considerations of GenAI in mental health.

In "Exploring Bias(es) of Large Language Models in the Field of Mental Health – A Comparative Study Investigating the Effect of Gender and Sexual Orientation in Anorexia Nervosa and Bulimia Nervosa Case Vignettes" [13], the authors showed that LLMs assigned lower mental health–related quality of life scores to men compared to women with a similar eating disorder severity, with no real-world epidemiological evidence for such a pattern. This may reflect historical underrepresentation and societal biases in the data used for training the model and raises questions about how such biases can be mitigated by users as well as developers.

Next, we address the ethical implications of humanizing AI and the importance of empathy in therapeutic contexts.

The paper "The Role of Humanization and Robustness of Large Language Models in Conversational Artificial Intelligence for Individuals With Depression: A Critical Analysis" [14] explores the use of LLMs, such as OpenAI's ChatGPT-4, in mental health care. It highlights their potential to offer personalized therapeutic support for patients with depression through context-aware interactions. However, it also identifies significant ethical and technical challenges, including the risks of humanizing LLMs and their lack of contextualized robustness. Humanization can lead to unrealistic expectations and overtrust, while inadequate robustness may cause inconsistent and potentially harmful responses. The authors recommend clear communication of AI limitations, fine-tuning with high-quality data, and interdisciplinary research to responsibly integrate LLMs in mental health care, thereby enhancing patient support while minimizing risks.

The paper "The Machine Speaks: Conversational AI and the Importance of Effort to Relationships of Meaning" [15] explores the implications of using conversational AI in place of human effort in interpersonal relationships. The authors emphasize that effort in relationships conveys intrinsic value and meaning, which can be lost when machines take over these interactions. They discuss the importance of maintaining human effort in

XSL•FO
RenderX

therapeutic contexts to preserve the meaningful engagement and personal growth that come from human-to-human interactions. This paper encourages a critical examination of the potential losses in meaning and opportunities for self-understanding when relying on GenAI.

Following this, the paper "Considering the Role of Human Empathy in AI-Driven Therapy" [16] addresses the critical role of empathy in therapy. It evaluates whether AI-driven therapy can replicate empathic interactions. The authors define different aspects of empathy, compare the empathic capabilities of humans and GenAI, and discuss when human empathy is most needed in therapeutic settings. They call for ongoing research and dialogue to ensure that AI-mediated therapy maintains the essential human element of empathy, which is crucial for effective therapeutic outcomes.

In "The Artificial Third: A Broad View of the Effects of Introducing Generative Artificial Intelligence on Psychotherapy" [17], the authors introduce the concept of the "artificial third" in psychotherapy, following Freud's theory of narcissistic blows. They argue that GenAI represents a significant shift in how we perceive society, interrelationships, and self. They raise important questions about transparency, autonomy, and the irreplaceable human elements in therapy, suggesting that with ethical consideration, the artificial third can enhance but not replace the human touch in therapeutic relationships.

GenAI Alignment With Values and Virtues

Finally, we consider the alignment of GenAI with human values and regulatory perspectives.

The study "Assessing the Alignment of Large Language Models With Human Values for Mental Health Integration: Cross-Sectional Study Using Schwartz's Theory of Basic Values" [18] evaluates whether LLMs align with human values, using Schwartz's theory of basic values. The authors found that while this framework can characterize value-like constructs within LLMs, there are significant divergences from human values, raising ethical concerns. They call for standardized alignment processes to ensure that LLMs are integrated into mental health care in a way that respects and reflects diverse human values.

Another important contribution is the article "Regulating AI in Mental Health: Ethics of Care Perspective" [19], which argues that the dominant responsible AI approach is insufficient because it overlooks the impact of AI on human relationships. The author proposes an ethics of care approach to AI regulation, which addresses AI's impact on human relationships and establishes clear responsibilities for developers. They highlight the potential for emotional manipulation and the risks involved, proposing a series of considerations grounded in the ethics of care for developing AI-powered therapeutic tools.

Finally, the article "An Ethical Perspective on the Democratization of Mental Health With Generative AI" [20] explores the historical context of democratizing information and argues that GenAI technologies represent a new phase in this movement, offering improved accessibility to mental health knowledge and care. However, it also highlights the significant risks and challenges that need careful consideration. The paper proposes a strategic questionnaire for assessing AI-based mental health applications, advocating for an approach that is both ethically grounded and patient-centered.

Conclusions

The papers comprising this special issue make essential and exciting contributions to the field of digital mental health, specifically focusing on the responsible integration and use of GenAI. These studies showcase the already remarkable abilities of LLMs and allude to the potential of integrating GenAI in mental health diagnosis, treatment, rehabilitation, and recovery while also raising awareness of technical, clinical, philosophical, and ethical challenges related to safety and efficacy.

This theme issue is merely one stepping stone that is part of an ongoing global effort. Responsible AI frameworks for mental health must be adapted and integrated into local and international governance frameworks, thereby acknowledging that the current extraordinary opportunity also presents a profound professional and societal challenge. By fostering ongoing dialogue and collaboration among researchers, clinicians, ethicists, policy makers, and technologists, we can harness the benefits of GenAI to enhance mental health care while upholding principles, values, and virtues fundamental to humanistic care.

Together, we can ensure that this technology serves as a tool for doing good, augmenting human capabilities while avoiding harm and respecting and retaining the socially important humanistic elements of empathy, authenticity, and connection.

Abstract

Despite the growing enthusiasm for and a proliferation of digital mental health innovations, their integration into routine clinical care remains limited—often stalled at the pilot, research, or demonstration stage. This editorial argues that the successful adoption, scale-up, and sustainability of digital mental health innovations require intentional infrastructure, not just technology. Using the Non-Adoption, Abandonment, Scale-Up, Spread, and Sustainability (NASSS) implementation science framework, we examine how challenges across the seven framework domains (condition, technology, value proposition, adopters, organization, wider context, and their interactions over time) continue to hinder meaningful progress. We describe a focused digital mental health innovation infrastructure as a model for overcoming these barriers. Drawing on experiences from the Digital Innovation Hub at Canada’s largest mental health and addictions teaching hospital, we illustrate how investing in the right infrastructure may move digital mental health innovations from “promising” to “impactful.” We call for global collaboration to share knowledge and accelerate the real-world integration of digital innovations in routine mental health clinical care.

(JMIR Ment Health 2025;12:e78791) doi:10.2196/78791

KEYWORDS

mental health; psychiatry; implementation science; technology; digital health; innovation

Introduction

Digital mental health innovations have rapidly transitioned from the sidelines to a core area of innovation in mental health care [1,2]. Across clinical practice, research, and the technology industry, interest in using digital mental health innovations has increased significantly [3-5]. These innovations hold promise in addressing long-standing and emerging challenges in mental health clinical care that persist around the world, such as limited access to care, health human resource challenges, care inequities, and a rising demand for timely and personalized interventions and treatments [6]. The demand for services simply does not match those currently available.

Digital innovations like App4Independence (A4i), MindLAMP, and Hope by Centre for Addiction and Mental Health (CAMH) are examples in the mental health field. A4i is an app that was codeveloped with service users to support individuals living with psychosis, offering features such as appointment reminders, medication tracking, and communication with care providers [7-9]. MindLAMP is a platform that enables digital phenotyping by collecting passive and active data to support personalized mental health care and early intervention [10,11]. Hope by CAMH is a digital safety planning intervention embedded in an app for supporting suicide prevention [12,13]. These and other such digital innovations hold the potential to extend the reach of mental health services beyond traditional in-person settings, enable continuous monitoring and early intervention, and support personalized mental health care while attempting to address scalability in ways that traditional clinical service models cannot [14]. Yet, despite this potential, the field remains stuck in a cycle of fragmented, small-scale initiatives that rarely reach full-scale implementation in routine clinical care [1,5,15,16]. Although numerous digital mental health innovations show promise [10,17-19], few are integrated into the realities of mental health clinical care. This disconnect highlights a critical need for more than innovation; infrastructure, sustained commitment, and thoughtful investment are required to integrate digital mental health innovations into routine clinical care. As we examine these needs, the Non-Adoption, Abandonment, Scale-Up, Spread, and Sustainability (NASSS) implementation science framework offers a valuable lens for understanding the complexities that hinder the widespread and long-term uptake or sustainability of digital mental health innovations [20].

Using Implementation Science to Understand the Current State

The NASSS implementation science framework, which was developed by Greenhalgh and colleagues [20], offers a

XSL•FO
RenderX

comprehensive lens for examining why many digital mental health innovations struggle with wide-scale adoption and with being sustainable. The framework highlights the following seven interconnected domains that influence the success and failure of health technologies (inclusive of digital mental health innovations): (1) the condition, (2) the technology, (3) the value proposition, (4) the adopter system, (5) the organization, (6) the wider context (eg, policy), and (7) the dynamic interaction among these domains over time. When applied to digital mental health, these domains present persistent challenges. Mental health conditions are inherently complex and are often chronic and fluctuating, with high rates of comorbidity [21]. Yet, digital tools are frequently designed for singular diagnoses or narrowly defined user needs, failing to capture the clinical reality of patients. On the technology side, many tools are not interoperable with existing health information systems [22], are cumbersome to use, or are not developed with direct input from the clinicians and patients they aim to serve [23]. These usability gaps and poor contextual fit reduce engagement, adoption, and sustainability. Furthermore, the value proposition of digital mental health innovations is often mismatched among those involved in their development and use; developers or investors may prioritize metrics like download rates or short-term engagement, while patients and clinicians may seek tools that meaningfully improve outcomes and fit within clinical care processes. Regarding the adopter system, clinicians and patients are frequently expected to integrate new technologies without adequate training, support, or alignment with existing workflows [24]. Skepticism, digital literacy gaps, limited trust, and added burden further limit uptake [24]. Organizationally, many health care institutions are not structurally prepared to support innovation. They may lack governance frameworks, dedicated personnel, or protected time for staff to explore and integrate new tools, leading to isolated pilots, research studies, or demonstration projects that never scale [25]. In the wider context, policies, regulations [26], and funding models have lagged behind technological advancements. Reimbursement pathways remain unclear, data privacy regulations vary, and national strategies for digital mental health are often fragmented or absent [27].

The success of digital mental health innovations depends on the systems in which they are present, that is, these systems' ability to evolve and adapt as technologies, user needs, and societal conditions change. Innovations that face complexity across multiple NASSS domains are particularly vulnerable to failure. Even well-intentioned, evidence-based tools are likely to fail in these conditions. Therefore, understanding and addressing the full range of challenges across all NASSS domains is critical to transforming digital mental health from a landscape of "promise" to one that can be scaled and sustained.

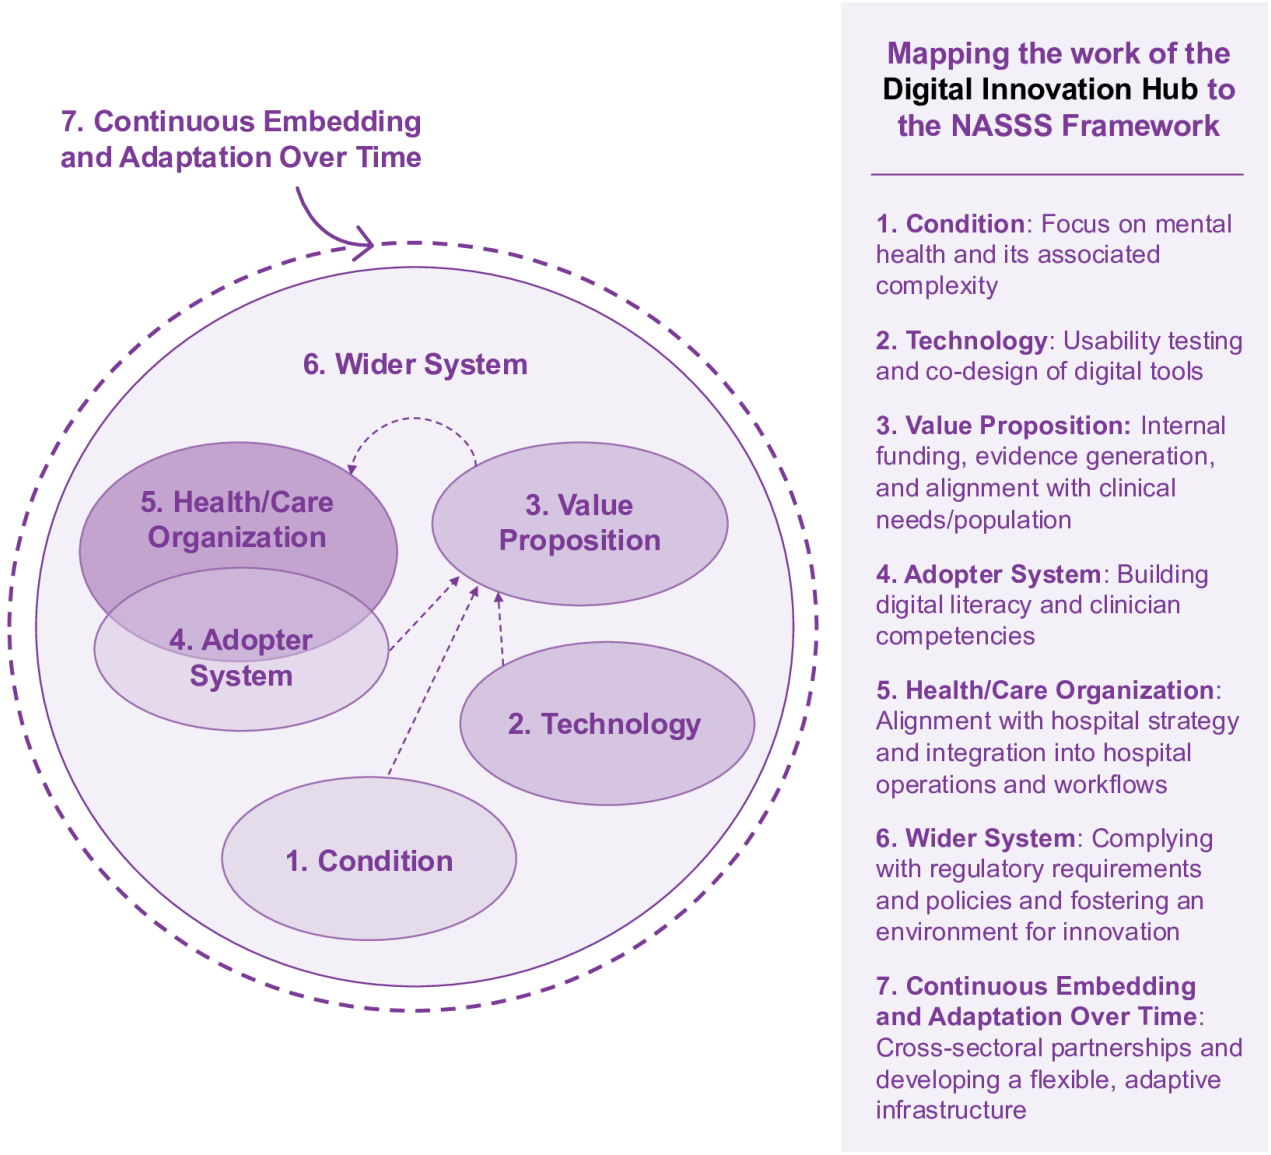
Although the NASSS framework provides a structure for understanding barriers to digital mental health innovation, the broader discipline of implementation science offers a set of approaches for addressing these barriers. Strategies derived from implementation science, such as stakeholder/partner engagement, co-design, and many others, are central to the success of digital interventions. Leveraging the diversity of implementation science tools and methods can help ensure that digital innovations move beyond the pilot stage to achieve sustainable integration in complex health systems [28]. By doing so, implementation science not only diagnoses barriers but also actively guides the "how" of embedding, adapting, and scaling digital tools within routine clinical care.

The NASSS framework was selected for its capacity to capture the layers of complexity of digital mental health implementations [29]. Compared to other frameworks, the NASSS framework explicitly considers the evolving and interconnected nature of domains, which are factors that are important in digital mental health innovation. The NASSS framework also uniquely addresses the temporal dimension of implementation, allowing for consideration of how interventions and systems coevolve over time. Given that many digital mental health tools fail not due to lack of efficacy but due to misalignment with health system structures and support processes, the NASSS framework's holistic and dynamic design makes it particularly well suited for identifying the root causes of implementation challenges in this field.

Building the Conditions for Sustainable Digital Mental Health in Canada

Structured, strategic infrastructure is critical to moving beyond the pattern of isolated, short-term projects in digital mental health innovation. The Digital Innovation Hub (DIH) at CAMH in Toronto, Canada, is an example of an embedded model for advancing digital mental health innovation. The idea of the DIH came about as a result of the growing potential utility of digital mental health tools and interventions and the lack of infrastructure for supporting meaningful adoption and use. The goal of the DIH is to support the development of scientifically evaluated digital solutions which aim to prevent and support treatment of mental illness, and have the potential for global impact. The DIH was designed to address the real-world challenges present in the context of digital mental health innovation development, use, and scaling, as outlined in the NASSS domains. It operates across four integrated streams of work that collectively support the full life cycle of digital health innovation. Stream 1 focuses on ensuring that digital interventions are scientifically evaluated and aligned with clinical needs. The DIH provides support for usability testing, implementation evaluation, and co-design with clinicians and patients, helping to ensure that tools are clinically meaningful and grounded in evidence. Stream 2 addresses the digital readiness of patients, ensuring that they have the skills and access needed to effectively use digital tools. One example is the coadaptation of a digital mental health literacy program (Digital Outreach for Obtaining Resources and Skills [DOORS] Canada) [30] that was co-designed with input from people with lived experience and integrated into the Collaborative Learning College (formerly Recovery College) [31]. Stream 3 is centered on building clinician competencies in digital mental health. The DIH offers education [32], mentorship, and practical support to clinicians to promote the effective and confident use of digital tools in practice. These include training, co-design workshops, and opportunities to lead or participate in innovation projects. Stream 4 supports the seamless integration of digital

XSL•FO
RenderX



technologies into clinical care processes and supports scaling initiatives. One of these initiatives is the further development of the digital navigator role [33] in partnership with those who have championed this role in the past. By embedding itself within the hospital's operational infrastructure, the DIH facilitates alignment with organizational priorities, streamlines processes for conducting research in this space, and ensures that innovations are adopted and sustained within clinical workflows. One example of work in this space is a close collaboration with the hospital's Industry Partnerships and Technology Transfer Office to identify ways of supporting commercialization and scaling.

The work of the DIH purposefully aligns closely with the NASSS implementation science framework by addressing challenges across all seven domains (Figure 1). The *condition* domain is addressed through a focus on mental health and its associated complexity. The *technology* domain is supported in a number of ways, including through rigorous usability testing and co-design to ensure that digital tools are user-friendly and clinically relevant. With regard to the *value proposition* domain, value proposition is enhanced through internal funding, evidence generation, and alignment with clinical needs. The *adopter system* domain is tackled through dedicated efforts to build digital mental health literacy among patients and competencies among clinicians. The *health organization* domain is engaged through the DIH's integration into hospital operations, supporting research and innovation within real clinical settings. The *wider system* domain is considered (in one way) through partnerships with industry and technology transfer offices to support commercialization and scale-up. Finally, the *embedding and adaptation over time* domain is addressed by fostering a large, cross-disciplinary community and offering flexible infrastructure that supports continuous iteration and learning. Through the DIH's infrastructure, which has been developed to map onto the NASSS framework, the hub exemplifies a strategy for supporting sustainable digital mental health innovation.

Although the DIH is still in its early stages (having begun in late 2024), its impact is already evident. A community with over 260 members promotes cross-disciplinary collaboration and knowledge sharing. By operating across the aforementioned four streams and providing infrastructure that supports the full innovation journey, the DIH helps overcome the common pitfalls that hinder digital mental health innovations. It offers a model for embedding, scaling, and sustaining digital mental health innovation, and it does so by bridging evidence, experience, and implementation.

XSL•FO
RenderX

Figure 1. The Digital Innovation Hub and Non-Adoption, Abandonment, Scale-Up, Spread, and Sustainability (NASSS) framework mapped.

Global Collaboration Is Necessary

Looking ahead, advancing digital mental health will require greater collaboration across institutions, countries, and disciplines. Rather than working in isolation, organizations can achieve more by intentionally leveraging each other's infrastructure, expertise, and communities. For example, a meeting was held by teams from several countries (United States, Canada, and Australia) working on the digital navigator role. Examples of how the role has been implemented and evaluated in these countries and lessons learned from these countries were shared among attendees [8,34,35]. This knowledge is essential in the refinement, further development, and scaling of such roles both within countries and internationally.

By working together, we can share implementation knowledge and practical lessons that are aligned with frameworks like the NASSS framework, thereby reducing duplication and accelerating progress. Joint efforts in training, evaluation, and technology development can help address persistent challenges, such as those regarding adoption gaps, digital literacy, and workflow integration. For example, supporting roles like the digital navigator role, which helps bridge the gap between patients, clinicians, and digital tools, can be more widely adopted and refined when multiple partners collaborate. This kind of shared, cross-institutional work does not require uniformity or a one-size-fits-all approach; rather, it enables context-sensitive innovation by aligning on core principles, adapting shared tools to local needs, and managing complexity collectively.

Conclusion

As the field of digital mental health matures, the challenge is no longer a lack of innovation but a lack of sustained integration into clinical care. The NASSS framework reveals that navigating complexity across multiple domains, from the nature of mental health conditions to the dynamics of organizational change and evolving policy landscapes, is critical to realizing the full potential of digital mental health innovations. Success depends not only on the quality and efficacy of the technology but also on whether the right infrastructure, support systems, and collaborative relationships are in place to embed that technology

XSL•FO
RenderX

into everyday routine care. Transforming digital mental health care requires investing in the infrastructure for impact. This means prioritizing people, partnerships, and processes as much as we prioritize the digital platforms themselves. It also means committing to and investing in the "long game" that moves beyond pilots and toward meaningful, measurable, and sustained change. The time to act is now. Implementation science gives us the road map. It is up to us to follow it together.

Abstract

Background: Although contingency management has shown some efficacy in substance use disorder treatment, digital contingency management (DCM) needs more evidence supporting its value in treating substance misuse.

Objective: This study aimed to evaluate the effectiveness of DCM in treating substance use disorder by examining 2 key outcome variables—abstinence and appointment attendance.

Methods: A 12-month quasi-experimental design was conducted by enrolling patients into 2 groups using an alternating assignment process: one group receiving treatment-as-usual plus DCM and the other receiving treatment as usual with no contingency management. Propensity score matching was conducted to match groups on covariates. After matching, *t* tests were conducted to examine the difference between groups on urine abstinence and appointment attendance rates.

Results: Two cohorts of propensity-matched patients (66 interventions and 59 controls) were analyzed. Abstinence was significantly higher in the DCM group (mean 0.92, 95% CI 0.88 - 0.96) than in the treatment-as-usual group (mean 0.85, 95% CI 0.79 - 0.90; *P*<.01). Appointment attendance also demonstrated significant differences between the groups, with the DCM group achieving a mean rate of 0.69 (95% CI 0.65 - 0.74) compared with 0.50 (95% CI 0.45 - 0.55) in the treatment-as-usual group (*P*<.001). This notable increase highlights the role of DCM in fostering engagement with care, an essential factor for successful treatment outcomes.

Conclusions: The results suggest that DCM can be an effective treatment modality for substance use disorder.

Introduction

Background

Substance use disorders (SUDs) are a worldwide public health concern that impacts millions of people and weighs heavily on health care systems, families, and communities [1,2]. Over the past decade, substance use problems have been linked to a significant rise in both sickness and death rates globally [3]. Even with the presence of proven treatments, treatment-related attendance and follow-up remain significant barriers to recovery, and the rate of dropout ranges between 20% and 70% for different treatment programs [4,5]. Treatment adherence (ie, appointment attendance) and continued substance abstinence are 2 crucial elements that impact the outcome of treatment [6,7]. However, traditional treatment protocols struggle with multiple problems, such as low appointment attendance as well as long-term abstinence and relapse rates [8].

Contingency management (CM) is one of the most research-validated behavioral treatments to increase abstinence and treatment adherence in SUD treatment [9]. The foundation of CM is operant conditioning, which holds that actions leading to favorable outcomes are more likely to be repeated, whereas actions that result in unfavorable outcomes are less likely to be repeated. CM can be used to address several health behaviors, including medication adherence, substance use, weight loss, and quitting smoking. Based on behavioral economics and operant conditioning, this methodology is a systematic offering of material reward or incentive, depending on verified target outcomes such as passing drug tests or attending appointments [10]. The efficacy of CM has been consistently shown in meta-analyses for a range of SUDs, and in some studies, CM

XSL•FO
RenderX

can boost medication adherence, therapy attendance, and abstinence rates [8]. Despite this solid evidence base, traditional CM implementation has limitations, including excessive administrative overheads, frequent in-person testing of target behavior, cumbersome reward systems, and policy obstacles, such as US federal antikickback and beneficiary inducement monetary and criminal sanctions [11].

Previous Work

Digital contingency management (DCM) combines the traditional CM paradigm with digital health tools, which is the next generation of SUD treatment delivery. DCM involves using remote, technology-based techniques (such as the internet and smartphones) to track drug status using biochemical sensors (such as breath alcohol and carbon monoxide monitors) and to provide desired outcomes, such as monetary rewards depending on drug abstinence [12,13]. Such online enhancements are not only efficient at providing CM but also offer unparalleled data collection and program optimization.

Digital technologies offer multiple benefits for CM over other forms of implementation. First among these is greater accessibility as digital services transcend geographic boundaries and transportation expenses, especially for patients living in congested urban, rural, or underserved communities. Digital platforms remove much of the administrative cost as automated solutions cut staff time compared with manual CM systems while keeping similar verification accuracy rates. In addition, DCM systems' real-time data collection capabilities allow dynamic program optimization: machine learning algorithms can recognize patterns in patient usage and adjust reward schedules to optimize treatment. Data show that personalized digital incentives better drive program retention than traditional fixed-schedule solutions [14]. DCM implementations may be affordable, with programs averaging per-patient costs less than traditional CM while achieving equal or better outcomes.

Even with the promising potential of digital CM, there is still a lack of comprehensive understanding of how it compares with traditional CM methods. Existing literature provides substantial evidence supporting the efficacy of traditional CM in SUD treatments, particularly for smoking cessation and alcohol use disorders [15]. However, more research is needed to evaluate its effectiveness in treating drug use. While DCM shows significant potential as an innovative approach, there remains a critical need for robust empirical evidence to validate its efficacy and broader applicability [15].

Study Objectives

CM is underutilized in clinical settings [12]. If proven effective, DCM could present a better modality for widespread adoption. There is a pressing need to understand the interrelationships between appointment attendance, abstinence outcomes, and DCM interventions [10,16]. This understanding is crucial for developing more effective, integrated treatment approaches to better support individuals in their recovery journey [17].

In this study, we attempted to fill critical gaps in understanding the impact of DCM on SUD treatment by evaluating its effectiveness on 2 key outcomes: appointment attendance and abstinence. In particular, we compared a standardized DCM intervention with treatment as usual across multiple sites in a time-randomized controlled trial. These results will be part of the scientific evidence base for digital behavioral interventions in SUD treatment and should guide the development of more effective, accessible, and long-term treatment solutions. Here, we aim to provide some evidence-based recommendations for enhancing SUD treatment protocols. This research aimed to answer the following research questions: (1) How does DCM impact treatment adherence, as measured by appointment attendance? (2) How does DCM impact treatment outcomes, as measured by substance test abstinence rates?

Methods

Study Design

DynamiCare Health provided the DCM platform. We conducted a 12-month quasi-experimental study of DCM in a SUD population seeking treatment in partnership with providers located in the Greater Cincinnati Metropolitan Statistical Area. This quasi-experimental design used 2 groups to compare treatment outcomes between a non-DCM treatment-as-usual control group and a DCM experimental group. Participants were assigned to their group using an alternating assignment process based on the sequence of their enrollment in the program, rather than through random assignment. This approach was adopted due to pragmatic and ethical constraints in operating in a real-world clinical setting. Pure randomization was not feasible at intake because clinicians had to obtain informed consent before assigning a patient to the experimental group. To mitigate bias, intake coordinators were instructed to follow a strict alternating pattern, regardless of patient characteristics or interest, with no discretion in who was offered participation.

The study was carried out over a 4-year period from 2021 to 2024. Clients used the DynamiCare Health mobile app on smartphones to check into their treatment appointments (verified by GPS) and track any financial rewards they earned. These rewards were provided on a smart debit card that blocked access to charges in bars, liquor stores, and cash withdrawals.

Due to practical constraints of this real-world implementation study, a formal a priori power analysis was not conducted. The sample size was determined by the number of eligible patients who consented to participate in the study during the enrollment period. While our final matched sample (66 interventions and 59 controls) was relatively modest for a 12-month study, it proved sufficient to detect statistically significant differences in our primary outcomes. However, we acknowledge that the relatively small sample size may have limited our ability to detect smaller effect sizes, particularly for secondary outcomes or subgroup analyses.

In our study, missing data and attrition were minimal. Participants' appointment attendance and urine test results were extracted from electronic health records, which systematically document all scheduled appointments and urine screens, including missed visits and missed tests. Therefore, nonattendance and missing urine tests were captured as part of the outcome measurement rather than treated as missing data.

XSL•FO
RenderX

Participants who disengaged from treatment or failed to provide urine samples were included in the denominator when calculating appointment attendance rates and urine test success rates, in accordance with an intention-to-treat principle. No participants were excluded due to missing data. As a result, there was no attrition bias requiring adjustment.

Procedure

Patients were assigned to groups using an alternating assignment process. During intake, an intake coordinator described the DCM project to the first patient. If this patient were interested in participating, they were consented and placed in the experimental group. The next patient the intake coordinator saw would automatically be placed in the treatment-as-usual control group without receiving any project description. This alternating process continued, offering participation in the project to every other patient. The intake coordinator then informed therapists of each patient's group assignment, and therapists explained the DynamiCare system to those in the experimental group during their second appointment. Participants in the control group were not given any further instructions; they just received treatment as usual. The electronic health record system documented all treatment events in which the experimental and control groups participated and their medical histories.

The enrollment order assignment is not true randomization and could introduce bias. To address this, we used patient ID as a proxy for enrollment sequence and tested whether our outcomes showed systematic trends over the enrollment period. To address this, we conducted time series analyses to check for secular trends in our outcome measures during the enrollment period. We found no significant temporal patterns in either abstinence rates (P=.59) or appointment attendance (P=.47) across the study time frame for the experimental group. We conducted the same analyses for the control group with similarly nonsignificant results (P=.49 for urine abstinence rate and P=.28 for appointment rate). These findings provide strong evidence that time-dependent confounding was not a concern in our study. The lack of significant temporal trends in our outcomes suggests that the sequential assignment of participants did not introduce systematic bias beyond what was addressed by our propensity score matching approach.

Intervention DCM

There were only 2 differences between the experimental group and the control group. First, the experimental group received financial awards for completing prescribed treatment activities and for remaining sober. The control group engaged in the same treatment and testing regimen; however, it received no financial rewards for success. And second, the experimental group used a phone app as part of its treatment protocol, while the control group did not use a phone app as part of its treatment protocol. The experimental group's app allowed the participants to check into their appointments online, which DynamiCare could then use to verify attendance by a location tracker. The app also tracked the cash value to the experimental group participants' debit card as they received rewards for complying with their prescribed treatment activities and purchased allowable items or services. The DynamiCare company disbursed the reward funds as each of the experimental participants completed each prescribed activity successfully.

Patients in the experimental group used their own iOS or Android smartphones in this study. The intake coordinator assisted patients in downloading and logging into the app for the first time. At the time of primary data collection for this study, the HIPAA (Health Insurance Portability and Accountability Act)-compliant mobile DynamiCare app was used only to locate patients during scheduled therapeutic appointments and to reward patients completing specific, verified, and scheduled activities (the app now includes many interactive features).

In the experimental group, cash rewards were promptly provided for attending scheduled counseling appointments and receiving a negative outcome in urine screens. The system recorded negative "weeks since onboarded" as an automatic process from the account creation. Usually, patients downloaded the app shortly after receiving the invitation, but there were occasions when the users did not access the app for weeks (or at all). Four sites implemented the intervention between October 16, 2020, and September 13, 2023.

Participants could earn up to US $600 in rewards over a 12-month period, with incentives front-loaded during the first 3 months to foster engagement and a pattern of active effort. During this initial period, participants could earn US $100 per month, with the rewards tapering down in subsequent months. Specifically, months 4 - 6 offered US $50 per month, months 7 - 9 provided US $40 per month, and months 10 - 12 offered US $25 per month.

Both experimental and control group participants underwent the same therapy and urine testing sequences, following the protocols of their individual behavioral health units. Both the experimental and control groups participated in clinical activities, as per the protocols of the individual treatment facilities (these did not differ by group, although they could differ by individual, depending on medical recommendations). But the recommendations were not determined by app usage; rather, in both groups, participants were treated as they ordinarily would have been, regardless of the DCM intervention.

Outcome Variables

The outcome variables were abstinence and appointment attendance. Abstinence was measured using objective methods, specifically, urine drug screening. Urine test success is measured as the number of negative urine test results or medically consistent results divided by the total number of urine tests logged by providers in their electronic medical records. A test was marked consistent, or abstinent, if it met medical expectations: negative for illicit substances, with positive results for prescribed substances allowed. Appointment attendance was calculated as the number of attended appointments divided by the total number of scheduled appointments.

All participants who enrolled in the program were included in the analysis regardless of their level of engagement. Missed appointments and missing urine screens were treated as part of the outcome definitions rather than missing data, using the following formula for appointment attendance rate: appointment

XSL•FO
RenderX

attendance/(total number of missed appointments + total number of attended appointments). No participants were excluded due to missing information, ensuring a complete analysis under an intention-to-treat framework. We examined the potential time-dependent confound arising from our enrollment order assignment and did not find any significant temporal trends in our outcomes.

While we did not conduct a formal a priori power analysis due to the pragmatic nature of this implementation study, we assessed the adequacy of the sample size post hoc by evaluating the observed effect sizes and associated *P* values for our primary outcomes. We used G*Power (version 3.1.9.7) to determine the statistical power of the study. To detect a medium effect size (Cohen *d*=0.50) with a 1-tailed independent samples *t* test at a significance level of α=.05, and using our matched sample sizes (66 in the treatment group and 59 in the control group), we achieved a power of 87.1%. This means that there is an 87.1% probability of detecting a true medium-sized effect if one exists, which exceeds the conventional 80% threshold typically considered acceptable in most fields. Our matched sample of 125 participants (66 treatment and 59 control) thus provides sufficient power to detect medium effects in our primary outcomes. We have added this explanation to the "Study Design" section.

Propensity Score Matching

Propensity score matching (PSM) was used to remove confounding bias [18-22] as our experimental study was randomized based only on the time of program entry. To control for selection bias, we used nearest neighbor 1:1 matching. A binary logistic regression was used to estimate the propensity score. Variables' association with treatment and outcome, as well as both treatment and outcome, was considered and reported. The variables used in the PSM model included gender, race, relationship status, and insurance. Selection of these covariates was based on previous research [23] reporting on the impact that various sociodemographic factors have on appointment attendance and substance use outcomes among individuals receiving treatment for SUDs. In particular, women are less likely to receive SUD treatment than men [24]. Marriage was associated with lower rates of SUD [25]. Race and ethnicity have been linked to treatment completion [26]. Health insurance coverage seems to be linked to better abstinence outcomes among US adults with mental health and substance use disorders [27].

This study aimed to estimate the effect of DCM on abstinence and appointment attendance. The challenge in estimating these effects is to plausibly separate them from confounders that might affect patients' outcomes and to isolate those associated with digital CM. PSM was performed to design balanced samples. We selected an experimental group for each patient receiving DCM that had similar observed characteristics at intake. PSM was performed using a 1:1 nearest neighbor matching algorithm with replacement with distances determined by logistic regression using the Stata package PSMatch2. Standardized mean differences (SMDs) were used to evaluate the balance between treated patients and matched controls. Before and following matching, this measure is used to balance the variables [18]. SMDs less than 0.2 suggested a reasonable balance for group comparison following matching [21]. After matching, standardized differences between covariates were generally well balanced with values ranging from 0.01 to 0.08, within the recommended threshold of less than 0.2. However, gender maintained a moderate imbalance with an SMD of 0.23, slightly exceeding our predefined threshold. This residual imbalance was considered in subsequent analyses and interpretation.

To assess the quality of matching, SMDs were calculated and checked for all variables included in the propensity score model. Following Austin's recommendation, we considered SMDs less than 0.2 to indicate adequate balance between treated and control groups. To evaluate the robustness of our findings to potential unmeasured confounding, we conducted postmatching sensitivity analysis using Rosenbaum bounds. This approach helped determine how significant an unmeasured confounder would need to be to negate the observed treatment effects. The sensitivity analysis tested a range of gamma values (Γ) from 1 to 3, with Γ=1 representing no hidden bias and higher values indicating increasingly strong unmeasured confounding.

Statistical Analysis

Group comparison and linear regression were used to assess the average treatment effect of DCM on abstinence and appointment adherence. Statistical analyses were performed in Stata (version 18; StataCorp) and 2-sided *P* value of <.05 indicated statistical significance. *P* values for continuous values were calculated using a weighted *t* test, and a chi-square test was used for categorical comparisons. We also conducted the robustness check by conducting a sensitivity analysis.

Ethical Considerations

Institutional review board (IRB) approval was obtained from the Northern Kentucky University IRB (IRB number 914) under expedited review according to 45 CFR 46.110: (4) Collection of data through noninvasive procedures and (7) research on individual or group characteristics or behavior. Participant consent was obtained at the treatment facilities during patient onboarding; all possible participants could opt out of the study at any time. Consent language included: "Your participation is completely voluntary; you are free to change your mind at any time and quit the study. Whatever you decide will in no way result in loss of medical or health benefits or services to which you are otherwise entitled."

There were no secondary analyses using data with primary consent. All patient information and data were deidentified using random numbers as identifiers. No one engaged in data analysis had access to any identifying information. All data associated with this study are kept on a secure HIPAA-compliant server. Because participant compensation comprises part of the study design, it is described in the "Intervention DCM" subsection.

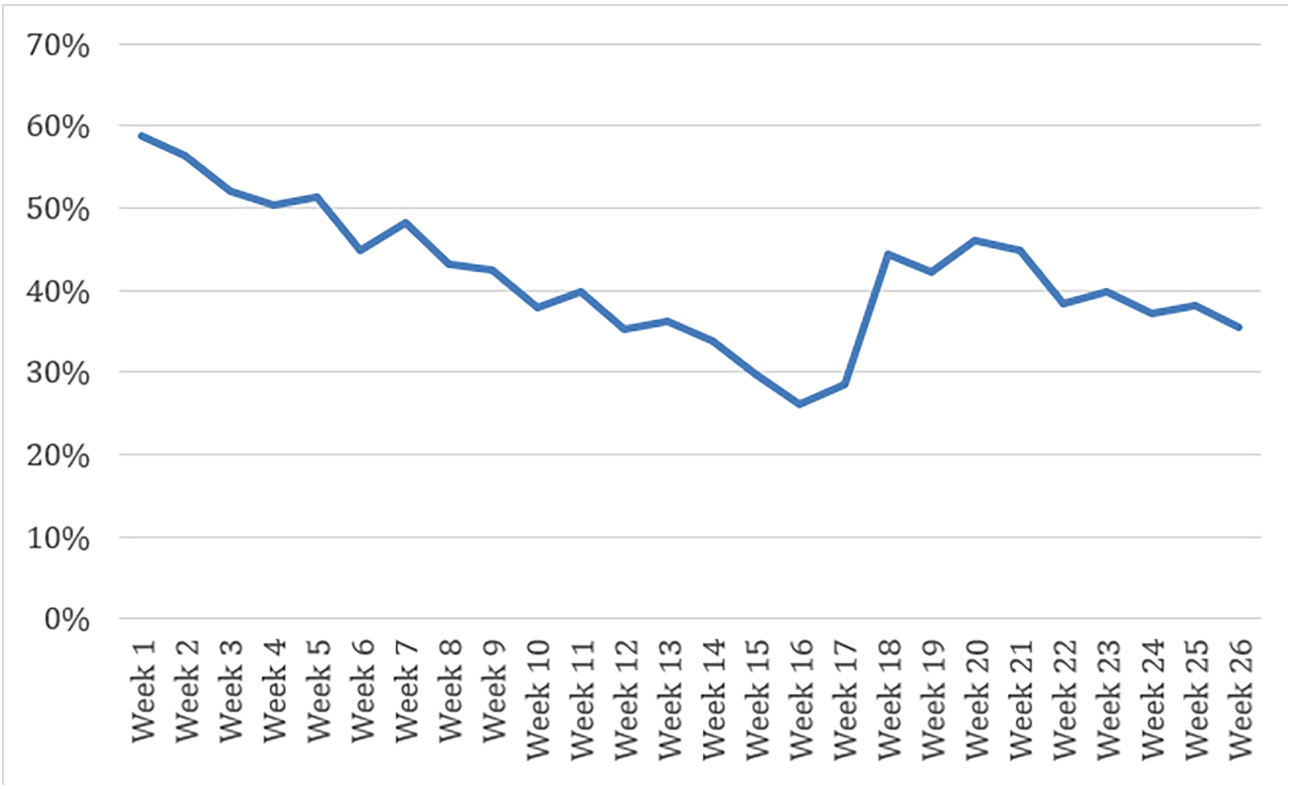
Results

Overview

Figures 1 and 2 show the consistent urine rate and appointment attendance rate for patients using DCM.

XSL•FO
RenderX

Figure 1. Urine consistency rate with digital contingency management.



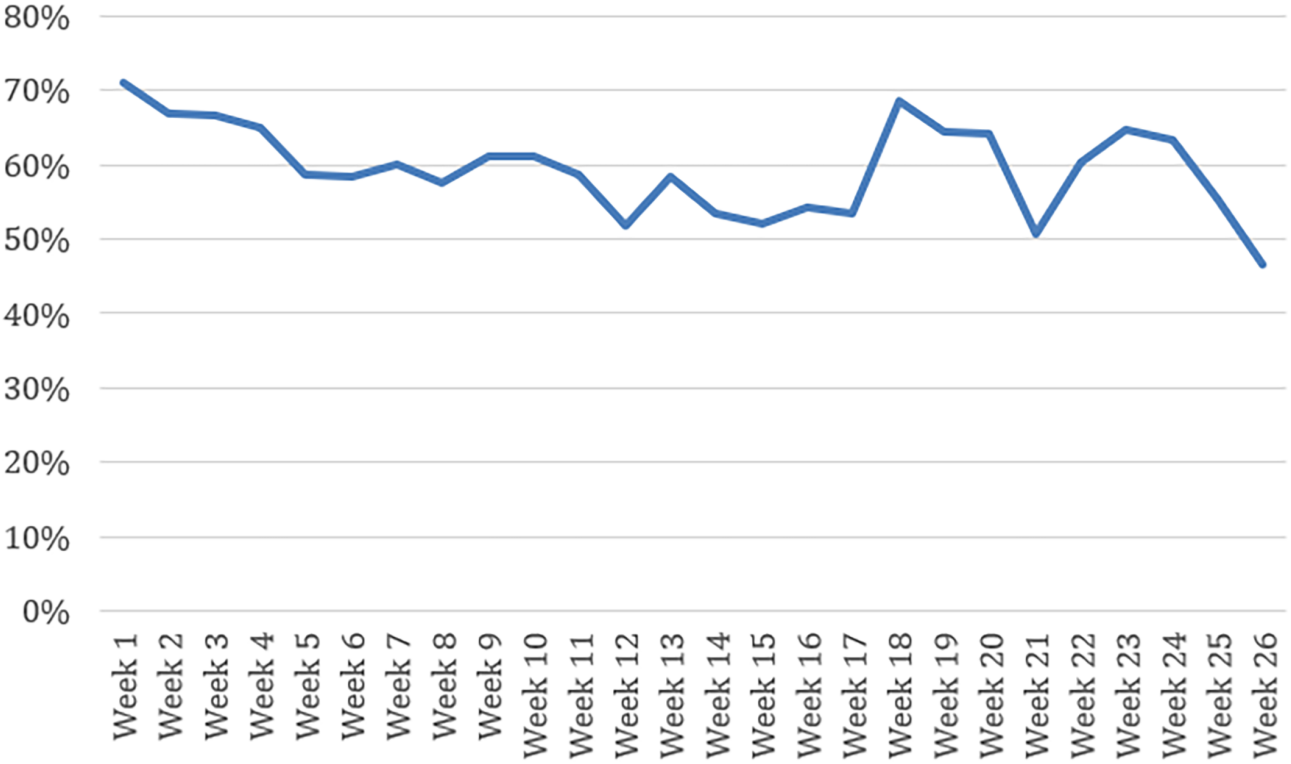


Figure 2. Appointment attendance rate with digital contingency management.

Cohort Characteristics

Table 1 shows the demographic and insurance-related characteristics of the experimental group (n=74) and the control group (n=119) in the unmatched sample. The *P* values indicate statistical significance, and standardized differences provide a measure of the imbalance between groups. Females were more prevalent in the experimental group (44/74, 59.5%) than in the control group (30/74, 42.86%). Males were more prevalent in the control group (68/119, 57.14%) than in the experimental group (30/74, 40.5%). With *P*=.025 and SMD=−0.31, there is a significant difference between groups in terms of gender. Race and education exhibit comparable characteristics between the unmatched cohorts. Relationship status shows a moderate

XSL•FO
RenderX

imbalance (P<.05; SMD=−0.58), while insurance type shows a significant imbalance (P<.02; SMD=0.35).

Table . Comparison of characteristics of study cohorts in the original unmatched sample.

Characteristics	Treatment (n=74)	Control (n=119)	*P* value	Standardized differences
Sex, n (%)			.03	−0.31
Female	44 (59.50)	51 (42.86)		
Male	30 (40.50)	68 (57.14)		
Race, n (%)			.37	0.11

[a]N/A: not applicable.

[b]This is insured by both Medicare and Medicaid.

Table 2 shows the characteristics of matched cohorts. After matching, the sample size for the treatment was 66, whereas the sample size for the control was 59. All the characteristics are well balanced between the matched cohorts. While most variables achieved excellent balance after matching (SMDs <0.1), gender retained a moderate imbalance (SMD=0.23) despite the matching procedure. This moderate imbalance in gender distribution represents a limitation of our matching process that warrants consideration when interpreting the results.

XSL•FO

Abstinence

After PSM, we conducted *t* tests to compare urine rate between the control and experimental groups for the matched sample of 125 observations (59 controls+ 66 treated). Table 3 shows the urine test consistency rate test statistics between the treatment and control cohorts. This suggests that the treatment intervention likely had a positive impact on urine rate outcomes. The urine test abstinence rate, as indicated by the urine rate, was significantly higher in the DCM group (mean 0.92, 95% CI 0.88 - 0.96) than in the treatment-as-usual group (mean 0.85, 95% CI 0.79 - 0.90; *P*<.01).

XSL•FO
RenderX

Table . *t* test results after matching.

Group	Observed	Mean (SD)	95% CI	*P* value
Urine rate				.01
Control	59	0.85 (0.21)	0.79-0.90	
Treatment	66	0.92 (0.16)	0.88-0.96	
Appointment rate				.001
Control	59	0.50 (0.20)	0.45-0.55	
Treatment	66	0.69 (0.19)	0.65-0.74	

Appointment Attendance Rate

Table 3 shows the appointment attendance rate statistics between the treatment and control cohorts. The appointment adherence rate was substantially higher in the DCM group (mean 0.69, 95% CI 0.65 - 0.74) than in the treatment-as-usual group (mean 0.50, 95% CI 0.45 - 0.55), with an even stronger statistical significance (*P*<.001).

Sensitivity Analysis

We conducted a sensitivity analysis using Stata's mhbounds command, which implements Rosenbaum bounds to evaluate the robustness of treatment effects to potential unmeasured confounding. This method assesses how much hidden bias (Γ) would be required to invalidate the statistical significance of the observed treatment effect. Our findings demonstrate that the treatment effects for both urine test rate and appointment attendance rate are robust to unmeasured confounding across a wide range of Γ values (1-3).

Complete sensitivity analysis results are shown in Tables S1 and S2 in Multimedia Appendix 1. Table S1 in Multimedia Appendix 1 on urine test rate shows that both sig+ and sig− values remain at 0 across all Γ values (1-2), indicating that the treatment effect maintains statistical significance even under strong assumptions of unmeasured confounding. The treatment effect estimate (t-hat) shows remarkable stability, ranging from 0.90 at Γ=1 to 0.86 (t-hat+) and 0.93 (t-hat−) at Γ=2. This minimal change suggests that the effect is highly robust. The CI values remain relatively narrow throughout (0.88 - 0.91 at Γ=1 to 0.84-0.95 at Γ=2), further supporting the stability of the findings.

Table S2 in Multimedia Appendix 1 on appointment rate shows that both sig+ and sig− values remain at 0 across all Γ values, indicating sustained statistical significance. The treatment effect ranges from 0.67 at Γ=1 to 0.58-0.74 at Γ=2, showing slightly more variation than the urine rate analysis but still maintaining clinical significance. While the CI values widen somewhat with increasing Γ values (0.63 - 0.69 at Γ=1 to 0.55-0.77 at Γ=2), they remain within interpretable bounds.

For both outcomes, the experimental group consistently outperformed the control group with statistically significant differences (*P*<.05). The minimal changes in treatment effect estimates and CI values across increasing levels of Γ suggest that our results are highly robust to potential unmeasured confounding. These findings support the conclusion that the intervention was likely effective in improving both urine test abstinence and appointment attendance rates.

Discussion

Principal Findings

Our study aimed to evaluate the effectiveness of DCM in comparison with treatment-as-usual for individuals with SUD. The findings reveal statistically significant differences in both urine test abstinence and appointment attendance among participants in the DCM group compared with the treatment-as-usual group. Patients in the DCM group showed higher urine abstinence rates (92% vs 85%; *P*<.01) and substantially better appointment attendance rates (69% vs 50%; *P*<.001). These results align with a previous study [28], which found that digital health interventions can effectively enhance medication adherence among individuals with opioid use disorder. Also, DeFulio [14] found that inner-city patients with SUD who were mostly treated with buprenorphine and the DynamiCare app showed significantly higher rates of treatment attendance in study months 2-4 (9.6% - 18.0% increases) and odds ratio of 4.84 for greater drug abstinence and medication adherence than the treatment-as-usual group (*P*<.05). These results highlight the potential of DCM as an innovative intervention for improving key treatment outcomes in SUD care. Our findings extend the existing literature on traditional CM approaches and contribute to the much-needed evidence on the efficacy of DCM for drug treatment, supporting the broader transition toward digital therapeutic interventions in addiction treatment [12].

These results suggest that integrating digital tools into CM can enhance both treatment abstinence and engagement in care, consistent with previous studies highlighting the promise of digital interventions in substance misuse treatment [10,14]. This finding suggests that DCM interventions are effective in promoting abstinence, a critical metric in SUD treatment. Such gains align with previous findings on CM's efficacy in motivating behavior change. Mobile apps can better communicate between the care team and the patients and could potentially save lives [29].

A 19% increase in appointment attendance with DCM is clinically meaningful, consistent with previous findings on digital interventions on treatment adherence [25]. This increase highlights the role of DCM in fostering engagement with care, an essential factor for successful treatment outcomes. By leveraging digital tools to deliver incentives, DCM may reduce

XSL•FO
RenderX

the impact of logistical challenges, thus promoting consistent participation in scheduled appointments [30]. Compared with patients who received treat-as-usual alone, those who had treatment-as-usual coupled with app-based CM had a noticeably higher chance of remaining in treatment for longer [31]. These results corroborate earlier research that concluded that receiving rewards motivates patients to maintain treatment compliance [10].

The digital platform can decrease obstacles to incentive receipt and help remove infrastructure barriers that may impact attendance rates. Urban-rural disparities exist in CM availability [32]. Digital interventions could expand access to a broader patient population [33,34], suggesting that DCM could help reduce this disparity. Thus, DCM could help address the inequalities in health care support for the underserved groups [35,36].

According to earlier studies, digital interventions decrease the impact of logistical obstacles to participation, such as schedule conflicts and travel time, which are frequent problems in conventional therapy settings. The results support these views, which highlight DCM's capacity to encourage long-lasting behavioral improvements in SUD populations [14,37]. In sum, DCM interventions align with behavioral reinforcement principles by providing timely rewards for desirable behaviors, thus enhancing adherence and reducing substance misuse [10].

Limitations

Despite these promising findings, certain limitations warrant consideration. First, the study did not explore differences in outcomes across social determinants of health, motivation levels, or comorbidity. Future studies will explore the efficacy of DCM on SUD treatment relative to educational level, economic stability, transportation availability, and housing stability. Nevertheless, our sample's high proportion of Medicaid and noncommercial insureds suggests that patients at risk due to social determinants of health challenges may benefit. The gender imbalance may affect the generalizability of our findings. Future research should include larger samples, powered to support more robust gender-stratified analyses.

Second, the study may have excluded individuals less familiar with digital technology. App features and user experience could affect engagement with DCM. This digital divide may disproportionately affect certain demographic groups, such as older adults or those from lower socioeconomic or educational backgrounds, potentially limiting the generalizability of the findings to all individuals with SUD. However, the front-loading of rewards is designed to motivate patients to overcome tech unfamiliarity.

Third, the study focused on outcomes, specifically drug abstinence and appointment adherence, during the intervention. While these measures are critical indicators of treatment success, the study did not assess the sustainability of behavior changes following the conclusion of the intervention. Follow-up was determined to be ineffective due to changing patient contact information and availability to be able to continue data collection post intervention. The 12-month duration of the study, however, exceeds that of many previous trials.

Fourth, this study used a quasi-experimental design with alternating assignment rather than true randomization. The selection of participants was based on a sequential allocation process where every other patient was offered participation in the DCM intervention. The nonrandom assignment process introduces selection bias. Patients who chose to participate in the DCM project may differ systematically from those who declined to do so, particularly in terms of motivation, technological aptitude, or other unmeasured characteristics that could influence treatment outcomes. Self-selection into the experimental group could mean that more motivated or tech-savvy patients were overrepresented in the experimental group, which could impact the generalizability of results. However, we conducted postmatching analyses to reduce observable confounding, and the statistically significant differences observed in primary outcomes suggest that the intervention still had a meaningful impact despite this limitation.

While our PSM approach attempted to balance observed characteristics between groups, it cannot account for unmeasured confounders that might have influenced both group assignment and outcomes. Although we conducted sensitivity analyses to assess the robustness of our findings to unmeasured confounding, selection bias remains an inherent limitation of our design. At the same time, anecdotally, it does not appear that technology was a limiting feature for those opting out. In addition, the variability observed within the appointment and urine rates suggests that individual differences, including socioeconomic status, comorbid conditions, and personal motivation, may affect treatment outcomes. Future research should explore these contextual factors to identify and address potential barriers to successful implementation and should use randomized controlled designs when feasible.

Finally, while our PSM successfully balanced most covariates between treatment and control groups, a moderate imbalance in gender (SMD=0.23) persisted after matching. This exceeds our predetermined threshold of 0.2 and represents a potential limitation. The potential influence of this residual gender imbalance on our results cannot be fully ruled out and should be explored in future studies with larger sample sizes that would enable gender-stratified analyses. Future studies should use more stringent matching algorithms or consider exact matching on gender to eliminate this potential source of bias.

Conclusions

This article supports the validity of DCM as an intervention to improve treatment adherence and outcomes for people with SUD. For the DCM group, urine test abstinence and appointment attendance were significantly higher than those in treat-as-usual recipients. These results suggest that technology-enabled interventions can improve patient compliance and engagement.

The improvements in both abstinence and appointment attendance suggest that DCM could be a cost-effective addition to SUD treatment, especially considering associated potential reductions in health care utilization, emergency services, and societal costs associated with SUDs. DCM additionally allows for greater accessibility while also removing administrative overhead due to automation. As cell phone usage continues to grow, potential equity concerns should be diminished.

XSL•FO
RenderX

The findings could provide additional support for enacting policies that reimburse DCM as a viable medical protocol that improves treatment compliance and outcomes. Our retention and abstinence outcomes support the inclusion of DCM in emerging value-based payment models. Currently, most state Medicaid programs do not have specific billing codes for CM. However, DynamiCare platform's verification features address a key concern in current reimbursement policies by providing robust documentation of incentive distribution and behavioral verification, directly meeting Medicaid's increasing requirements for service documentation and accountability. At the same time, we recommend that state and federal regulatory bodies establish clear guidelines for DCM implementation that address privacy concerns and verification standards.

Acknowledgments

The authors are grateful to DynamiCare Health, Talbert House, Journey Recovery Care of St. Elizabeth Healthcare, the Greater Cincinnati Behavioral Health Services, and the Center for Addiction Treatment in Cincinnati for their interest, support, and participation in this research project. Funding was provided by Realworks (grant 4001541), an Ohio-based nonprofit. The authors are grateful for it. Generative artificial intelligence (Copilot) was used to proofread a small portion of the manuscript for grammar check and readability.

Data Availability

The data are not publicly available per the data use agreements with each of the participating sites and the funder.

Authors' Contributions

XZ contributed to writing and analysis of the original draft. VH contributed to conceptualization, reviewing, and editing of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Integrated digital interventions for the treatment of comorbid depression and substance use disorder have been developed, and evidence of their effectiveness is mixed.

Objective: This study aimed to explore potential reasons for mixed findings in the literature on integrated digital treatments. We described the methodologies and core characteristics of these interventions, identified the presence of evidence-based treatment strategies, examined patterns across digital modalities, and highlighted areas of overlap as well as critical gaps in the existing evidence base.

Methods: In June 2024, a literature search was conducted in Google Scholar to identify digital integrated interventions for comorbid major depressive disorder and substance use disorder. Articles were included if they described interventions targeting both conditions simultaneously; were grounded in cognitive behavioral therapy, motivational interviewing, or motivational enhancement therapy; and were delivered at least in part via digital modalities. In total, 14 studies meeting these criteria were coded using an open-coding approach to identify intervention characteristics and treatment strategies (n=25). Statistical analyses summarized descriptive statistics to capture the frequency and overlap of these strategies.

Results: Studies included a range of digital modalities: internet (n=6, 43%), computer (n=3, 21%), smartphone (n=2, 14%), and supportive text messaging interventions (n=3, 21%). Half (n=7, 50%) of the studies included participants with mild to moderate depression symptom severity and hazardous substance use. Only 36% (n=5) of the studies required participants to meet full diagnostic criteria for major depressive disorder for inclusion and 21% (n=3) required a substance use disorder diagnosis. Most interventions targeted adults (n=11, 79%), with few targeting young or emerging adults (n=4, 29%), and only 36% (n=5) reported detailed demographic data. Treatment duration averaged 10.3 (SD 6.8) weeks. Internet-based interventions offered the widest range of treatment strategies (mean 11.7), while supportive text messaging used the fewest (mean 4.6). Common treatment strategies included self-monitoring (n=11, 79%), psychoeducation (n=10, 71%), and coping skills (n=9, 64%). Interventions often combined therapeutic strategies, with psychoeducation frequently paired with self-monitoring (n=9, 64%), assessment (n=7, 50%), coping skills (n=7, 50%), decisional balance (n=7, 50%), feedback (n=7, 50%), and goal setting (n=7, 50%).

Conclusions: Among integrated digital interventions for comorbid depression and substance use, there was noteworthy variability in methodology, inclusion criteria, digital modalities, and embedded treatment strategies. Without standardized methods, comparison of the clinical outcomes across studies is challenging. These results emphasize the critical need for future research to adopt standardized approaches to facilitate more accurate comparisons and a clearer understanding of intervention efficacy.

Introduction

Structured, evidence-based approaches in face-to-face (F2F) settings have proven beneficial for treating major depressive disorder (MDD) and substance use disorder (SUD) [1,2], which frequently co-occur. Researchers are increasingly leveraging digital platforms to enhance the reach and accessibility of these treatments. This shift is particularly relevant given that, among treatment-seeking individuals with MDD, the prevalence of concurrent SUDs ranges from 8.6% to 25%, with lifetime prevalence estimates as high as 42.8% [3,4]. Co-occurring MDD and SUD are associated with heightened symptom severity [5], psychosocial instability, and substantial societal and medical burdens due to disability and health care costs [6-9].

Current treatment guidelines recommend integrated treatment for individuals with co-occurring MDD and SUD to improve treatment outcomes and promote long-term recovery [10]. Cognitive behavioral therapy (CBT), proven effective for both disorders individually in F2F settings [11,12], has been adapted into integrated cognitive behavioral therapy (ICBT) to address the specific challenges of co-occurring illness. ICBT focuses on helping individuals identify and challenge unhelpful thought patterns—such as catastrophizing, black-and-white thinking, and negative self-evaluation—that contribute to both low mood and substance use. In addition, ICBT emphasizes engaging in healthy activities, building a supportive social network, and incorporating motivational interviewing (MI) and motivational enhancement therapy (MET) to encourage behavior change [1,13-16]. Early sessions include clinical assessment, diagnostic feedback, case formulation covering the development and maintenance of the conditions, psychoeducation about the relationship between depression and substance use, and MI to elicit behavior change planning. ICBT addresses maladaptive cognitions by helping individuals identify harmful thought patterns, generate alternative, healthier thoughts, and practice thought-challenging techniques in situations that could potentially lead to substance use relapse or heightened depressive symptoms. It also encourages individuals to plan and schedule activities that promote positive affect and manage pressures that could lead to relapse. Socially, ICBT provides assertiveness and communication training to strengthen social interactions and boost confidence in resisting social pressures to use substances. Finally, ICBT encourages individuals to build coping skills, emergency plans, and relapse prevention strategies.

Despite the availability of ICBT and growing evidence for its effectiveness, most individuals with comorbid MDD and SUD do not receive this recommended treatment [17-19]. Among adults with both conditions, 66% receive substance use treatment, 52% receive mental health treatment, and only 13% receive care for both [20-22]. This siloed approach results in inadequate care [23,24]; some studies show that treating MDD or SUD alone does not increase remission rates of the untreated disorder [25,26]. Many treatment settings lack the resources to meet these individuals' needs [27]. There is a clear need for accessible, scalable, and effective integrated MDD and SUD treatment programs.

Systematic reviews and meta-analyses have shown that digital interventions can effectively reduce depression severity [28] and substance use [29] when addressed individually. Recent studies suggest that digital integrated treatment may also be effective for co-occurring disorders [30,31]. However, the evidence base for digitally integrated interventions remains limited, with mixed results regarding effectiveness [30,31]. The variability in treatment outcomes among digitally integrated treatments makes it unclear why some interventions succeed in improving depression and substance use outcomes while others fall short.

This review examines digital modalities, methodological approaches, inclusion and exclusion criteria, and evidence-based treatment strategies across existing integrated digital treatments for MDD and SUD. It identifies commonly used strategies, as well as critical gaps and overlaps, to distill effective approaches that can be tailored to specific population needs [32]. In doing so, this analysis aims to highlight treatment strategies that may enhance the efficacy of future digital integrated treatments.

Methods

Digital Intervention Identification

In June 2024, the first author (GJ) conducted a literature search in Google Scholar for digital, integrated interventions for MDD and SUD. Eligible articles included one of the terms in Table 1 in the title, abstract, keywords, or article text. The reviewer also screened the reference list of all eligible articles, plus a search of all articles that had cited the included papers.

XSL•FO
RenderX

Table 1. Inclusion criteria keywords for digital major depressive and substance use disorders intervention studies.

Category	Term
Digital technology	"digital health," "digital intervention," "eHealth," "mHealth," "online," "internet," "text messages," "text-messaging," "mobile," "mobile phone," "smartphone," "smartphone app," "app," "computer," "computer-based"
Depression-related	"major depressive disorder," "MDD," "depressive," "depression," "depressed mood"
Substance use–related	"substance use disorder," "SUD," "alcohol misuse," "alcohol use disorder," "hazardous alcohol use," "alcohol use," "alcohol abuse," "cannabis," "smoking cessation"
Comorbidity	"dual diagnosis," "comorbidity," "co-occurring"
Study design	"randomized trial," "randomized controlled trial," "clinical trial," "pilot study"
Intervention or methodology	"intervention," "program," "treatment," "therapy," "integrated treatment," "integrated"

Inclusion and Exclusion Criteria

A report of a digital intervention trial of MDD and SUD treatment was included if (1) the article reported on an intervention intended to improve substance use and depression simultaneously, and encompassed various severity levels from mild symptoms to diagnostic thresholds; this included participants diagnosed with MDD and SUD, as well as those without confirmed diagnoses; (2) the treatment described was grounded in CBT, MI, or MET; (3) the treatment was delivered entirely or partially via digital modality (computer, smartphone, internet, and text message) outside of the traditional F2F therapy setting; and (4) the article was written in English as a peer-reviewed journal article. Studies were excluded if they (1) targeted only depression or only substance use, (2) were published protocols without preliminary outcomes or findings, (3) did not specify theoretical underpinnings or an evidence-based rationale for the treatment, or (4) were based on approaches other than CBT, MI, or MET.

Identification of Study Characteristics

For each study included in the review (Multimedia Appendix 1), we extracted and summarized inclusion and exclusion criteria, study design, measures used to assess MDD, SUD, treatment adherence, and other outcomes the digital modality used, as well as study duration.

Treatment Strategies Coding Procedure

Twenty-five treatment strategies (Table 2) were coded in July and August 2024. The content analysis coded any mention of used treatment strategies. The intensity of treatment strategies, specifically the frequency of their presentation within the interventions, was not systematically assessed. In addition, the authors did not independently verify whether these strategies were actually implemented beyond the descriptions provided in the articles and associated supplemental materials. In total, three authors (GJ, QG, and HA) coded all reports (n=14) using an open-coding approach [33]. Initially, we conducted a line-by-line coding of each original article, allowing treatment strategies to emerge directly from the data without using a predefined codebook. This inductive process was followed by team discussions to compare our codes to existing evidence-based treatment strategies [13,17,34-37]. Any disagreements in coding were resolved through consensus among the researchers to confirm that the final coding was consistent with and reflective of the included studies [38].

XSL•FO
RenderX

Table 2. Treatment Strategies (n=25) identified in the reviewed apps (n=14).

Treatment strategy	Definition
Activity scheduling	Planning or scheduling activities that counter low mood or substance use (eg, planning and logging daily activities, setting reminders for activities, and tracking activity progress)
Assertiveness training	Teaching individuals to express needs and desires confidently or respectfully (eg, roleplaying communication skills)
Assessment	Assessment of symptoms or behaviors (eg, completing self-report questionnaires like PHQ-9[a])
Change plans	Creating a structured outline of steps needed to achieve behavioral change, identifying goals to achieve plan, barriers, resources, and strategies to overcome (contingency plans and detailed action steps)
Cognitive restructuring	Identifying and challenging negative thought patterns (eg, reframing and reviewing automatic thoughts)
Coping skills	Teaching strategies to manage mood and cravings
Decisional balance	Weighing the benefits and drawbacks of changing versus maintaining current behaviors (eg, advantages or disadvantages analysis or pros and cons)
Drug refusal skills	Specific content related to effectively refusing substances (eg, interactive scenarios and practice exercises)
Feedback	Providing users with personalized feedback based on their input (self-report questionnaires or assessments), progress, or behavior patterns
Goal setting	Any mention of setting goals or setting specific, measurable, achievable, relevant, and time-bound objectives
Harm reduction	Strategies to reduce negative consequences of substance use
Homework assignments	Tasks for users to complete between sessions
Interpersonal effectiveness	Improving social, communication, and relationship skills
Mindfulness	Exercises to increase present-moment awareness or reduce stress (eg, mindful meditations)
Problem-solving	Developing effective solutions to challenges and obstacles
Psychoeducation	Information about depression, substance use, the relationship between mood and substance use, description of symptoms, connection between thoughts, mood, and behaviors
Relapse prevention	Strategies to sustain progress and prevent relapses (eg, discussion of how to maintain wellness)
Relaxation	Techniques to reduce physical or mental tension (eg, guided progressive muscle relaxation)
Reminders	Alerts to prompt engagement with intervention or health-related activities (eg, daily reminders for the use of intervention, medication, activities, or mindfulness)
Resources	Providing access to additional support or therapeutic options and information outside of intervention
Risk management	Identifying and mitigating potential risks to substance use or mood, learning to recognize situations and emotions that lead to use or depressive episodes, stimulus control, and managing environmental cues that trigger use or negative emotions.
Self-care	Encouraging healthy lifestyle habits to support recovery (eg, exercise, sleep hygiene, and diet)
Self-monitoring	Tracking or logging symptoms, behaviors, progress, daily experiences, and emotions (eg, writing in a diary, mood monitoring, and tracking substance use)
Social supports	Building or maintaining a supportive network (eg, forums or chat features for peer support)
Time management skills	Techniques to organize and prioritize tasks

[a]PHQ-9: Patient Health Questionnaire-9.

Statistical Analyses

The number, frequency, and percentage of treatment strategies used in the included interventions were summarized using R (version 4.3.2; R Core Team). Plots summarizing the frequencies and overlap of treatment strategies were generated using the "ggplot2" [39] and "pheatmap" [40] packages in R.

Results

Intervention Characteristics

Of the 14 studies that met inclusion criteria (Multimedia Appendix 1) [41-55], half of the studies (n=7, 50%) cited a protocol paper with an in-depth description of the research methodology, including participant recruitment procedures, data collection methods, and statistical analysis plans [56-62].

Study Design

The majority of studies were randomized controlled trials that compared their integrated digital treatment against treatment as usual (n=5, 36%) [44,47,48,50,55], assessment only condition (n=2, 14%) [42,54], digital health monitoring (eg, HealthWatch; n=1, 7%) [43], or the provision of psychoeducational materials (n=1, 7%) [46].

Some studies compared their integrated treatments against digital mood- or substance-only conditions (n=2, 14%) [44,45].

XSL•FO
RenderX

A minority (n=2, 14%) of studies used an active, in-person comparator, such as F2F integrated treatment or person-centered therapy [41,52], or had no comparator (n=2, 14%; eg, single-arm feasibility trials) [51,53].

Eligibility Criteria and Participants' Characteristics

Only 5 (36%) studies required participants to meet *DSM* (*Diagnostic and Statistical Manual of Mental Disorders*) criteria for MDD, which was confirmed using the Structured Clinical Interview for *DSM-IV* (SCID) [63] or Psychiatric Research Interview for Substance and Mental Disorders (PRISM) [64]. Only three (21%) studies required diagnostic verification of SUD [48-51].

Half (n=7, 50%) of the studies enrolled participants based on the presence of mild to moderate depression symptoms without confirmation of *DSM* criteria [41-47]. These symptoms were assessed via the Beck Depression Inventory-II (BDI-II), Depression, Anxiety, and Stress Scale-21 items, Center for Epidemiologic Studies Depression Scale (CES-D) or Patient Health Questionnaire-9 (PHQ-9) [65-68]. These studies also included participants with problematic or hazardous alcohol or cannabis use, assessed by the Alcohol Use Disorders Identification Test [69] or by how often they used these substances each week.

Two (14%) studies did not require any formal clinical diagnosis or symptomatology of either depression or substance use, but targeted mood and substance use [53,54].

Most studies (n=11, 79%) evaluated intervention effectiveness among adults (≥18 years). Of these, 4 (29%) studies tested interventions among emerging and young adults (ages 18-35 years) [42,43,46,55]. Three (21%) studies included adolescent participants, with 2 (14%) enrolling individuals aged 16 years and older [41,52], and 1 (7%) enrolling those aged 17 years and older [54]. Only 5 (36%) studies reported detailed demographic information, including race, ethnicity, sexuality, socioeconomic status, and educational background, within their participant samples [42,46,47,53,54].

Digital Modality

Regarding the type of technology, the majority were internet-based (n=6, 43%) [42-46,55], followed by offline, computer-based (n=3, 21%) [51,52,70], supportive text messages (n=3, 21%) [48-50,53], and smartphone apps (n=2, 14%) [47,54]. Half were self-guided (n=7, 50%) [42,43,45,47,48,50,53]. The other half involved some level of human support (n=7, 50%) delivered by a licensed psychologist or therapist (n=3) [41,51,52], by supervised doctoral students (n=1) [55], or by trained volunteers (n=1) [54]. Two guided studies did not provide details on the human supporters' educational background or training qualifications [44,46].

Treatment Duration and Adherence

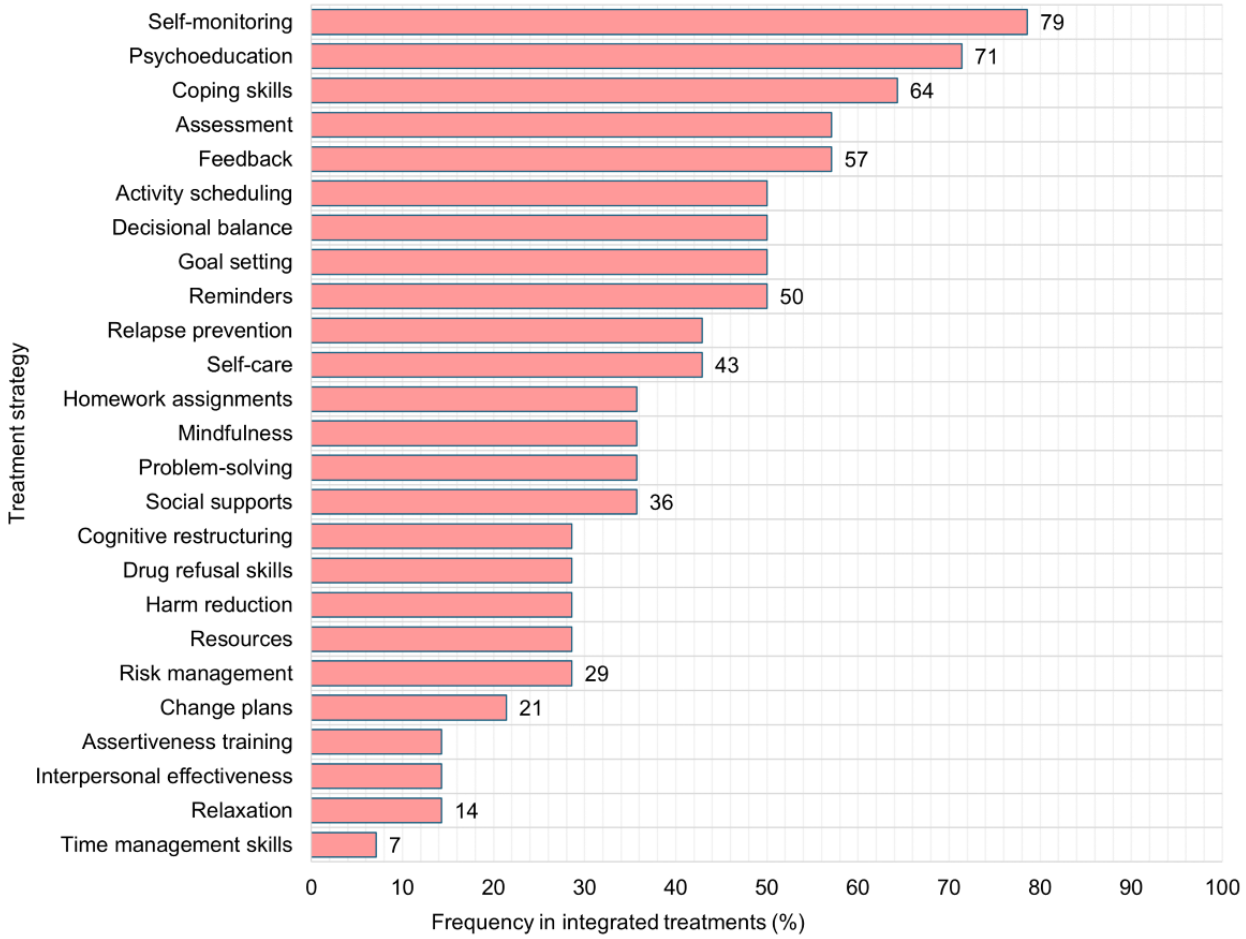
Intervention length ranged from a single session (n=1, 7%) [42], to 4-6 weeks (n=3, 21%) [43,44,54], 8-10 weeks (n=5, 36%) [41,46,47,51,52], and 12-24 weeks (n=5, 36%) [45,48,50,53,55]. Several of the interventions had participants completing multiple modules within a week. On average, the interventions were 10.3 (SD 6.8, median 10, range 0-24) weeks, with text messages having the longest average duration of 20 (SD 6.9) weeks, followed by computer-based (mean 10, SD 0), internet-based (mean 7, SD 4.7), and smartphone apps (mean 6, SD 2.8). Follow-up assessments were conducted for 1 month (n=3, 21%) [42,51,54], 3 months (n=9, 64%) [41,43-45,48,50,52,53,55], 6 months (n=9, 64%) [43-46,48,50,52,53,55], and 12 months (n=3, 21%) [50,52,55]. Most studies (n=11, 79%) included information about the number of sessions or modules completed or the total amount of time the intervention was used; though this metric was not assessed consistently across studies [41,43-47,51-55].

Outcome Measurement

Studies reported changes in depression symptom severity using the BDI-II (n=6, 43%) [41,42,48,50,52,66], CES-D (n=4, 29%) [44-46,55], or PHQ-9 (n=3, 21%) [43,51,54]. One (7%) study used the Clinical Outcomes in Routine Evaluation to measure overall changes in psychological health and well-being [53,71].

Almost all studies focused on alcohol as the primary comorbid substance (n=13, 93%) [42-46,48,50,53,55], with some (n=4, 29%) of these also examining problematic cannabis use [41,51,52,54] or tobacco smoking (n=1, 7%) [54].

Substance use outcomes were reported using a variety of measurement tools across studies. The most commonly used instrument was the Timeline Follow-Back (n=6, 43%) [44,46,48,50,51,55,72]. Other measures included the Alcohol Use Disorders Identification Test (n=2, 14%) [45,54,69], the Opiate Treatment Index (n=2, 14%) [41,52,73], the Daily Drinking Questionnaire (n=1, 7%) [42,74], the Rutgers Alcohol Problem Index (n=1, 7%) [42,75], and beverage-specific past week consumption (n=1, 7%) [43]. One (7%) study focused on mental well-being more broadly (distress reduction), so they did not directly assess or report substance use outcomes [53]. Using these measures, studies' primary substance use outcomes were the number of drinks over 7 days (n=6, 43%) [42-46,55], substance use consequences (n=3, 21%) [42,45,46], cumulative abstinence duration (n=2, 14%) [48,50], days to first drink (n=2, 14%) [48,50], and urine toxicology results (n=1, 7%) [51].



Intervention Content

Overview

All the studies included (n=14, 100%) contained treatment content based on CBT, MI, or MET. Figure 1 shows the frequency of inductively identified treatment strategies (n=25) across all digital treatment modalities.

XSL•FO
RenderX

Figure 1. Treatment strategies across integrated digital tools.

Fewer than half of the studies (n=5, 36%) reported session-by-session details about the evidence-based treatment strategies offered in the intervention [43,44,47,54,55].

All studies used multiple treatment strategies (mean 9.71, SD 5.08, median 8.5, range 3-19). Most studies used between 5 and 14 treatment strategies. A detailed list of coded strategies in each study can be found in Multimedia Appendix 2. The most frequently used strategies were self-monitoring (n=11, 79%), psychoeducation (n=10, 71%), coping skills (n=9, 64%), feedback and assessment (n=8, 57%). Half of the studies (n=7, 50%) included activity scheduling, decisional balance, goal setting, and reminders. Less common strategies were time management skills (n=1, 7%), relaxation, interpersonal effectiveness, and assertiveness training (n=2, 14%).

We evaluated the overlap of treatment strategies in the interventions across digital modalities. See Figure 2. Psychoeducation had the highest overlap with other strategies, implemented most frequently in combination with self-monitoring (n=9, 64%), assessment (n=7, 50%), coping skills (n=7, 50%), decisional balance (n=7, 50%), feedback (n=7, 50%), and goal setting (n=7, 50%). Self-monitoring also showed substantial overlap with feedback (n=6, 43%) and coping skills (n=7, 50%). Coping skills were commonly combined with goal setting (n=4, 29%) and feedback (n=6, 43%). Several strategies had minimal overlap with others, including time management skills, assertiveness training, interpersonal effectiveness, relaxation, and mindfulness.

XSL•FO
RenderX

Figure 2. Heatmap of treatment strategy overlaps across digital modalities.

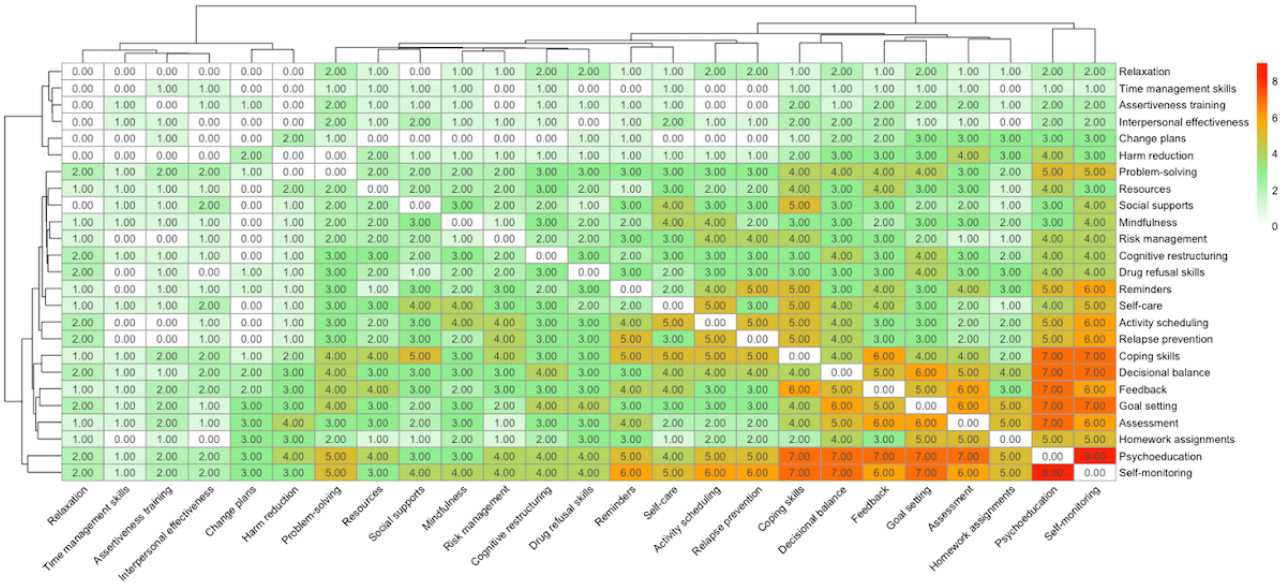


Figure 2 visualizes the overlap of treatment strategies across different interventions. Each row and column represent a treatment strategy, the number within each cell indicates the frequency of overlapping between pairs of treatment strategies across interventions. For example, self-monitoring and psychoeducation are used as strategies in 9 of the 14 studies reviewed. The heatmap uses a color gradient where white and green represent no or minimal overlap and orange or red represents high overlap.

Internet-Based Interventions

The internet-based interventions (n=6) offered the widest range of treatment strategies (mean 11.7, SD 6.0, median 13.5, range 3-19; Figure 3). A total of 5 of 6 included psychoeducation and feedback. Four included self-monitoring, reminders, relapse prevention skills, decisional balance, coping skills, activity scheduling, and assessment. Only 3 of the 25 identified treatment strategies (12%) were not included in any of the internet-based interventions.

XSL•FO
RenderX

Figure 3. Percentage of treatment strategies by digital modality.

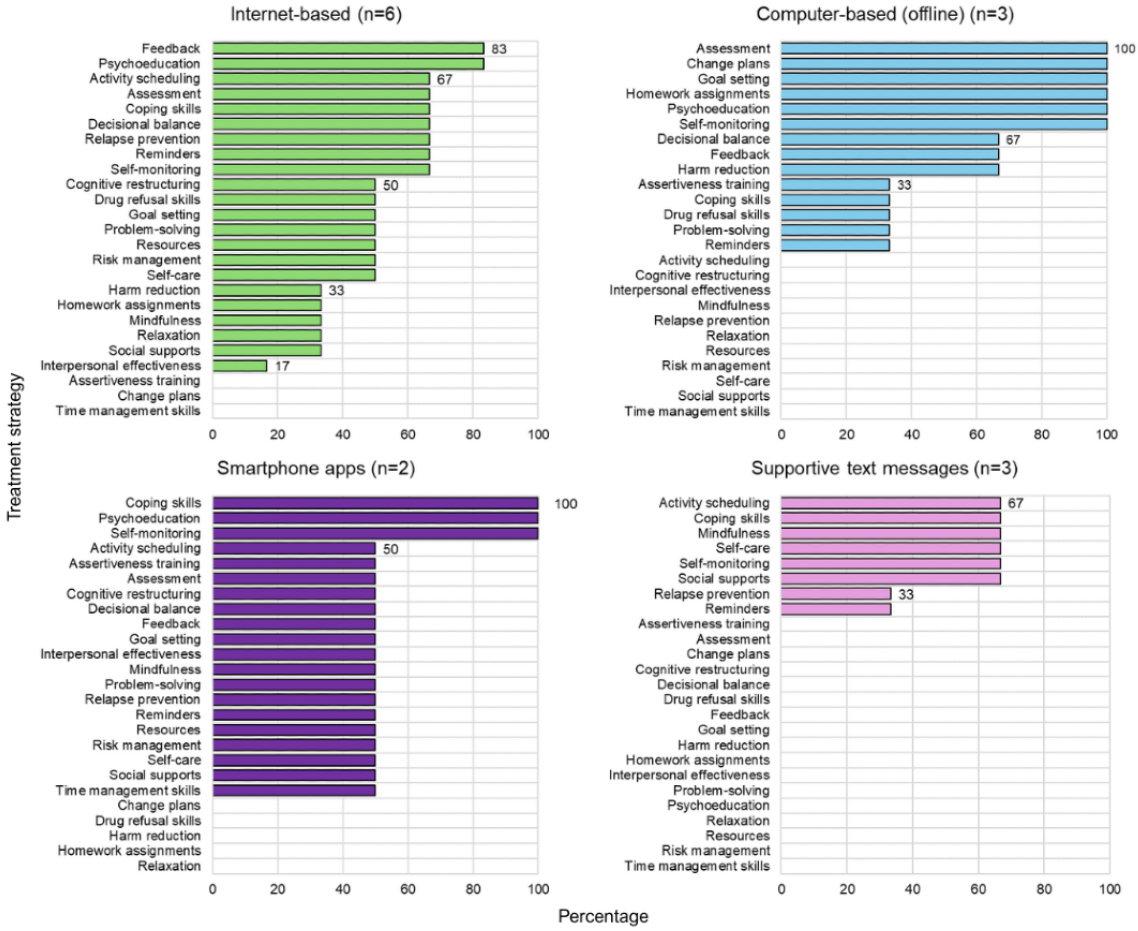

Figure 3 shows the frequency of treatment strategies organized by type of digital modality with the denominator for each graph being the total number of interventions within that digital modality.

Computer-Based Interventions

The computer-based interventions (n=3) included an average of 9.7 treatment strategies (SD 2.08, median 9.0, range 8-12; Figure 3). All included self-monitoring, psychoeducation, homework assignments, goal setting, change plans, and self-assessments. Two also included harm reduction skills, feedback, and decisional balance. A larger number of strategies were missing from computer-based interventions: 11 of the 25 strategies (44%) were not included in this modality.

Smartphone Apps

The smartphone apps (n=2) included an average of 11.5 (SD 6.36, median 11.5, range 7-15; Figure 3) treatment strategies. Both included self-monitoring, psychoeducation, and coping skills. Additional strategies included activity scheduling, assertiveness training, assessment, cognitive restructuring, decisional balance, feedback, goal setting, interpersonal effectiveness, mindfulness, problem-solving, relapse prevention, reminders, sources, self-care, and time management skills, as well as social support (1/2, 50%). Overall, 5 of the 25 (20%) treatment strategies identified across all interventions were not included in either smartphone app.

Supportive Text Messages

The supportive text-messaging interventions (n=3) had the fewest strategies on average, with a mean of 4.6 (SD 0.58, median 5.0, range 4-5; Figure 3). Two of the 3 (67%) interventions included messages related to coping skills, mindfulness, self-care, self-monitoring, and social support. Out of all the digital modalities, supportive text-messaging integrated the fewest treatment strategies, omitting 17 of the 25 (68%) strategies.

Discussion

Principal Results

This study aimed to review integrated digital interventions that support individuals with co-occurring MDD and SUD, focusing on study design and characteristics, demographic inclusivity, and therapeutic strategies. Our findings indicate that these interventions often exhibit significant methodological variability, use inconsistent diagnostic criteria, lack demographic diversity, and implement treatment strategies inconsistently. Addressing these issues is critical for making digital integrated interventions more effective and widely applicable for diverse populations with different levels of comorbidity.

Demographic Diversity and Inclusion Criteria Considerations

Comorbid MDD and SUD vary widely in severity and affect individuals across diverse racial, ethnic, financial, and

XSL•FO
RenderX

educational backgrounds. A main finding of our review was the considerable variation in inclusion and exclusion criteria across studies. Most studies targeted individuals with mild to moderate depression and hazardous substance use, with few requiring clinically validated diagnoses. This focus on mild cases and alcohol use is consistent with current F2F treatments, which primarily address depression or anxiety alongside alcohol misuse [18,76,77]. Emerging interest in cannabis misuse [78,79] is beginning to address a broader scope, but significant gaps remain regarding the effectiveness of digital interventions for other substances. While F2F treatments have tested efficacy in clinically diagnosed MDD and SUD [80], the current focus of existing digital interventions on individuals with subclinical or mild-to-moderate symptom severity raises questions about their applicability for those on the more severe end of the comorbidity spectrum.

Demographic data in these studies were generally limited to age and gender, with few studies reporting on racial or socioeconomic diversity. Diverse sample recruitment is critical for advancing equitable mental health care [81]. Known disparities in MDD and SUD treatment access, where some racial groups face unique barriers such as language differences, cultural mistrust, and lack of social support, demonstrate the need for detailed demographic reporting [82]. Without such data, particularly for socially vulnerable communities, assessing whether these interventions are culturally relevant, effective, or capable of providing necessary access is challenging.

Finally, most studies targeted adult populations, with a limited focus on young adults. This is a significant gap, as young adulthood is a formative period where substance use and mood symptoms have the potential to escalate [83,84]. Early intervention for young adults could promote healthier coping mechanisms, resilience, and overall well-being, potentially thwarting the onset of more severe comorbidity later in life and reducing health care burden [85]. Programs for young adults should be tailored to reach individuals at risk or showing early signs of depression or substance use, even if they have not yet been clinically diagnosed.

Future research should expand inclusion criteria to encompass a broader range of MDD and SUD severity, including clinically validated diagnoses, to evaluate these interventions across diverse clinical profiles. It should also expand beyond alcohol to other substances to address gaps in integrated treatments for varying substance use types. Finally, improved demographic reporting is essential to ensure these interventions are accessible, equitable, and effective across diverse racial, ethnic, and socioeconomic backgrounds.

Methodological Considerations in Assessing Effectiveness

Our review found significant methodological variability across studies, including differences in study design, treatment length, therapist involvement, follow-up periods, outcome measures, and adherence reporting. Study designs varied, with some comparing interventions to active treatments, while others only used assessment or psychoeducation as controls. Treatment duration ranged from a single session to 24 weeks, and therapist involvement also differed, with some interventions being guided and others self-guided. Follow-up periods were inconsistent, from no follow-up to 12 months. Outcome measures varied widely, with depression assessed using tools like the BDI-II and PHQ-9 and substance use measured by tools such as the Timeline Follow-Back with monitoring periods from 7 to 90 days. Adherence reporting was inconsistent as well, with some studies tracking total modules completed and others measuring time spent on the intervention.

Standardizing methodological components would support the identification of effective strategies across diverse populations and clinical settings. For instance, brief smartphone-based interventions may be ideal for community settings or ongoing recovery support, whereas longer, more intensive computer-based programs may better serve individuals requiring intensive, structured care. Standardization would allow for clearer comparisons across studies and more precise matching of intervention tools to treatment needs and stages.

Variability and Integration of Treatment Strategies Across Digital Modalities

The reviewed interventions consistently included evidence-based strategies grounded in CBT, MI, and MET, though fewer than half provided detailed session-by-session descriptions. The number of strategies used varied widely, with web-based interventions including the most (3 to 19 strategies), followed by smartphone apps, computer-based programs, and supportive text messaging, which used the fewest.

The most frequently used strategies across digital modalities were self-monitoring, psychoeducation, coping skills, feedback, and assessment. About half of the studies incorporated activity scheduling, decisional balance, goal setting, and reminders, while less common strategies included time management, relaxation, interpersonal effectiveness, and assertiveness training. These findings align with existing literature on CBT for MDD and SUD. For instance, a study of CBT experts rating effective components of CBT for depressed adults emphasized the importance of psychoeducation, feedback, and activity scheduling and monitoring [86], reflecting the presence of these strategies in our findings. Similarly, a meta-review of effective interventions for alcohol use disorder identifies feedback, goal setting, and self-monitoring as commonly used strategies, further supporting the frequent use of these strategies in the included studies [87]. However, strategies such as assertiveness training, drug refusal skills, and contingency management, important for SUD treatment [88-90], were less frequently used in the digital interventions we analyzed, highlighting areas for further exploration, especially in addressing the substance use aspect of these integrated treatments.

To our knowledge, this study is the first to map the overlap of integrated digital strategies for MDD and SUD. The heatmap (Figure 2) shows that strategies like psychoeducation often overlap with assessment, goal setting, feedback, and coping skills, covering core elements of ICBT [16]. However, the map also reveals a “scattered” implementation pattern across different modalities. Although CBT is a protocolized treatment, the map demonstrates that there is no standardized approach to integrating these evidence-based strategies, potentially contributing to the variability in treatment outcomes. Some

XSL•FO
RenderX

critical strategies for MDD and SUD, such as activity planning (for depression) [91] and drug refusal skills (for substance use) [87], appear less frequently despite being widely recognized as effective in the literature. While future research should explore innovative ways to adapt these more challenging strategies to a digital format, it's important to acknowledge that some may not fully translate, presenting a persistent limitation of digital approaches. To address this challenge, integrated hybrid models that combine digital interventions with in-person components may offer a more effective solution [92,93].

The scattered distribution also suggests that some interventions may over-rely on strategies that lend themselves well to digital formats (eg, psychoeducation and self-monitoring) while neglecting others that, although potentially more effective, are harder to adapt digitally (eg, practicing drug refusal skills, interpersonal effectiveness, or roleplaying). The nature of some modalities, such as text messaging, inherently limits the strategies that can be implemented. For instance, the simplicity and brevity required for text messaging make it difficult to include more complex strategies, which may require interactive or intensive engagement, such as practicing communication skills or cognitive restructuring. Researchers should recognize that different digital modalities may be suited to different purposes; for example, text messaging may be better suited for ongoing recovery support, while smartphones or internet-based platforms might be more appropriate for delivering more detailed, longer-duration interventions. This understanding should guide the design and evaluation of future digitally integrated interventions, ensuring that each modality is used for its strengths rather than attempting to incorporate all treatment strategies, which could overwhelm the capabilities of certain modalities.

The variability in strategy implementation within digital treatments for MDD and SUD identifies areas for advancement in research and clinical practice. While reflecting the flexibility of digital interventions, these inconsistencies make it difficult to understand whether the issues lie within the digital format itself or the strategies themselves. Future research should focus on testing specific strategies within defined digital modalities to clarify their impact. Comparative studies could, for instance, assess whether strategies like psychoeducation, self-monitoring, and activity planning are more effective on particular platforms (eg, smartphone apps) for specific demographics, such as young adults or those with severe SUD. Identifying the most impactful strategies will help tailor interventions to better meet patient needs based on comorbidity severity.

Strengths and Limitations

This study reviewed all available digitally integrated treatments for MDD and SUD rather than limiting to only one kind of digital modality. The results offer a broad picture of the present status of digital treatments and their treatment strategies. This review will guide future research and development of these tools by encouraging developers and researchers to be more transparent about the evidence-based strategies incorporated in these interventions, contributing to the effectiveness or lack thereof. This review is limited in that it serves as a descriptive analysis, primarily focused on observing and cataloging the characteristics of the individual treatments and identifying frequencies of treatment strategies used in integrated digital interventions for MDD and SUD. While it provides an idea of the strategies used across different modalities, this study lacks the methodological grounding necessary to draw definitive statistical connections between specific strategies and their effectiveness. As a result, we cannot confidently infer which strategies are most closely associated with successful treatment outcomes or which combinations might be more effective in different contexts. Furthermore, the description of intervention characteristics was based on whether the study provided session-specific details about the implemented evidence-based strategies delivered during the intervention, which may have limited the precision of our treatment coding. Therefore, this study's findings should be viewed as preliminary, observing trends that warrant further investigation.

Conclusion

Digital integrated treatments for MDD and SUD have the potential to expand access to evidence-based treatments for individuals with comorbid MDD and SUD. Existing digital integrated treatments offer a wide range of treatment strategies. However, methodological variability in research to date makes summarizing efficacy challenging at this time and highlights study reporting details that will be important for future replicability and generalizability of this literature.

Acknowledgments

This research was supported by a NIDA Career Development Program in Substance Use and Addiction Medicine (principal investigator AEE, K12 DA043490).

Authors' Contributions

GKJ contributed to conceptualization, methodology, investigation, writing—original draft, and formal analysis. QG handled the investigation, writing—review, and editing. HA performed investigation, writing—review, and editing. AEE managed writing–review and editing, supervision, and funding acquisition.
SW managed writing—review and editing, and supervision.

Conflicts of Interest

SW is a presenter for the Massachusetts General Hospital Psychiatry Academy in educational programs supported through independent medical education grants from pharmaceutical companies. She has received royalties from Guilford Publications,

XSL•FO
RenderX

New Harbinger Publications, Springer, and Oxford University Press. SW has also received speaking honoraria from various academic institutions and foundations, including the International Obsessive Compulsive Disorder Foundation, the Tourette Association of America, and the Centers for Disease Control and Prevention. In addition, she received honoraria for her role on the Scientific Advisory Board for One-Mind (PsyberGuide), Koa Health Digital Solutions LLC, and Noom, Inc. SW has received research support from Koa Health Digital Solutions LLC.
AEE has received speaking honoraria from various academic institutions. She has received editorial support from Pfizer Inc for manuscripts related to the EAGLES trial. In addition, she received honoraria for her role on a Report from the Surgeon General. AEE has received research support from her institution from Korea Advanced Institute of Science and Technology and the National Institutes of Health through a subcontract from Charles River Analytics, Inc.

Abstract

Background: Digital social activity, defined as interactions on social media and electronic communication platforms, has become increasingly important. Social factors impact mental health and can contribute to depression and anxiety. Therefore, incorporating digital social activity into routine mental health care has the potential to improve outcomes.

Objective: This study aimed to compare treatment augmented with an electronic dashboard of patient's digital social activity versus treatment-as-usual on patient-rated outcomes symptoms of depression in a randomized trial of patients with mood and anxiety disorders.

Methods: We developed a personalized electronic dashboard summarizing a participant's digital social activity. This dashboard, collaboratively discussed during mental health visits, was used to augment clinical care and tested in a randomized trial against treatment-as-usual. Clinicians and patients were recruited from outpatient psychiatry clinics. Patients were eligible if they were 12 years or older and were receiving treatment for a mood or anxiety disorder. Psychiatric symptoms measures for depression (primary outcome measure) and anxiety (secondary outcome measure) were obtained at each clinic visit as part of measurement-based standard of care. Baseline and 3-month follow-up assessments included a measure of mental health status and therapeutic alliance measure. Collateral information and clinical action scale were also collected at each visit.

Results: A total of 103 patients consented to participate, 97 of whom were randomized to the dashboard arm (n=49) or the treatment-as-usual arm (n=48). There were no differences in psychiatry symptom rating scores or mental health status between the two arms. However, there was a significant increase in the discussion of digital social activity with the intervention, and it did not appear to change patient therapeutic alliance.

Conclusions: The incorporation of a personalized electronic dashboard into clinical care was feasible and led to an increased discussion of digital social activity, but there was no impact on mental health outcomes.

Introduction

This study reports on the results of a randomized trial for patients with mood or anxiety disorders comparing treatment-as-usual (TAU) augmented with an electronic dashboard provided to clinicians for tracking their patients' digital social activity versus TAU. Digital social activity is defined as patient interactions on social media or through electronic communication such as texting. It is well established that social factors—such as social support, stressful life events, social isolation, discrimination, socioeconomic status, family dynamics, peer networks—are important in the development and progression of depression and anxiety disorders [1-5]. Moreover, our social lives, especially among adolescents and young adults, are increasingly carried out online via various digital platforms [6]. Therefore, providing a clinical tool allowing clinicians and patients to collaboratively monitor their digital social activity could help identity issues to be addressed in treatment and improve clinical outcomes [7].

A growing body of research suggests that useful clinical insights about patients' mental health can be gleaned from their digital social activity. Both clinicians and patients have reported they feel comfortable discussing the patients' social media activity in therapy sessions [8-10]. Moreover, several studies [8,11,12] have found that many clinicians will ask patients about their electronic communication on social media because they believe this information is helpful in providing more effective treatment [12]. Additionally, a number of studies have shown that quantifiable signals derived from patterns of activity and language used on different social media and electronic communication platforms can be used to develop computational models that help distinguish the presence of different mental illnesses [13-22], as well as predict meaningful changes in the clinical trajectories of these illnesses [14,23-26]. More recently, two additional studies were conducted. In the first, an electronic dashboard was developed to display the results of computational analyses carried out with data on patients' digital social activity, but it was not formally tested in clinical practice [27,28]. In the second, patient digital activity was tracked as part of clinical care; although it was feasible, it did not improve mental health outcomes [29]. Taken together, these studies provide a compelling rationale for further study on the potential benefits of systematically monitoring patient digital social activity to assist in clinical care.

Towards this end, we developed an electronic dashboard for displaying information about patients' digital social activity for clinicians to use with patients during routine clinical visits to inform treatment decisions. We envisioned the dashboard to be part of a next-generation measurement-based care program in which multiple sources of collateral information about patients, including patient-rated outcome measures, are available to inform collaborative treatment decisions between clinicians and patients. Consistent with the principles of a measurement-based care program [7,30], we hypothesized that providing the electronic dashboard could improve downstream patient outcomes through two mediating pathways. First, it could lead to earlier detection of issues in the patients' social lives that would benefit from more timely intervention. Second, it may improve the therapeutic alliance by fostering more informed and open communication between patients and clinicians [31]. With this in mind, we set out to clinically test whether augmenting TAU with the electronic dashboard could improve treatment outcomes on clinical symptoms compared to TAU alone, and whether it did so by impacting either of the hypothesized mediating pathways.

Methods

Dashboard Intervention

The design and development of the electronic dashboard intervention have been described previously [7]. The personalized electronic dashboard was designed to display salient information about the patient's digital social activity in easy-to-interpret graphical formats. This included displays of usage statistics such as the frequency of messages sent/received over the past week, the list of platforms used to send/receive the messages, and the timing of when the messages were sent/received during the day/week; content metrics describing the major thematic elements of the messages sent/received as characterized by, for example, linguistic inquiry and word count (LIWC) analysis and trends in the use of certain pronoun forms that may be indicative of mental health status [32-34]; and specific content including snippets of messages that were algorithmically selected to be representative of the major themes identified over the past week. Regarding the latter, the specific content was masked on the dashboard, and clinicians were instructed to unmask and review the content only after patient permission during clinical encounters.

The patient's social media and electronic communications activity data used to generate the dashboard were collected using Bark [35]. Bark is a commercially available parental/caregiver monitoring app that scans children's on-line activity, including over 30 social apps, web browsers, emails, and texts. We worked with the company to adapt the app to shut down alert features to use it exclusively for data collection. Bark had access only to anonymous study IDs. The collected data were transferred from Bark through an encrypted HTTPS/TLS connection to a Johns Hopkins University network drive. Data were then processed to remove images, videos, geolocation tags, and internet usage (not including search engine queries), leaving natural text that was further processed to mask personal identifiers by replacing them with synthetic alternatives [22]. Computational algorithms were run on the processed data to derive the measures and visual displays described. The personalized dashboard was securely delivered as an HTML to clinicians for review before each clinic visit. Clinicians had access only to their patients' dashboards.

Study Sample

The study was conducted at the Johns Hopkins Medical Institution and the Kennedy Krieger Institute, which is an independent hospital affiliated with the Johns Hopkins Medical Institution. We engaged collaborative care outpatient psychiatry clinics, in which patients see a psychiatrist for medication-assisted care and a master's level therapist or doctoral level psychologist for psychotherapy, as study sites. We first recruited clinicians from these sites to participate in

XSL•FO
RenderX

the study who then referred their potentially eligible patients to learn more about the study. Patients aged 12 years and above with a mood or anxiety disorder in care at any stage of their illness were eligible to participate in the trial. There were no exclusion criteria other than if the treating clinician determined that the patient was not able to provide informed consent.

Study Procedures

This pragmatic trial was implemented in as close to a real-world setting as possible to facilitate participation and enhance the generalizability of the findings. Patients were randomized in a 1:1 ratio with blocks of size 2 within treating clinicians to either the intervention (the dashboard arm) or TAU (the TAU arm). Randomization was implemented using REDCap and an allocation table generated to determine the randomization sequence for assigning patients to the comparison arms in a process that was blinded to the clinicians and patients. This helped promote balance in the number of patients in the two treatment arms seen by each clinician to minimize the influence of differences between treating clinicians. For patients in the TAU arm, the treating clinician did not receive a clinical dashboard. For patients in the dashboard arm, clinicians had access to the electronic dashboard prior to every scheduled clinic visit. The clinician and patient collaboratively decided on the use of the dashboard in clinical sessions. After the initial visit to download the Bark app, there were no further study-specific visits, and patients were seen by their clinicians as clinically indicated. We considered the first regularly scheduled clinic visit with their clinician after the patient consented and downloaded the Bark app to be the study baseline visit. We originally planned to follow-up patients for 1 year, but due to the impact of the COVID-19 pandemic on the start of the trial and patient recruitment, we modified the protocol to follow-up patients for 3 months.

Study Measures

The full set of measures collected during the trial and the schedule of their collection have been described previously [7]. Here, we describe the measures used to evaluate the trial results. Patients completed the 9-item Patient Health Questionnaire-9 (PHQ-9) [36] to measure depressive symptoms and the 7-item General Anxiety Disorder-7 (GAD-7) [37] to measure general anxiety symptoms as part of an established measurement-based care program program in which these measures are collected as standard of care through the electronic health record before each clinic visit. In addition, they completed the 13-item Short-Form 36 Health Survey Mental Health Component (SF36-MHC) at baseline and after 3 months [38] to measure overall mental health status, and the 12-item Working Alliance Inventory–Short Revised (WAI-SR) to measure therapeutic alliance on aspects related to the goals, tasks, and bonds in treatment. The clinicians completed the McLean Collateral Information and Clinical Actionability Scale (M-CICAS) [39] after every clinic visit with patients in the trial. The M-CICAS was developed to quantify the types of collateral information that are reviewed during mental health related clinical sessions and to understand how this collateral information translates into clinical decision-making. It is a 7-item scale divided into three parts that collect information on the collateral sources of information reviewed, clinical actions taken, and shared decisions made between a clinician and a patient in a clinical session.

Patient diagnoses were obtained from the electronic health records and defined based on the most recent International Classification of Diseases-10 codes assigned by treating clinicians at clinic visits. Diagnoses were categorized as any bipolar disorder, any depressive disorder, or any anxiety disorder. Patients assigned a diagnosis in more than one category were categorized in a hierarchical fashion in the order of priority of bipolar disorder, depression, then anxiety disorder.

Statistical Analysis

We provided basic descriptive statistics of the sample with comparisons between the two treatment arms made using χ^2 tests. We then compared patient outcomes between the two treatment arms. The primary outcome was the difference in depressive symptoms as measured using the total PHQ-9 scores [36] over follow-up. Secondary outcomes included differences in overall mental health status as measured using the SF36-MHC scores [38] and general anxiety as measured using the total GAD-7 scores [37]. We first compared these outcomes by taking the means of the scores within patients over the follow-up and comparing the means between the two treatment arms using *t* tests. We then used random effects linear regression models to test for differences in repeated measures of the scores over follow-up. We included fixed effects terms for the treatment arm (dashboard versus TAU arms), as well as for time of follow-up in days and other potential confounders including age, sex, race, and diagnosis. We included random effects for individuals to account for the correlation in outcome measures within repeated measures of the same individual. The fixed effect term for treatment provided an estimate of the mean differences in the outcome measures between the two treatment arms controlling for time and the other covariates. Given that patients were pragmatically enrolled into the study regardless of their current mental health status as long as they were in care, we considered the results from this model to be our primary test of interest. However, we also compared changes in these outcomes scores over follow-up between the two treatment arms using *t* tests of the delta in scores from baseline to the last available measure and a random effects model similar to the one described above but this time including an interaction term between the treatment arm and time while controlling for the other patient covariates. We carried out a series of diagnostic tests to confirm the validity of the assumptions for using random-effects models with these data. Visual inspection of residual plots revealed evidence of heteroscedasticity, so we used robust SEs in all our final models.

In secondary analyses, we examined whether there were differences in the two treatment arms on measures of therapeutic alliance and the detection of clinically actionable targets, both of which we hypothesized mediate the therapeutic effect of the intervention. In particular, we tested whether there were differences between the two treatment arms on scores on the WAI-SR (which measured therapeutic alliance) and the M-CICAS (which captured information about the detection of clinically actionable targets and if subsequent treatment

XSL•FO
RenderX

adjustments were made). For the WAI-SR score, we took the means of all measures over follow-up per patient and compared them using *t* tests as well as using linear regression controlling for length of follow-up and patient covariates. For the M-CICAS, which is captured after every clinic visit, we tallied at how many clinical encounters issues related to the patient's social media activity or electronic communications were discussed and subsequent treatment adjustments were made. We then compared the number of times digital social activity was discussed using *t* tests as well as linear regression controlling for length of follow-up and patient covariates. In other secondary analyses, we carried out stratified analyses to test whether there were differences in the primary outcomes by patient age and by a measure of clinician adherence to using the dashboard intervention. We repeated all univariate tests described above using non-parametric Mann-Whitney *U* tests to address concerns about potential violations of the assumptions of *t* tests, such as normality or equal variances of the underlying data between groups, and we observed nearly identical results (results not shown).

We planned, at the beginning of the study, to recruit a sample size of 100 based on the calculation that such a sample would have 80% power to detect differences in the primary outcome between the two treatment arms with a Cohen *d* effect size of at least 0.5 assuming at least 3 repeated measures. We used the conventional threshold of $P<.05$ to declare findings statistically significant, with the understanding that the multiple tests of the secondary outcomes and analyses were exploratory in nature.

Ethical Considerations

The study protocol was approved by the Johns Hopkins University School of Medicine Institutional Review Board (IRB #00184638). We obtained informed consent from both patients and clinicians who participated in the study. We obtained assent from patients who were aged <18 years and consent from their guardians. Patients were compensated for participation in the study as described previously [7]. All data were deidentified before data analyses were conducted.

Results

The trial was initiated in April 2019, but due to delays in the start-up period that persisted through the onset of COVID-19 pandemic, the first patient was not randomized until October 2020. Enrollment was completed in February 2024.

A total of 103 patients were enrolled and provided consent (Figure 1). Of these, 6 patients withdrew from the study before randomization; 97 participants were randomized. Of those randomized, 11 (4 randomized to the Dashboard arm and 7 to the TAU arm) withdrew before providing evaluable data with at least one primary or secondary outcome measure. Thus, a total of 86 patients had evaluable data and were included in the primary analysis.

Figure 1. CONSORT diagram of patients who provided consent and were followed-up during the trial. Evaluable data are defined as providing at least one primary or secondary outcome measure.

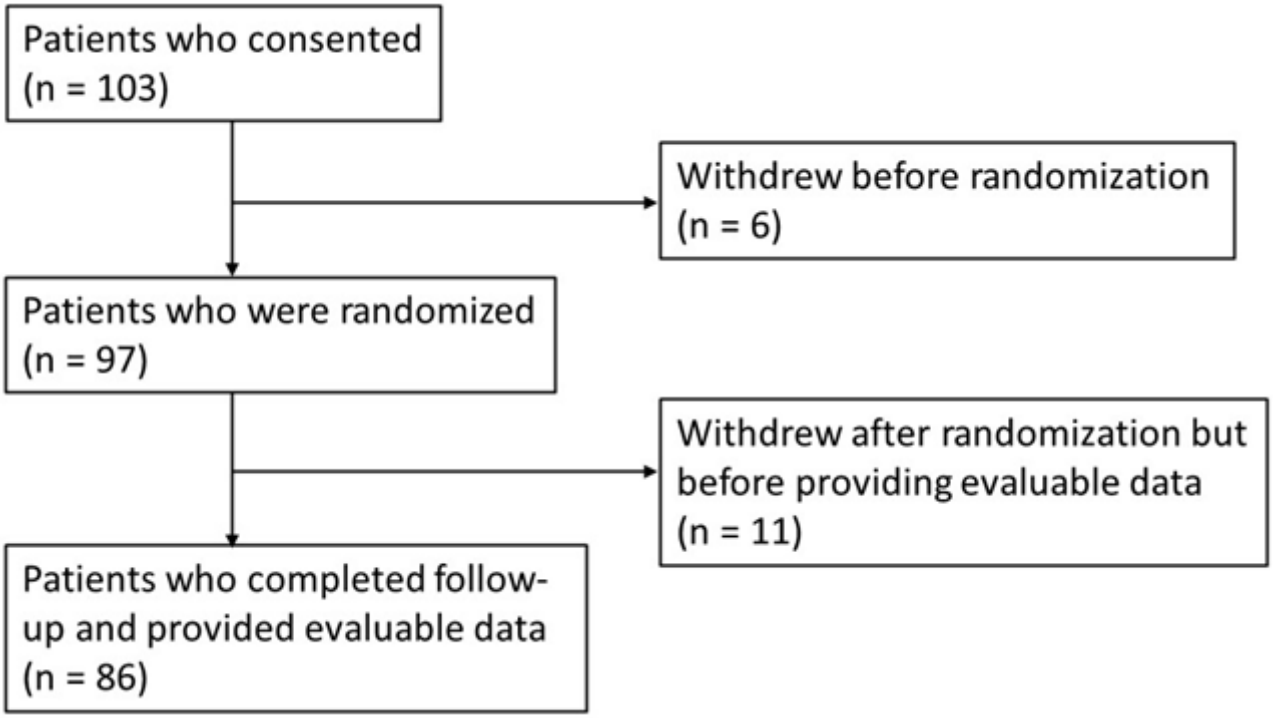

Table 1 shows a breakdown of the demographic characteristics of the sample who were randomized by treatment arm. A majority of the sample were women (79.4%), White (73.2%), and young with an age breakdown of <18 years (41.2%), between 18 and 25 years (36.1%), and >26 years (22.7%). Most patients had a depressive disorder (73.2%), while relatively fewer had a bipolar disorder (11.3%) or a primary anxiety disorder (15.5%). Importantly, we found no significant differences between the two treatment arms in any of these characteristics, or in the number who withdrew before providing evaluable data (all comparisons: $P>.05$). In addition, recalling the pragmatic study design in which the number of follow-up

XSL•FO
RenderX

visits for each patient was determined solely based on clinical indication, there was not a significant difference in the mean number of follow-up visits between the two treatment arms (dashboard vs TAU: 8.29 vs 9.63; t_{84}=-1.22; *P*=.22).

Table . Characteristics of patients randomized by treatment arm.[a]

	Dashboard arm (n=49)	TAU[b] arm (n=48)	Total (n=97)
Sex, n (%)			
Male	11 (22.5)	6 (12.5)	17 (17.5)

Bipolar Disorder	4 (8.2)	7 (14.6)	11 (11.3)
Withdrew	4 (8.2)	7 (14.6)	11 (11.3)

[a]All differences on the patient characteristics were not significantly different between the dashboard and TAU arms (*P*>.05).

[b]TAU: treatment-as-usual.

[c]66 of the patients with depression and 8 of the patients with bipolar disorder also had a history of comorbid anxiety.

In the primary analysis, the mean PHQ-9 scores were 8.67 in the dashboard arm versus 9.56 in the TAU arm (t_{75}=−0.72; *P*=.48; Figure 2A). Using a mixed effect linear regression model with repeated observations of the outcome (Table 2), the difference between the two arms was not statistically significant after controlling for follow-up time and patient covariates ($\beta_{Difference}$=−.83; SE=1.31; *P*=.53). We further examined changes in PHQ-9 scores between baseline and the last observation (Figure 2B) and noted that the scores declined by a mean of 0.58 points for the dashboard arm versus 0.35 for the TAU arm (t_{60}=0.20; *P*=.85). Again, using a mixed effect linear regression model this time including an interaction term between treatment arm and time, we found that the change over time was not significantly different between the two arms after controlling for the other patient covariates ($\beta_{Interaction}$=.007, SE=0.01, *P*=.48). We carried out a similar set of analyses with the secondary outcomes (SF36-MHC and GAD-7 scores) and likewise did not find any significant differences between the two treatment arms (Multimedia Appendix 1).

Figure 2. Box plots of (a) mean PHQ-9 scores over follow-up and (B) change in the PHQ-9 scores between baseline and the last available measure for patients in the dashboard versus the treatment-as-usual (TAU) arms. PHQ-9: Patient Health Questionnaire–9.

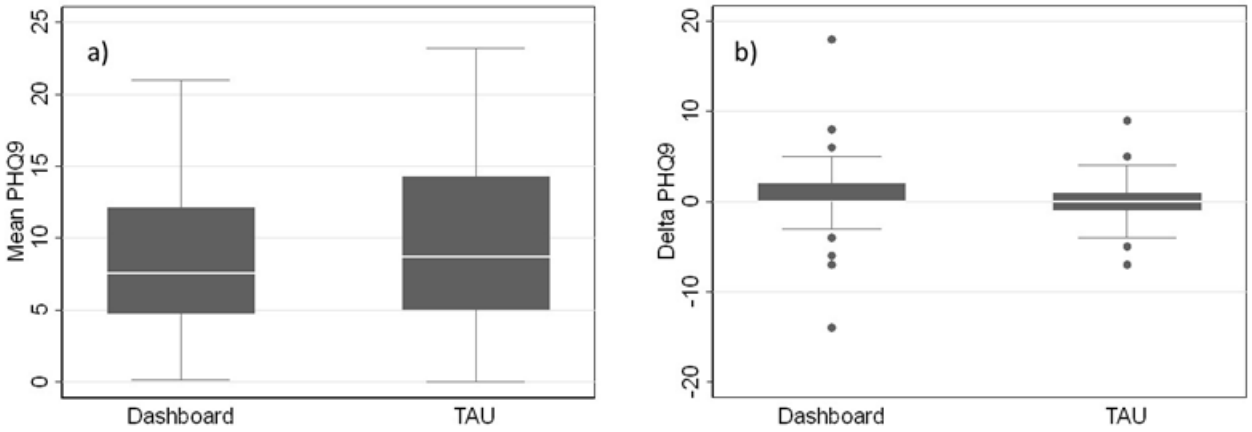

Table . Model results comparing the dashboard versus treatment-as-usual arms considering the primary outcome and hypothesized mediators.

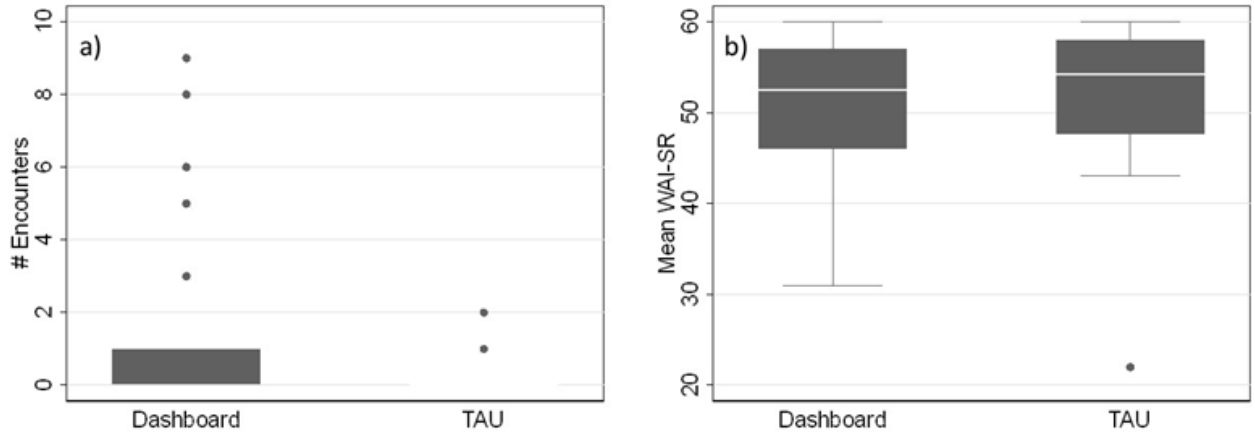
Model[a]	Outcome	Covariates	β (SE)	95% CI (*P* value)	*P* value
1	PHQ-9[b] score	TrxArm[c]	−0.83 (1.21)	−3.19 to 1.53	0.49
		Time	−0.003 (0.006)	−0.015 to 0.009	0.62
2	PHQ-9 score	TrxArm	−1.14 (1.39)	−3.87 to 1.59	0.41
		Time	−0.006 (0.007)	−0.021 to 0.008	0.40
		TrxArm[a] and Time	0.007 (0.012)	−0.017 to 0.031	0.58
3	M-CICAS[d]	TrxArm	1.00 (0.38)	0.24 to 1.76	0.01
4	WAI-SR[e]	TrxArm	−1.35 (1.88)	−5.11 to 2.41	0.48

[a]Models 1 and 2 are from mixed effects linear regression of the outcome as a function of the covariates shown plus age, sex, race, and diagnosis, and including a random effect for individual to account for repeated measures of the outcome. Models 3 and 4 are from linear regression models of the outcome shown as a function of the covariates shown plus patient characteristics including age, sex, race, diagnosis and length of follow-up in days.

[b]PHQ-9: Patient Health Questionnaire–9.

[c]TrxArm: treatment arm. This refers to the generic variable that can take on the values of either "dashboard" or "treatment-as-usual (TAU)", and is used to represent the variable in the model that captures the comparison of results between the two levels of this variable: the Dashboard arm vs the TAU arm.



[d]M-CICAS: McLean Collateral Information and Clinical Actionability Scale

[e]WAI-SR: Working Alliance Inventory – Short Revised.

In secondary analyses, we examined whether the dashboard intervention was associated with factors that were hypothesized a priori to mediate the potential therapeutic effect of the intervention [7]. Using data from the M-CICAS to test whether the dashboard intervention was associated with an increase in the number of times that patients' digital social activity was discussed in clinical sessions (Figure 3A), we found the mean was significantly greater in the dashboard arm versus the TAU arm (dashboard vs TAU arm: 1.07 vs 0.18; t_{77}=2.40; *P*=.02). This difference remained significant even after controlling for the length of follow-up and patient covariates ($\beta_{Difference}$=1.00, SE=0.38, *P*=.01). However, we did not find that the increased discussion of the patients' digital social activity led to any increase in the number of encounters in which a clinical adjustment was made as also measured using the M-CICAS, before or after controlling for the length of follow-up and patient covariates ($\beta_{Difference}$=−.41, SE=0.56, *P*=.46). We then used data from the WAI-SR to examine whether the dashboard intervention was associated with differences in patient-rated therapeutic alliance compared with TAU (Figure 3B). We found there was not a significant difference in the mean patient-rated alliance scores over time between the dashboard arm and the TAU arm (dashboard vs TAU: 51.16 vs 52.18, t_{71}=-0.59, *P*=.56), even after controlling for the length of follow-up and patient covariates ($\beta_{Difference}$=−1.35, SE=1.88, *P*=.48).

Figure 3. Box plots of (A) the number of encounters in which digital social activity was discussed and (B) the mean WAI-SR scores over the course of follow-up for patients in the dashboard versus treatment-as-usual (TAU) arms. WAI-SR: 12-item Working Alliance Inventory–Short Revised.

In other exploratory secondary analyses, we re-analyzed the data on the primary outcome (PHQ-9) after stratifying by age at baseline at ages <18, 18 - 25, and >25 years, corresponding with typical developmental milestones through adolescence and young adulthood. We did not find any significant differences in PHQ-9 scores over the course of follow-up between the two treatment arms for any of the age sub-groups, although the resulting sample sizes in each group were relatively small (results not shown). In addition, we re-analyzed the primary outcome data after stratifying for an indicator of clinician engagement with the electronic dashboard during the trial. Here, we re-analyzed the data specifically within the sub-group of patients (n=24 vs 23 in the dashboard and TAU arms, respectively) cared for by clinicians who reported on the M-CICAS using the electronic dashboard at more than one encounter. Again, we did not find any significant differences in PHQ-9 scores over the course of follow-up between the two treatment arms in this sub-group (results not shown).

Discussion

This randomized trial tested whether providing clinicians with an electronic dashboard that displayed information about their patients' digital activity on social media and electronic communications platforms would facilitate more informed and collaborative treatment decisions and improve outcomes for individuals with mood or anxiety disorders. We did not find evidence that providing such a dashboard significantly improved outcomes. However, it tended to promote greater discussion about the patients' digital social activity during the course of treatment, and it did not negatively impact patients' therapeutic alliance with their clinicians. The latter is noteworthy because it was unclear at the onset of the trial whether providing the dashboard would facilitate dialogue and greater alliance between patients and their clinicians or, alternatively, harm alliance by raising concerns among patients about their privacy.

There is growing interest in the role of social media in influencing mental health, especially among adolescents and young adults [40]. However, there have been relatively few efforts to evaluate the potential impact of systematically tracking patients' digital social activity and using this information in clinical care. One study reported on the development of an electronic dashboard for monitoring digital activity of patients on a variety of social media platforms but did not test it in clinical care [27,28]. Another study asked patients to share at least one type of social media (eg, Facebook wall posts) or digital data (eg, Google or YouTube video search queries, or smartphone metrics such as steps walked or screen status) before clinic visits. They tested whether providing a dashboard that displayed the shared information to clinicians improved health-related quality of life or depressive and anxiety symptoms. Although it was feasible to use the dashboard in routine clinical care, it did not improve patient outcomes [29]. We adapted a commercially available mobile app that allowed us to comprehensively monitor patients' self-selected social media activity and electronic communications platforms to provide detailed information on what platforms they were using, when they were using them, as well as on specific content posted on these platforms. Still, we observed broadly similar findings as the previous study.

Using the app-based approach to monitor patients' digital social activity presented certain challenges due to concerns about potential intrusion into patients' privacy. We adopted a number of strategies to minimize these concerns. We developed a pipeline for collecting and processing the social activity data that prioritized protecting the patients' privacy by removing personal identifiers from the data streams and linking the data to an anonymous study ID, processing and presenting the data behind the Johns Hopkins firewall, and looking at the processed data only when clinicians were in session with patients. In addition, we allowed patients to decide which social media platforms to share through the app, the clinicians to decide when to use the dashboard in clinical sessions, and the clinicians and patients to decide together when to review specific content. These decisions promoted patient control over what information was revealed, with the goal of facilitating trust and greater collaboration between clinicians and patients in using the dashboard to inform treatment sessions. In the end, these strategies were helpful in building trust with patients, but recruitment remained challenging and prolonged due to lingering questions about privacy. However, we observed that, for patients

XSL•FO
RenderX

who agreed to participate, these concerns were not apparent and did not impact the alliance they had with their clinicians.

The COVID-19 pandemic also had a significant impact on the start of the trial and on-going recruitment. We were not able to randomize our first patient until a half-year into the pandemic, and we had to modify procedures to accommodate the evolving clinical landscape, which included the rapid transition to telehealth. Due to this transition, we had to recruit and follow patients virtually, which led to challenges that slowed recruitment and made it more difficult to follow-up patients over time, contributing to the losses in follow-up.

There were several other limitations of the study that merit consideration. Our decision to allow patients to control what information they shared and clinicians to decide when to use the dashboard in clinical sessions, while good intentioned, may have diminished the ability of the intervention to have a meaningful clinical impact. It is possible that clinically salient information from the patients' digital social activity was not shared or discussed, and this could have reduced any potential benefit of the intervention. We did not have a measure of how often the clinicians and patients used the dashboard and reviewed its contents during clinical sessions, and as a result, we could not tell how engaged they were with the intervention. Instead, we had a measure of how often digital social activity was discussed in these clinical sessions. While we did show a difference with the dashboard, the number of times that such discussions came up in clinical sessions overall was relatively modest. Future studies of this approach should consider strategies to incentivize patients to share their digital social activity with the dashboard and clinicians to use the dashboard as part of every clinical session, much like they are encouraged to use other routine measures in traditional measurement-based care.

Another limitation is that patients were recruited into the study at any stage of their illness, which may have reduced the ability to detect a clinical benefit of the dashboard intervention. Moreover, our primary outcome measure using the PHQ-9 may not have been optimal for detecting such a benefit. While the PHQ-9 is widely used in studies of depression and anxiety, there are likely multiple complex factors that contribute to its trajectories over time, limiting the ability of the dashboard intervention from having a meaningful impact over only 3 months of follow-up. Future studies may want to consider other wellness or other non-traditional outcome metrics to measure the impact of the intervention, as well as longer follow-up durations to allow sufficient time for the intervention to have a meaningful impact. Despite the challenges and equivocal findings with regard to the primary outcomes, we believe the trial provided valuable lessons that motivate further research into this important area. We found that it was feasible to implement the novel dashboard intervention in real-world clinical care, it did not negatively impact patient-clinician alliance despite concerns over privacy, and using the intervention did increase discussions about the patients' digital social activity that may have impacted their mental health as hypothesized. As a result, we contend more research is warranted to improve the clinical utility of the electronic dashboard and further test the intervention in real-world clinical care.

Abstract

Background: Suicide-related internet use encompasses various web-based behaviors, including searching for suicide methods, sharing suicidal thoughts, and seeking help. Research suggests that suicide-related internet use is prevalent among people experiencing suicidality, but its characteristics among mental health patients remain underexplored.

Objective: This study aimed to examine the sociodemographic, clinical, and suicidality-related characteristics of suicidal mental health patients who engage in suicide-related internet use compared with those who do not.

Methods: A cross-sectional survey was conducted from June to December 2023, recruiting participants aged 18 years and older with recent contact with secondary mental health services in the United Kingdom. The survey assessed sociodemographic characteristics, psychiatric diagnoses, suicidal thoughts and behaviors, and engagement in suicide-related internet use. Statistical analyses included chi-square tests, Wilcoxon tests, and multivariable logistic regression to identify predictors of engaging in suicide-related internet use.

Results: Of 696 participants, 75% (522) engaged in suicide-related internet use in the past 12 months. Those who engaged in suicide-related internet use were almost 3 times as likely to have attempted suicide in the past year (32.5% vs 9.2%, P<.001). They were more likely to have a diagnosis of personality disorder (34.4% vs 18.5%, P<.001) and to disclose suicidal thoughts to someone (87.8% vs 72.8%, P<.001). They also reported higher levels of suicidal ideation intensity (median =6.6 vs 5.1, P<.001). There were no significant sociodemographic differences between groups, including age.

Conclusions: The findings suggest that suicide-related internet use is a common behavior among suicidal mental health patients across various age groups, challenging the notion that it is primarily a concern for younger populations. The association between suicide-related internet use and increased suicidality highlights the need for clinicians to incorporate discussions about web-based behaviors in suicide risk assessments. Given the high rate of disclosure of suicidal thoughts among suicide-related internet users, clinicians may have an opportunity to engage in open, nonjudgmental discussions about their patients' internet use.

KEYWORDS

suicide-related internet use; suicidality; mental health patients; online behaviour; suicide prevention; mental illness

Introduction

For people experiencing suicidal thoughts and behaviors, suicide-related internet use can encompass a wide range of behaviors, including web-based searching for information about suicide methods, sharing suicidal thoughts, and seeking help [1]. Suicide-related internet use has become an important focus of research due to its potential influence on suicidal ideation and behavior. Understanding how people who engage in suicide-related internet use differ from those who do not is important for designing interventions, such as targeted web-based resources to promote help-seeking, improving digital literacy programs, and enhancing clinical strategies for suicide prevention.

Due to the inherently private nature of suicide-related internet use, precise prevalence rates of engagement in this behavior are not available; instead, estimates rely on cross-sectional and longitudinal studies. These studies reveal suicide-related internet use to be prevalent among suicidal people, with proportions of people engaging in it varying between 36% and 59%, depending on the population and timeframe studied, but often characterized by small sample sizes and focus on young people, often university students [2-5]. Therefore, the current literature does not fully represent the whole population of those who engage in suicide-related internet use. Previous research has consistently found differences between those who did and did not engage in suicide-related internet use, most notably that those engaging in suicide-related internet use tend to be younger and have

XSL•FO
RenderX

higher levels of suicidal ideation [2-5]. This has also been reported among those who engage in suicide-related internet use only to seek help [6].

Mental health patients, in particular, represent a vulnerable and underresearched group when it comes to using the internet for suicide-related purposes. This group has closer access to treatment and support due to their engagement with health care services, and they experience significantly higher rates of suicide compared with the general population [7]. Therefore, their engagement in suicide-related internet use warrants closer investigation to uncover unique factors associated with this behavior and intervention opportunities. A 2018 UK study identified contrasting patterns of internet use between young people in the community and young self-harm patients [8]. Young community people ambivalent about suicide exhibited shifting between help-seeking and accidental exposure to web-based prosuicide content, often seeking connection. In contrast, self-harm patients with stronger suicidal intent engaged in calculated, methodical searches for lethal means, avoiding support resources entirely. This behavior aligns with the Interpersonal Psychological Theory of Suicide, particularly the concept of acquired capability, suggesting that specific web-based behaviors, such as focused search or avoidance of help sites, may signal elevated risk and should be evaluated by clinicians [9].

Proportions of mental health patients who have engaged in suicide-related internet use vary from 8% in patients who died by suicide to 27% of adult and 43% of adolescent psychiatric in-patients [10-12]. A case-control study on suicide-related internet use in mental health patients who died by suicide found those who engaged in this behavior were more likely to be younger (aged 25 years or younger), have a diagnosis of autism spectrum disorder, and have a history of childhood abuse [10]. In samples of both adult and adolescent hospitalized patients with affective disorder, those who engaged in suicide-related internet use were more likely to be younger and to have a higher incidence of suicide ideation and suicide attempts [11,12]. Patients who were hospitalized for self-harm and who engaged in suicide-related internet use also disclosed higher levels of suicidality compared with those who did not [8]. These findings mirror trends seen in general population studies, suggesting that suicide-related internet use is also linked to higher suicidal intent among mental health patients.

Despite these insights, research on suicide-related internet use in mental health patients remains scarce. To develop effective interventions, both web-based and offline, it is important to explore the characteristics of patients who use the internet for suicide-related purposes and examine whether they differ from those who do not. Examining which patients turn to suicide-related internet use while remaining in contact with mental health services can provide valuable information for clinical risk assessment and reveal potential gaps in knowledge on this type of behavior. In addition, this can help inform targeted web-based interventions as well as policies aimed at protecting at-risk people and promoting safer web-based environments. Therefore, this study aims to compare the sociodemographic, clinical, and suicidality characteristics of suicidal mental health patients who engage in suicide-related internet use with those who do not.

Methods

Study Design

This was a cross-sectional study using a web-based survey. The questionnaire was hosted on the Qualtrics platform from June 1, 2023, to December 31, 2023.

Ethical Considerations

Participants provided informed consent to participate in the survey. All survey responses were anonymous and no compensation was provided for participants. Ethical approval was obtained from the University of Manchester Research Ethics Committee 1 on April 3, 2023 (ref: 2023-16133-28055).

Eligibility Criteria

Inclusion criteria were presented at the start of the survey and consisted of (1) being aged 18 years and older, (2) being in contact with secondary mental health services in the past 12 months, (3) experiencing suicidal thoughts or behaviors in the past 12 months, (4) using the internet, (5) living in the United Kingdom, and (6) having a good command of the English language.

Recruitment

We advertised the study on social media (X, Reddit, Facebook, BlueSky, Mastodon, TikTok, Instagram, and LinkedIn), University of Manchester staff and student mailing lists, newsletters of mental health and social care charities, and through webpages of mental health and wellbeing-related organizations, and radio. The recruitment materials were commonly shared throughout platforms. For participating in this study, the participants were not offered any financial incentives, such as monetary compensation or vouchers. Finally, participants were not asked to disclose any identifiable data (ie, name, email address, and geographical location), nor were their IP address data collected.

Materials

The questionnaire was initially developed by the author [LB], based on existing literature and the author's own experience of navigating online spaces. Coauthors [IH, SF, SI, and PT] and 2 members of a Patient and Public Involvement Group with lived experience of suicidality provided input on the phrasing of survey questions and design of the recruitment materials. There were 45 questions in total, most in multiple-choice format with free-text options to provide additional information. Participants were asked about lifetime psychiatric diagnoses and those received in the past 12 months due to the potentially high level of distress, self-stigmatization, and need for information following new diagnoses that might motivate patients to engage in suicide-related internet use [13,14]. For questions on the amount of support from family, friends, or community, satisfaction with mental health service provision, how intense their thoughts of suicide were, and the amount of planning involved in suicide attempt, participants provided answers using a visual analog scale (VAS). VAS scores ranged

XSL•FO
RenderX

from 0 to 10 and were interpreted as follows: 0 - 2, very low or minimal; 2.1 - 4.0, moderate low; 4.1 - 6.0, neutral or mixed effects; 6.1 - 8.0, moderate high; and 8.1 - 10.0, very high. There were 4 free-text questions relating to search terms to look for suicide-related information, disclosure of suicide-related internet use to clinicians, and any additional thoughts on suicide-related internet use participants might have had; qualitative findings from this free-text data will be presented elsewhere. To ensure data quality, the survey also included 1 attention-checking question. The full survey is available as part of the supplementary material (Multimedia Appendix 1).

Procedure

Before commencing the questionnaire, participants were presented with the study information sheet, and informed consent was obtained. A list of resources, such as helplines and services they could contact if they became distressed, was provided. The survey consisted of 4 sections (Figure 1). The first 2 sections covered sociodemographics and mental health history. The third section covered suicidal thoughts and attempts, adverse life events (ie, relationship breakdown and financial difficulties) that may have contributed to their suicidality, and perceived support received from friends, family, or their community. Trigger warnings for questions related to suicidal thoughts and attempts were provided. The fourth section covered suicide-related internet use defined as:

> *Suicide-related internet use is any internet use related to your thoughts, feelings and behaviors connected to suicide. This kind of use can be, for example, expressing suicidal feelings or thoughts on social media or using the internet to get help and support when feeling suicidal.*

Participants were asked if they engaged in suicide-related internet use in the past 12 months. If they answered "no," they were exited from the questionnaire. Those who answered "yes" continued with section 4 on suicide-related internet use. All participants were provided with a list of helplines and services.

XSL•FO
RenderX

Participants

Out of a total of 1057 people who started the survey, 260 (25%) did not meet the inclusion criteria (72 did not answer inclusion criteria questions, 110 had no contact with secondary mental health services, 43 did not confirm suicidal thoughts or behaviors, and 35 failed to meet both inclusion criteria). Furthermore, 23 participants met the inclusion criteria but did not answer any questions. Of the remaining 797 participants, 23 were excluded based on missing data on all questions, 3 for failing the attention check question, and 5 for aberrant or joking answers. In total, 766 participants completed at least 3 sections of the survey (sociodemographic and clinical characteristics and suicidal thoughts or attempt, Figure 1), including 70 participants who did not provide information on whether they had used the internet for suicide-related purposes. As there was no way to interpolate this data, these 70 participants were excluded from the analysis. There were no differences in the sociodemographic and clinical characteristics and suicidal thoughts or attempts between those who provided information about their suicide-related internet use and those who did not. Therefore, there were 696 participants in the final analysis. Those who reported that they only came across suicide-related content accidentally (n=50) were grouped with those who reported they did not engage in suicide-related internet use, as those who accidentally came across suicide-related content did not actively seek it out, similar to those who did not engage in suicide-related internet use at all. There were no differences in the sociodemographic and clinical characteristics and suicidal thoughts or attempts between those who did not engage in suicide-related internet use and those who only came across suicide-related content accidentally.

Statistical Analysis

Frequencies and percentages were used to present a descriptive analysis of categorical data. For data obtained through a visual analog scale, median and IQR were used for analysis as recommended [15]. The textual answers to open-ended questions were coded into existing variables or set up as new variables for quantitative analysis. The denominators in all estimates were the number of valid cases for the item, that is, if an item of information was not known for a case, that case was removed from the analysis of that variable. Comparisons between those who did and those who did not engage in suicide-related internet use were examined using the chi-square test for categorical variables and the Wilcoxon test for visual analog scales. Multivariable logistic regression with all variables that differed significantly between participants who did and did not engage in suicide-related internet use as predictors was carried out. We performed multiple imputations for multivariable logistic regression using chained equations; the direction and significance of the results, albeit with narrower CIs, were confirmed using this analysis (Multimedia Appendix 2). To compensate for multiple comparisons, Bonferroni correction was applied to all *P* values; therefore, *P* values less than .001 (.01/number of comparisons) were considered statistically significant. All analyses and designs of figures were carried out in RStudio (Posit PBC, version 2024.12.0.467) [16].

Results

Sociodemographic Characteristics

Of 696 participants, 523 (75.1%) had engaged in at least 1 type of suicide-related internet use in the past 12 months. Sociodemographic characteristics and comparisons of participants are presented in Table 1. Most were aged 25 years and over (553/696, 79.5%), with the most common age group being 25 to 34 years old (324/696, 46.4%) followed by 35 to 44 years (148/696, 21.3%). Almost two-thirds (444/696, 63.8%) were women, and 29.3% (204/696) were men. For 103/696 (14.8%) participants, gender did not match the sex assigned to them at birth. Most participants were of white ethnicity (611/696, 87.8%). Over half (384/696, 55.2%) of all participants were nonheterosexual. Most participants held higher education qualifications, with over half having a university degree (392/696, 56.3%). There was no statistically significant difference in sociodemographic characteristics between participants who did and did not engage in suicide-related internet use, even though almost twice as many participants aged 25 years or younger (23.1% vs 12.7%, *P*=.01) engaged in this behavior.

[a]SRIU: suicide-related internet use.

[b]includes asexual, pansexual, and questioning.

[c]includes homemaker, training scheme, and retired.

Clinical and Mental Health Service Characteristics

Those who engaged in suicide-related internet use were more likely to receive a diagnosis of personality disorder compared with those who did not (34.4% vs 18.5%, *P*<.001; Table 2). Most participants had been prescribed psychotropic medication in the last 12 months (554/696, 79.6%), and 112/696 (16.1%) had been admitted for psychiatric in-patient care. When asked about their satisfaction with their mental health service provision, participants were, on average, moderately dissatisfied (VAS score median=4.0, IQR=2.0 - 6.3); this did not differ between those who did and did not engage in SRIU nor between different diagnoses.

[e]*P*≤.001.

[f]ADHD: attention deficit hyperactivity disorder.

Suicidal Thoughts and Behaviors

One of the inclusion criteria was having experienced suicidal thoughts in the past 12 months; therefore, all participants had contemplated suicide. However, 19 participants (19/696, 2.7%) chose not to provide additional information about their suicidal thoughts. Twelve months before completing the survey, 507/677 (74.9%) participants had thoughts of suicide at least once a week, including 214/677 (31.6%) who had thoughts of suicide daily or almost daily. Participants who had engaged in suicide-related internet use were more likely to have thoughts of suicide every day or almost every day compared with those who did not engage in this behavior (35.0% vs 17.9%, *P*<.001). The average intensity of thoughts of suicide for all participants was moderately high (median=6.4, IQR=4.9 - 7.6); those who had engaged in suicide-related internet use were more likely to report higher intensity of suicide thoughts compared with those who did not engage in it (VAS score median=6.6, IQR=5.0 - 7.8, vs VAS score median=5.1, IQR=4.0 - 7.0, *P*<.001). Fifteen percent of participants (91/585, 15.5%) had not disclosed their thoughts of suicide to anyone; those who had engaged in suicide-related internet use were significantly more likely to disclose this compared to those who had not engaged in this behavior (87.8% vs 72.8%, *P*<.001). The majority of those who did (460/585, 79%) disclosed their thoughts of suicide to a mental health professional.

A quarter of participants reported attempting suicide in the last 12 months (186/696, 26.7%); this was more prevalent among those who had engaged in suicide-related internet use than those who did not (32.5% vs 9.2%, *P*<.001). Of those who had attempted suicide, over half (105/186, 56.5%) had done so more than once and 113/186 (60.8%) had subsequently been hospitalized. Participants who attempted suicide had, on average, reported moderately high levels of planning involved in the attempt (VAS score median=6.7, IQR=4.0 - 8.25). Most of those who attempted suicide did not disclose their plans to anyone (112/186, 60.2%).

Life events that were reported as contributing to suicidality were most commonly relationship difficulties with a partner or family (230/626, 36.7%), serious financial difficulties (193/626, 30.8%), and insomnia (180/626, 30.2%). There were no significant differences in reported life events between those who did and did not engage in suicide-related internet use, even though it seems that more patients who engaged in suicide-related internet use experienced insomnia (32.9% vs 21.9%, *P*=.01) and violence as victims (24.4% vs 13.5%, *P*=.01). When asked about the support for their mental health they had received from their friends, family, and community, participants overall reported a mixed level of support (VAS score median=5.8, IQR=3.1 - 8.0); there was no significant difference in perceived levels of support between those who did and did not engage in suicide-related internet use.

XSL•FO
RenderX

Logistic Regression

All significant variables from the descriptive comparisons were entered together in a multivariable logistic regression model with engagement in suicide-related internet use as the outcome. Patients who engaged in suicide-related internet use were twice as likely to have received a diagnosis of personality disorder and to disclose their thoughts of suicide to someone, and almost 3 times as likely to attempt suicide compared with patients who did not engage in this behavior (Table 3).

Table . Logistic regression model of predictors of engaging in suicide-related internet use among mental health patients (n=652).

	Adjusted ORs[a] (95% CI[b])	*P* value
Diagnosis of personality disorder	1.94 (1.22 - 3.08)	<.004
Thoughts of suicide every day	1.63 (1.03 - 2.58)	.03
Disclosed thoughts of suicide to someone	1.99 (1.22 - 3.25)	.007
Attempted suicide within the last 12 months[c]	2.81 (1.55 - 5.11)	<.001
Intensity of suicidal thoughts	1.11 (1.01 - 1.23)	.03

[a]OR: odds ratio.

[b]Confidence intervals.

[c]continuous variable.

Discussion

Principal Findings

In our UK sample, three-quarters of participants with suicidal thoughts or behaviors who were aged 18 years or older and in contact with mental health services in the past 12 months had engaged in suicide-related internet use. This suggests that suicide-related internet use is a common behavior among suicidal mental health patients who use the internet. There were no differences in sociodemographic factors between those who did and those who did not engage in suicide-related internet use; this provides additional evidence that suicide-related internet use is not a behavior present in young people only [10], underlying the need for clinicians to be aware of the potential for patients of all ages to engage in this behavior. Further findings indicate an association between suicide-related internet use and suicide attempts, personality disorder diagnosis, and disclosure of suicidal thoughts. Multivariable logistic regression revealed that suicide-related internet use was associated with a diagnosis of personality disorder, disclosure of suicidal thoughts, and suicide attempts in the past year.

Our observed proportion of suicide-related internet use is notably higher than what has been reported in similar studies [2-5]. There are several potential reasons for this finding. One possibility is that the usage of the internet increased over time, further boosted by the widespread adoption of smartphones and an increase in the time spent on the web since the COVID-19 pandemic [17,18]. This has made internet access more prevalent and immediate, particularly when compared with studies conducted nearly a decade ago. Alternatively, and perhaps more critically, our sample is unique in that it comprises people who had contact with mental health services. Unlike earlier studies that generally did not include mental health patients, our participants may have been more inclined to engage in suicide-related internet use as a means of supplementing their ongoing mental health care or during periods of distress. This difference could be a key factor contributing to the higher observed prevalence of suicide-related internet use in our study.

Although sociodemographic characteristics did not differ between those who did and those who did not engage in suicide-related internet use, our findings provide important insights into the characteristics of patients who engaged in this behavior. The majority of those who have engaged in suicide-related internet use were women, likely due to their higher survey participation rates [19,20] and the gender paradox in suicide, where women experience more suicidal ideation despite lower suicide mortality rates. Nonetheless, the higher prevalence of women in our sample could also be due to women engaging more frequently in suicide-related internet use. Similarly, our sample was also highly educated, with over half holding a university degree. While those who engage in suicide-related internet use may be more educated, survey participation is generally higher among highly educated people [21]. Despite 85% of all participants aged 25 years or younger engaging in suicide-related internet use, the overall age distribution demonstrates the presence of this behavior in all age groups. This supports the notion that suicide-related internet use is not limited to younger age groups [10]. In addition, a notable proportion of participants identified as gender or sexual minorities. This may be because LGBTQ people have higher rates of suicidality compared with their heterosexual and cisgender peers [22]. LGBTQ people are often more reliant on web-based platforms for mental health support due to systemic barriers in traditional care settings. These barriers include pervasive experiences of discrimination, microaggressions, and a lack of culturally competent care within mental health systems [23,24]. Consequently, many turn to the internet not only for information but also to find community, validation, and anonymity, which can be particularly important in navigating sensitive topics such as suicidality. Specifically, transgender and nonbinary people often encounter additional barriers such as being misgendered, denied care, or subjected to pathologization in clinical settings, which can further drive them to seek alternative support online [25]. In addition, participation in surveys may be viewed by some LGBTQ people as a form of advocacy or community contribution: an opportunity to shed light on mental health disparities affecting their communities [26]. Most participants in the study identified as white, with a

XSL•FO
RenderX

notable minority of those with a mixed heritage background; this mirrors the ethnic composition of suicide rates in both general and patient populations [27,28]. However, suicidality among ethnic minority groups in the United Kingdom remains under-researched [28], and this gap seems to also extend to suicide-related internet use.

Clinically, most participants were diagnosed with affective or anxiety disorders, similar to the general patient population [29]. Among those who attempted suicide, over half were subsequently hospitalized, highlighting the severity of suicidal intent in our sample. In addition, our participants were moderately dissatisfied with the mental health service provision they received, which may have contributed both to the higher prevalence of suicide-related internet use and participation in our survey, as those dissatisfied with care provision might have been more inclined to engage in suicide-related internet use and to participate in the study. A similar situation was true for support for their mental health they had received from their friends, family, and community; mixed levels of perceived support may have contributed to the higher prevalence of suicide-related internet use in our sample. Notably, even though not significant due to a more stringent significance cut-off value, almost a third of patients who have engaged in suicide-related internet use experienced insomnia, and a further quarter experienced violence as a victim: these characteristics warrant further investigation.

In general, our sample was highly suicidal, with almost three-quarters of participants experiencing thoughts of suicide every day, and we found a greater likelihood of suicide attempts in the past year and an increased intensity of suicidal thoughts among mental health patients who engaged in suicide-related internet use. This supports findings from studies conducted on both general [2-6] and clinical populations [12,30]. A high intensity of suicidal thoughts can point to a higher risk of suicide attempts among patients who have engaged in suicide-related internet use, but it can also show how increasing suicidality can lead people to seek new web-based help resources and ways to cope [2,4,6]. Indeed, findings from another piece of research informed by this dataset show that for participants in our sample, the most common motivations for engaging in suicide-related internet use were searching for help and searching for suicide methods [31]. Therefore, the higher prevalence of engaging in suicide-related internet use in those with more frequent and intense thoughts of suicide may indicate help and support-seeking intentions. On the other hand, there is a possibility that suicide-related internet use engagement may have informed participants' suicide attempts; previous research has shown that suicide attempts of mental health patients were often shaped by their web-based searches [10,30], with evidence showing that these searches were directly connected to suicide attempts in 58% - 65% of patients [32,33]. This underscores the potential role of the internet in planning and facilitating suicide attempts, a significant concern given the influence web-based searches can make in the selection of novel and highly fatal suicide methods [10]; however, this was not examined in this study.

Those who engaged in suicide-related internet use were more likely to have received a diagnosis of personality disorder compared with those who did not engage in suicide-related internet use. While, to the authors' knowledge, there is currently no research on personality disorders and suicide-related internet use, research on personality disorders and internet use, in general, has shown a higher incidence of internet addiction and problematic social media use, such as using social media as a distraction from interpersonal problems, reassurance seeking, and self-confidence issues in people meeting criteria for personality disorder [34,35]. This may indicate that people with personality disorders are more vulnerable to developing maladaptive web-based behaviors, including suicide-related internet use. Given that personality disorders are often characterized by difficulties in emotional regulation, impulsivity, and unstable self-image [36], it is plausible that these people may turn to suicide-related internet use as a coping mechanism, to manage distress, or to seek validation. In addition, while no differences in satisfaction with services were found between diagnostic groups in our sample, overall satisfaction with service provision was low. Research has shown that patients with personality disorders often experience challenges in mental health service provision [37] due to the commonly present stigma associated with these diagnoses and the tendency for it to obscure the individual needs of the patient [38,39]. As a result, mental health patients diagnosed with personality disorders may turn to the internet for suicide-related purposes when they do not feel adequately supported by services. Future research should explore the specific mechanisms underlying the relationship between personality disorder diagnosis and suicide-related internet use to better understand its potential risks and implications.

Mental health patients who used the internet for suicide-related purposes were more likely to disclose their thoughts of suicide to someone compared to those who did not, most often a mental health professional. A recent meta-analysis showed that less than half (44%) of mental health patients who have experienced suicidal thoughts or behaviors disclosed this to someone [40]; the prevalence of disclosure of suicidal thoughts was much higher in our sample (84%). One reason for this might be the self-selection of our participants, that is, those who were more likely to disclose their suicidal thoughts and behaviors by participating might also be more likely to disclose this to others. However, 2 studies reported that those who were motivated by seeking help to engage in suicide-related internet use were less likely to disclose their issues with suicide or self-harm and to seek treatment offline [2,41]. As both of these studies concerned this behavior in young people, our results offer potential evidence that the interaction between suicide-related internet use and disclosure may be different in adults.

Strengths and Limitations

To the authors' knowledge, this is one of the first national studies to focus on suicide-related internet use in suicidal adults in recent contact with mental health services. While previous research has predominantly examined this behavior in younger populations, this study brings more insight into the suicide-related internet use of adults. A further strength of this study lies in the comparatively large sample of participants; notably, our sample size is 3 to 5 times larger than in previous

XSL•FO
RenderX

studies, potentially enhancing the representativeness of our findings.

However, the results should be considered in light of certain limitations, most of which are common for cross-sectional survey studies in general. First, the cross-sectional design means we cannot establish causality. Second, our study sample consists of UK-based people in contact with secondary mental health services. Therefore, the generalizability of our findings to other nations is limited by differences in internet infrastructure, suicide prevention resources, and access to mental health care. The results may also not be generalizable to primary care patients and people without diagnoses of mental illness. Third, the self-selection bias of our participants, manifesting in over- and under-representation of certain groups, potentially impacted several aspects of the results. Therefore, we are unable to generalize our results to all suicidal mental health patients. Specifically, the comparisons between those who did and those who did not engage in suicide-related internet use were impacted by unequal group sizes (3:1 ratio), which was partially addressed using Bonferroni correction. Overall, results suggest that suicide-related internet use is a common behavior among suicidal mental health patients who use the internet, though it is important to interpret the findings with caution as this prevalence is based on participants' self-report. The study's retrospective design could have introduced recall bias. However, we attempted to mitigate this by focusing on events within a consistent and short time frame (the past 12 mo). While the lack of standardized measures in our study limits comparability, we believe that it brings additional strengths by reducing recall bias and socially desirable responding. However, we could not verify participants' reported mental health histories against official records.

Another limitation is the lack of measurement regarding the temporal relationship between suicidal thoughts or attempts and suicide-related internet use, namely, whether suicide-related internet use preceded, coincided with, or succeeded suicidal thoughts or attempts. For instance, suicide-related internet use may precede a suicidal attempt. This temporal pattern would suggest a critical window for early intervention, where identifying and responding to such web-based behaviors could help mitigate the progression toward more severe mental health crises. Early detection through digital trace data could enable mental health professionals, platforms, or support systems to offer timely resources or outreach before suicidal ideation fully develops. Alternatively, if suicide-related internet use follows a suicide attempt, it may reflect a person's need to seek understanding, share their experiences, or make sense of what happened. This could also indicate postattempt distress, confusion, or a continued risk of harm. However, suicide-related internet use is often not a single event; rather, it tends to occur repeatedly over time as people may engage in multiple instances and types of this behavior [30]. Furthermore, suicidal people may engage in suicide-related internet use during varying stages of distress, sometimes as a means of coping or information-seeking and at other times as a response to immediate crises. Consequently, this complexity makes it challenging to determine which behaviors precede or succeed others, suggesting the need for alternative study designs, such as longitudinal or ecological momentary assessment methods, to capture the temporal aspect of this behavior.

A recent scoping review called for the increased use of validated questionnaires in the field of suicide-related internet use research [42]. While we agree that using validated questionnaires increases reliability and comparability across studies, there is currently no validated tool that comprehensively addresses suicide-related internet use, especially not for our target population of adult mental health patients [42]. Consequently, we maintain that the current questionnaire, developed with input from Patient and Public Involvement and Engagement, meets rigorous standards of scrutiny for this study.

Conclusion

By recognizing suicide-related internet use as a prevalent behavior among high-risk groups, mental health professionals can be better equipped to identify it and engage with patients. As recommended in previous work by this group [10,43], a direct, nonjudgmental inquiry on whether and why a patient has engaged in suicide-related internet use should be a part of the assessment in mental health services. Our findings on high levels of suicidal ideation disclosure, particularly to clinicians, suggest a possible pathway for suicide-related internet use inquiry; once a patient discloses suicidal thoughts to a mental health professional, a follow-up inquiry about suicide-related internet use could be beneficial. An open discussion about suicide-related internet use and the role it fulfills in a patient's life, whether as an additional coping mechanism or a supplement to service provision, may help clinicians discover any unmet needs. Through a collaborative approach, clinicians and patients can explore effective ways to address these needs. This approach has the potential to enhance therapeutic outcomes, reduce suicide risk, and improve the quality of mental health care for vulnerable people.

Our previous findings underscore the importance of ensuring that people engaging in suicide-related internet use encounter supportive, educational, and appropriately tailored web-based content [31]. Given the widespread nature of such searches, suicide prevention results represent a critical first line of defense. However, their effectiveness may depend on algorithmic sensitivity, as well as the integration of multimodal crisis services and educational materials. Furthermore, our previous study revealed that many users lack awareness of how to navigate suicide-related content safely, highlighting the need to improve digital literacy. This aligns with previous work identifying mental health literacy gaps as barriers to effective web-based help-seeking and suggests a dual approach: integrating adaptive web-based interventions while empowering clinicians to address suicide-related internet use directly and constructively in care settings [31].

The Web-Based Recognise and Respond Gatekeeper Training Program: Noninferiority Randomized Trial

Abstract

Background: Gatekeeper training teaches community members to identify individuals at risk of suicide and assist them with help-seeking. A new online program, Recognise and Respond (R&R), was developed to address the need for a program specific to the Australian context, created in consultation with clinicians, researchers, and people with a lived experience of suicide.

Objective: This study aimed to evaluate whether the R&R gatekeeper training is noninferior to the established Question, Persuade, Refer (QPR) online program, in improving confidence to identify and support individuals experiencing suicidal thoughts. Secondary objectives examined the short- and medium-term effects of R&R on attitudes toward suicide prevention and knowledge of appropriate responses to signs of suicide.

Methods: A total of 524 participants were enrolled at baseline and were then randomized to receive access to either R&R (n=263) or QPR (n=261). The primary outcome—gatekeeper confidence in identifying and supporting an individual experiencing suicidal thoughts—was assessed using a noninferiority framework. Secondary outcomes, including attitudes toward suicide prevention and knowledge of appropriate responses to signs of suicide, were assessed using superiority testing. Outcomes were assessed via online surveys at baseline, postintervention, and the 3-month follow-up. The trial was conducted entirely online, with no face-to-face contact with participants. Data were analyzed using mixed effects linear models.

Results: Participants in both groups reported significant improvements in confidence across time indicating noninferiority of the R&R program. Both groups showed significant improvements on attitudes and knowledge scores at postintervention and the 3-month follow-up, 3. to baseline. Improvement in attitude scores between baseline and postintervention and follow-up were greater for the QPR group compared to the R&R group. Gains at postintervention were maintained at follow-up for both groups considering all outcomes. There were no other between-group differences.

Conclusions: The findings demonstrate that R&R is as effective as QPR online in improving gatekeeper confidence to identify and support someone having thoughts of suicide.

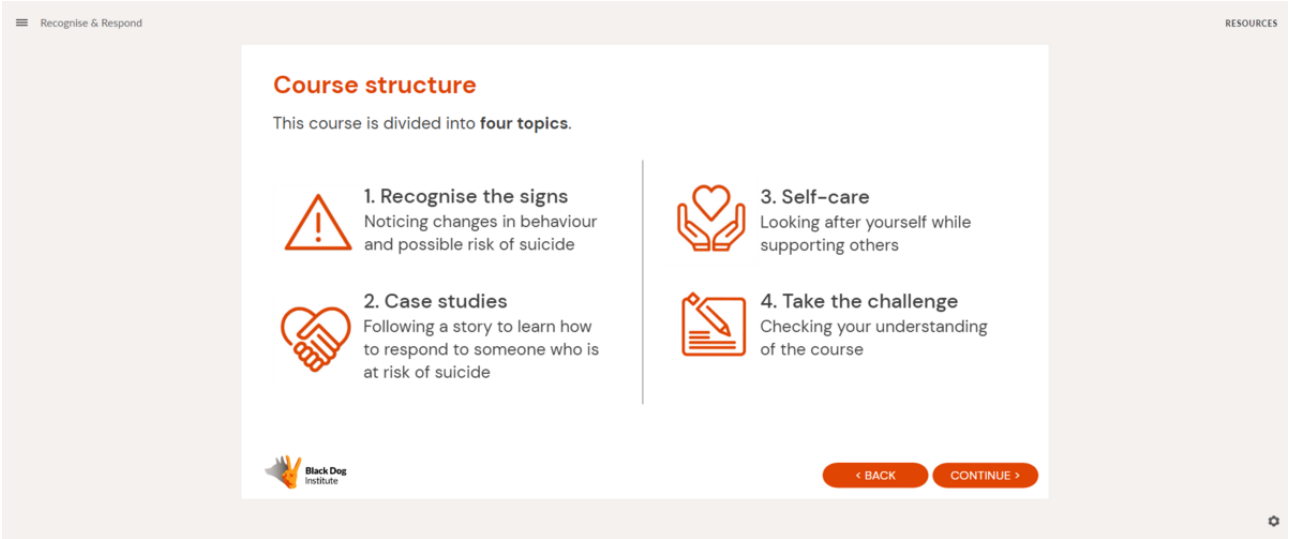
Introduction

Suicide continues to be a global public health priority, claiming more than 700,000 lives worldwide each year [1]. Within Australia, over 3000 people were lost to suicide in 2022, and 1.5 million indicated that they had made a suicide plan during their lifetime [2]. A combination of systemic and personal barriers often prevents at-risk individuals from seeking help for suicidality, including limited-service availability and personal hesitation due to the perceived risk of stigma regarding mental health difficulties [3]. Two-thirds of individuals who die from suicide do not access care from a mental health professional or receive a mental health diagnosis prior to their death [4,5]. However, individuals at risk of suicide do often express their distress to those in their community, particularly family and friends, through observable and identifiable behaviors [6,7]. Effective suicide prevention strategies within the community are essential to provide support to individuals who may not seek professional clinical support but actively seek help from the community.



XSL•FO
RenderX

Gatekeeper (or community) training programs are a promising strategy to address this need and facilitate engagement with professional services for people at increased risk of suicide [8-10]. These programs provide training to members of the public or community workers who are identified as potential "gatekeepers"—individuals who may incidentally encounter people with increased suicide risk, are able to identify them by recognizing suicide risk warning signs, and who may assist the person to access care [11]. Potential gatekeepers are not restricted to roles with formal training in suicide crisis response and management. Examples of potential gatekeepers can also include primary healthcare providers, school staff, first responders, and social workers [10]. Evidence suggests that training can improve gatekeepers' suicide knowledge, attitudes towards people with suicidal behaviors, and confidence in their ability to intervene [11-13].

The Question, Persuade, Refer (QPR) program is a well-recognized and widely used gatekeeper training program [14,15] shown to increase participants' confidence, as well as knowledge and self-reported help-giving behaviors [16-20]. The QPR program teaches gatekeepers a three-stage model of intervention, beginning with recognizing the warning signs of increased suicide risk in an individual and questioning that person about their suicidal thoughts and feelings (Question). The program then trains gatekeepers to have supportive and reassuring conversations with individuals, during which the individual may be open to accepting referrals of help (Persuade). Finally, gatekeepers are trained to refer at-risk individuals to clinical support, intervention, and treatment (Refer). Early intervention is ideal under this model as it leads to more positive outcomes for individuals experiencing suicidality [21]. In addition to an effective face-to-face training module [22], QPR can also be delivered through an online "e-learning" module. The online module is as effective as the face-to-face format at improving outcomes on confidence for identifying and supporting those experiencing suicidality, knowledge about suicide and suicide prevention, and intentions to engage in suicide prevention [23].

The Black Dog Institute's (BDI) LifeSpan suicide prevention trial delivered the QPR program online for community and workplace gatekeeper training within a larger trial [24]. Participant feedback indicated a need for a program with greater cultural relevance in the Australian context, rather than being culturally specific to the United States. This is consistent with literature suggesting that suicide is impacted by a complex interplay of factors including social and cultural influences [25], which may vary from nation to nation. Particularly relevant to the Australian context is the prevalence of culturally and linguistically diverse communities, for whom the role of sociocultural factors such as acculturation, stigma, social networks and family, and culturally driven intervention preferences must be considered [26]. In response, the BDI developed the Recognise and Respond (R&R) program—a gatekeeper training program that uses instructional design principles, includes diverse Australian case studies, and provides local referral options. The program was designed in consultation with clinicians, researchers, community organizations, and people with a lived experience of suicide. The R&R program consists of four topics with interactive activities, case studies depicting interactions between a person experiencing thoughts of suicide and a helper, and scenario-based challenges to test learning (Figure 1).

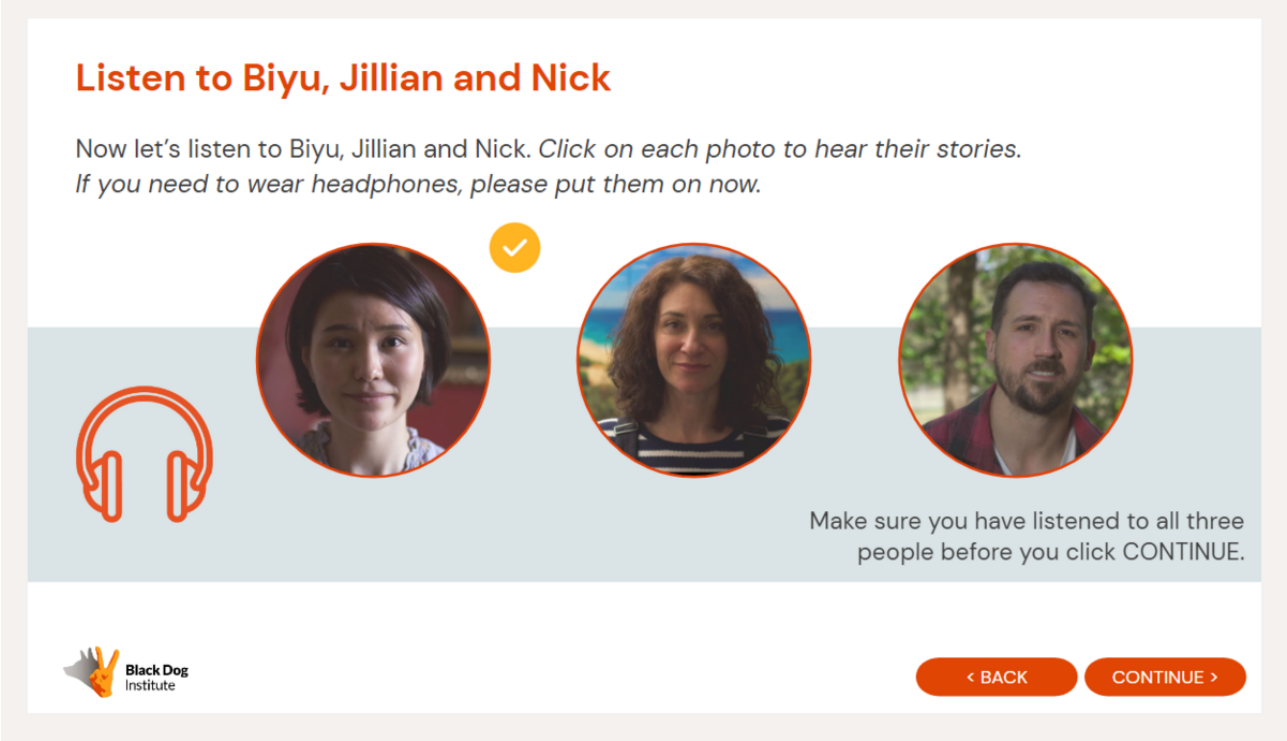


Figure 1. Overview of the R&R program.

The content covered in interactive lessons is reinforced through PDF resources that users can download and keep for future reference. The case studies included in R&R (Figure 2, images in the training program used with consent) are tailored to focus on Australian populations that are disproportionately affected by suicidal risk and behavior including Aboriginal and Torres Strait Islanders, the LGBTQIA+ (lesbian, gay, bisexual, transgender, queer/questioning, intersex, asexual) community, men, refugees and migrants, and Australians living in rural and remote communities [27]. The inclusion of these priority populations is to ensure that prospective gatekeepers are aware of the nuances that place these groups at heightened risk and to provide them with the contact details for tailored and locally relevant mental health services.

Figure 2. Case studies to learn how to respond to someone who is at risk of suicide.

Beyond the Lifespan trial, internet-delivered gatekeeper programs have yet to be extensively evaluated in the Australian context. To leverage the potential benefits of online interventions in enhancing dissemination and accessibility [28], such as increased flexibility and cost-effectiveness [29], R&R was designed to be an internet-delivered training program. This paper reports outcomes of a noninferiority trial, a design used to determine whether a new intervention performs at least as well (noninferior) as an established intervention within a prespecified margin, rather than aiming to demonstrate superiority. This approach was chosen to evaluate whether the Australian R&R program could achieve comparable results to the established and effective international online QPR program when delivered with an Australian sample.

Objectives of the Current Study

The primary objective of the present study is to assess whether the R&R gatekeeper training program is noninferior to QPR in improving confidence in identifying and supporting an individual experiencing thoughts of suicide at postintervention and follow-up. Secondary objectives were to evaluate the short-and medium-term impacts of the R&R program relative to QPR on attitudes towards suicide prevention and knowledge of appropriate responses to signs of suicide, using a superiority framework

It was hypothesized that participants who completed the R&R and QPR online gatekeeper programs would show a similar (noninferior) improvement from baseline to posttraining and at the 3-month follow-up on confidence in gatekeeper skills (primary hypothesis). Additionally, it was hypothesized that there would be no significant differences between R&R and QPR participants on improvements in attitudes towards suicide prevention, and knowledge of appropriate responses to signs of suicide (secondary hypotheses).

Methods

Ethical Considerations

The trial was approved by the University of New South Wales Human Research Ethics Committee (HC200105) and registered with the Australian New Zealand Clinical Trials Registry (ACTRN12620000489998p). Eligible participants were provided with a Participant Information Sheet and asked to provide consent using an online consent form. Participants received a 20 AUD (US$ 13.05) gift voucher for each survey completed (baseline, posttraining, and 3-month follow-up). Participant data ere deidentified.

Design

A noninferiority randomized controlled trial was conducted to compare the R&R program with the QPR online program. Study outcomes were collected via self-report surveys at baseline, 2 weeks postbaseline, and at the 3-month follow-up. The study took place between July 2020 and March 2021 and was conducted online, with no face-to-face contact with participants.

Participants and Sample Size

Eligible participants were required to be aged 18 years or over, have sufficient English literacy skills, and access to a computer, tablet, or smart phone to complete the training and surveys. To test that the R&R program was not inferior to the QPR program, a minimum of 170 participants in each group were needed to have 90% power to detect that the lower limit of a one-sided 97.5% CI (or equivalently a 95% two-sided CI) would be above the noninferiority limit of −5. A total attrition rate of 55% was expected at postintervention and follow-up, bringing the initial target sample size to 378 participants in total.

XSL•FO
RenderX

Recruitment and Consent

Participants were recruited via two methods: a paid social media campaign of study advertisements on Facebook and Instagram, and the distribution of study details through the University of New South Wales (UNSW) and community organizations using flyers, posters, and websites. Advertisements contained a brief description of the training program and the study, and the inclusion criteria. Prospective participants who clicked on study advertisements were redirected to the study website where they were able to complete the eligibility screener.

Procedure

All consenting participants were randomly allocated to the intervention or active comparator group using block randomization (4 per block). Participants were not blinded to their group allocation. Participants were given 1 week to complete the pretraining survey. If they did not complete it within this time, they were automatically withdrawn from the study. Participants had 2 weeks access to complete their assigned training. Automated invitations to complete the posttraining and follow-up surveys were sent at 2 weeks and 3 months after completing baseline, respectively. During this time, participants had 2 weeks to complete each survey, after which surveys were closed. Participants were encouraged to complete the surveys prior to closure via email reminders. For the baseline survey, email reminders were sent 3 days after the initial invitation. For the posttraining and follow-up surveys, reminders were sent 1 week after the initial survey invitations.

Intervention Condition

Participants in the intervention condition received the R&R gatekeeper training program, described in the Introduction. R&R is an Australian program that teaches nonclinical gatekeepers to recognize and respond helpfully to someone exhibiting suicide warning signs and behaviors. It comprises four interactive learning modules, case studies, referral options, and a short test on the content covered in the training. The program is self-directed and takes 60 to 90 minutes to complete.

Active Comparator Condition

Participants in the active comparator group received the QPR online gatekeeper training program [24]. The QPR online program is a mental health intervention that teaches lay and professional gatekeepers to recognize and respond helpfully to someone exhibiting suicide warning signs and behaviors. It is a US-based course that comprises an introductory video, presentations on QPR concepts and skills, and a short test on the content covered in the training. The online version of QPR is self-paced and users were encouraged to complete the program in their own time. On average, the program takes 60 - 90 minutes to complete.

Outcome Measures

Confidence

The primary outcome for this study was participants' self-confidence in gatekeeper skills. A 6-item self-report questionnaire was created based on existing literature and the Mental Health First Aid (MHFA) guidelines for suicidal thoughts and behaviors to assess confidence. Items included statements such as, "I am able to recognize the signs that someone may be having thoughts of suicide," and "I can work with someone to keep them safe from suicide" and were rated on a 5-point Likert scale ranging from "strongly disagree" (1) to "strongly agree" (5). Items were summed to give a total score ranging from 6 to 30. Higher scores indicated greater levels of confidence. In this study, the Cronbach α was 0.83, 0.92, and 0.87 at baseline, posttest, and follow-up, respectively.

Attitudes Towards Suicide Prevention

The ATSP (Attitudes Towards Suicide Prevention) scale is a 13-item self-report questionnaire used to assess health professionals' attitudes towards suicide prevention. Items included statements such as "Suicide prevention is not my responsibility," and "Since unemployment and poverty are the main causes of suicide, there is little that an individual can do to prevent it." For the present study, 3 items not applicable to community members were removed (eg, "working with suicidal patients is rewarding"). The remaining 10 items were scored on a 5-point Likert scale ranging from "strongly disagree" (1) to "strongly agree" (5). Higher scores indicate more negative attitudes. In this study, the Cronbach α was 0.63, 0.73, and 0.72 at baseline, posttest, and follow-up, respectively.

Suicide Intervention Response

The SIRI-2 (Suicide Intervention Response Inventory revised) was designed to assess health professionals' knowledge of appropriate responses to suicide. For the current study, participants were asked to evaluate the degree of appropriateness of two different response remarks to 5 suicidal item-statements, on a 7-point Likert scale ranging from +3 (highly appropriate response) through 0 (neither appropriate nor inappropriate response) to −3 (highly inappropriate response). As this is an edumetric scale, the Cronbach alpha is not reported.

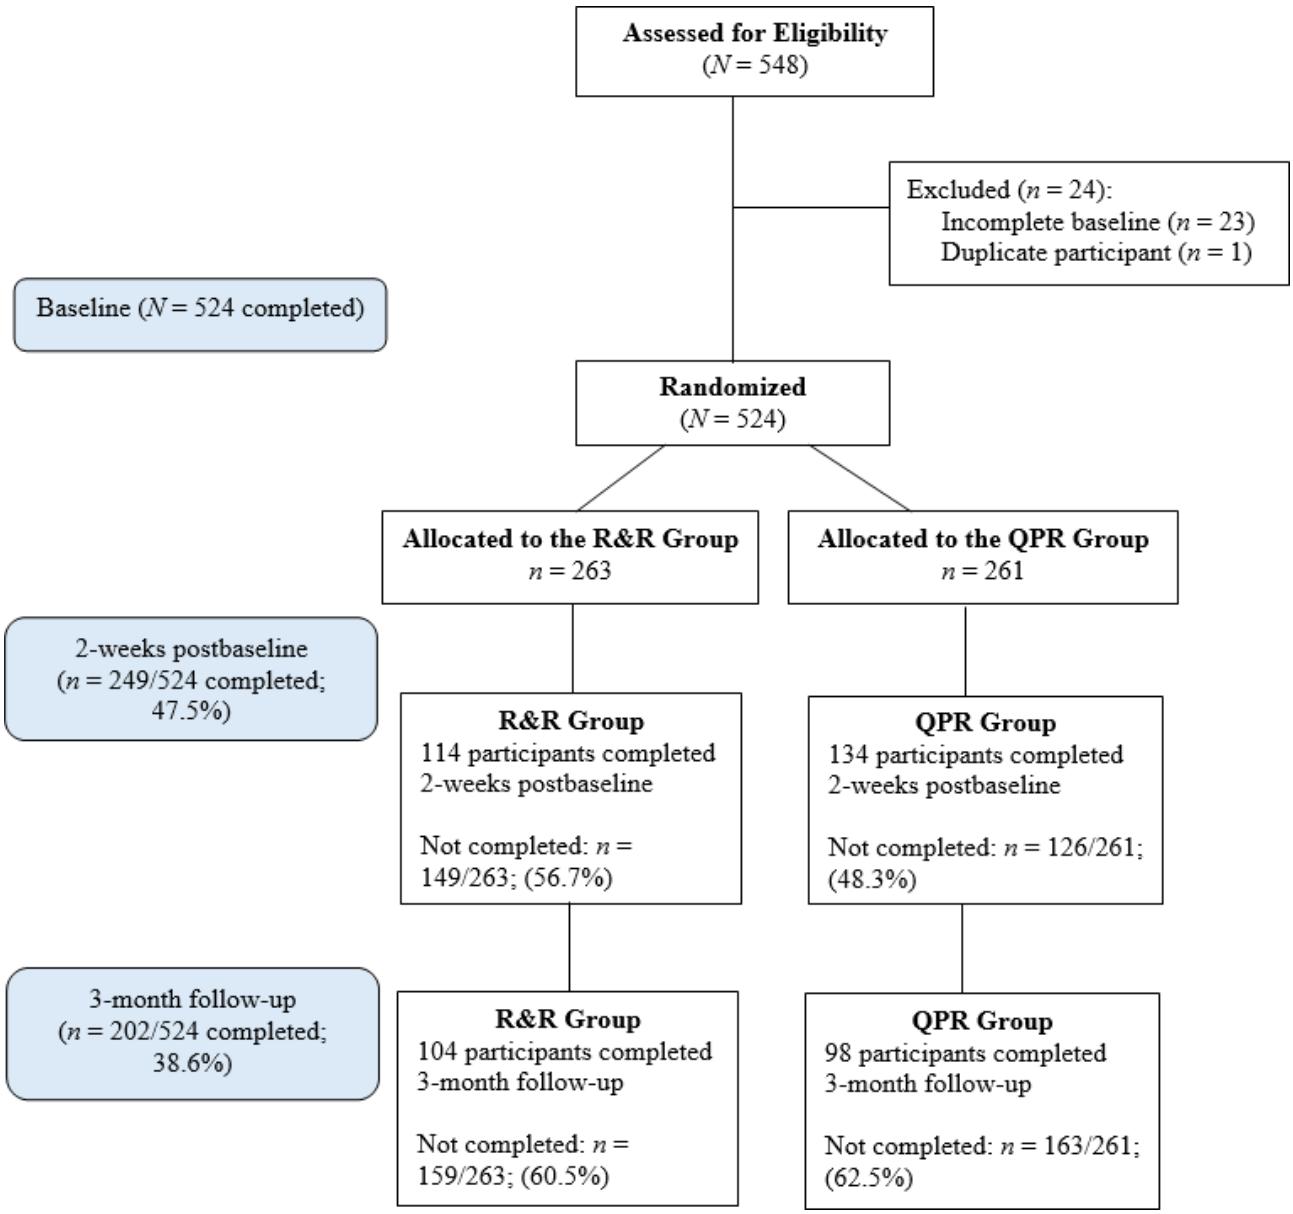
Demographics

At baseline, participants reported how they had found out about the study (open text), their age (in years), gender identity (male, female, other, or prefer not to answer), personal experience of suicide (Please select all statements that apply to you: I have had or continue to have suicidal thoughts, I have attempted suicide, I have cared for someone or continue to care for someone who is suicidal or who has attempted suicide, or I am bereaved by suicide) and whether they have received any prior suicide prevention training (No or Yes).

Data Collection and Analysis

The BDI research engine was used to securely store collected data. Data were then exported to Microsoft Excel and SPSS (version 28.0.1.0; IBM Corp) for cleaning and analysis. Analyses were undertaken on an intent-to-treat basis, including all participants as randomized, regardless of whether participants completed the program or post and follow-up assessments. Descriptive statistics were used to summarize participant demographics and baseline scores for primary outcome of confidence, and secondary outcomes of attitudes and knowledge. For the primary hypothesis, a mixed-model repeated measures analyses of variance was conducted, using one-sided statistical tests due to the noninferiority design. This mixed-effects model provides an intention-to-treat analysis that accounts for all

XSL•FO
RenderX



available data under the missing at random assumption [30]. A priori planned comparison of change from baseline to the posttraining endpoint (2 weeks) and follow-up (3 months) was used to test the primary hypothesis. The noninferiority margin for the primary outcome (confidence) was predefined as −5 points, and the confidence interval approach was used to assess noninferiority. This margin was selected using a heuristic approach, as the confidence scale had not been previously validated for noninferiority testing. Specifically, the margin was based on the assumption that a difference of less than one response choice per item would not be practically meaningful. An alpha level of 0.05 was used. For secondary hypotheses, the same mixed-effects models were used, but with two-sided statistical tests. In addition, we explored baseline factors associated with completion of the posttest and follow-up assessment using a logistic regression. All primary and secondary outcome variables assessed at pretest were included as independent variables in this regression analysis, along with age, gender, personal experience of suicide, and prior suicide prevention training history.

Results

Participants and Baseline Demographics

A total of 584 community members and UNSW staff self-registered for the study. From this, 524 participants completed baseline and were randomized. Two-hundred and thirty-six participants were assigned to the intervention condition and 261 were assigned to the active comparator condition (Figure 3, Checklist 1).

Figure 3. CONSORT study flow diagram of participant recruitment and participation. Note: Completed = participants who answered all questions in the assessment.

The majority of participants were female (446/524, 85.1%) with a mean (SD) age of 38.94 (13.12) years (range 18 - 78 years; Table 1). At baseline, 42.7% of participants (224/524) reported that they have had or continue to have suicidal thoughts and 41.6% had experience caring for someone with suicidal ideation or attempt (218/524; Table 2). A small proportion (76/524,

XSL•FO
RenderX

14.5%) reported having previously attempted suicide. A quarter of participants reported having been bereaved by suicide (132/524, 25.2%). Over a quarter of participants reported that they had received prior suicide prevention training (152/524, 29%).

Table . Characteristics of the baseline sample.

Outcome	Total (N=524)		R&R group (n=263)		QPR group (n=261)	
	Range	Mean (SD)	Range	Mean (SD)	Range	Mean (SD)
Age, years	18 - 78	38.94 (13.12)	18 - 75	39.00 (13.10)	18 - 78	38.88 (13.17)
Confidence score	6 - 30	20.47 (4.24)	6 - 30	20.22 (4.48)	6 - 30	20.72 (3.98)
Attitude towards suicide prevention score	11 - 43	20.21 (4.35)	12 - 43	20.46 (4.63)	11 - 31	19.96 (4.04)
Knowledge score	0 - 10	7.81 (1.65)	1 - 10	7.82 (1.62)	0 - 10	7.80 (1.67)

Table . Suicide experience and sex of participants at baseline.

Characteristics	Total (N=524), n (%)	R&R group (n=263), n (%)	QPR group (n=261), n (%)
Female	446 (85.1)	225 (85.6)	221 (84.7)
Have had or continue to have suicidal thoughts	224 (42.7)	108 (41.1)	116 (44.4)
Have attempted suicide	76 (14.5)	41 (15.6)	35 (13.4)
Have had or continue to care for someone who is suicidal or has attempted	218 (41.6)	106 (40.3)	112 (42.9)
Bereaved by suicide	132 (25.2)	63 (24)	69 (26.4)
Have received any prior suicide prevention training	152 (29)	75 (28.5)	77 (29.5)

Baseline Factors Associated With Completion

Two baseline variables were significantly associated with study retention. Age was negatively associated with dropout (B=−0.016, SE=0.008, *P*=.035, OR=0.984) indicating that older participants were slightly more likely to complete all timepoints. Participants who have had or continue to care for someone who is suicidal or has attempted suicide were significantly more likely to complete the study (B=0.609, SE=0.254, *P*=.016, OR=1.838). Overall, the logistic regression model was not a strong predictor of study retention (χ^2_{13}=20.32, *P*=.088, R^2=.054), explaining 5.4% of the variance in completion status.

Primary and Secondary Outcomes

Baseline scores on confidence, attitudes, and knowledge did not differ significantly between groups (Table 3). There was a significant main effect of time for all outcomes such that both groups showed improvements in confidence, attitude, and knowledge scores between baseline and posttest (*P*<.001), and baseline and follow-up (*P*<.001). There were no significant changes in confidence, attitude, or knowledge scores between posttest and follow-up in either group.

XSL•FO
RenderX

Table . Estimated marginal means and standard errors of the confidence, attitudes towards suicide prevention, and knowledge measures.

Measure	Baseline		Posttraining		Follow-up	
	R&R group, mean (SE)	QPR group, mean (SE)	R&R group, mean (SE)	QPR group, mean (SE)	R&R group, mean (SE)	QPR group, mean (SE)
Confidence (primary outcome)	20.22 (0.25)	20.72 (0.25)	24.59 (0.36)	25.06 (0.34)	24.90 (0.40)	25.80 (0.40)
ATSP[a]	20.46 (0.27)	19.96 (0.27)	19.17[b] (0.34)	16.68[b] (0.33)	18.86[b] (0.36)	16.91[b] (0.37)
Knowledge	7.82 (0.10)	7.80 (0.10)	8.47 (0.13)	8.10 (0.12)	8.55 (0.14)	8.34 (0.14)

[a]ATSP=Attitudes towards suicide prevention.

[b]$P<.05$

The estimated raw mean differences (95% CI) in confidence scores between R&R and QPR were −0.46 (95% CI −1.44 to 0.51) at post-test, and −0.90 (95% CI −2.00 to 0.21) at follow-up. The lower limit of the 95% CI was above the prespecified noninferiority margin of −5 points at both timepoints, indicating that improvements in confidence in R&R at posttest and follow-up were noninferior to QPR.

No significant between-group differences were observed for knowledge scores at any timepoint. However, there was a significant between-group difference in attitude scores at posttest and follow-up (*ps*<.001), with participants in the QPR group showing greater improvement relative to the R&R group (between group Cohen *d*=0.46 at posttest; *d*=0.33 at follow-up).

Discussion

Principal Findings and Comparison With Previous Works

This noninferiority trial aimed to evaluate the efficacy of the R&R gatekeeper training program for improving confidence in gatekeeper skills, attitudes towards suicide prevention, and knowledge of appropriate responses to signs of suicide compared with the established QPR online program. The R&R gatekeeper training program is the first gatekeeper program that has been developed and evaluated to suit the Australian context. The results were consistent with the primary hypothesis that the R&R program was noninferior to QPR for self-reported confidence. Participants who received the R&R program showed improvements in their scores on confidence, attitudes, and knowledge at the end of the 2 weeks, with improvements in these scores present at the 3-month follow-up. Individuals who received the R&R gatekeeper training program showed similar improvements in their confidence and knowledge to those that received the QPR training program. Both groups improved on the measure of attitudes towards suicide, with the QPR group improving more at posttest and follow-up relative to baseline.

Both the R&R and QPR programs were found to have a positive effect on outcomes. Consistent with current literature, these findings suggest that e-learning gatekeeper training programs can improve users' short- and medium-term confidence in identifying and supporting an individual experiencing thoughts of suicide, attitudes towards suicide prevention, and knowledge of appropriate responses to signs of suicide [23,31,32]. Further, the Australian R&R program was found to be noninferior to the established international QPR program for confidence. These findings imply that the addition of contextually relevant case studies and resources did not lessen the effectiveness of gatekeeper training in improving users' confidence to recognize and respond to the signs of suicide compared to QPR.

While both groups showed improvements in attitudes towards suicide prevention, the magnitude of this improvement at posttest and follow-up was greater for the QPR group relative to the R&R group. Although this finding requires further investigation, it may reflect differences in content or interactivity. It is possible that a greater emphasis on connection with community and the meaningful impact of gatekeeper intervention may be necessary to provide similar change in attitudes such as felt responsibility and realistic achievability of suicide prevention. However, the small-moderate benefit of QPR on attitudinal change did not lead to differential increases in confidence or knowledge.

Future research should focus on assessing the long-term impacts (a 6-month follow-up or later) of the R&R program, given that the present study only assessed short- and medium-term impacts. Lancaster et al [23] found that, while showing initial improvements in knowledge, self-efficacy, and behavioral intention, participants showed a decrease in these outcomes between posttest and 6 months after completing the QPR training. As such, it is worth examining the long-term impacts of R&R compared to other established gatekeeper programs. Future research could examine whether participants accessed the PDF resources after training, and if indefinite access to the training content is sufficient to mitigate reductions in the effectiveness of training over time [11]. To further explore the efficacy of the R&R program in the Australian community, future studies should also assess changes in participants' behavioral intention and gatekeeper behavior, preferably within a randomized controlled trial. This would involve measuring participants' willingness to intervene, and their ability to recognize the signs of suicide, ask an individual if they are having thoughts of suicide, and the use of referral pathways. Examining behavioral outcomes is essential for progressing the broader research of gatekeeper training, given that supportive behaviors are rarely assessed despite being a necessary outcome in the success of any gatekeeper program [11]. Finally, it would be valuable to examine whether the inclusion of local referrals in the R&R program led to greater use of referral pathways compared to a gatekeeper program without this tailoring.

XSL•FO
RenderX

Limitations

This study was impacted by greater attrition for survey completions than initially anticipated, with a 61.5% attrition rate at postintervention and a 69% attrition rate at follow-up. However, these rates were not significantly different between the groups. Logistic regression analyses indicated that younger participants were more likely to not complete all timepoints, but this effect was small. Future studies may benefit from increasing reimbursements for the completion of assessments or by incorporating additional survey reminders to minimize the attrition rate. The generalizability of the study's findings is limited by the demographic composition of the sample, which consisted of 85.1% women. Further, the present study did not collect detailed demographic information such as the ethnicity, migrant status, or rurality of participants. As a result, the effectiveness of gatekeeper training may not be fully applicable to men or other gender diverse groups, and efficacy across other demographic factors is unknown. Diverse participants may have entered the trial with varied expectancies or goals about the intervention and its potential benefits that may have influenced how and why they chose to engage with the program, with the potential for differential impacts on efficacy. Future studies should consider assessing more nuanced demographic information and the expectancies and goals of participants enrolling in the study to allow for the evaluation of these possibilities. There may be some value in evaluating interventions with more well-defined and representative groups of suicide prevention stakeholders to allow for the elucidation of these issues and broader applicability of the study findings. Although the consideration of the diversity of potential users is difficult in a population-based trial [33], this may be critical when delivering gatekeeper training within a closed environment such as a healthcare setting or school district.

Additionally, our data analysis did not examine the relationship between training program completion and outcome measures on confidence, attitudes, and knowledge. It is worth assessing how program engagement influenced outcome measures. Further, the internal consistency of the attitude measure was moderate, suggesting the need for further development of suitable measures of gatekeeper training outcomes.

Conclusions

This study was the first to rigorously evaluate an e-learning gatekeeper training program specific to the Australian context. Both programs were efficacious in improving gatekeepers' confidence, attitudes, and knowledge. The R&R online program provides equivalent outcomes to the established QPR online program using collaboratively developed content suited to the Australian context.

Acknowledgments

We would like to thank all the organizations and individuals who contributed to the co-design of the development of the program, and the University of New South Wales for their support in recruiting research participants. We acknowledge and thank all people with lived experience that participated in focus groups, contributed and provided their voice to the development of the program.

Conflicts of Interest

The Recognise & Respond program is owned by the Black Dog Institute. Users pay a fee for the program. CC, AM, and DR are employed by the Black Dog Institute. FS is employed by the University of New South Wales but is based at the Black Dog Institute. This trial was conducted before Recognise & Respond was made publicly and commercially available. Abstract

Background: The impact of smartphone use on mental health is being rigorously debated. Some questionnaire-based research suggests that smartphone use correlates with nonsuicidal self-injury (NSSI). Self-reported data seem unlikely to capture actual smartphone use precisely, requiring objective measures to advance this field.

Objective: The aim of the study is to examine whether objectively measured smartphone use was associated with NSSI among college students.

Methods: This multicenter cross-sectional study was conducted from 2022 to 2024, enrolling college students from 559 classes across 6 universities in China. NSSI was measured by the Ottawa Self-Injury Inventory including 10 items of NSSI without suicidal intent within the past month. Participants answering "ever" were classified as having NSSI. Objectively measured smartphone screen time and number of smartphone unlocks were obtained from screenshots of smartphone use records. The association between objectively measured smartphone use and NSSI was analyzed using binary logistic regression models and restricted cubic spline regression.

Results: Of 16,668 included participants, 627 (3.8%) reported NSSI. Mean (SD) smartphone screen time and number of smartphone unlocks were 48.8 (28.8) hours per week and 271.6 (291.0) times per week. The models adjusted for different factors showed a significant association between smartphone use and NSSI. Compared to participants with 0-21 hours per week of smartphone screen time, those with ≥63 hours per week of smartphone screen time had higher odds of NSSI (odds ratio [OR] 1.63, 95% CI 1.32 - 2.01). Likewise, compared to participants with 0-50 times per week of smartphone unlocks, those with ≥400 times per week of smartphone unlocks had higher odds of NSSI (OR 1.53, 95% CI 1.25 - 1.88). No significant NSSI risk increase was observed for participants with 21-42 and 42-63 hours per week of smartphone screen time nor for those with 50-150 and 150-400 times per week of smartphone unlocks. Moreover, restricted cubic spline analyses showed that the increasing risk of NSSI was associated with elevated smartphone screen time and number of smartphone unlocks.

Conclusions: These findings emphasize that ≥63 hours per week of smartphone screen time and ≥400 times per week of smartphone unlocks are risk factors for NSSI among college students, and interventions targeting NSSI should consider the apparent association with smartphone use.

smartphone screen time; number of smartphone unlocks; nonsuicidal self-injury; objective; college students

Introduction

The role of smartphone use in mental health has been rigorously debated by the public and academia [1,2]. Some literature suggests that excessive smartphone use is related to poor mental health conditions [3-5], such as depression, anxiety, and sleep disorders. However, other evidence implies that adverse daily life outcomes of smartphone use may be overestimated [1]. Much of the discourse regarding smartphone use and mental health has focused on smartphone addiction and dependence, which typically reflect the subjective experience of smartphone use. Smartphones are now a ubiquitous part of everyday life.

XSL•FO
RenderX

The prevalence of smartphone ownership and excessive smartphone use has increased exponentially in recent years among both youths and adults. The widespread use of smartphones in everyday life points to the need for rigorous and objective methods that can adequately capture the true association between smartphone use behaviors and mental health. Several investigations have explored associations between smartphone use behaviors—including smartphone screen time of use, number of smartphone unlocks, and text message volume—and mental health outcomes [5-8]. Nevertheless, most research relied on participants' self-reported smartphone use [6-8]. This is an important limitation because prior studies showed that self-reported smartphone use has significant recall bias and misclassification probability [9-11], and such self-reporting does not correlate well with objectively measured smartphone use. Moreover, it should be particularly noted that using self-reported methods to evaluate the unconscious behavior of smartphone use may be especially inappropriate for people with psychological problems, as they are likely to either underestimate or overestimate their actual smartphone use behaviors [9].

Nonsuicidal self-injury (NSSI) refers to the intentional act of harming one's own body without the aim of ending life [12]. NSSI is a complex phenomenon with a wide variety of underlying causes and contributing factors. Repeated engaging in NSSI can desensitize individuals to sensations of pain, harm, fear, and mortality, thus increasing the likelihood of suicide attempts [13]. Notably, unlike suicide prevention, NSSI has been neglected by governments internationally. The association between smartphone use and NSSI may be especially relevant for college students, who tend to exhibit more severe and widespread excessive smartphone use. Indeed, during the crucial phase of transitioning to adulthood, college students are particularly prone to external stressors, including pressures from peers, academic responsibilities, employment pressure, and social anxiety [14]. They exhibit a high risk of NSSI, albeit lower than middle and high school students. The social learning hypothesis of Nock's integrated model of NSSI also believes that observing others' NSSI behavior can prompt individuals to translate NSSI ideation into actual action [15]. With the widespread adoption of smartphones among college students, it has also become the primary means for them to obtain information about NSSI, learn NSSI methods, and connect with peers who are involved in NSSI. Additionally, the vivid and repetitive descriptions of pleasure and harming ways on smartphones may lead to an underestimation of the seriousness and consequences of NSSI [16]. Some literature suggests that excessive smartphone use can supplant sleep and physical activity [17] as well as social interaction [18,19], all of which are known to be beneficial to mental health. Moreover, smartphone use might interfere with self-regulation strategies [20], which may be correlated with NSSI.

To our knowledge, little research has examined the association between excessive smartphone use and NSSI. The extant studies [21-25], primarily based on self-reported surveys, have connected smartphone addiction or dependence to NSSI. Only 2 studies specifically investigated the relationship between self-reported time spent on smartphones and NSSI in middle school student populations [21,22]. To date, no research has examined the role of smartphone use behaviors in NSSI among college students or used methods that can measure objective smartphone use behaviors. Emerging conceptual frameworks posit smartphone use as a multidimensional construct with differential mental health impacts. Smartphone screen time and number of smartphone unlocks represent distinct aspects of smartphone use behavior [26,27]. Specifically, smartphone screen time quantifies the cumulative duration of active or passive content consumption, whereas the number of smartphone unlocks reflects habitual checking behaviors. Compared with smartphone screen time, number of smartphone unlocks involves compulsive, notification-driven interactions and is more strongly associated with anxiety, addiction, and problematic use patterns. What is more, prior findings on the associations of these 2 smartphone metrics and mental health have been inconsistent [28-30]. A study using the objective method showed that objective smartphone time and number of smartphone unlocks might reflect differences in smartphone use patterns [28]. Specifically, it revealed that depression and anxiety severity were correlated with the number of smartphone unlocks but not related to smartphone screen time. While a recent study using smartphone sensing technology found that longer smartphone screen time predicted higher internalizing and externalizing symptoms in youths, more smartphone unlocks were associated with lower internalizing symptoms [29]. Notably, another investigation reported a positive association between the number of screen unlocks and loneliness [30]. However, the sample sizes of these studies were extremely limited, with a maximum of only a few hundred participants. Adding to the limited relevant studies at present, further research is required.

This study assessed objective smartphone screen time and number of smartphone unlocks by collecting screenshots of participants' smartphone use records, with the aim of examining whether objectively measured smartphone use was associated with NSSI in college students. Furthermore, we performed subgroup analyses by sex and grade to better understand the relationship between smartphone use and NSSI within this crucial demographic.

Methods

Ethical Considerations

The Second Affiliated Hospital of Xi'an Jiaotong University granted ethics approval for this research (approval ID: 2022 - 248). All participants gave their electronic informed consent prior to participating in the study. The study adhered to the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) reporting guideline. Data were analyzed from December 2023 to October 2024. The identifiable features of participants in the paper or Multimedia Appendix 1 are not visible.

Recruitment

In this cross-sectional study, we collected data from a representative group of college students in Shaanxi province, located in Northwest China. The study design and investigation process have been previously described [31]. First, 6 universities were randomly selected from a pool of 57 universities of

XSL•FO
RenderX

Shaanxi province, comprising 4 public universities of 34 and 2 private universities of 23. Afterward, for each of the universities under investigation, we randomly selected 2 to 4 classes from each grade within every department or college. All students enrolled in these chosen classes were encouraged to take part in the survey. The consistency of the proportion of students participating in the survey across universities was maintained by adjusting the number of selected classes. Prior to the investigation, we organized a 2-phase training to explain the objectives and processes to the students, including training of 2 officers from each chosen class, who then trained all other students in their respective classes.

In total, 20,165 undergraduates from 559 classes at 6 universities were invited to join in the study. We included all 16,668 students who provided clear screenshots of their smartphone use records.

Measures

Objectively Measured Smartphone Use

In this study, the objective smartphone use included smartphone screen time and number of smartphone unlocks. We gathered the objective smartphone use data by collecting screenshots of participants' smartphone use records. Two weeks before the formal investigation, we instructed the participants to activate the function for smartphone records to ensure the availability of objective data. Then, we provided step-by-step instructions for finding screenshots of smartphones with different brands and types and required them to submit the screenshots covering (1) smartphone screen time during the past week and (2) number of smartphone unlocks during the past week. According to the present distribution of data and previous studies on smartphone screen time [32-34], we classified participants into 4 groups (0-21, 21-42, 42-63, and ≥63 hours per week). To ensure that the analysis aligns with our dataset distribution and offers practical interpretability, we partitioned smartphone unlocks into quartiles using integer thresholds. Consequently, we classified participants into 4 groups for number of smartphone unlocks (0-50, 50-150, 150-400, and ≥400 times per week).

Nonsuicidal Self-Injury

The Ottawa Self-Injury Inventory, a commonly used instrument, was used to assess NSSI [35]. It comprises 10 NSSI behaviors, including hitting, head banging, stabbing or cutting, pinching, scratching, biting, burning, drowning, excessive or indiscriminate medication use, and swallowing or drinking inedible items. Participants who responded "ever" during the past month were classified as having NSSI. The Ottawa Self-Injury Inventory has demonstrated both validity and reliability within the Chinese population [36]. In this study, the Cronbach α coefficient was 0.94.

Covariates

We developed a structured questionnaire to collect several confounding factors that have been recognized as relevant to both smartphone use and NSSI [37,38], including sociodemographic information, health-related lifestyles, and negative life events. Sociodemographic information incorporated sex, grade, race, registered permanent residence, siblings, and parental educational attainment.

As described in a previous study [39], health-related lifestyles included current smoking, current drinking, physical activity, and rational diet. Participants who smoked at least 1 cigarette in the last 30 days were classified as current smokers. Similarly, those who consumed at least 1 glass of wine during the past 30 days were categorized as current drinking. We used the International Physical Activity Questionnaire Short Form to assess physical activity, categorizing activity levels into low, moderate, and high according to established metabolic equivalent calculations. Irrational diet was defined as participants consuming red meat every day or vegetables or fruits less than daily. The negative life events included family disasters, hospitalization experiences, failed examinations, and failed relationships within the last year.

Statistical Analyses

Frequencies and proportions for categorical variables, as well as mean and SD for continuous variables, were used to depict the characteristics of participants. We calculated odds ratios (ORs) and 95% CIs for NSSI using binary logistic regression models, with adjustment for sex, grade, race, registered permanent residence, siblings, parental educational attainment, current smoking, current drinking, physical activity, rational diet, family disasters, hospitalization experience, failed examinations, and failed relationships. Restricted cubic spline regression was used to estimate the dose-response relationship between objectively measured smartphone use and NSSI, with knots optimized by minimizing both the Akaike information criterion and Bayesian information criterion. Furthermore, we tested for separate interactions between objectively measured smartphone use and (1) sex and (2) grade to determine whether these variables modify the connection between objectively measured smartphone use and NSSI. In addition, chi-square and Spearman correlation tests were used to estimate the relationship between smartphone screen time and number of smartphone unlocks.

Sensitivity analyses were conducted to check the robustness of our estimations. First, to reduce the possible effects of the unbalanced sex ratio of participants, we performed a weighted logistic regression. Second, to ensure that the use of different measurement time frames of NSSI (eg, NSSI within the past month or 12 months) did not affect the results, we analyzed the association of objectively measured smartphone use with NSSI during the past 12 months. Third, to mitigate the class clustering effects, we performed multilevel modeling with classes as random effects.

In all tests, a 2-sided $P<.05$ was used as the significance threshold. R software (version 4.0.2; R Foundation for Statistical Computing) was used for all data analyses.

Results

Table 1 presents the characteristics of participants involved in the study. Of the 16,668 participants, 5881 (35.3%) were male, and 10,787 (64.7%) were female. A total of 16,169 (97%) were Han ethnicity, 8993 (54%) from rural, and 4940 (29.6%) from single-child families (Table 1). Notably, 627 (3.8%) reported committing NSSI during the past month. Overall, the mean

XSL•FO
RenderX

smartphone screen time was 48.8 (SD 28.8) hours per week, and the mean number of smartphone unlocks was 271.6 (SD 291.0) times per week.

[a]NSSI: nonsuicidal self-injury.

We observed positive associations between smartphone screen time and number of smartphone unlocks with NSSI among college students (Table 2). In the model adjusted for sociodemographic factors (Table 2, model 1), participants with ≥63 hours per week of smartphone screen time had significantly higher odds of NSSI (OR 1.63, 95% CI 1.32 - 2.01) as compared to those with 0 - 21 hours per week of smartphone screen time. Likewise, compared to participants with 0-50 times per week of smartphone unlocks, those with ≥400 times per week of smartphone unlocks had higher odds of NSSI (OR 1.53, 95% CI 1.25 - 1.88). A 21 hours per week increase in smartphone screen time (OR 1.18, 95% CI 1.11 - 1.25) and a 50 times per week increase in the number of smartphone unlocks (OR 1.04, 95% CI 1.03 - 1.05) were significantly associated with greater likelihoods of NSSI. In the model adjusted for sociodemographic factors and health-related lifestyles (Table 2, model 2), the associations between objectively measured smartphone use and NSSI were slightly attenuated. In the model fully adjusted for sociodemographic factors, health-related lifestyles, and negative life events (Table 2, model 3), compared with participants with 0-21 hours per week of smartphone screen time, those with ≥63 hours per week of smartphone screen time had significantly higher odds of NSSI (OR 1.54, 95% CI 1.25 - 1.90), those with 21-42 hours per week (OR 0.96, 95% CI 0.73 - 1.26) and 42 - 63 hours per week (OR 1.12, 95% CI 0.88 - 1.41) of smartphone screen time exhibited no significant increase in NSSI odds. A 21 hours per week increase in smartphone screen time was significantly associated with a greater likelihood of NSSI (OR 1.15, 95% CI 1.08 - 1.23). Regarding the number of smartphone unlocks, participants with ≥400 times per week of number of smartphone unlocks had significantly higher NSSI odds (OR 1.43, 95% CI 1.16 - 1.77) than those with 0-50 times per week, whereas for those with 50 - 150 times per week (OR 0.91, 95% CI 0.73 - 1.14) and 150-400 times per week (OR 1.15, 95% CI 0.92 - 1.43), number of smartphone unlocks showed no significant increase in NSSI risk. A 50 times per week increase in the number of smartphone unlocks was significantly linked to a higher NSSI likelihood (OR 1.03, 95% CI 1.02 - 1.04).

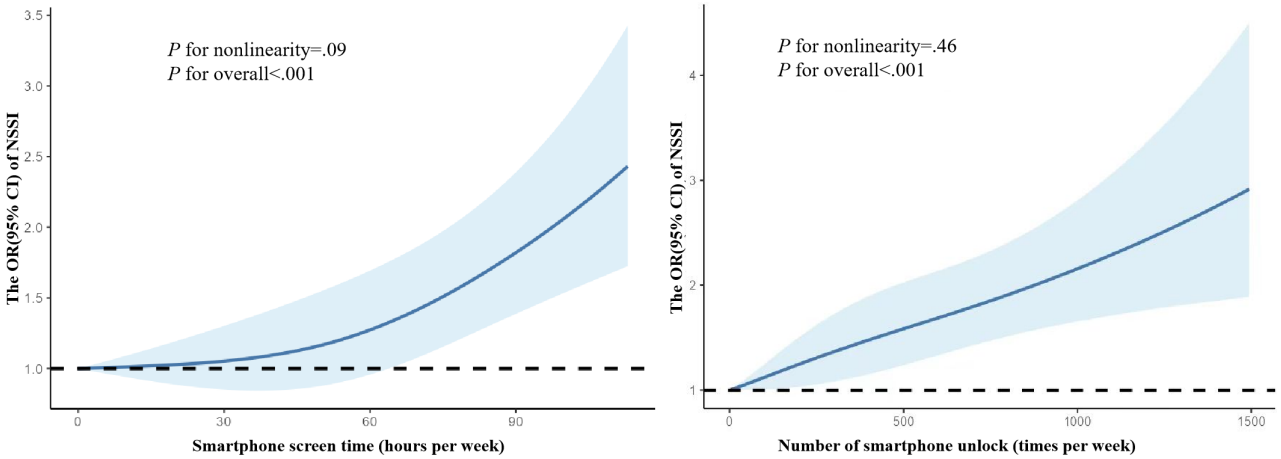
[a]NSSI: nonsuicidal self-injury

[b]OR: odds ratio.

[c]*P* for trend<.001.



[d]Model 1: adjusted for sex, grade, race, registered permanent residence, siblings, and parental educational attainment.

[e]Model 2: adjusted for sex, grade, race, registered permanent residence, siblings, parental educational attainment, current smoking, current drinking, physical activity, and rational diet.

[f]Model 3: adjusted for sex, grade, race, registered permanent residence, siblings, parental educational attainment, current smoking, current drinking, physical activity, rational diet, family disasters, hospitalization experience, failed exams, and failed relationships.

In all models, increasing smartphone screen time and number of smartphone unlocks were significantly associated with higher risks of NSSI, with all trend tests significant (all *P* for trend<.05; Table 2). We used a restricted cubic spline to flexibly model and visualize the relationships. The results suggested a positive association between NSSI risk and increasing smartphone screen time. The risk of NSSI was increased relatively slowly until approximately 45 hours per week of smartphone screen time, after which it showed an accelerated upward trend (*P* for nonlinearity=.09). By contrast, NSSI risk exhibited a monotonically increasing trend with a number of smartphone unlocks (*P* for nonlinearity=.46; Figure 1).

Figure 1. Restricted cubic spline regression analysis of objectively measured smartphone use with NSSI risk. Adjusted for sex, grade, race, registered permanent residence, siblings, parental educational attainment, current smoking, current drinking, physical activity, rational diet, family disasters, hospitalization experience, failed examinations, and failed relationships. NSSI: nonsuicidal self-injury; OR: odds ratio.

The results of sex-stratified and grade-stratified analyses are presented in Table 3. Objectively measured smartphone use was related to NSSI both in male and female participants. Male participants (OR 1.96, 95% CI 1.35 - 2.84) with ≥63 hours per week of smartphone screen time had a higher risk of NSSI compared to female participants (OR 1.36, 95% CI 1.05 - 1.76). Regarding the association between the number of smartphone unlocks and NSSI, it was significant among female participants

XSL•FO
RenderX

but not so significant among male participants. While no significant sex-specific difference was observed in the associations (all *P* for interaction>.05). Grade-stratified analyses showed that associations between smartphone screen time and NSSI were significant among freshmen (OR 2.14, 95% CI 1.33 - 3.43 for ≥63 hours per week of smartphone screen time vs 0-21 hours per week) and sophomores (OR 1.83, 95% CI 1.24 - 2.71 for ≥400 times per week of smartphone unlocks vs 0-50 times per week) but not evident among juniors, seniors, and higher grade students. However, the grade interaction effect was also not significant (all *P* for interaction>.05). Similar patterns were observed for the number of smartphone unlocks (Table 3).

Table . Sex-specific and grade-specific associations of objectively measured smartphone use with NSSI[a, b].

In the sex-weighted logistic regression model, objectively measured smartphone use remained significantly associated with NSSI (Table S1 in Multimedia Appendix 1). The results of sensitivity analyses were comparable when NSSI was defined as having occurred within the last 12 months (Table S2 in Multimedia Appendix 1). Multilevel modeling with classes as random effects showed that the significant association between objectively measured smartphone use and NSSI was also not changed materially (Table S3 in Multimedia Appendix 1). What is more, there was a moderate correlation between smartphone screen time and number of smartphone unlocks (χ^2_9=3209.2;

XSL•FO
RenderX

P<.001; *r*=0.347; *P*<.001; Table S4 and S5 in Multimedia Appendix 1).

Discussion

Principal Findings

To our knowledge, this is the largest study to date to measure actual smartphone use using an objective method and the first study to comprehensively analyze the association between objectively measured smartphone use and NSSI among college students. College students with longer smartphone screen time and more smartphone unlocks showed a higher risk of NSSI.

Comparison to Prior Work

In recent years, smartphones have penetrated various aspects of daily lives. Self-reported surveys commonly used to measure smartphone use have notoriously unreliable estimates of use time and unlock frequency. This study makes an important contribution to the extant literature because of the extreme deficiency in objectively measured smartphone use data, particularly for Chinese populations, where smartphone ownership and addiction rates are at the forefront globally [40]. This study found that the average smartphone screen time and number of smartphone unlocks, measured by screenshots of participants' smartphone use records, were significantly higher than previous self-reported smartphone use among college students [41,42]. They were also much higher than the results reported in some previous studies with objective measurement. For instance, a study from the United States measured smartphone use of 99 college students using iOS' ScreenTime feature and found that the average smartphone screen time is 5.48 (SD 2.18) hours per day [10]. Rozgonjuk et al [28] tracked the objective smartphone screen time and unlocked number of 101 college students by installing the Moment app on their Apple phones, reporting that an average objective smartphone use time was 4.05 (SD 1.72) hours per day. The differences in the above research findings further indicate the necessity of using objective measurements of smartphone use behavior in future studies.

To our knowledge, few studies have evaluated the association between smartphone use and NSSI [21-23]. For example, a study found that self-reported high-intensity smartphone use predicted NSSI in middle and high school students [21]. Another Japanese study also reported that smartphone use after lights out increases the NSSI of adolescents [22]. However, neither of the 2 studies was based on objective data. Bye et al [23] proposed a protocol for a 6-month cohort study of 600 participants, which extracted smartphone metadata by installing apps on the participants' smartphones to analyze the correlation between smartphone use and self-harm. To date, the results remain unpublished. Our investigation provides an important contribution by exploring the relationship between objectively measured smartphone use and NSSI. Moreover, the research showed that there was no significant sex and grade disparity in the association between smartphone use and NSSI, which was unexpected [43] but mirrors several similar studies [25,44]. The challenges of excessive smartphone use and NSSI are continuously intensifying. Our findings confirm this positive association, suggesting that addressing excessive smartphone use is important in college students' NSSI initiatives.

Possible Explanations of the Associations

Several factors may contribute to the association. First, the results in this study align with the integrated motivation-volition model of NSSI [15]. The model proposes that an individual's decision to act on NSSI ideation depends on having the capability, knowing others who engage in NSSI, and having access to means. People who spend more time on smartphones are more likely to come across peers engaged in NSSI and relevant information, increasing the propensity to imitate. Indeed, a study reported that 43% learn NSSI from others, and 21% from media [45]. Second, both NSSI and excessive smartphone use serve as emotion regulation strategies [20,46], which may be another reason for the association. The compensatory internet use theory suggests that individuals under stress or experiencing negative emotions frequently resort to using technology, such as smartphone use, to relieve emotional discomfort [47]. According to the four-function model of NSSI [48], emotion regulation was one of the most important functions of NSSI. The practice of NSSI can trigger acute physiological experiences, and internal emotional issues can be alleviated by being redirected to the physiological experiences of NSSI. Third, sleep is another possible reason for the association. Prolonged smartphone screen time and more smartphone unlocks can decrease sleep quality and shorten sleep duration, both of which are risk factors for NSSI [49,50]. Finally, social support plays an important role. Prolonged smartphone use time and more smartphone unlocks will take up large time and attention, reducing real-world interaction and objective social support [51]. In addition, negative views of college students' excessive smartphone use also greatly impair subjective support [18]. While the protective effect of high social support on NSSI has been widely recognized [52]. Previous research found that interpersonal problems act as a mediator in the connection between excessive smartphone use and NSSI risk [21].

Notably, although statistical analysis suggested a linear dose-response relationship for both smartphone screen time and number of smartphone unlocks with NSSI, the response curve for smartphone screen time indicated a potential nonlinear association with NSSI (*P* for nonlinearity=.09). Given the limited prior research, the underlying reasons for the discrepancy in the *P* for nonlinearity remain unclear. We posit that this divergence is likely rooted in the distinct behavioral meanings of these 2 metrics and the nuanced app-specific use patterns. First, smartphone screen time quantifies cumulative user engagement—encompassing both active and passive content consumption—and serves as a proxy for use intensity. Some prior literature suggests that excessive smartphone screen time is related to depression and anxiety [4,53], while 2 other studies showed that smartphone nonusers are more likely to experience depression and anxiety [54,55]. The marginal *P* for nonlinearity between smartphone screen time and NSSI in this study appears to align with this nonlinear hypothesis. In contrast, the number of smartphone unlocks reflects compulsive device-checking behavior, often driven by notification dependency or nomophobia (the fear of disconnection), which is a core component of smartphone addiction [56]. Such behavior is

XSL•FO
RenderX

tightly linked to reward-seeking loops (eg, dopamine-driven responses to notifications) [57]. Unlike smartphone screen time—which may involve passive activities such as video-watching with minimal interaction—unlocks represent inherently active, goal-directed behaviors such as communicating via social media. The *P* for nonlinearity of .46 in this study suggests that each additional smartphone unlock reinforces compulsive tendencies, cumulatively increasing NSSI vulnerability in a dose-dependent manner. Additionally, smartphone screen time encompasses diverse app uses (eg, social media, gaming, and productivity tools), each carrying distinct mental health implications. Passive consumption (eg, endless browsing of the internet) may induce rumination, whereas purposeful use (eg, communicating via social media) could exert protective effects [29,58]. This heterogeneity in smartphone screen time composition may dilute potential nonlinear signals, leading to marginally significant statistical findings. By contrast, the number of smartphone unlocks, which is more directly associated with addictive mechanisms, is likely less affected by the behavioral diversity inherent in smartphone screen time metrics. Future research should therefore dissect the distinct pathways through which these behaviors influence NSSI risk, alongside the nuanced impacts of specific app use patterns.

Limitations, Strengths, and Implications

The following limitations should be noted: first, although the models included a wide range of demographic and lifestyle factors, some confounding variables may have remained unaccounted for, potentially influencing the study findings. Second, a retrospective questionnaire was used to assess NSSI behavior, which may result in recall bias. Third, due to the cross-sectional study design, it is difficult to infer whether excessive smartphone use leads to NSSI or vice versa, which should be addressed in future studies. Fourth, although this study measured smartphone use time and frequency objectively, it did not specify the functional types of smartphone use, which may have implications for mental health. Finally, although the multilevel model treating class membership as a random effect yielded substantially unchanged results, the study did not account for clustering effects stemming from shared living or social environments (eg, dormitories and clubs). Future research could address these clustering effects by implementing simple random sampling methods, which would help minimize potential biases arising from nonindependent observations.

Conclusions

This study suggests a significant association between excessive smartphone use and NSSI. These findings have important implications for public health and school-based interventions, highlighting the importance of evaluating NSSI risk among adolescents with excessive smartphone use. In line with extant clinical guidelines, taking smartphone use into account when working with youths engaged in NSSI is important and may help to facilitate treatment.

Abstract

Background: The dual nature of suicide-related internet use (SRIU) as preventative or harmful is well-documented, but its characteristics in the mental health patient population remain underresearched. Some evidence suggests mental health patients engage in SRIU differently from the general population.

Objective: This study aims to explore the types, motivations, frequency, and perceived impacts of SRIU in suicidal mental health patients, as well as their engagement with web-based prevention resources.

Methods: A cross-sectional study was conducted using an anonymous web-based survey distributed between June and December 2023. Participants (n=696) were UK adults with secondary mental health service contact and recent suicidal thoughts or behaviors. Of these, 523 (75%) participants engaged in SRIU. Collected data included sociodemographic details, clinical history, types and motivations for SRIU, and interactions with suicide prevention resources. Analysis used descriptive statistics, chi-square, and Wilcoxon tests, with multiple testing corrections applied.

Results: The most common SRIU type was searching for suicide-related content (456/523, 87.4%), followed by connecting with others (271/523, 51.8%). Motivations included seeking information on suicide methods (313/523, 60.8%) and support for suicidality (271/523, 57.2%), with significant overlap. Participants perceived SRIU as neither harmful nor helpful overall, with those seeking suicide methods rating it as more harmful. Most participants encountered suicide prevention messaging, but less than half engaged with it. Only 27.5% (n=144) participants disclosed their SRIU to clinicians, with only 1 in 10 being asked about it by their clinician.

Conclusions: This study underscores the dual role of SRIU as both a source of support and a potential risk for mental health patients. Despite high exposure to suicide prevention messaging, engagement was limited, suggesting inefficiencies in current intervention designs. Clinicians rarely inquired about SRIU, and voluntary disclosure by patients was low, representing missed opportunities for intervention. Proactive discussions about SRIU in clinical settings could improve risk identification and support planning. Addressing its harmful aspects while leveraging its potential for support requires integrated online and offline strategies.

(JMIR Ment Health 2025;12:e70458) doi:10.2196/70458

KEYWORDS

mental helath patients; suicide; internet; online searches; online survey

Introduction

Studies have shown that people who struggle with suicidality can feel empowered by accessing information via the web, enabling them to seek support, access help resources, and connect with others who may be experiencing similar issues [1]. Nevertheless, using the internet for suicide-related reasons is not without risks and can facilitate access to information on suicide methods and reinforce suicidal thoughts and self-harm [2]. This dual nature of suicide-related internet use (SRIU) is typically explained in the literature by whether the content is perceived by the suicidal person to be helpful (preventative) or harmful (prosuicide). However, categorizing behaviors related to accessing suicide-related content (SRC) into prosuicide and preventative categories has not been shown to predict users' suicidal behavior or ideation [3,4]. Additionally, research suggests that people who use the internet when suicidal rarely access just one type of content, with a UK study showing most young people who accessed prosuicide sites also accessed suicide prevention sites [5]. SRIU is a complex behavior that cannot be easily categorized as purely harmful or preventative, nor can its impact on a person's suicidal thoughts and behaviors be reliably predicted.

Evidence suggests that those in contact with mental health services may engage in SRIU in a different way than those in the general population. A UK study found that those admitted

XSL•FO
RenderX

to hospital for self-harm had primarily focused on researching suicide methods and purposefully avoided helpful resources in contrast to those in the general population who often accessed suicide prevention content [6]. Mental health patients often turn to the internet to fill gaps in service provision by researching their illness and medications, while also frequently finding support within web-based communities to counteract the marginalization and stigmatization they may experience [7,8]. Given the specifics of SRIU in mental health patients, discussing their internet use with clinicians could inform prevention efforts by identifying and recognizing risk factors, as well as provide insights into their suicidality. However, recent qualitative research indicated that clinicians rarely inquire about SRIU, relying instead on patients to self-disclose this behavior [9]. This puts the burden of disclosure on the patient and, if they are already struggling, underscores the need for clinicians to take a more proactive approach.

Web-based prevention efforts are equally needed to curb potentially harmful aspects of SRIU. According to a Google blog, since 2010 Google's "suicide prevention result" (SPR, also known as Google OneBox), most commonly a banner with a suicide hotline number presented after suicide-related search results, has been considered a first line of defense for harmful SRIU [10]. Additionally, the World Health Organization's web-based media guidelines suggest the inclusion of information on where and how to seek help for suicidal thoughts within suicide-related media content [11]. However, there is a paucity of evidence on whether people, who use the internet for suicide-related purposes, including mental health patients, contact advertised helplines or use other prevention resources when engaging in this behavior [12].

More studies are needed that directly recruit people who use the internet when suicidal to understand the motivation, frequency, and outcomes of their SRIU [13] and this is especially true in mental health patient populations. The aim of this study was to describe the types of and motivations behind SRIU of suicidal mental health patients, its frequency, perceived helpfulness, and any engagement with web-based suicide prevention resources.

Methods

Study Design

This study used a cross-sectional design using an anonymous web-based survey hosted on Qualtrics (Qualtrics International Inc) between June 1, 2023, and December 31, 2023.

The 45-question survey (available in the Multimedia Appendix 1), developed with input from coauthors and members of a patient and public involvement group, was split into four sections: (1) sociodemographic details, (2) clinical history, (3) suicidal thoughts and behaviors, and (4) SRIU. Section 4 comprises questions on the type of and motivation for SRIU, frequency and perceived helpfulness/harmfulness of SRIU, and interaction with Google's "suicide prevention result." Participants could select more than one type of and more than one motivation for SRIU (Textbox 1). Furthermore, participants were asked whether they searched for specific suicide-related sites, knowledge of safe internet use when engaging in SRIU, and whether they had disclosed their use to their clinician; this was captured using multiple choice questions. There were 4 free-text questions relating to search terms used to look for suicide-related information, details of any disclosure of this behavior to their clinician, and any additional thoughts on SRIU participants might have had; qualitative findings from this free-text data will be presented elsewhere. The survey also included visual analog scales (VASs) for questions on the perceived helpfulness/harmfulness of SRIU in general and of SPRs. VAS scores ranged from 0 to 10 and were interpreted as follows: 0 - 2: very helpful; 2.1 - 4.0: moderately helpful; 4.1 - 6.0: neither helpful nor harmful; 6.1 - 8.0: moderately harmful; and 8.1 - 10.0: very harmful.

XSL•FO
RenderX

Textbox 1. Types and motivation for suicide-related internet use (SRIU). Participants were able to select multiple responses.

Types of SRIU

- Searched for suicide related content/information (eg, browsing the internet or social media) because of your own suicidal thoughts and feelings.
- Created suicide related content/information (eg, blogging or posting pictures).
- Engaged with (eg, commented or reposted) suicide-related.
- Accidentally came across suicide-related content while browsing internet/social media.
- Used the Internet to interact/connect with others because of your own suicidal thoughts and feelings.
- None of the above.

Motivations for SRIU

- Seeking information on support/help for my own mental health (eg, Samaritans, NHS [National Health Service] web pages).
- Seeking information on methods of suicide/harming oneself.
- Seeking support from friends/peers.
- Interacting with celebrity bloggers/influencers.
- Engaging in discussions about suicide/harming oneself (eg, forums, Twitter).
- Sharing personal experiences of suicidality (eg, on social media).
- Researching medication (eg, side effects) that you have been taking for your mental health.
- Curiosity about suicide.
- Raising awareness or campaigning for suicide prevention.

Procedure

A list of resources such as helplines and services participants could contact if they became distressed was provided. The first 2 sections covered sociodemographics and mental health history. The third section covered suicidal thoughts and attempts, adverse life events (ie, relationship breakdown and financial difficulties) that may have contributed to their suicidality, and perceived support received from friends, family, and their community. Trigger warnings for questions related to suicidal thoughts and behaviors and the opportunity to skip them were provided. The fourth section covered SRIU defined as: "Suicide-related internet use is any internet use related to your thoughts, feelings and behaviors connected to suicide. This kind of use can be, for example, expressing suicidal feelings or thoughts on social media or using the internet to get help and support when feeling suicidal." Participants were asked if they engaged in SRIU in the past 12 months and if they answered "no," they were exited from the questionnaire. Those who answered "yes," continued with section 4 on SRIU. All participants were provided with a list of helplines and services on exiting the survey.

Recruitment

Eligibility criteria included adults aged 18 years or older, a history of suicidal thoughts or behaviors within the past 12 months, living in the United Kingdom, and contact with secondary mental health services. In the United Kingdom, secondary mental health services provide specialized care for people with severe and complex mental health conditions. Participants were recruited via the web and on radio; via social media (X, Reddit, Facebook, BlueSky, Instagram, Mastodon, TikTok, and LinkedIn); and via mailing lists, web pages, and newsletters of charities and the University of Manchester, with the recruitment materials often organically shared throughout and between platforms.

Participants

Of 1057 initial respondents, 72 (6.7%) respondents did not answer questions pertaining to inclusion criteria, and 188 (17.8%) respondents did not meet the inclusion criteria. Specifically, 110 out of 188 (58.5%) respondents had no contact with secondary mental health services, 43 (22.8%) respondents did not report suicidal thoughts or behavior, and 35 (18.6%) respondents failed to meet both inclusion criteria. A further 23 respondents met the inclusion criteria but did not answer any of the questions. The survey also included one attention-check question and data were manually checked for joking or aberrant answers to ensure data integrity; 3 participants were excluded for failing the attention-check question, and a further 5 for aberrant or joking answers. There were no fully duplicated responses (ie, no evidence that the very same answers had been submitted multiple times). Finally, 70 participants did not provide information on whether they had used the internet for suicide-related purposes. In total, 696 participants met the inclusion criteria and completed the survey, and 523 (75%) participants indicated they had engaged in SRIU. Participants who reported only encountering SRC accidentally (n=50) were grouped with those who did not engage in SRIU, as they did not actively seek out such content.

Statistical Analysis

Descriptive analysis of categorical data was conducted using frequencies and proportions. The denominator for each estimate was the number of valid cases for the specific variable, meaning cases with missing information were excluded from the analysis of that variable. Percentages of missing values for each variable

XSL•FO
RenderX

are presented in Table 1. For data collected via VASs, the median and IQR were used for analysis, as recommended by Heller et al [14]. Different types and overlaps of types of motivations for SRIU have been visualized using an UpSet diagram. An UpSet diagram displays the sizes of individual sets alongside their intersections. The plot includes a matrix of dots indicating intersecting sets, with a bar chart above showing the size of each intersection and a bar chart to the left showing the total size of each set. Chi-square tests were used for comparisons of categorical variables, while the Wilcoxon test was used for comparisons of VAS data. To account for multiple testing, the Bonferroni correction was applied to *P* values, with values below .001 (.01 divided by the number of comparisons) considered statistically significant. All analyses and figure generation were performed using RStudio (RStudio Team, 2022).

Table . Missingness pattern of analyzed variables.

	Missing values, n/N (%)
Type of SRIU[a]	0 (0)
Motivation for SRIU	25/523 (4.8)
Searching for specific suicide-related websites/forums	23/523 (4.4)
Frequency of SRIU	23/523 (4.4)
Perceived helpfulness/harmfulness of SRIU	28/523 (5.4)
Encountering SPR[b] online	21/523 (4.0)
Interacting with SPR	8/425 (1.9)
Perceived helpfulness/harmfulness of SPR	3/193 (1.6)
Knowledge about safe internet use while engaging in SRIU	30/523 (5.7)
Clinician's enquiry about SRIU	30/523 (5.7)
Participant's disclosure to the clinician about SRIU	30/523 (5.7)

[a]SRIU: suicide-related internet use.

[b]SPR: suicide prevention result.

Ethical Considerations

Ethics approval for the study was granted by the University of Manchester Research Ethics Committee (ref: 2023-16133-28055). Before commencing the questionnaire, participants were presented with the study information sheet and informed consent was obtained. Participants were not offered any financial incentives, such as monetary compensation or vouchers, for their participation in this study. Finally, participants were not asked to disclose any identifiable data (ie, name, email address, geographical location) nor were their IP address data collected.

Results

Characteristics of Participants Who Have Engaged in SRIU

In total, 523 participants had engaged in some type of SRIU in the past 12 months. While a forthcoming study using the same dataset will examine the demographic and clinical characteristics of these individuals in greater detail, we will briefly present their key characteristics here. Of those who have engaged in SRIU, 64% (n=337) were female, and most were aged between 25 and 34 years (239/523, 46%). The majority were White (459/523, 88%), and more than half identified as nonheterosexual (304/523, 58%). Gender identity differed from birth sex for 16% (n=85) of the participants, and most had higher education qualifications, with 56% (n=291) holding a university degree or higher.

Regarding clinical characteristics, the most common psychiatric diagnoses, both in the last year and historically, were affective disorder and anxiety disorders. Most participants (424/519, 81%) had been prescribed psychotropic medication in the last year and 18% (n=95) had been admitted for psychiatric in-patient care. Most participants were moderately dissatisfied with their mental health service provision.

Participants who engaged in SRIU reported moderately high-intensity of suicidal thoughts, 35% (n=183) of them daily. Furthermore, 88% (n=459) participants reported disclosing these thoughts to someone, most likely to mental health professionals (364/523, 70%). One-third (170/523) of the participants had attempted suicide in the last year with moderately high planning involved and 34% (57/158) participants disclosed the plans of this attempt to someone. Life stressors, including relationship difficulties (38%, 179/471), financial problems (152/471, 32%), and insomnia (155/471, 33%) were also common among participants and they reported moderately low support from family and friends. Figure 1 depicts the survey sections and flow.

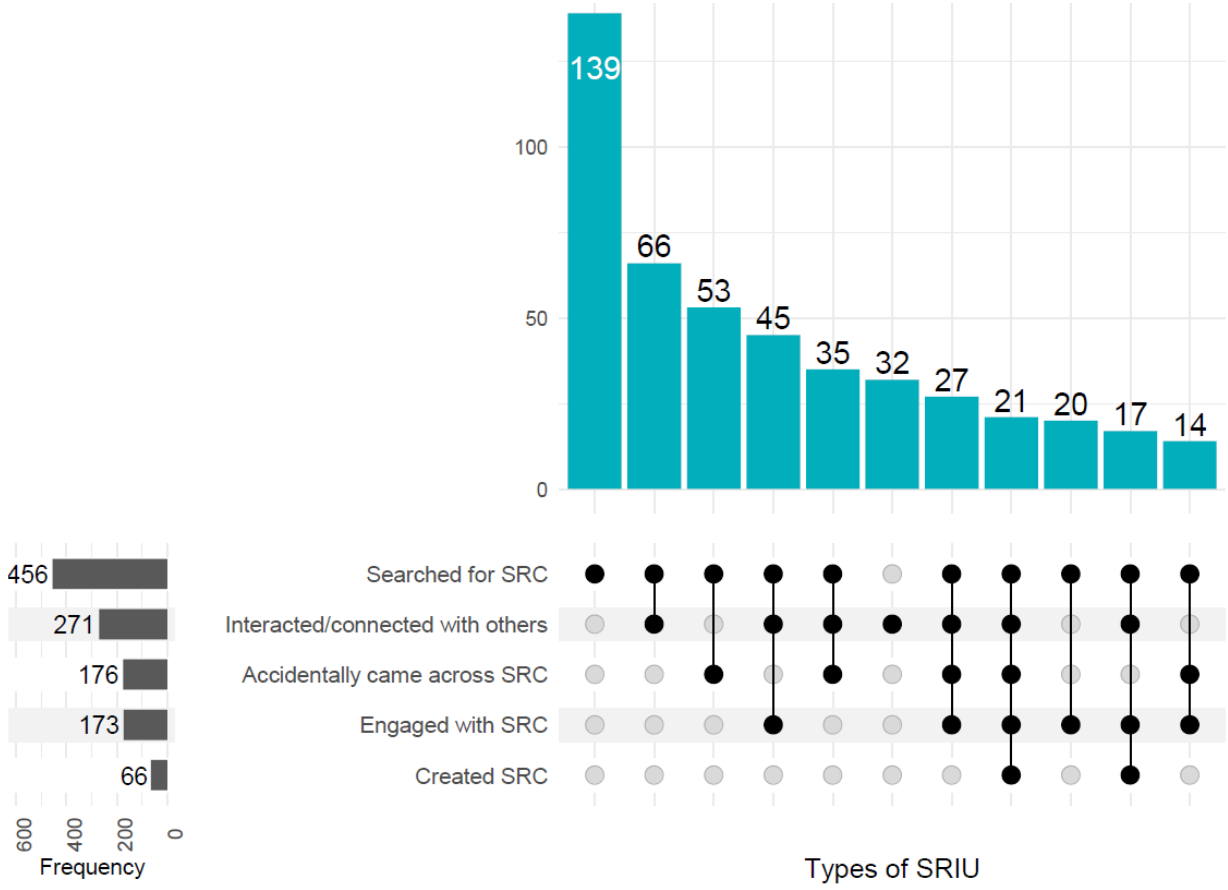
Types and Motivations for SRIU

The different types of and motivations for engaging in SRIU are shown in Figures 2 and 3. These were not mutually exclusive, meaning participants could select multiple types of SRIU as well as multiple motivations.

Two-thirds of participants (345/523, 67.7%) engaged in more than one type of SRIU, with 21 (4%) participants having engaged in all types (Figure 2). The most common type was searching for SRC (456/523, 87.4%), and the second most common was interacting or connecting with others for reasons relating to the participants' suicidality (271/523, 51.8%). A third (173/523, 33.1%) of the participants had engaged with (ie, commented and reposted) and 66 (12.6%) participants had created SRC themselves. Another third (176/523, 33.7%) of participants also came across SRC accidentally while browsing the internet.



A third (32.3%) of participants reported only engaging in one type of SRIU in the past 12 months. Of these, the vast majority (139/178, 78.7%) primarily searched for SRC, representing 26.4% of all participants. The remaining participants who only engaged in one type of use (32/178, 18.0%) engaged solely in interactions or connections with others due to their suicidality.

Similarly, the majority of participants had more than one motivation to engage in SRIU (397/523, 75.9%). The most common motivations were seeking information on methods of suicide (318/523, 60.8%) and seeking information on support or help for one's own suicidality (299/523, 57.2%; Figure 3). Other common motivations were researching medication that participants were taking (257/523, 49.1%), seeking support from friends and peers for one's suicidality (144/523, 27.5%), sharing personal experiences of suicidality (126/523, 24.1%), and engaging in discussions about suicide (118/523, 22.6%). The most common combination of motivations to engage in SRIU was seeking information on both help and support as well as suicide methods and researching medication (43/523, 8%; Figure 3).

Of the 101 (19.9%) participants who only reported one motivation to engage in SRIU, most were only motivated to search for suicide methods (55/101, 54.5%), 11% of all participants. A further 22 (21.8%) were only motivated to search for helpful resources, 4% of all participants. Notably, 25 participants (4.8%) did not report any motivation to engage in SRIU.

Figure 3 shows the interplay of types of SRIU with motivation for engaging in it; a participant could choose multiple types of SRIU and multiple motivations for it. Regardless of the motivation, searching for SRC was the most common type of SRIU participants engaged in. Interacting with others for reasons relating to one's own suicidality was a common type of SRIU in those who were motivated to seek support from friends or peers and to share personal experiences of suicidality (Figure 4).

Figure 2. UpSet diagram representing frequency and overlap between different types of SRIU of mental health patients (n=523) (Overlaps <8 have not been shown; therefore, the number in the figure does not total 523). SRC: suicide-related content; SRIU: suicide-related internet use.

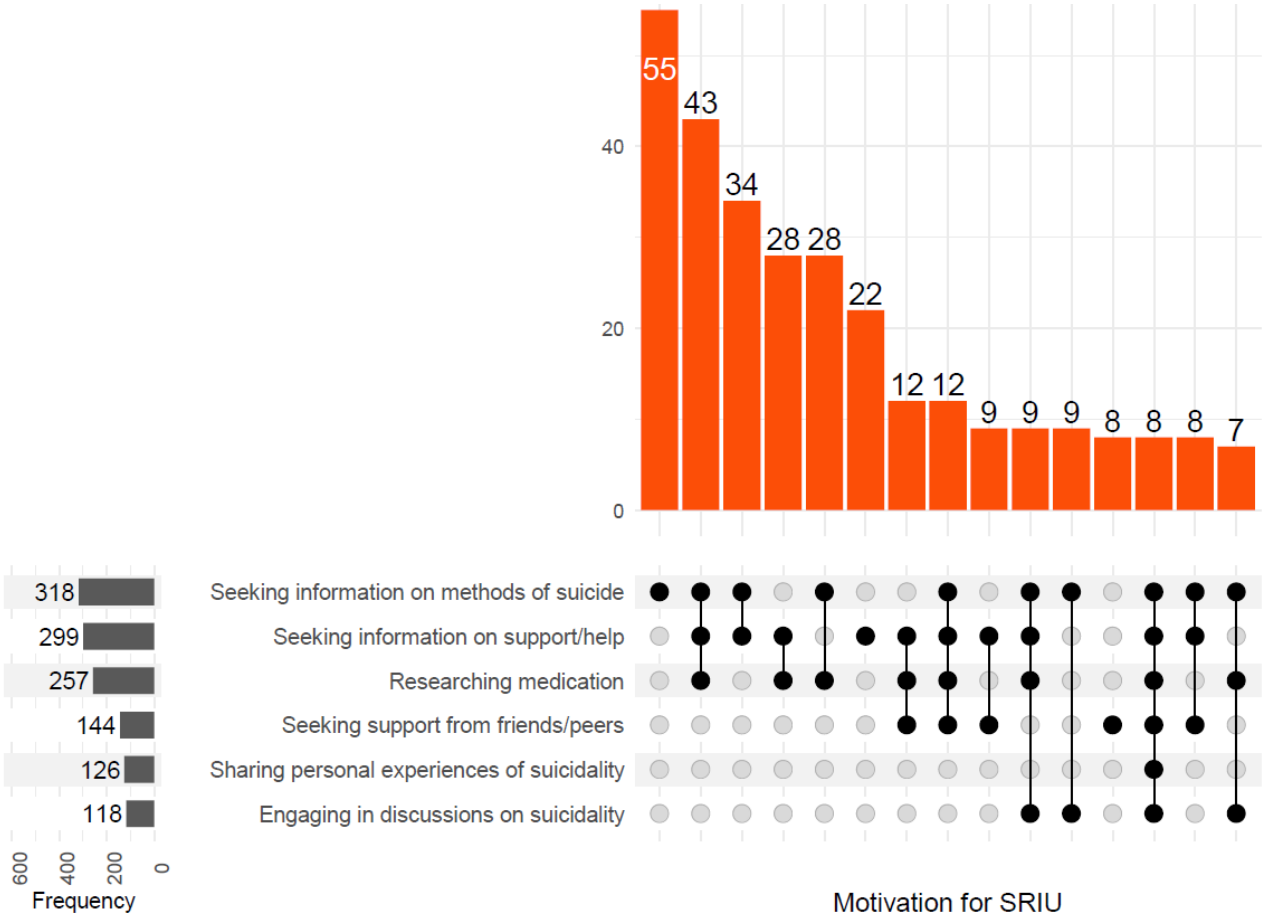

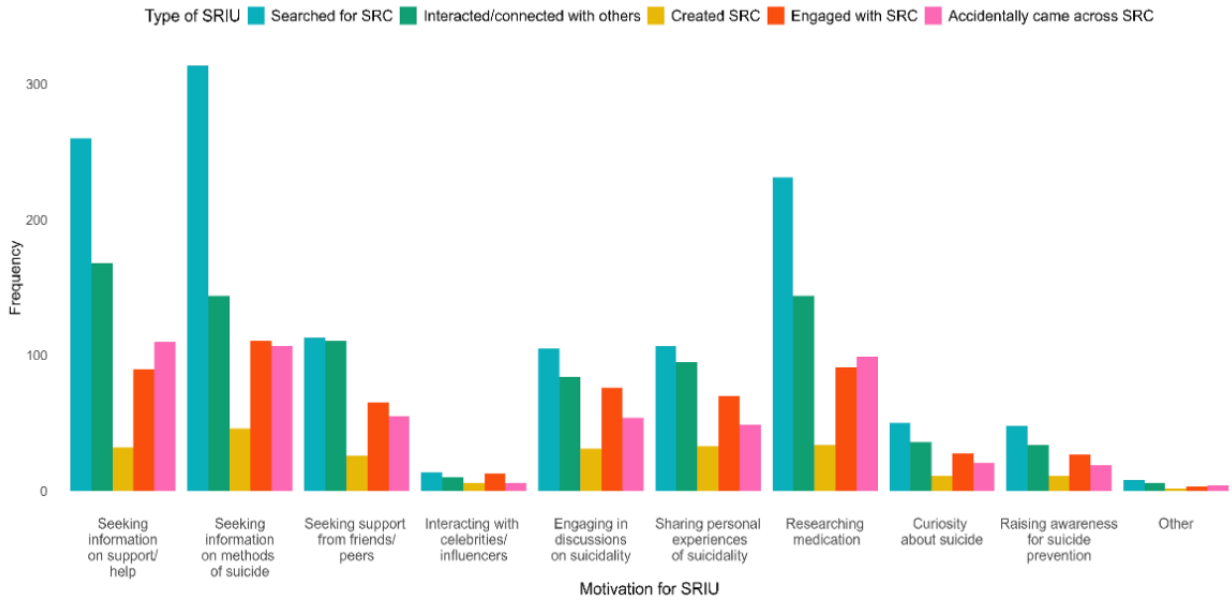

Figure 4. Types of and motivations for SRIU (n=523). SRC: suicide-related content; SRIU: suicide-related internet use.

Characteristics of SRIU

In the whole sample, the average perception of SRIU was neither helpful nor harmful (VAS score median 5, IQR 4.1 - 6.1). Those who searched for SRC perceived their SRIU as somewhat more harmful than those who did not (VAS score median 5.0, IQR 4.4 - 6.4 vs VAS score median 4.9, IQR 3.3 - 5.0; *P*<.001). There was no difference in perceived harm/helpfulness for any other type of SRIU. Furthermore, those who were motivated to engage in SRIU by seeking suicide methods perceived their internet use as somewhat more harmful compared with those who were not motivated by this (VAS score median 5.0, IQR

XSL•FO
RenderX

4.9 - 6.6, vs VAS score median 5.0, IQR 3.5 - 5.3; *P*<.001); again, there was no difference in perceived harm/helpfulness for any other motivation for SRIU. Among participants, 43.2% (n=216) used the internet for suicide-related purposes at least once a week.

Most participants did not search for specific suicide-related web pages, groups, or profiles (397/500, 75.9%). Participants who had engaged with SRC were more likely to search for specific sites compared with those who did not (51.5% vs 27.7%, *P*<.001). In terms of motivation, those who were motivated by seeking information on suicide methods and by wanting to discuss suicidality were more likely to search for specific sites compared with those who did not (79.6% vs 58.9%, *P*<.001; and 37.9% vs 19.4%, *P*<.001 respectively). Less than half of the participants (241/493, 46.1%) who had used the internet for suicide-related purposes knew where to find information on how to use the internet safely.

While engaging in SRIU, most participants had seen suicide prevention messaging (425/502, 84.7%) and nearly half (193/425, 45.4%) had interacted with these messages, including following links to helpful content or calling the helpline number. Participants who searched for SRC were more likely to see suicide prevention messaging (89.9% vs 72.7%, *P*<.001), and those who were motivated to seek help via the web were more likely to engage with these interventions compared with those who were not motivated to seek help via the web (73.6% vs 49.6%, *P*<.001). Those who interacted with suicide prevention messaging found them neither helpful nor harmful (VAS score median 5, IQR 4.0 - 7.0) and there was no difference in the perceived harmfulness/helpfulness of these interventions regarding the type of or motivation for SRIU.

Most participants had not been asked by a clinician about their SRIU (466/523, 89.1%). Around a quarter (144/523, 27.5%) self-disclosed SRIU to their clinician. There was no difference in disclosure regarding the type of or motivation for SRIU.

Discussion

Main Findings

This study, conducted in the United Kingdom, found the most common form of SRIU in our sample was searching for SRC via the web, with 87.4% (n=456) of participants engaging in this behavior. A quarter engaged in searching for SRC only without other types of SRIU. Additionally, 51.8% (n=271) of participants interacted with others via the web about their suicidality, and 12.6% (n=66) created SRC. We found that common motivations for engaging in SRIU included seeking information on suicide methods (318/523, 60.8%) and finding support for their own suicidality (299/523, 57.2%). Participants who searched for SRC were more likely to view it as harmful, particularly if motivated by a desire to learn about suicide methods. Less than half of participants who have seen web-based suicide prevention messaging choose to engage in it and have perceived it as neither helpful nor harmful.

Previous epidemiological studies have shown moderate associations between web-based searches for SRC and deaths by suicide [15-17]. A high prevalence of searching for SRC was also found among mental health patients who either attempted or died by suicide [6,18-20]. In our study, it was possible to delineate the type of SRIU by motivation. The most common motivations for engaging in SRIU were searching for help and searching for suicide methods; this duality aligns with a recent study on a clinical suicidal population which noted that patients include the internet as both a potentially helpful factor and a harmful one in their self-made safety plans [21]. A systematic narrative review on web-based mental health help-seeking in young people also found that web-based searching was the most common help-seeking behavior, followed by participation in web-based communities and discussion forums [22], as was the case in our study. Research on mental health discussion forums has shown that most participants join suicide-related discussions to seek help from others who they feel understand them and that these interactions can reduce suicidality [8,23]. Additionally, our results show that mental health patients rarely have only one motivation for SRIU; however, when this was the case, they were more likely to be motivated to search for information on suicide methods than for help. Researching suicide methods via the web is almost always considered harmful by researchers and clinicians since it can expose people to detailed information on how to harm themselves which can increase the risk of suicide [24].

In previous research conducted by this team [9,18], obtaining information on suicide methods via the web was the most common type of SRIU in mental health patients who died by suicide, and also the most common type of SRIU patients disclosed to clinicians. We hypothesized that this is likely to have occurred because the disclosure of research methods via the web naturally happens during risk assessments when clinicians ask patients about their suicide planning. This combination of the high prevalence of actively searching for SRC via the web and motivation to seek information on suicide methods was self-reported by suicidal mental health patients in this study. Taken together, the evidence suggests the significant role that web-based searches, especially those concerning methods of suicide, can play in the suicidality of mental health patients, especially in the choice and potential lethality of suicide methods. Our findings also suggest that participants who searched for SRC, particularly those motivated to search for methods, perceived their SRIU as more harmful on average. This finding may be explained in 2 ways: first, searching for SRC, especially information on suicide methods, might indicate higher suicidality and thus higher distress; second, exposure to this content can be emotionally disturbing and traumatic, especially for those already struggling with mental health issues [20,25].

The majority of participants did not search for specific suicide-related web pages, groups, or profiles. This lack of targeted searching suggests that users may be more open to engaging with a variety of content they encounter in their search results, potentially including information about suicide methods. This underscores the importance of the quality and nature of SRC that appears in search results, as it could have a significant impact on vulnerable individuals. Notably, in our sample, participants who were motivated to engage in SRIU by wanting to search for methods were more likely to search for specific

XSL•FO
RenderX

sites. This suggests that these patients are more proactive in their search, potentially indicating higher intent, as previously reported [26].

This study was the first to ask suicidal mental health patients about their interaction with search engines' "suicide prevention result." The high prevalence of actively searching for SRC in our sample highlights the importance of web-based prevention efforts, as these searches represent opportunities to reach a significant number of people who may be experiencing a crisis. We found that most participants (85%) have seen some suicide prevention messaging while engaging in SRIU and those who were motivated by help-seeking were more likely to engage with them. The neither harmful nor helpful way the SPR was perceived among participants and higher engagement by those motivated by help-seeking suggest potential shortcomings in its current design. The one-size-fits-all approach of displaying the same SPR regardless of what is being searched and who is searching it seems to be lacking [12,27-29]. To improve the effectiveness of SPR, it would be helpful to target variable messaging based on user demographics and search history, provide different formats such as text, videos, and interactive tools, and create age-appropriate messaging tailored for different age groups.

The importance of timely disclosure of SRIU for creating prevention opportunities has been highlighted in previous research, alongside the lack of routine inquiry about it by clinicians in the United Kingdom [9,30,31]. This study supports these findings from the patients' perspective, showing that only about 1 in 10 patients in our sample have been asked about SRIU by their clinician. Additionally, it provides a first insight into patients' self-disclosure of SRIU, revealing that only around a quarter have voluntarily disclosed this information. This is a concerning finding, as clinicians reported relying on patients' spontaneous disclosure to learn about SRIU [9,31]. Consequently, the low rates of both inquiry and self-disclosure suggest that many opportunities for intervention and exploration of the significance of SRIU are missed. Given these findings, it is crucial for clinicians to take the initiative in asking about SRIU, as this first step can significantly increase the chances of identifying and addressing this behavior, potentially opening up important avenues for intervention and support.

Strengths and Limitations

One key strength of this study is its large and national sample, which enhances the reliability of our findings; in comparison, the next largest sample for a similar study was 3 times smaller (n=205) [32]. Furthermore, as we delineated the type of SRIU and the motivations behind it, we were able to examine the SRIU characteristics in more detail than in other studies. Additionally, our study is the first to ask about the perception of and interaction with suicide prevention search results in mental health patients who engage in SRIU, a highly vulnerable population. However, several limitations may influence the study's results. First, our study was conducted in the United Kingdom, and the generalizability of our findings on other nations is limited by national differences in internet infrastructure, suicide prevention resources, and cultural attitudes toward help-seeking. In some regions, limited internet access means that individuals may not rely on web-based sources for suicide-related information, potentially leading to different patterns of information-seeking behavior. Moreover, Google's OneBox suicide prevention feature and other search engine interventions are not globally uniform, with some countries lacking equivalent prevention tools due to the absence of a national suicide hotline. Therefore, while our findings offer valuable insights into SRIU among mental health patients in the United Kingdom, they may not be fully generalizable to other contexts where internet infrastructure and suicide prevention resources differ. For instance, we did not ask participants about the timing of their SRIU relative to their suicidal ideation or attempts. This prevents us from exploring the direction of the relationship between suicidality and SRIU in the context of time. This study's cross-sectional design prevents causal conclusions, and participant self-selection introduced biases, with some groups or behaviors potentially being over- or underrepresented. As a result, the findings may not be generalizable to all mental health patients who engage in SRIU. Moreover, as this is a cross-sectional study, we are unable to track potential fluctuations in SRIU over time. Consequently, this research should be seen as a "snapshot" of SRIU among mental health patients. Finally, we inquired about SRIU in general and did not focus on any specific search engine, webpage, or social media. This decision was made due to the constantly changing landscape of the internet, with the aim of improving the generalizability of the findings.

While this study focuses on the characteristics of SRIU itself, a forthcoming study using this dataset will specifically examine the characteristics of individuals who have engaged in SRIU. This will provide a deeper understanding of the demographic, clinical, and suicidality factors associated with engagement in SRIU, complementing the findings presented here.

Implications for Prevention

Our results highlight the need for consideration of the web-based content available to users, ensuring that those engaging in SRIU are met with helpful and educational resources. The high prevalence of actively searching for SRC via the web suggests that SPR and similar web-based interventions are a first line of defense, and should be improved. For example, a recent study found that internet users with different levels of suicidality respond and engage differently depending on the wording in SPR [29]. This suggests that algorithms displaying SPR should consider tailoring the wording for different groups of web-based users in order to maximize effectiveness, especially given that search engines like Google already possess user data that could enable more targeted prevention strategies [33]. Additionally, advancements in artificial intelligence, now integrated into search engines, are improving the ability to detect nuanced queries, triggering SPR even when searches are not explicitly suicide-related [34]. Once triggered, the prevention potential of SPR seems to lie in its versatility, such as offering both telephone- and text-based services [35]. It may be beneficial to integrate contact information for local crisis services, especially those with different modalities of contact (ie, telephone, text, and web-based), along with educational materials on SRIU, into existing SPRs. These educational materials could provide technical solutions to reduce harmful SRIU, such as resetting

XSL•FO
RenderX

their social media accounts if they are being shown harmful SRC, installing browser extensions that block such content, and offering support options instead.

Our finding that more than half of the participants were unaware of how to safely navigate web-based suicide content, highlights the need for continuous education on internet safety. This aligns with Pretorious and colleagues [22] who identified a lack of mental health literacy as a barrier to effective web-based help-seeking. Expanding the reach of resources like the "#chatsafe" guidelines, which promote safer communication about suicidality via the web, by integrating them into existing SPR could be valuable [36,37]. However, these guidelines were designed for young people, and it remains unclear whether they are suitable for adults and mental health patients' populations or if adaptations are needed.

Apart from integrating these resources via the web, mental health patients can benefit from direct engagement with clinicians who can guide them toward beneficial and help mitigate harmful SRIU. Clinicians should understand this distinction to develop safety plans addressing both suicidal thoughts and behaviors, including SRIU. Additionally, clinicians can signpost patients to verified and high-quality web-based resources on suicidality and mental illness, as well as educational materials on how to navigate the internet in a safer way. As previous research has emphasized, a critical aspect of addressing SRIU in the mental health services setting is the clinician's direct and nonjudgmental inquiry into whether and why a patient is engaging in such behavior.

Conclusions

This study underscores the need for both web-based and offline strategies to address SRIU among mental health patients, highlighting key gaps in these areas. Given that searches for SRC via the web represent the most common type of SRIU, there is a need to enhance existing web-based interventions. Currently, these interventions are not perceived as particularly helpful or harmful and are primarily accessed by those already inclined to seek help. Meanwhile, clinicians have untapped potential to reduce harmful and promote beneficial SRIU in their patients, though inquiry and disclosure around SRIU remain rare in clinical settings. Finally, empowering mental health patients with knowledge about safe internet practices should be a shared objective between web-based platforms and mental health service providers.

Abstract

Background: Internet-based interventions for depression are increasingly integrated into health care due to their effectiveness, availability, and cost-effectiveness. However, negative effects have largely been ignored.

Objective: This study aimed to evaluate both positive and negative effects of an unguided intervention.

Methods: In total, 303 participants were analyzed using mixed models for repeated measures to assess changes in depressive symptoms via Beck Depression Inventory-II (primary outcome) after 12 weeks compared to waitlist controls with care as usual. Secondary endpoints included depressive symptoms (Patient Health Questionnaire-9 [PHQ-9]), self-esteem, and quality of life. Negative effects were evaluated using the positive and negative effects of psychotherapy scale for internet-based interventions (PANEPS-I). Moderation analyses were conducted to explore influential effects on treatment outcomes.

Results: The intervention group showed greater reduction in depressive symptoms compared to controls, with small to medium effect sizes (g=0.30 - 0.42) with averaged 14 logins. Although improvements in self-esteem and quality of life were not observed in intention-to-treat analyses, the completer sample indicated higher self-esteem in the intervention group. Negative effects were reported by 22% (22/100) to 68% (66/97), with the highest rates for program-related effects (eg, not addressing personal problems). No moderation effects were identified.

Conclusions: The intervention effectively reduces depressive symptoms. Although negative effects were present, they did not impact treatment outcome, tentatively suggesting that overall benefits may outweigh the negative effects for users.

KEYWORDS

iCBT; adverse effects; digital interventions; implementation

Introduction

Depression is one of the leading causes of disability worldwide [1,2], globally causing 158% higher direct health care excess costs in depressed compared to nondepressed adults [3]. However, there is a worldwide treatment gap for mental disorders and depression in particular [4]. Only around half of those affected by depression receive adequate treatment [5]. Hence, low-threshold and widely available digital therapy formats are evolving. To this day, various studies on internet-based therapy programs for depression, mostly based on internet-based cognitive behavioral therapy (iCBT), have demonstrated their effectiveness in depressive symptom reduction [6] and improved quality of life [7]. In addition, internet-based interventions allow easier access due to time- and location-independent use as well as a high degree of privacy and autonomy [8]. In addition, internet-based interventions are cost-effective compared to care as usual (for a review, refer to [9]).

iCBT in the Treatment of Depression

The advantages of internet-based interventions have led to their incorporation in national treatment guidelines for various disorders [10,11], and internet-based interventions are recommended as a treatment option for mild depressive episodes [12]. In their review of the cost-effectiveness of internet-based interventions, Mitchell et al [9] stated that such programs should be included in health care systems by policy makers. In December 2019, Germany passed the Act to Improve Healthcare Provision through Digitalization and Innovation (Digital Healthcare Act), which facilitates the prescription of digital health care applications such as iCBT programs. Health insurance now fully covers the costs for those programs that have been approved by the Federal Institute for Drugs and Medical Devices.

XSL•FO
RenderX

One of the new digital health care applications is the Novego Depression program. Novego Depression has been previously investigated in 3 studies with different patient groups [13-15]. Beiwinkel et al [13] examined the Novego program under the name HelpID in a study with a sample of 180 patients with mild to moderate depressive symptoms. The study showed a significantly greater improvement in depressive symptoms in the intervention group compared to the control group. Miegel et al [14] found a significant improvement in depressive symptoms in the framework of a randomized controlled trial with 142 chronic pain patients with depressive symptoms. Participants in the intervention group showed a significant decrease in symptom severity with a small to moderate effect size (η_p^2=0.04 in the intention-to-treat analysis and η_p^2=0.06 in the per-protocol analysis). Another study evaluating the Novego Depression program demonstrated significant improvement in depressive symptoms in a sample of 58 patients with schizophrenia with comorbid moderate to severe depressive symptoms [15]. The authors found a significantly greater decrease in depressive symptom severity after using the program compared to a control group with a medium to large effect size (η_p^2=0.18).

Negative Effects of iCBT

Despite the large and growing body of literature demonstrating the efficacy and other advantages (such as cost-effectiveness) of iCBT for depressive disorders, there still is limited research on its negative effects. Negative effects in internet-based interventions are comparable to those in face-to-face psychotherapy [16]. Meta-analyses found deterioration rates around 6% under iCBT interventions [17,18]. Fenski et al [19] examined negative effects of an internet-based intervention beyond deterioration of symptoms. Their qualitative content analysis revealed various program- and participant-related negative effects that were reported by 8% of the participants. Another study on a self-help intervention for body-focused repetitive behavior showed high frequencies of subjective negative effects (14% - 52%; [16]). The most frequently reported negative effects were lack of positive goal orientation (52%), not addressing personal problems (49%), a feeling of time or performance pressure (21%), shame regarding using the intervention (16%), and concerns about data privacy (14%). Notably, there is not yet a clear consensus on how to define and assess negative effects in internet-based interventions. However, it seems that various kinds of negative effects do occur. Most of the reported negative effects are typically program-related, underlining the relevance and importance of assessing negative effects in internet-based interventions. Program-related effects can be resolved by revising the intervention and its content.

Aims

The demand to implement iCBT in the health care system seems well justified in view of the confirmed effectiveness, cost-effectiveness, and low-threshold accessibility of the interventions. Yet, noneconomic costs for patients, such as experiencing negative effects, need to be considered in the evaluation of such programs before implementing them in the health care system. This study investigated the effectiveness and possible negative effects of the 12-week iCBT program Novego Depression (trial registration: German Clinical Trials Register, DRKS00027459). This randomized controlled trial compared an intervention group (IG) with a waitlist control group (WCG) regarding the reduction of depressive symptoms, improvement of self-esteem, and quality of life. In addition, negative effects and satisfaction with the program as well as treatment expectations were evaluated.

Methods

Design

The study was designed as a 2-arm randomized controlled trial with an IG and a WCG (with access to care as usual [CAU]) and 3 measurement time points (baseline assessment [T0], interim assessment 6 weeks after baseline [T1], and post assessment 12 weeks after baseline [T2]). All assessments took place online via the survey software Qualtrics.

Procedure

Recruitment was carried out in collaboration with 3 medical care centers in Germany. Patients were diagnosed according to the *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*) through standardized interviews with specialists or psychotherapists. Potential participants were both patients already undergoing treatment and individuals who had only visited the medical care center for diagnostic purposes and had not yet received therapy or were waiting for it. Patients who had been diagnosed with depression and were interested in participating were given access to the baseline survey providing detailed information on the study. Upon consenting to participate, respondents were directed to the baseline questionnaire. If they did not give consent, the survey was automatically canceled. During the baseline survey, further inclusion and exclusion criteria were checked. Eligible individuals who completed the baseline survey were automatically randomly assigned to one of the 2 groups (IG or WCG) in a 1:1 ratio using an algorithm within the Qualtrics survey software. IG participants subsequently received an email containing their personal access code for the intervention program as well as instructions on how to register for the program. Participants in both study groups had unrestricted access to CAU during the study period. After 6 and 12 weeks, all participants received invitations to participate in the interim and postsurveys via email with the link to the online assessment. Upon completion of the postassessment, all participants received compensation for their participation in the form of a €10 (US $11.48) online shopping voucher. Participants in the control group additionally received an access code to the intervention program. The first patient was recruited on January 6, 2022, and the last patient finished on June 6, 2023. In total, 311 participants were randomized.

Participants

The study protocol originally envisaged the recruitment of 200 participants. In the course of the study, a new sample size calculation was performed to take into account a probable dropout rate of 20% and to gain more statistical certainty. Based on an assumed effect of *d*=0.4, an alpha of 5%, and a power of 80%, the sample size calculation was carried out on the reduced

XSL•FO
RenderX

effect size of $d=dx(1-0.2)=0.32$ using G*Power. This resulted in a number of cases of N=310, or n=155 per arm. The recruitment and the study procedure did not change and remained in line with the protocol. Criteria for inclusion were (1) an *ICD-10* diagnosis on the depressive spectrum without psychotic symptoms, (2) at least mild depressive symptoms at baseline (PHQ-9 Score >4), (3) age between 18 and 75 years, (4) informed consent to participate in the study, (5) access to the internet, (6) sufficient knowledge of the German language, (7) willingness to participate, and (8) a stable treatment situation (pharmacotherapy or psychotherapy or waiting for treatment, ie, no active therapy) for at least 4 weeks before randomization. Individuals were excluded from participating if (1) a psychotic or bipolar disorder had been diagnosed (lifetime), (2) acute suicidal behavior had occurred within the past 4 weeks, (3) dementia was present, (4) alcohol or substance dependence within the last 6 months had been diagnosed, (5) antipsychotics were being taken currently, or (6) a serious illness was present that would preclude the patient's participation in the study until after the end of the study.

Intervention

The web-based program Novego is based on evidence-based methods of CBT as well as systemic therapy and mindfulness-based therapy.

The content of the program is based on the German national guidelines for depression [20]. In addition to imparting knowledge about the disorder (psychoeducation), the program implements the 4 elementary components of CBT based on Hautzinger [21]. Thus, the content of individual modules focuses on overcoming inactivity or one-sided stressful activity through activity lists and reinforcement plans. In addition, role plays lead to improvements in social behavior, mindfulness exercises, and concentration strategies improve dysfunctional attitudes, and relapse prevention techniques enable the development of coping skills [21]. The integration of CBT third-wave approaches such as mindfulness exercises complements the program [22]. The program consists of 12 weekly modules that are automatically compiled from a total of 16 available modules based on the user's responses to an initial in-program questionnaire. The content and images are also tailored to the personal situation of the participants. The composition is determined based on information about, for example, activity (eg, less active participants will receive Module 4a, "Discovering Activity," whereas more active participants will receive Module 4b, "Self-Discovery"), and comorbidities such as heart disease or chronic pain. In addition, the communication with participants is tailored to their expectations of the program, and examples are adjusted based on participants' age and gender. Each module takes approximately 45 to 60 minutes to complete. The modules include psychoeducational texts, audio files, videos, exercises, illustrations, and pictures, as well as several diary templates. In addition, users can choose to receive motivational emails and text message reminders. The entire program is made available to participants for one year after the initial 12-week period ends. Many working materials, documents, and exercises can be downloaded for long-term use. The program is web-based; installing an app is not necessary, and the program can be used on any device with an internet browser.

Measures

Primary Outcome

The primary endpoint to assess efficacy of the intervention was defined as the change in severity of depressive symptoms from T0 to T2, as measured by the Beck Depression Inventory II (BDI-II; [23). The BDI-II is a valid and reliable tool for evaluating depression symptoms [24,25]. The questionnaire consists of 21 items rated on a 4-point Likert scale from 0 to 3. A sum score is calculated to assess symptom severity in the previous 2 weeks. The total score ranges from 0 to 63, with higher scores indicating a greater impairment (0-8 no depression, 9-13 minimal depression, 14-19 mild depression, 20-28 moderate depression, and 29-63 severe depression). The BDI-II was assessed at T0, T1, and T2.

Secondary Outcomes

Patient Health Questionnaire-9

The Patient Health Questionnaire-9 (PHQ-9) [26,27] assesses the severity of depression in a self-report questionnaire covering the past 2 weeks, with 9 items answered on a 4-point Likert scale. The total score ranges from 0 to 27, with higher values indicating higher levels of depression severity. Categorization is based on the following: none or minimal (0-4), mild (5–9), moderate (10–14), and severe (15–27) depression. The PHQ-9 has high internal consistency (Cronbach α=0.86 to 0.89; [27]). The PHQ-9 was assessed at T0, T1, and T2.

Rosenberg Self-Esteem Scale

The Rosenberg Self-Esteem Scale (RSES) [28] assesses self-esteem through self-reporting using 10 items answered on a 4-point Likert scale ranging from (1) "strongly agree" to (4) "strongly disagree." The expression of self-esteem is determined by the total score, which can range from 10 to 40. A higher score indicates a stronger sense of self-esteem. The internal consistency of the scale (Cronbach α=0.77 to 0.88) is considered good [28]. The RSES was assessed at T0 and T2.

World Health Organization Quality of Life–BREF

The World Health Organization Quality of Life–BREF (WHOQOL-BREF) [29] measures subjective quality of life using 26 items. It serves as a shortened version of the WHOQOL-100 questionnaire and consists of 4 subscales (psychological well-being, physical well-being, social relationships, and environment). The response format is a 5-point Likert scale (1 to 5). For each of the 4 subscales, mean scores can be calculated, with higher values indicating better quality. Across all items, a summary score (subscale mean–4)×(100/16) between 0 and 100, with higher scores indicating better quality of life. The internal consistency (Cronbach α ranging from 0.68 to 0.82 for the four subscales) is between acceptable and good [30]. The WHOQOL-BREF was assessed at T0 and T2.

XSL•FO
RenderX

Positive and Negative Effects of Psychotherapy Scale for Internet-Based Interventions

The Positive and Negative Effects of Psychotherapy Scale for Internet-Based Interventions (PANEPS-I) [16] is a self-report instrument to assess unintended positive and negative effects of digital psychotherapeutic intervention. It consists of 27 items on 4 subscales: positive effects (8 items), side effects (7 items), malpractice (11 items), and unethical procedure (3 items). Responses are given on a Likert scale ranging from 1 ("agree") to 4 ("disagree") plus a fifth category of 5 "not applicable." The PANEPS-I was assessed only in the IG, at T2.

Treatment Expectation Questionnaire

The Treatment Expectation Questionnaire (TEX-Q [31]) is a 15-item questionnaire that measures a patient's self-reported expectations of an upcoming treatment. The questionnaire consists of 6 subscales, for each of which a mean value can be calculated: symptom improvement (items 1 to 3), positive effects (items 4 to 6), side effects (items 7 to 9), negative effects (items 10 and 11), process (items 12 and 13), and behavioral control (items 14 and 15). The items are answered on an 11-point Likert scale (0 to 10), where 0 corresponds to no expectation and 10 corresponds to the greatest conceivable expectation. If the items of the negative subscales (items 7 to 11) are inverted, an overall mean value can be calculated in which higher values represent a greater positive treatment expectation. The TEX-Q was assessed in both groups at T0.

Client Satisfaction Questionnaire

The Client Satisfaction Questionnaire (CSQ-8 [32]) was used to assess participants' satisfaction with the intervention. The 8 items are rated on a 4-point Likert scale, and a sum score is calculated. Negative items are recoded so that a higher score represents higher satisfaction. The CSQ-8 has demonstrated strong validity and reliability (Cronbach α ranging from 0.87 to 0.92; [32]). The CSQ-8 was assessed in the IG at T2.

Statistical Analyses

Statistical analyses were conducted using IBM SPSS Statistics 27 and R version 4.3.2. Differences in baseline measurements between the WCG and IG were examined using *t* tests for independent samples and chi-square tests.

Efficacy

Mixed-effects models for repeated measures (MMRM) as well as regression analyses with multiple imputation (MI) were used to evaluate efficacy of the program in the intention-to-treat (ITT) sample. The MI analysis used the iterative Markov Chain Monte Carlo method with 10 iterations. For each iteration and variable with missing values, the method fitted a univariate model using all the other variables in the model as predictors and then imputed the missing values for the variable being fitted. The method continued until the maximum number of iterations was reached. Group allocation, age, and education level were included in the model as predictors for imputation, with 100 imputations performed.

To test for sensitivity, complete case (CC) and per protocol (PP) analyses using analysis of covariance (ANCOVA) were conducted. The CC sample included data from participants with complete datasets, and the PP sample included data from participants with complete datasets; for IG participants, the sample also included those who logged into the program at least 4 times. For the ANCOVA, the dependent variables were the differences between T0 and T2. The baseline values were included as covariates in the analysis to control for regression to the mean.

The effect sizes of the analyses were calculated using Hedges *g* (g≈0.2: small effect, g≈0.5: medium effect, and g≈0.8: large effect) and partial eta-squared (η_p^2=0.01: small, η_p^2=0.06: medium, η_p^2=0.14: large). In addition, mean differences (least squares mean differences [LSMD]) were calculated.

Negative Effects

Negative effects were analyzed descriptively. Frequencies of each negative effect as assessed with the PANEPS-I were reported in valid percentages. In addition, the mean and SD of the sum of reported effects per subscale were calculated.

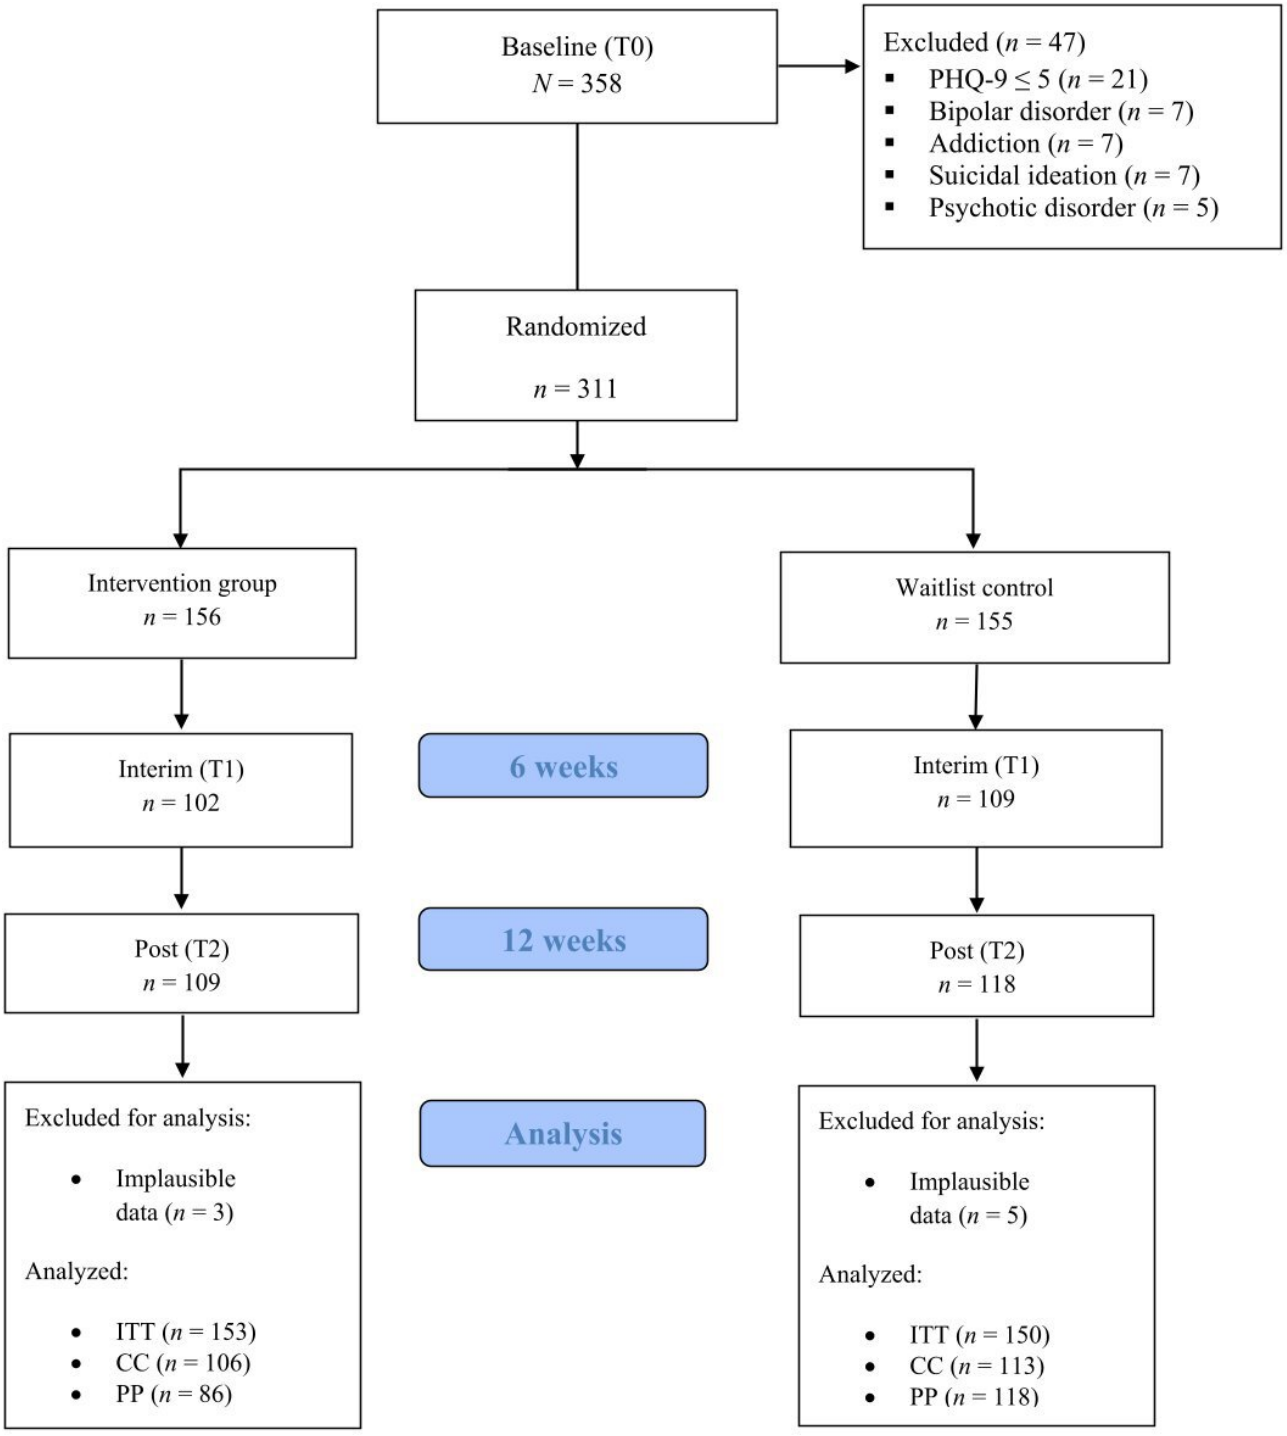
Moderation Analyses

To identify potential variables that impacted the effect, moderation analyses were conducted using the SPSS macro PROCESS (developed by Andrew F Hayes). The exploratory endpoints (mean score of TEX-Q, sum of reported effects for each PANEPS-I subscales, and sum score of CSQ-8) and severity according to PHQ-9 categories (minimal, mild, moderate, and severe) were included as independent variables. The dependent variable was the primary endpoint (difference scores of BDI-II sum score T2–T0).

Ethical Considerations

The study was approved by the Local Psychological Ethics Committee of the University Medical Center Hamburg-Eppendorf (ID: LPEK-0405). All participants provided informed consent. Participants were free to withdraw from the study at any time. Data were anonymized for data analysis.

Results



Overview

A total of 358 individuals participated in the baseline survey. However, 47 individuals were excluded at T0 as they did not meet the inclusion criteria (21 individuals with a PHQ-9 score below 5) or met an exclusion criterion (7 individuals with bipolar disorder, 5 individuals with psychotic disorder, 7 individuals with substance dependence, and 7 individuals with suicidal ideation). Thus, 311 participants were randomized. The included participants were randomly assigned to either the IG (n=156) or the WCG (n=155). Eight additional participants (5 from the WCG and 3 from the IG) were excluded post hoc due to implausible responses. A result was considered implausible if the *z* score standardized T2 scores of the 2 depression measures BDI-II and PHQ-9 deviated from each other by at least 1.5 SD and if the change in the BDI-II deviated from the mean change by at least 1 SD. These participants showed contrasting courses, with improvements in one and deteriorations

XSL•FO
RenderX

in the other depression scale. The final analysis thus included 303 participants (see Figure 1).

Figure 1. Flow chart.

Sample

The sample was predominantly females (218/303, 71.9%), with an average age of 40.68 (SD 12.50) years and a relatively high level of education (188/303, 62.0% at least with university entrance qualification; see Table 1). The psychiatric evaluation of the participants at baseline demonstrated an average level of depressive symptom burden (BDI-II, PHQ-9), a moderate level of self-esteem (RSES), and a moderate level of overall quality of life (WHOQOL-BREF global score; see Table 1). The accompanying CAU was well balanced among the total sample, with 47% (143/303) of participants not being in psychotherapeutic treatment at the time of baseline assessment and 41% (125/303) of the sample taking medication.

[a]BDI-II: Beck Depression Inventory-II.

[b]PHQ-9: Patient Health Questionnaire.

[c]RSES: Rosenberg Self-Esteem Scale.

[d]WHOQOL: World Health Organization Quality of Life Short Questionnaire.

[e]TEX-Q: Treatment Expectation Questionnaire.

Overall, 219 participants (219/303, 72.2%) completed the post survey (T2, 12 wk after baseline). The retention rate did not differ significantly between the IG (106/153, 69.3%) and the WCG (113/150, 75.3%; χ^2_1=1.39, *P*=.239). Non-completers (those who did not complete the post survey; mean 38.4, SD 11.62) were younger than those who completed the post survey (mean 41.57, SD 12.73, t_{301}=2.00, *P*=.047). Regarding experience with psychotherapy before the study, noncompleters (number of previous psychotherapies: mean 2.67, SD 2.42) and completers (mean 3.75, SD 8.20) did not differ significantly (t_{298}=1.18, *P*=.241). Additionally, no significant differences were found regarding gender (χ^2_2=3.08, *P*=.215), education level (χ^2_4=6.25, *P*=.181), or depressive symptom burden at the

XSL•FO
RenderX

time of the baseline survey (BDI-II; dropouts mean 24.89, SD 9.85, completers: mean 27.07, SD 9.19; t_{301}=1.81, *P*=.071).

Intervention Adherence and Satisfaction

Participants in the IG logged in to the Novego program an average of 14 times (mean 14.88, SD 17.61) over the 12-week intervention period, with a range of 0 to 142. Of the 153 participants in the intervention group, 35 (22.8%) did not start the program. Satisfaction with the program, as measured by the CSQ-8, was on average 22.54 (SD 5.18), with 72.8% (75/103) of users saying they were either very or fairly satisfied with the program and 74.7% (77/103) saying they would recommend the program.

Efficacy

Intention To Treat Analyses

For the primary endpoint (change in BDI-II at T2), the MMRM showed a significantly greater reduction in depressive symptoms in the IG compared to the WCG (see Table 2).

Table . Results of the ITT[a] analyses with MMRM for the primary endpoint (BDI-II).

ITT	WCG	IG	Effect sizes and *P* values
Change from T0 to T1			LSMD[d]=2.65; Hedges *g*=0.36; *P*=.015

Mean (SD)	−4.52 (8.31)	−6.91 (8.36)	
LS Mean (SE)	−4.51 (0.73)	−7.04 (0.76)	

[a] ITT: Intention-to-treat.

[b]*n*: Number of participants with baseline values in the analysis.

[c]*N*: Participants with baseline values.

[d]LSMD: Mean difference of least squares.

[e]LS Mean (SE): mean of leastsquarese.

Similarly, there was a significantly greater reduction in the secondary endpoint change in the sum score of PHQ-9 at T2 in the IG compared to the WCG (LSMD 1.65, 95% CI 0.71 to 2.59; *P*=.001, *g*=0.42).

Sensitivity Analyses

Using MI as the imputation method for the ITT sample, regression analyses confirmed a significantly greater reduction in depression observed in the IG compared to the WCG between T0 and T2, both in the BDI-II (*P*=.039, *g*=0.24) and in the PHQ-9 (*P*=.002, *g*=0.39). In the RSES, there was only a trend in favor of the IG (*P*=.073, *g*=0.22). No significant difference was found between the groups in the WHOQOL-BREF (*P*=.482, *g*=0.15). To further test the robustness of the ITT results for the primary endpoint, an additional ANCOVA using last observation carried forward as the imputation method was conducted. This analysis further confirms the results, showing a significantly greater reduction in depressive symptoms in the IG compared to the WCG ($F_{1;300}$=4.68, *P*=.031, η_p^2=0.02).

In the CC population (WCG n=113, IG n=106), for the primary endpoint, a significantly greater reduction in depressive symptoms was observed in the IG, as measured by the BDI-II, compared to the control group ($F_{1;216}$=5.51, *P*=.020, η_p^2=0.03; see Table 3). This result was confirmed by the PHQ-9, which also showed a significant group difference in the difference score between T0 and T2 ($F_{1;215}$=9.88), *P*=.002, η_p^2=0.04; see Table 3). For the RSES, a significant improvement in self-esteem was observed in the IG compared to the WCG from T0 to T2 ($F_{1;213}$=4.13, *P*=.043, η_p^2=0.02; see Table 3). However, for the WHOQOL-BREF, no significant difference was found ($F_{1;215}$=0.55, *P*=.458, η_p^2=0.00; see Table 3).

[a]WCG: waitlist control group.

[b]IG: intervention group.

[c]ANCOVA: analysis of covariance.

[d]CC: complete case sample.

[e]PP: per protocol sample.

[f]BDI-II: Beck Depression Inventory-II.

[g]Not applicable.

[h]PHQ-9: Patient Health Questionnaire-9.

[i]RSES: Rosenberg Self-Esteem Scale.

[j]WHOQOL: World Health Organization Quality of Life Short Questionnaire.

The improvement in depressive symptoms was already evident at the interim survey (6 wk after the initial survey). A significant difference in favor of the intervention group was also observed in the BDI-II ($F_{1;201=}$8.71, P=.004, η_p^2=0.04). However, this was not confirmed in the PHQ-9 ($F_{1;201}$=2.82, P=.095, η_p^2=0.01).

In the PP sample (WCG n=118, IG n=86), a significantly greater reduction in depressive symptoms was observed in the primary outcome in the IG, measured by the BDI-II, compared to the WCG ($F_{1;193}$=9.90, P=.002, η_p^2=0.05; see Table 3). This result was confirmed by the secondary endpoint parameter, measured by the PHQ-9 ($F_{1;192}$=15.20, P<.001, η_p^2=0.07; see Table 3).

For the RSES, there was a significant improvement in self-esteem in the IG compared to the WCG from T0 to T2 ($F_{1;193}$=7.16, P=.008, η_p^2=0.04; see Table 3). No significant group differences were observed for the WHOQOL-BREF scores ($F_{1;192}$=0.66, P=.418, η_p^2=0.00; see Table 3).

Negative Effects

In the postsurvey, the PANEPS-I assessed unintended positive and negative effects of the intervention. All IG participants with complete postsurveys were included in these analyses.

The frequencies of agreement per item for the positive and negative effects are shown in Tables 4 and 5, respectively.

XSL•FO

Table . Numbers and percentages of agreement with statements regarding negative effects. Missing values represent the choice of the response option 5 (“not applicable”). Percentages are valid percentages.

PANEPS-I[a] items 7 - 27	n	Agreement n (%)
Side effects		
I am afraid that my social network will find out that I have been doing an online program.	98	4 (4.1)
The online program has worsened my relationship with my family and/or friends.	93	3 (3.2)
It bothers me that my family or friends treat me differently since I did the online program.	90	0 (0.0)
Since using the online program, I feel labeled as a mentally ill person.	91	8 (8.8)
My family or friends are embarrassed that I did an online program.	92	1 (1.1)
I am embarrassed that I have done an online program.	97	4 (4.1)
I’m afraid that I didn’t correctly implement certain exercises or understand the content and that, as a result, my condition has worsened.	93	14 (15.1)
Malpractice		
I experienced technical difficulties with the online program that bothered me.	93	11 (11.8)
The online program only worked towards “eliminating the problem”; there was no positive goal orientation.	72	9 (12.5)
The online program made me feel like I was to blame for my problems.	90	8 (8.9)
From my point of view, the applied therapeutic techniques of the online program were wrong.	77	6 (7.8)
The online program did not sufficiently address my personal problems.	84	35 (41.7)
I learned behaviors through the online program that were very harmful to me (eg, saying no excessively, setting myself apart).	87	7 (8.0)
The exercises and information in the online program did not match what my therapist or doctor told me.	72	4 (5.6)
I felt that my problems were not taken seriously in the online program.	87	10 (11.5)
I feel that I have changed for the worse as a result of the online program.	86	2 (2.3)
I did not feel addressed by the online program (eg, due to lack of gender-appropriate language or lack of customization).	86	12 (14.0)
The online program took too much time and/or put too much performance pressure on me.	94	46 (48.9)
Unethical procedure		
I felt pressured by the online program to do things I didn’t really want to do.	89	22 (24.7)
The online program seemed intolerant of my origin, religion, sexual orientation, or gender.	88	5 (5.7)
I had concerns about the privacy of my data.	94	5 (5.3)

[a]PANEPS-I: Positive and Negative Effects of Psychotherapy Scale for Internet-Based Interventions.

XSL•FO
RenderX

Over 60% (38/63) of the participants reported that their willingness to engage in conventional face-to-face therapy was increased due to the program. More than half reported increased confidence in their own abilities and responsibility for themselves.

At least one side effect was reported by 22.0% (22/100) of the participants (range 0 - 5). Agreement with one or more items on the malpractice subscale gave 68.0% (66/97, range 0 - 8), and one or more unethical procedure items were reported by 29.1% (29/97, range 0 - 2). The most frequently reported negative effect was related to fear of incorrect implementation or understanding of the content and subsequent (subjective) deterioration (14/93, 15.1%). Regarding malpractice, 48.9% (46/94) said the program put too much time or performance pressure on the user and 41.7% (35/84) felt the program did not address personal problems sufficiently. An unethical procedure was reported by 24.7% (22/89) who felt pressured to do things they did not want to do.

Because of the significant age difference between completers and dropouts in this study, an exploratory analysis of age differences for the most frequently reported items of the PANEPS-I of each negative effect subscale was conducted using an independent *t*-test. For item 24 ("The online program took too much time and/or put too much performance pressure on me") on the subscale, significantly younger participants (mean age 39.28, SD 11.47) reported this effect compared to those who did not agree with this item (mean age 47.65, SD 11.17; t_{94}=3.63, P<.001). No significant difference in age was found for MP item 13 ("I'm afraid that I didn't correctly implement certain exercises or understand the content and that, as a result, my condition has worsened") on the side effects subscale (t_{93}=−0.80, P=.429). There was a trend for younger age when agreeing (mean age 39.27, SD 13.00 vs mean age 44.93, SD 11.52) for item 25 ("I felt pressured by the online program to do things I didn't really want to do"), but no significance was found (P=.055).

Moderation Analyses

Moderation analyses were computed using the data from both the PP sample and the ITT sample, when applicable. The negative effects of the intervention (combined for the subscales of side effects, malpractice, and unethical procedure) had no significant moderating effect for the decrease in symptom severity in intervention users (PP, P=.184). Furthermore, treatment expectation did not significantly moderate the treatment effect in either the ITT sample (P=.489) or the PP sample (P=.773), and patient satisfaction did not significantly moderate the decrease in symptom severity in intervention users (PP, P=.896). Severity category according to the PHQ-9 did not demonstrate any significant interaction with the reduction in symptom burden (ITT: P=.984; PP: P=.967). In addition, for the ITT sample, experience with psychotherapy (dichotomized) independent of current treatment situation was evaluated as a moderator, but no interaction effect was found (P=.694). Effects of the moderation analyses are displayed in Table 6.

Discussion

Principal Findings

Meta-analyses affirm the effectiveness of internet-based interventions for depression for alleviating symptoms and report advantages such as cost-effectiveness relative to CAU. However, not all users benefit, and negative effects can occur. Adverse events and side effects are largely neglected in research, which means that such costs for patients are scarcely considered. The aim of this two-arm randomized controlled trial was to investigate the effectiveness in terms of medical benefits of the internet-based program Novego Depression in adults with a depressive disorder and to assess negative effects occurring in users of the intervention.

The primary ITT analysis showed a significantly greater reduction in depressive symptom severity in the IG compared to the WCG after 12 weeks, both in the primary endpoint parameter (BDI-II) and in the secondary (PHQ-9), with small to medium effect sizes. The effect was already evident after 6 weeks. Sensitivity analyses (CC and PP) confirmed the results with greater effect sizes overall. For the secondary endpoints of self-esteem and quality of life, the hypothesized effects were not evident in the ITT analyses. However, in the CC and PP populations, a significantly greater improvement in self-esteem was found in the IG compared to the WCG.

The reduction of depressive symptoms is in line with previous findings on prior versions of the Novego Depression program with various patient groups [13-15]. The effect sizes are comparable to those found in meta-analyses with unguided interventions for depression (eg, [33]). The results of the present study now demonstrate that the intervention is effective in patients with a confirmed, primary diagnosis of depression who are already in contact with health care professionals because of their depression compared to waitlist controls with CAU. This emphasizes the benefits of this kind of interventions not only for those who do not want or cannot access face-to-face therapy but also for patients who want to "refresh" their therapy knowledge or want to have something to complement their ongoing therapy in daily life. Over 80% of participants experienced additional nonmedical positive effects when using the intervention, for example, gaining confidence or feeling proud of completing the online program.

Despite the positive effects of the intervention, users also experienced negative effects. Reported negative experiences were often related to concerns about using the program incorrectly and thus worsening one's own condition or about feeling pressured by the program. The fact that side effects generally occur with online interventions is consistent with the results of other studies on adverse effects with similar interventions (eg, [17,19]). Usually, if adverse events are evaluated, the rate of symptom deterioration is reported. Karyotaki and colleagues [17] found in their meta-analysis that around 6% of internet-based intervention users experienced a worsening of symptoms. In this study, symptom deterioration was not evaluated, so no direct comparison can be made. However, 14.6% of the intervention users in this study reported concerns about worsening of symptoms due to their not implementing the psychotherapeutic methods properly. Other studies with a more qualitative evaluation of negative effects had comparable rates to the findings in this study (8% - 14% of users report side effects; [19,34]). The majority of the reported negative effects in those studies were program-related (eg, difficulty in understanding or implementing the exercises; 19), which is consistent with our results. Outliers with a higher rate in the current study were two items of the subscale MP (not sufficiently addressing personal problems and feeling pressured by the program), both with over 40%. When interpreting the results, it should be noted that these negative effects were assessed based on the purely subjective perspective of the users. Program-related negative effects like these might indicate a mismatch with the patient's expectations or needs rather than actual malpractice. In addition, it must be mentioned that the questionnaire used for assessing negative effects only provides information about the occurrence of negative effects, not whether or to what extent these events actually had a negative, stressful, or damaging impact on the user.

Importantly, negative effects and other factors (expectation, satisfaction, and experience with psychotherapy) in this study did not moderate the change in depressive symptom severity. Therefore, although the frequency of these effects was not negligible, the experience of adverse effects during the intervention period did not exert a detrimental influence on the effect of the therapy. This also underlines the lack of assessing the valence or perceived extent of the reported negative effects. Fenski et al [19] found that experiencing negative effects with an internet-based intervention for depression predicts poor adherence, and Baumeister and colleagues [35] reported more program-related negative effects in non-responders among users of a digital self-help intervention for body-focused repetitive behaviors. Interestingly, in explorative analyses, age differences were found regarding reported negative effects. In line with the higher dropout rate in younger participants, those who reported feeling pressured by the program were significantly younger. These results further indicate that the acceptability of internet-based interventions might be dependent on age (and/or other patient characteristics).

Limitations

The interpretative value of these results is compromised by some limitations that should be mentioned. The generalizability of this study is limited due to the predominantly female and well-educated sample and because all participants were German. Additionally, the results regarding negative effects of the intervention might be biased since only complete cases were analyzed. Missing data for the questionnaire used to assess negative effects (PANEPS-I) were not imputed. Further, the sample in this study was rather experienced with psychotherapy. This might also have an influence on the experience of possible negative effects. Less experienced users might feel more uncomfortable with challenging situations during the intervention and/or have different needs. Additionally, negative effects were assessed at the end of the 12-week intervention period. It is possible that the retrospective assessment distorted the participants' answers. Because there was no follow-up assessment, no inference can be drawn regarding the sustainability of the treatment effects.

XSL•FO
RenderX

Lastly, as the questionnaire for assessing negative effects used in this study does not allow direct conclusions on the severity of the impact of experiencing these effects, a definite risk-benefit analysis cannot be conducted using the reported results. The moderation analysis solely indicates that the number of reported negative effects did not moderate the treatment effect.

It seems important to further investigate and consider negative effects in internet-based interventions as they can occur and their impact on (or cost to) the patient has not been well studied. Further research is needed to better understand the role of negative effects in internet-based interventions. Future studies on negative effects in internet-based interventions should also focus on investigating the extent and impact of potential negative effects and their moderating effect on treatment outcome and adherence. It is essential to further investigate how side effects arise and impact various subgroups of patients in order to achieve a better alignment between treatments and patients' needs. This might help to further improve internet-based self-help interventions and better understand what works for whom.

Conclusion

Overall, the Novego Depression program proved to be effective in reducing symptom severity compared to waitlist controls. Evaluation of negative effects showed that although they did occur, they did not reduce the treatment effect. Although some limitations must be considered when interpreting these results, it can be concluded that for participants who completed the surveys in this study, the digital health care application is an effective treatment and its benefits outweigh the reported negative effects.

Acknowledgments

This trial was supported by IVPNetworks GmbH, Hamburg, Germany.

We acknowledge financial support from the Open Access Publication Fund of UKE - Universitätsklinikum Hamburg-Eppendorf.

Authors' Contributions

Abstract

Background: Suicide is a significant global public health concern. Individuals with suicidal behaviors often seek help in emergency departments (ED), making mental health providers critical to suicide prevention. Brief interventions such as safety planning are essential in these settings. However, there is a limited understanding of how mobile digital safety planning apps can aid in secondary suicide prevention.

Objective: This study evaluated the effectiveness of a digital safety plan, delivered through the *MeMind* app, in reducing ED visits associated with suicidal behavior (ie, suicidal ideation or attempt).

Methods: A one-year follow-up was conducted for individuals who presented to the ED for an index event of suicidal behavior (N=78). Participants were provided with a digital safety plan on their mobile devices and instructed to activate it during future suicidal crises.

Results: At follow-up, participants who activated the digital safety plan showed a 50% lower likelihood of returning to the ED, when compared to those who did not activate it.

Conclusions: These findings suggest that digital safety planning may serve as a scalable and accessible intervention with the potential to significantly contribute to suicide prevention efforts.

Introduction

Suicidal behavior is a complex and multifactorial phenomenon that constitutes a public health concern. The World Health Organization estimates that over 700,000 individuals die by suicide annually, with data suggesting that there are more than 20 attempted suicides for each suicide-related death [1,2]. Globally, the suicide rate is estimated at 9.4 per 100,000 people, particularly among those aged 15 to 34 years, with a higher prevalence in men compared to women [3]. In Spain, the estimated suicide rate is 8.4 per 100,000 people, representing the second leading cause of non-natural death by external causes, with approximately 11 suicides occurring daily [4].

The consequences of suicidal behavior have a significant impact on individuals, families, and the society, emphasizing the urgent need for health systems to prioritize suicide prevention and implement effective strategies [5]. However, there remains a need to enhance the effectiveness of current suicide interventions, particularly for individuals presenting to emergency departments (ED) and those hospitalized due to suicidal ideation or behaviors, who exhibit a high risk of reattempting suicide within the initial months' post discharge [6]. This increased risk of reattempt is further amplified when individuals have a history of suicide attempts and a diagnosed psychiatric disorder [7].

Studies indicate that face-to-face psychological interventions are effective in reducing suicidal behavior compared to treatment-as-usual. However, the anticipated outcomes are primarily observed in intensive and long-term intervention approaches [8]. Conversely, there is a growing interest in digital and brief interventions for managing suicidal behavior, driven by their cost-effectiveness and relevance when immediate access to mental health care is limited [9]. Brief interventions, administered by trained professionals in acute care settings, aim to provide tools for managing suicidal crises and reduce suicide risk and have demonstrated effectiveness in reducing subsequent suicide attempts [10].

Among brief interventions for suicide prevention, safety planning intervention (SPI) is commonly used [11]. SPI is a brief therapeutic practice, typically lasting 20 - 45 minutes, aimed at reducing the imminent risk of suicidal behavior. This is accomplished through a collaborative process between clinicians and patients, where a personalized plan is developed. This plan guides individuals to identify their thoughts, feelings, and experiences immediately preceding a crisis, and establishing coping strategies and activation of support resources upon the recurrence of suicidal thoughts. SPI includes personal warning signs, strategies for self-management, social support, emergency contacts, reasons for living, and measures to restrict access to lethal means [12]. Systematic reviews support the effectiveness of traditional SPI in reducing suicidal behaviors [10,11,13] with studies showing that SPI can decrease suicidal behaviors by up to 45% [14].

Safety planning is framed within a participatory care model, which emphasizes active collaboration between clinicians and patients to co-design personalized strategies for managing suicidal crises. This model fosters patient empowerment, shared decision-making, tailored interventions, and enhances patient satisfaction, improves treatment adherence, and reduces costs [15]. This participatory care model has been effectively applied in several suicide-specific interventions [16].

Despite the potential benefits of safety planning in reducing suicidal behavior, limited information exists regarding its usability outside of treatment settings. For example, it has been observed that individuals seeking help for suicide-related concerns are largely unaware of safety planning or have not incorporated it into their treatment plans [17]. Additional barriers related to safety plan usage include its implementation in the presence of depressive mood, particularly in the absence of collaborative development with a clinician [18]. Furthermore, as traditional SPIs are often paper-based, access barriers may arise during crisis situations due to difficulties in retrieving the information.

Digital safety planning via mobile-apps offers a viable alternative to overcome these limitations by enhancing immediate and ubiquitous access through personal mobile devices and providing a more dynamic and user-friendly platform. Through such apps, several functions can be incorporated to enable access to videos, photos, import of significant contacts, or location-based access to emergency services [19]. For instance, individuals can integrate family photos or directly access contact information for significant support persons or health care professionals or centers, potentially triggering coping strategies related to suicide more directly and effectively. These strategies embody a participatory care model, actively engaging patients in their own treatment [20]. Moreover, the use of an ecological momentary intervention (EMI) through mobile apps facilitates real-time monitoring and usability tracking of the digital safety plan [21]. Such data collection can provide insights into who uses the safety plan, when, and which strategies are most beneficial.

Previous studies have shown that mobile-app based safety plans demonstrate high acceptability and feasibility, although evidence regarding their effectiveness is still limited [19]. To date, only a few studies have evaluated the effectiveness of a digital safety plan. Two pilot studies found that the use of a digital safety plan reduced suicidal ideation [22,23] and a subsequent study with a larger sample found that the use of a digital safety plan increased suicide-related coping, which was associated with a reduction in suicidal ideation. Further, greater perceived utility of the digital safety plan (eg, by using customizable content) was associated with higher suicide-related coping [24]. However, the follow-up period in these studies was limited to three months, thereby precluding an evaluation of the long-term efficacy of digital safety plans or their ability to reduce in emergency department (ED) visits due to recurrent suicidal behavior.

In this study, a one-year follow-up was conducted among individuals who presented to the ED with suicidal behavior (ie, suicidal ideation or attempt). Participants were provided with a digital safety plan on their mobile devices and instructed to activate it during future suicidal crises. The study aimed to assess whether activating the digital safety plan reduced subsequent ED visits associated with suicidal behavior.

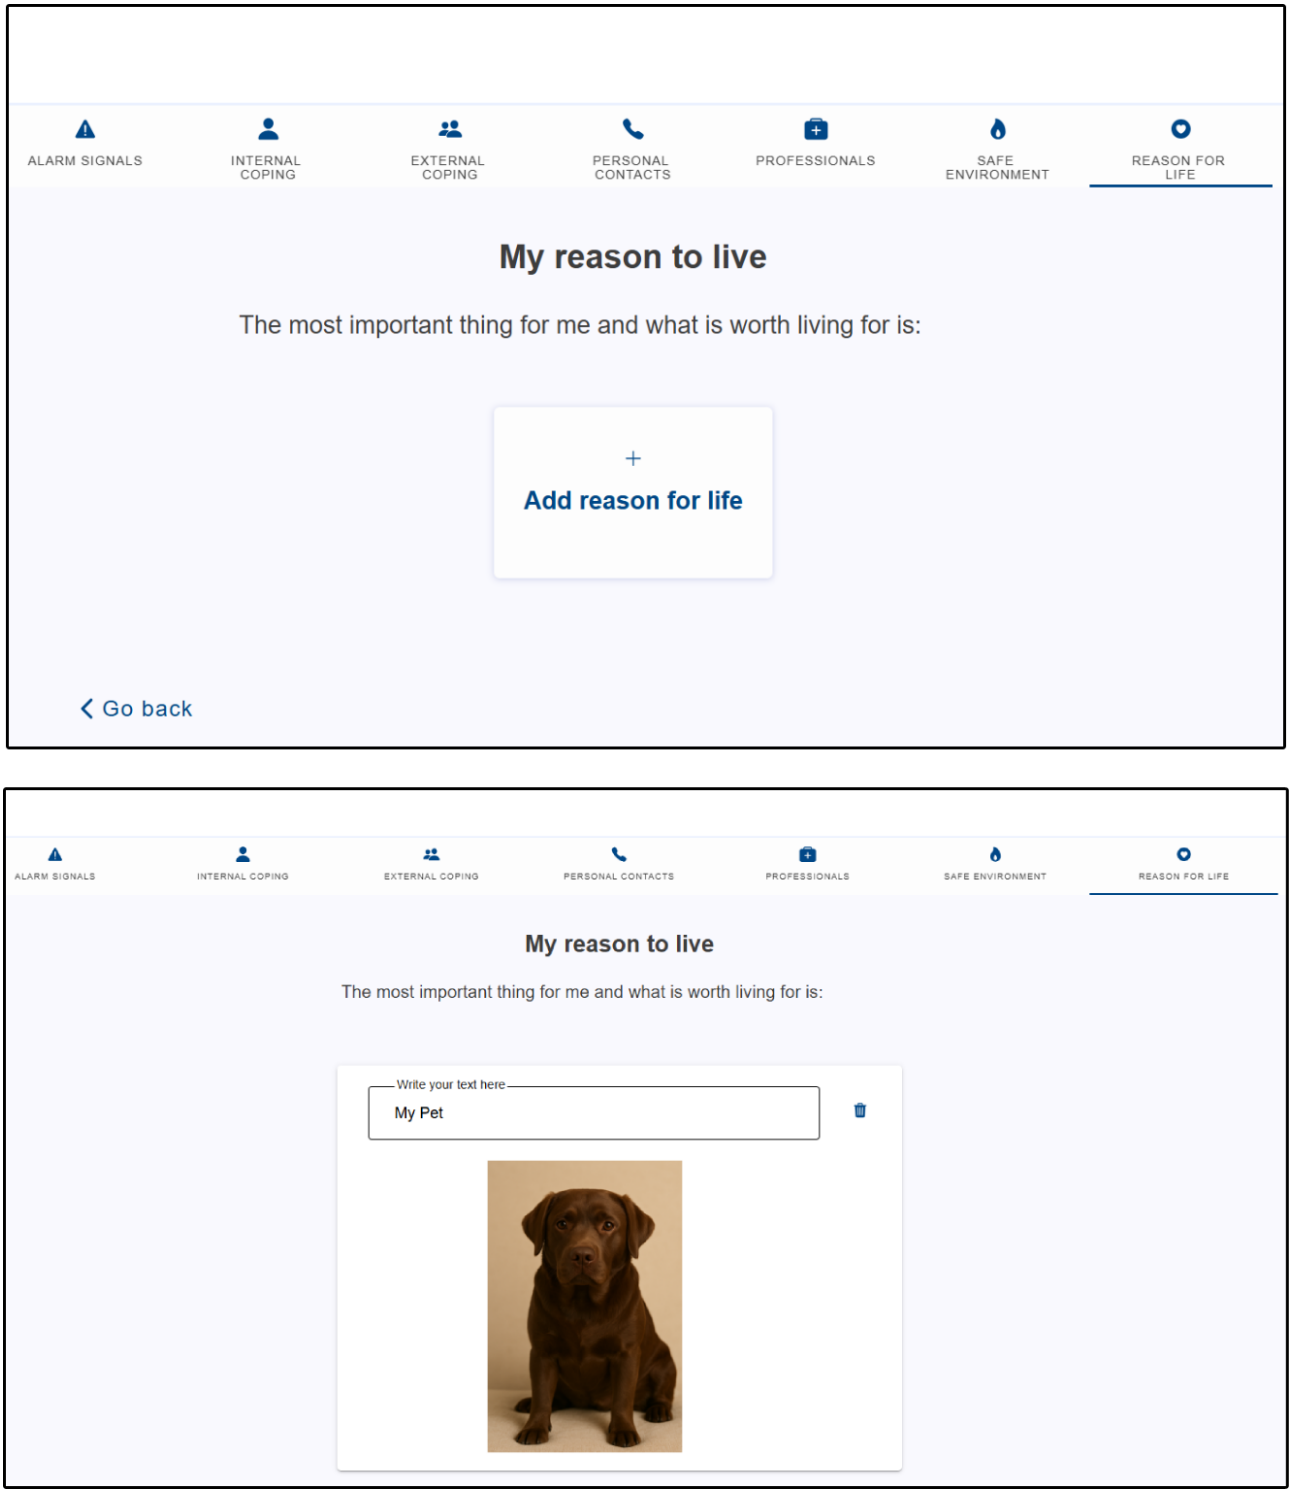
XSL•FO
RenderX

Methods

A quasi-experimental design and an EMI were employed to monitor the use and activation of a digital safety plan through the *MeMind* app [25].

Participants

Data were collected in the EDs of two hospitals in Madrid, Spain, between September 2022 and August 2023. Participants were adults (aged ≥18 years) presenting to the ED for suicidal behavior. Suicidal behavior was defined as any action or self-injurious act with the intent to die, encompassing both suicidal ideation and suicide attempts. Once potential participants received standard emergency care and were deemed medically stable, they were offered the opportunity to participate in the study prior to discharge. Those who consented to participate met with a psychiatrist for 30 - 40 minutes to receive a detailed explanation of the study, install the study app on their smartphones, and complete the digital safety plan. The inclusion criteria were (1) presentation to the ED for suicidal behavior; (2) ownership of a smartphone with internet connection; (3) speaking and understanding Spanish; and (4) being able to give informed consent. Exclusion criteria included unwillingness to install the app or limited smartphone access.



Measures

Digital Safety Plan

Participants received access to a digital safety plan for suicidal crises through the *MeMind* app [25] (Figure 1). *MeMind* is designed to be compatible with Android and iOS operating systems and can be downloaded for free on Google Play and the Apple App Store. After installation, participants collaborated with psychiatrists to configure the plan, which included seven customizable tabs: warning signs, internal and external coping strategies, personal and professional contacts, safe environments, and reasons to live. The app, which was validated in previous studies demonstrated good feasibility and acceptability [26]. Participants were instructed to activate the plan during subsequent suicidal crises. Data on digital safety plan configuration and activation were collected over a one-year follow-up. Specifically, the frequency of digital safety plan configuration and activation of each of the seven incorporated tabs or functions was recorded. Configuration allowed participants to use the “Configure Safety Plan” feature, enabling them to review or add new information to each tab or function outside of crisis periods. Activation involved using an in-app feature labeled “Activate Safety Plan,” which provided access to the information within the seven previously configured tabs or functions aimed at implementing coping strategies during suicidal crises. Participants were encouraged to configure the digital safety plan as needed and to activate it during crises triggered by the onset of suicidal behavior.

RenderX

Figure 1. Example of MeMind app safety plan configuration; artificial intelligence-generated image, in response to the request "Generate an image of a Labrador Retriever as a companion dog" (Generator: Copilot, Microsoft; June 11, 2025; Requestor: Carlos Schmidt) [27].

Suicidal Behavior

Baseline assessments used the Spanish version of the Columbia Suicide Severity Rating Scale (C-SSRS) [28]. The C-SSRS is a semi-structured interview that evaluates the occurrence, severity, and frequency of suicidal ideation and behavior [29]. Information on the severity of ideation (most severe ideation, intensity, frequency, duration, and controllability) and previous history of suicide attempts was collected.

Statistical Analyses

A Cox proportional hazards model with random effects was used to investigate the association between digital safety plan activation and subsequent ED visits for suicidal behavior (ie, suicidal ideation or attempt) during the one-year follow-up. The outcome variable was ED visits for suicidal behavior (yes vs no), with time measured in days over a 365-day follow-up period. The primary predictor variable was digital safety plan activation (yes vs no). This analysis assessed whether participants who activated the safety plan during the follow-up

XSL•FO
RenderX

period experienced fewer ED visits for suicidal behavior compared to those who did not (ie, quasi-control group). Age and sex were included as covariates. Random effects were specified for each participant, with participant ID and days of digital safety plan use (ie, configuration or activation) as random intercepts. All statistical analyses were conducted using a two-sided significance level of α=0.05. Analyses were conducted using R software (version 1.1.463; R Foundation for Statistical Computing), including the *survival* and *coxme* packages [30-32].

Ethical Considerations

The study was approved by the Research Ethics Committee of the Fundacion Jimenez Diaz Hospital (Approval number: EC005-21_FJD). All participants provided informed consent. Participants were free to withdraw from the study at any time or decline further participation during follow-up without affecting their medical care. All collected data were anonymized to protect participant identity. No compensation was provided for study participation.

Results

Demographic Characteristics

A total of 78 participants were included in the study, with a mean age of 39.08 (SD 13.45) years; most were female (n=56, 72%). According to the baseline suicidal behavior characteristics (ie, C-SSRS), 72 (90%) participants exhibited high-intensity suicidal ideation, and 63 (80%) participants reported prior suicide attempts (Table 1). Over the one-year follow-up, 24 (31%) participants returned to the ED services for suicidal behavior (ie, suicidal ideation or attempt).

Table . Baseline sociodemographic characteristics of the total sample.

Characteristics	Participants (N=78)
Age (years), mean (SD)	39.08 (13.45)
Sex (female), n (%)	56 (72)
Emergency department visits, n (%)	
Only 1 (index event)	54 (69)
≥2	24 (31)
Suicidality (C-SSRS)[a]	
SI[b] (yes), n (%)	72 (90)
Intensity of SI[c], mean (SD; range)	4.10 (1.03; range 1 - 5)
Frequency of SI[d], mean (SD; range)	2.67 (1.24; range 1 - 5)
Duration of SI[e], mean (SD; range)	3.19 (1.37; range 1 - 5)
Controllability of SI[f], mean (SD; range)	3.18 (1.47; range 0 - 5)
Previous suicidal attempts (yes), n (%)	63 (81)

[a]C-SSRS: Columbia Suicide Severity Rating Scale.

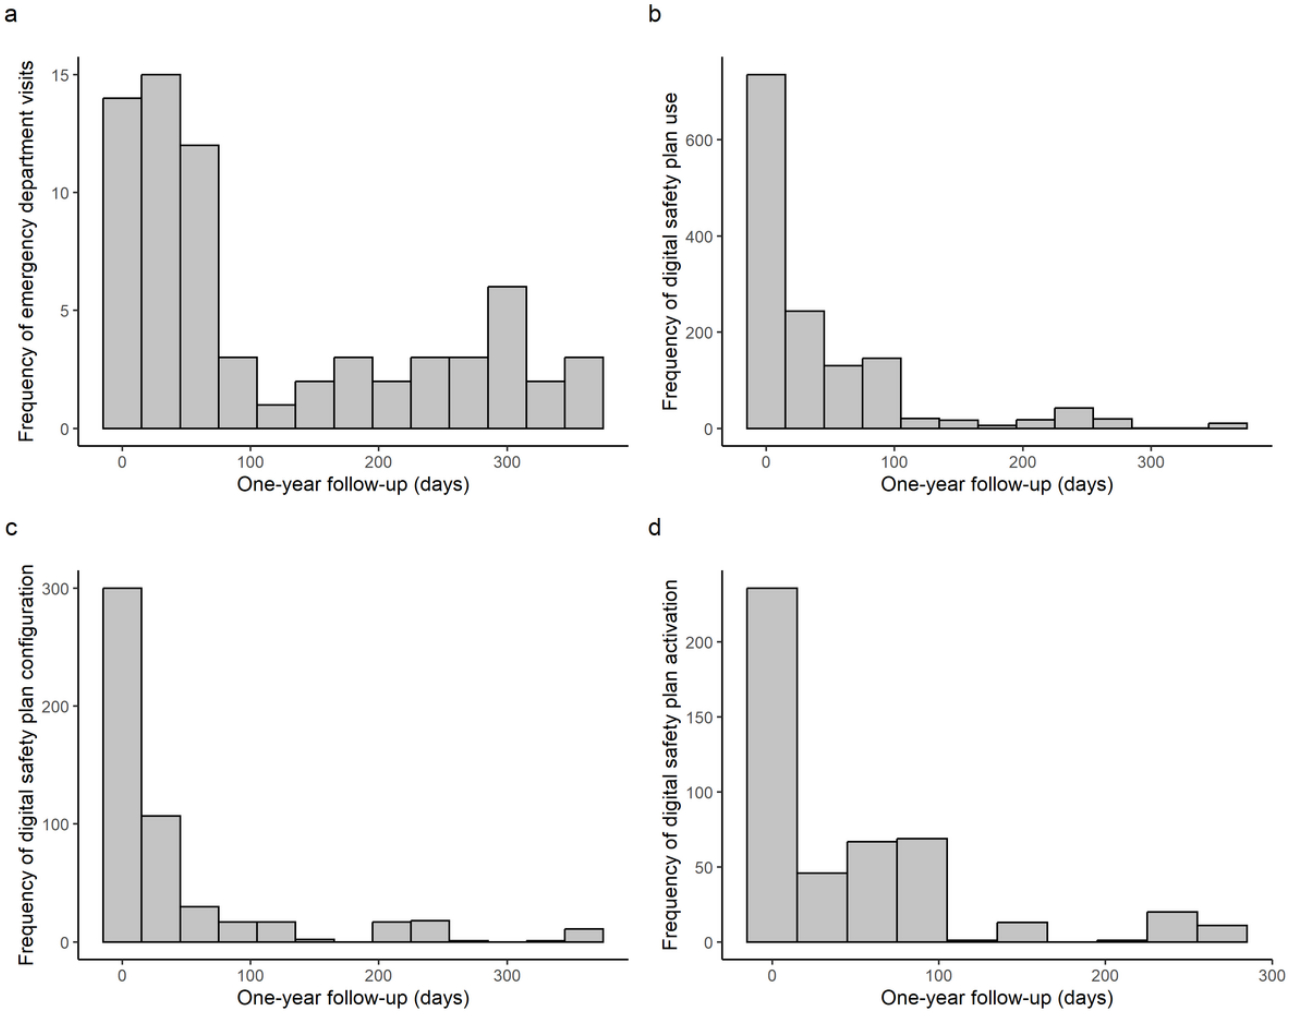
[b]SI: suicidal ideation.

[c]Intensity of suicidal ideation: severity of ideation, with 1 being the least severe and 5 being the most severe.

[d]Frequency of SI: "How often have you had these thoughts?", ranging from (1) less than once a week to (5) many times a day.

[e]Duration of SI: "When you have those thoughts, how long do they last?" ranging from (1) fleeting/a few seconds or minutes to (5) more than 8 hours/persistent or continuous.

[f]Controllability SI: "Could/can you stop thinking about killing yourself or wanting to die if you want to?" ranging from (1) You can control the thoughts easily to (5) You cannot control the thoughts, or (0) You do not try to control the thoughts.



Subsequently, the frequency of return to the ED and digital safety plan usability by the participants during the follow-up period were explored. A total of 2.768 observations were collected for the digital safety plan usage. Of the overall enrolled participants, 31 (40%) activated the digital safety plan during the follow-up period.

Given the non-normal distribution and positive skew of these variables, we reported the median (IQR) and 90th percentile (P90). Within the one-year follow-up, the median time for return to the ED postindex event was 55 (IQR 211, range 1 - 359; P90=301) days, with a higher frequency observed within the first 60 days, followed by a more uniform distribution throughout the remaining year (Figure 2A). Excluding the initial app installation and collaborative safety plan installation with the psychiatrist, the median overall digital safety plan usage occurred at 14 (IQR 47, range 2 - 359; P90=105) days (Figure 2B). When examining the frequency of digital safety plan configuration (ie, personalizing the safety plan), the median usage occurred at 11 (IQR 28, range 2 - 359; P90=107) days, with a decreased frequency throughout the rest of the year (Figure 2C). For digital safety plan activation (ie, accessing the safety plan during crisis moments), the median usage occurred at 15 (IQR 67, range 2 - 260; P90=112) days, with a stable frequency in the first 90 days and a significantly reduced frequency in the remaining follow-up period (Figure 2D). Overall, 90% (62/69) of participants returned to the ED due to

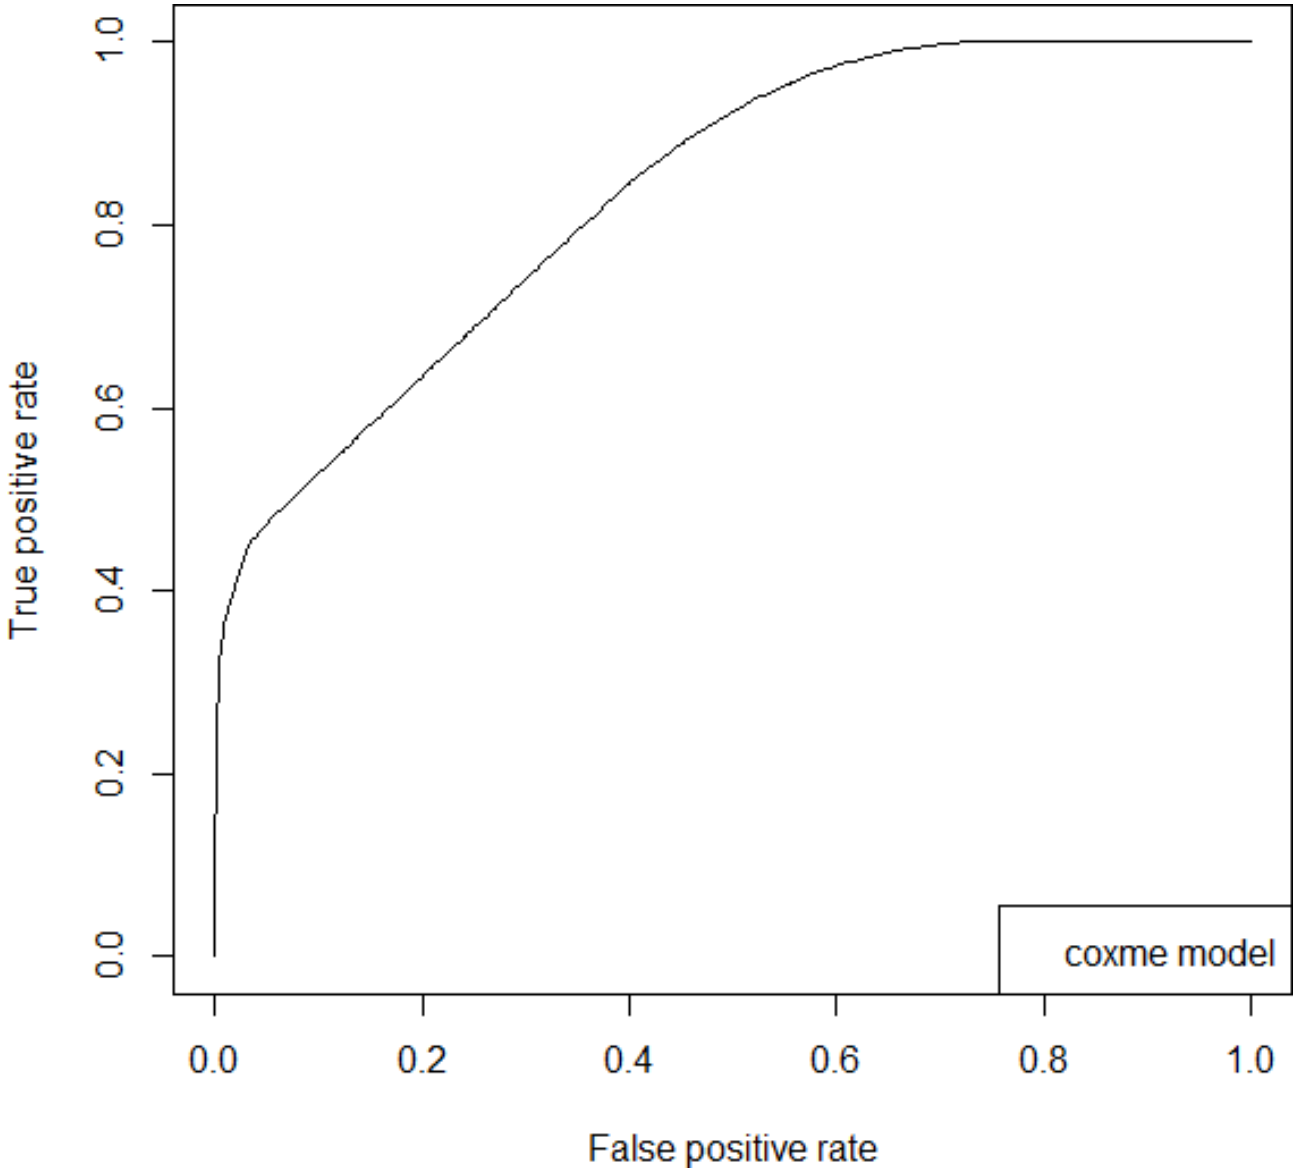
XSL•FO
RenderX

suicidal behavior within 300 days, while 90% of digital safety plan configurations (1392/1547) and activations (529/588) occurred within the first 100 days of follow-up.

Figure 2. (A) Frequency of emergency department returns due to suicidal behavior; (B) Frequency of total digital safety plan use; (C-D) Configuration and activation of digital safety plan during follow-up.

When examining the usage of the digital safety plan configuration, “external coping strategies” (n=362, 23.30%), “professional ask for help” (n=328, 21.10%), and “warning signals” (n=234, 15%) were the most frequently accessed functions, followed by “personal contacts” (n=188, 12.10%) and “internal coping strategies” (n=178, 11.40%); “creating a safe environment” (n=141, 9.10%) and “reasons to live” (n=124, 8%) were less frequently used. For digital safety plan activation, the most frequently activated tabs were “external coping strategies” (n=140, 22.90%), “warning signals” (n =125, 20.85%), “professional ask for help” (n= 120, 19.48%), “internal coping strategies” (n =74, 12.30%), and “personal contacts” (n =64, 10.42%); “creating a safe environment” (n= 50, 7.69%) and “reasons to live” (n= 41, 6.32%) were less frequently used. No significant differences were found in age, sex, suicidal behavior characteristics, or severity of suicidal ideation between those who activated the digital safety plan and those who did not (all *P* values >.05).

In general, while all safety plan function or sections were used to some extent, we observed a usage pattern that corresponded with the tab sequence in the app’s interface. Specifically, “creating a safe environment” and “reasons to live,” which were positioned at the end of the app’s interface, were least frequently used. This finding suggests that the arrangement of the functions influenced the usability of the digital safety plan.



Association Between Digital Safety Plan Use and Subsequent Emergency Department Visits

Participants who activated the digital safety plan had a lower frequency of ED visits compared to those who did not activate the plan (n=102, 16.6% vs n=313, 29.1%; χ^2_1=37.48, *P*<.001).

Subsequent analyses examined the predictive utility of digital safety plan activation for ED visits over the one-year follow-up period. Using the *coxme* function, we identified the best-fitting model with participant ID and days of safety plan usage as random effects. Receiver operating characteristic analysis demonstrated good discriminatory capacity of the model (area under the curve [AUC]=0.82) for predicting ED visits for suicidal behavior based on digital safety plan activation (Figure 3).

XSL•FO
RenderX

Figure 3. Receiver operating characteristic curve for survival model.

The Cox proportional hazards model, adjusted for participant demographics, revealed a significant association between digital safety plan activation and a reduced likelihood of subsequent ED visits. Participants who activated the safety plan had a 50% lower likelihood of returning to the ED for suicidal behavior (ie, suicidal ideation or attempt) compared to those who did not (Figure 4). Furthermore, male participants and those aged ≥30 showed a reduced likelihood of returning for subsequent ED visits (Table 2). These results suggest that engaging with the digital safety plan and consequently accessing preconfigured suicide-related coping strategies within the app, may enable individuals to effectively manage suicidal thoughts and prevent escalation during a suicidal crisis, potentially reducing the frequency of ED readmissions. Additionally, sex and age were important clinical factors and should be considered in predicting ED readmissions for suicidality.

Discussion

Principal Findings

Prior studies have established the relevance of safety plan usage in preventing or managing suicidal crises. However, to date, the effectiveness of a mobile digital safety plan in reducing ED visits for suicidal behavior has not been evaluated. This study found that participants who chose to activate a digital safety plan showed a 50% reduction in the likelihood of subsequent suicide-related ED visits, compared to those who did not activate it.

Additionally, male participants and those aged ≥30 were less likely to return to emergency services for suicidal behavior during the one-year follow-up after an index event, compared to female and younger participants. Generally, men are less inclined to seek assistance for suicide-related issues, even though they tend to use more hazardous methods and exhibit elevated fatal-suicide rates globally [3], including in European countries [33]. Nonetheless, no association was observed between digital

XSL•FO
RenderX

safety plan activation and participants' sex, age, or severity of suicidal ideation.

Our analysis also revealed that 30.8% of participants returned to the ED due to suicidal behavior following the index event, predominantly within the first 60 days. The initial three-month period post discharge represents a time of heightened risk for reattempt, thus highlighting the relevance of prevention and follow-up during this phase [6]. Similarly, the highest frequency of digital safety plan activation occurred within the first few weeks, with a median of 15 days. Consequently, digital safety plan usage was brief and strongly associated with the index event. Prior research has indicated that the usability of the digital safety plan is sporadic and concentrated in the early follow-up weeks [24]. Safety plans are designed for use during suicidal crises [12]; therefore, it is expected that users will engage with them only when necessary, particularly at the onset of suicidal thoughts.

The most frequently activated sections of the digital safety plan were "warning signs," "external coping strategies," and "professional contacts." In contrast, less frequently used sections included "reasons to live," "safe environments," "personal contacts," and "internal coping strategies." These findings suggest a potential preference for seeking external support during suicidal behavior, such as contacting professionals, rather than relying solely on internal resources. This observation is consistent with findings that indicate social support serves as a protective factor against suicidal behavior [34], particularly among individuals with a history of suicide attempts [35]. It is also possible that during periods of intense or severe suicidal ideation, internal coping strategies become more difficult to activate and manage independently, whereas external suicide-related coping are more readily accessible [36]. Additionally, the design and interface of the digital safety plan app may impact which features are prioritized by users. For example, the interface's tab order—with "warning signs" positioned first and "reasons to live" last—may impact usability. Future research should further explore the usability of the app and identify which sections are most useful to users. Suggested improvements could include in-app digital scales to assess satisfaction with app use and the perceived effectiveness of the functions included in the digital safety plan.

The findings of this study have important clinical and practical implications. The observed association between safety plan activation and reduced ED readmission for suicidal behavior underscores the potential of digital safety plans in secondary suicide prevention. Integrating such tools into routine postsuicide attempt care could provide an accessible, scalable, and potentially cost-effective intervention to mitigate future crises. Moreover, digital safety plans offer an ecologically valid approach by enabling real-time usage monitoring and empowering individuals with digital tools and suicide-related coping strategies to manage future suicidal crises [24].

Digital mental health interventions have the potential to leverage technology to increase user engagement in suicide prevention and ensure continuity of treatment between emergency or hospital services and outpatient care [37]. Furthermore, digital interventions could be cost-effective, given their promising cost-benefit ratio in suicide prevention within the framework of current mental health interventions, which could support increased public health policy investment in digital strategies [38,39]. In particular, digital safety plans for suicide prevention present a compelling alternative to traditional methods, offering enhanced usability and reduced access barriers. These plans can integrate multimedia elements such as personal photos, prerecorded messages, relaxation videos, and links to health resources [19]. Their immediate availability, customizable nature, and dynamic functionality—allowing for real-time updates—further distinguish them [26].

However, despite these advantages, the practical usability of digital safety plan outside clinical environments remains underexplored. Enhancing accessibility and monitoring use are crucial for understanding their preventive impact. Research indicates that many individuals seeking suicide-related support are unfamiliar with safety plans or lack these in their treatment plans [17]. Furthermore, depressive moods and a perceived lack of collaborative planning with clinicians may hinder effective use [18]. Future studies should prioritize the sustainability of these tools, focusing on identifying usage barriers and implementing user-driven improvements through rigorous follow-up. Integrating specialized telephone follow-up could also provide timely support and reinforce user engagement by offering guidance on coping strategies [14].

Limitations

First, the generalizability of our findings is limited by the small sample size, which was largely composed of women and did not include adolescents. Second, this study lacked detailed data on the duration of the use for each digital safety plan function and its perceived utility. Such data could provide valuable insights into which specific functions, or their combinations, are associated with the reduction of suicidal ideation and ED visits. Third, we did not collect information on participants who did not use or activate the digital safety plan. Understanding why some individuals did not engage with the tool (eg, due to perceived lack of need, usefulness, or technological barriers) would be valuable. Fourth, the absence of a control group limited our ability to directly compare the efficacy of digital versus traditional safety plan in suicide prevention. Finally, data on suicidal behavior features were based on baseline and self-reported measures. Future research could enhance these findings by incorporating real-time, in-app monitoring of suicidal ideation (eg, intensity and duration) and correlating it with digital safety plan use.

Conclusions

To our knowledge, this is the first study to demonstrate that activating a digital safety plan can reduce the likelihood of repeat suicide-related ED visits by 50%. While these results do not directly demonstrate a decrease in suicidal behavior among participants, the reduction in ED visits following an index suicidal event suggests that individuals may find supportive elements to manage a crisis by readily accessing suicide-related coping strategies through the activation of digital safety plan. This suggests that digital safety plans may serve as a valuable resource, as a complement to interventions delivered in the ED. Future research should investigate the dynamics of digital safety

XSL•FO
RenderX

plan use among participants, focusing on which functions (ie, tabs) are most frequently used and their specific associations with reductions in suicidal behavior and ED visits.

Abstract

Background: Numerous mental health apps purport to alleviate depressive symptoms. Strong evidence suggests that brief cognitive behavioral therapy (bCBT)-based mental health apps can decrease depressive symptoms, yet there is limited research elucidating the specific features that may augment its therapeutic benefits. One potential design feature that may influence effectiveness and user experience is the inclusion of virtual agents that can mimic realistic, human face-to-face interactions.

Objective: The goal of the current experiment was to determine the effect of conversational and animation features of a virtual agent within a bCBT-based mental health app on depressive symptoms and user experience in college students with and without depressive symptoms.

Methods: College students (N=209) completed a 2-week intervention in which they engaged with a bCBT-based mental health app with a customizable therapeutic virtual agent that varied in conversational and animation features. A 2 (time: baseline vs 2-week follow-up) × 2 (conversational vs non-conversational agent) × 2 (animated vs non-animated agent) randomized controlled trial was used to assess mental health symptoms (Patient Health Questionnaire-8, Perceived Stress Scale-10, and Response Rumination Scale questionnaires) and user experience (mHealth App Usability Questionnaire, MAUQ) in college students with and without current depressive symptoms. The mental health app usability and qualitative questions regarding users' perceptions of their therapeutic virtual agent interactions and customization process were assessed at follow-up.

Results: Mixed ANOVA (analysis of variance) results demonstrated a significant decrease in symptoms of depression (P=.002; mean [SD]=5.5 [4.86] at follow-up vs mean [SD]=6.35 [4.71] at baseline), stress (P=.005; mean [SD]=15.91 [7.67] at follow-up vs mean [SD]=17.02 [6.81] at baseline), and rumination (P=.03; mean [SD]=40.42 [12.96] at follow-up vs mean [SD]=41.92 [13.61] at baseline); however, no significant effect of conversation or animation was observed. Findings also indicate a significant increase in user experience in animated conditions. This significant increase in animated conditions is also reflected in the user's ease of use and satisfaction (F(1, 201)=102.60, P<.001), system information arrangement (F(1, 201)=123.12, P<.001), and usefulness of the application (F(1, 201)=3667.62, P<.001).

Conclusions: The current experiment provides support for bCBT-based mental health apps featuring customizable, humanlike therapeutic virtual agents and their ability to significantly reduce negative symptomology over a brief timeframe. The app intervention reduced mental health symptoms, regardless of whether the agent included conversational or animation features, but animation features enhanced the user experience. These effects were observed in both users with and without depressive symptoms.

Introduction

Background

The prevalence of depressive symptoms within the United States drastically increased from 17 million to 21 million, a nearly 25% increase, from 2018 to 2020 during the COVID-19 pandemic [1] with young adults and women disproportionately affected [2]. To address depressive symptoms, mental health apps have emerged to offer assistance and therapeutic techniques to the public. Cognitive behavioral therapy (CBT)-based mental health apps represent a viable option to improve access to mental health resources [3]. A form of CBT, brief cognitive behavioral therapy (bCBT) has been suggested for depressive individuals as a means of maintaining the user's attention while not requiring large amounts of the user's time or energy. This form of CBT has successfully delivered therapeutic interventions in a time-efficient manner, around 4 - 16 brief sessions [4,5] in both subclinical [6-8] and clinical populations [9]. Several bCBT-based apps, such as MoodMission [10], Pacifica [11], and SuperBetter [12], have demonstrated effectiveness in reducing depressive symptoms. Despite their effectiveness, it is unclear how specific app features may enhance user experience to maximize therapeutic benefits.

The use of virtual agents represents one avenue that may enhance mental health user experience, as virtual agents can be leveraged to mimic realistic human interactions and model social connection [13-15]. The term "virtual agent" refers to a noncontrollable, artificial intelligence (AI)-driven virtual entity, such as chatbots and embodied conversational agents (ECAs) designed to interact with users [16-18]. Chatbots communicate with the user through a textual or voice-based interface design but typically lack a visual embodiment [19]. ECAs are characterized by a human-like visual presence and have the capability to include both verbal or nonverbal communication behaviors [14,15]. While chatbots have demonstrated potential in numerous bCBT-based mental health apps, such as Woebot, Wysa, and Tess [20-22], ECAs offer a richer, more natural social presence [15], making them particularly suited for mental health interventions. Surprisingly, exceptionally few studies have evaluated the effectiveness of bCBT-based mental health apps with ECAs [6]. This study addresses this gap by incorporating an ECA-style virtual agent into the app design.

Given that a key component of ECA-style virtual agents is visual embodiment, the physical characteristics of a virtual agent may impact user experience. Research shows that similarity between a user's demographics and an agent's characteristics, such as gender and voice, fosters positive interactions by building trust and enhancing user motivation [23-26]. This aligns with the similarity-attraction effect, where users often prefer agents that mirror their own demographics, appearance, and voice [24]. In mental health contexts, such similarity has been shown to significantly increase users' willingness to engage in support activities [25]. To leverage these benefits, the mental health app in this study includes customization options for the agent's physical characteristics, aiming to create a greater sense of connection and comfort during interactions.

Beyond visual embodiment, 2 key features can be embedded into ECA-style virtual agents to convey the realism of human face-to-face interactions: conversational and animation features. Conversational behaviors, including lip-sync and speech, are used to replicate natural, verbal communication actions [15,27,28]. Virtual agent verbal cues that align with social norms, such as greetings, small talk, and thanking, foster trust and perceived knowledgeability [29,30], particularly when the agent uses a formal, familiar voice quality and style [31]. In addition, conversational agents can engage in turn-taking and provide feedback, mimicking the natural flow of human conversation [15]. Turn-taking allows users to feel that they are actively participating in the interaction, while feedback conveys that the agent is attentive and responsive [15]. A systematic review of mental health interventions leveraging conversational agents observed a significant reduction in psychological distress postintervention compared with baseline [32]. These findings underscore the preliminary efficacy of virtual agents with conversational features on mental health symptoms and suggests that virtual agent conversational feature may afford empathy and interactivity that mimics therapeutic dynamics [32]. However, few studies reviewed were empirical randomized controlled trials [32], and the variability in mental health symptoms limits understanding of how conversational features affect individuals with and without depressive symptoms.

On the other hand, animation supports natural communication by conveying nonverbal behaviors, such as facial expressions, co-speech gestures, body movements, and eye gaze [14,15]. Nonverbal cues, such as nodding and eye gaze indicate active listening and foster rapport [33-35], while facial expressions can convey emotional responsiveness [36]. It is critical for animations to appear natural, as overly expressive facial animations can seem unrealistic [37]. Natural animations encourage positive attributions toward virtual agents, such as greater acceptance, trust, credibility, and task appropriateness [31,38]. Natural animations also elicit stronger emotional responses and a greater sense of social presence compared with static or partially animated agents [39,40]. While natural animation cues, such as body movements and facial expressions, can enhance social presence, they are not always effective in conveying trustworthiness [31]. Factors like the user's age, the relevance of the animation to the task, and the context (eg, interviews, learning, or commerce) influence how animation impacts perceived trust [31,41], and the effectiveness of such animation features in mental health contexts remains underexplored.

In human-human therapeutic interactions, body language, tone, and other social cues are critical to conveying empathy and can influence therapeutic outcomes in individuals with depression [42-44]. Research with chatbots [13] and ECAs [45] has demonstrated that individuals experiencing depressive symptoms report high perceived virtual agent empathy and user-agent working alliance with levels mirroring that of CBT-based human interventions. These findings suggest that virtual agents may be able to mirror human-human therapeutic interactions by encouraging users to feel understood and supported. Such characteristics may be especially critical for individuals with depression, who often experience negative perceptions of

XSL•FO
RenderX

themselves, others, and their environment [46]. However, no studies have directly compared how these virtual agent features (eg, conversational vs animation) may influence mental health outcomes and user experience in users with and without depressive symptoms.

Objectives

This study builds on previous work [5-13,20-22,45] in several ways. First, this study directly compares how virtual agent conversational and animation features influence user experience in the context of mental health apps using a randomized controlled trial design. Second, this study assesses whether either of these features within a bCBT-based mental health app can reduce symptoms of depression, stress, and rumination over 2 weeks. Third, this study compares these features in a sample of users with and without depressive symptoms, addressing gaps in understanding how conversational versus animation features uniquely contribute to mental health outcomes in this population.

The study hypotheses for the quantitative analyses are outlined below:

H1: Individuals will exhibit significantly lower symptoms of depression, stress, and rumination after 2 weeks. This reduction will be more pronounced in the conversational and animated conditions.

H2: Individuals will have a more positive user experience with the agent in the conversational and animated conditions.

In addition to these quantitative analyses, we will query participants' rationale in designing their virtual agents in terms of gender and similarity to people they know through qualitative methods.

Methods

Study Overview

The goal of this 4-arm randomized controlled trial was to determine the effect of virtual agent conversational and animation features within a bCBT-based mental health app on user experience and change in depressive symptoms over a 2-week intervention period. The virtual agent conversational feature reflects dialogue-based interaction between the user and agent, and the virtual agent animation embodies dynamic body movements and facial expressions. Participants completed a baseline training and setup session along with baseline questionnaires through a face-to-face assessment; thereafter, participants completed the intervention and 2-week postintervention questionnaires remotely. In this section, we describe the design of the overall app and virtual agent with a focus on the manipulation of the conversational and animation features. We also describe the methodology and analytic approach used to evaluate these features in a sample of college students with and without depressive symptoms. We note that this study is based partially on dissertation work by lead author SS.

Participants

Following previous research evaluating AirHeart [6], an a priori power analysis (*F* test, repeated measures ANOVA (analysis of variance), within-between interaction) was conducted for H1. The analysis aimed for 80% power to detect effects at P=.05 with 4 groups and 2 time points, based on previous effect sizes [47]. Results indicated a required minimum sample of 136 participants. Multimedia Appendix 1 provides detailed information. We sought to recruit ≥25% (170 minimum) over the minimum to account for attrition and data exclusions.

A total of 209 college students completed the study and were randomized to one of the 4 experimental conditions (n= 209; mean age 19.97 years, SD 2.19; Table 1). Participants were incentivized to participate with compensation in the form of course credit, extra credit, or a $20 Amazon gift card, depending on their choice. Participants were excluded if they were outside the 18 - 30 years age range or did not have daily access to a smartphone. Data were excluded for 3 reasons: (1) the participant completed less than 2 CBT-based modules, (2) failed more than 1 attention check, or (3) did not submit the postintervention survey.

AirHeart Mental Health App

The AirHeart mental health app was designed using Unity 2021 and contains all themes and features of a version published in previous work [6] but included new features, such as a help section, additional customization options for the virtual agent, and an additional resources section. The virtual agent was introduced to participants as their “virtual coach“ who joined them on their journey and guided them through CBT topics. Given the importance of customization features to foster user-agent similarity [24-26], users were able to customize numerous features of their agent, including facial features, body shape, and clothing. The majority of the conversational and animation feature design choices were motivated by past research describing the importance of both verbal (ie, lip sync animation and co-speech gesturing) and nonverbal (ie, head nods and backchanneling) behaviors in conveying natural social communication information [14,15]. All user-agent communication was conducted through natural dyadic verbal exchanges. Users initiated verbal input using a speech-to-text engine, the speech recognition system plugin, while audio-based agent dialogue was created using the following text-to-speech (TTS) engines: RTVoice Native for Android+ AmazonWeb Services Polly Standard for iOS. Additional technical details regarding app development and virtual agent customization, conversational feature, and animation feature development can be found in Multimedia Appendix 2.

Experimental Conditions

The current experiment included 4 experimental conditions differing based on the presence or absence of conversational and animation features (conversational, animated; conversational, nonanimated; animated, conversational; nonconversational, nonanimated). All conditions had access to

XSL•FO
RenderX

all app features (ie, CBT modules, journaling, mood tracker, agent customization, help section, and additional resources section).

The animation feature involved dynamic body movements and facial expressions exhibited by the virtual agent. The animated condition included human-like nonverbal body movements, mouth movements, and gestures in association with the information provided by the virtual agent. The nonanimated condition displayed a static, nonmoving virtual agent with a blank facial expression.

The conversational feature was characterized by user-agent interactivity in whcih question-and-response style dialogue was embedded within the CBT modules. The virtual agent asked questions or instructed the participant to complete activities aloud. A microphone icon provided a visual cue for users to engage in conversation with the agent when red, the microphone is on, and white when off. The nonconversational condition did not allow the user to add their input or respond to questions. Figure 1 shows the visualization of the virtual agent in the 4 different conditions.

Figure 1. Example of a customized virtual agent in the (A) conversational, animated condition, (B) nonconversational, animated condition, (C) conversational, nonanimated condition, and (D) nonconversational, nonanimated condition. Users were able to customize their agents' clothes, hairstyle, hair, skin, eye colors, body and face shape, facial cosmetics, and accessories. Within the conversational condition, the microphone icon provided a visual cue for users such that red indicated the microphone was on, and white indicated when it was off.

Measures

Depressive Symptoms Questionnaire

The Patient Health Questionnaire-8 (PHQ-8) was used to estimate depressive symptom severity over the past 2 weeks ranging from mild (0 - 4) to severe (20+) [48,49].

Stress Symptoms Questionnaire

The Perceived Stress Scale -10 (PSS-10) is a subjective assessment of the user's stress symptoms during the past month [50,51]. Participants' scores ranged from 0 - 40, with responses scoring <14 suggesting low stress levels and those scoring >26 suggesting high stress levels.

Rumination Symptoms Questionnaire

The Response Rumination Scale (RRS) is a 22-item questionnaire that measures subjective levels of rumination tendencies [52]. Responses are summed, ranging from 0 - 88 with higher scores indicating more ruminative tendencies.

The mHealth App Usability Questionnaire

The mHealth App Usability Questionnaire (MAUQ) is a 21-item questionnaire comprised of 3 subscales: ease of use and satisfaction, system information arrangement and usefulness [53].

Open-Ended Qualitative Questions

Participants were asked the follow open-ended questions: (1) Did you make your virtual coach resemble yourself or someone you know? If so, why? (2) When creating your virtual coach, you were asked to select either a masculine or feminine agent. Please explain how you selected your virtual coach's gender. What was your thought process behind the selection? (3) Do you have any suggestions for how to improve the virtual coach?

Procedure

At the baseline assessment (Time 1), participants were first randomized to one of the 4 virtual agent conditions that varied in conversational and animation features. After providing written informed consent, they completed the mental health questionnaires (PHQ-8, PSS-10, and RRS). Users then downloaded and piloted the AirHeart app using TestFlight, a beta-testing app required for iPhones due to their additional security measures, while Android users could install the app directly. Next, they created an account, followed a tutorial to personalize their virtual agent, and completed the first CBT module. They used the app every other day for 2 weeks, which

XSL•FO
RenderX

included a minimum of 8 times for full completion, but additional usage was encouraged. When participants logged into the app for the first time that day, they were prompted to complete the daily questionnaire, view their mood tracker, and then taken to the home page where they had access to the CBT modules. After the 2-week intervention, participants were contacted through email to complete postintervention questionnaires. At this assessment (Time 2), participants completed the mental health (PHQ-8, PSS-10, RRS) questionnaires again as well as the user experience questionnaire (MAU-Q) and open-ended user experience questions.

Data Analysis

To investigate H1, separate 2 (conversational status: present vs absent) × 2 (animation status: present vs absent) × 2 (time: baseline vs postintervention symptoms) mixed effects ANOVAs was used to analyze changes in depressive, stress, and rumination symptoms, respectively. Conversational status and animation status were between-subjects factors; time was a within-subjects repeated measures factor. Sensitivity analyses were conducted that focused only on participants who reported experiencing depressive symptoms (PHQ-8 scores >4).

To assess H2 for the user experience predictions, separate 2 (conversational status: present vs absent) × 2 (animation status: present vs absent) × 2 (depressive status: depressive vs nondepressive state) multifactorial ANOVAs were performed for each of the 3 MAUQ subscales. Using the validated cutoff scores established in previous work [48,49], PHQ-8 scores ranging from 0 - 4 were considered normal (or nondepressive) and scores of 5 and above were considered in a depressive state. Inclusion of this factor allowed for distinguishing whether individuals with and without current depressive symptoms had user experience preferences for the virtual agent characteristics.

For quantitative data, we conducted parametric ANOVA analyses after verifying that the data were normally distributed and error variances were equivalent [54,55]. Box's test confirmed equality of covariance matrices, and Levene test verified homogeneity of variance. Mauchly test ensured sphericity. When appropriate, posthoc pairwise tests were conducted using the Tukey honestly significant difference for between-subjects variables and the Bonferroni adjusted alpha method for within-subjects variables. These methods are widely used in user studies and human factors research in computing [6,39,56-58]. For the open-ended qualitative questions, a reflexive thematic analysis was performed in order with the procedure specified by Braun and Clarke [59] which has been used in numerous user studies evaluating virtual agents [26,60-63]. Two researchers independently reviewed deidentified responses, manually created initial codes, and then grouped codes into categories. For each of the 3 qualitative questions, percentage agreement for categories between researchers was >85%. Researchers then reviewed the independently-generated categories, consolidated duplicates, and refined and labeled themes. Next, the study conditions (ie, conversational and animated) and depressive group (depressive vs nondepressive) were reattached to the responses to create a frequency data table.

Ethical Considerations

The study procedures were approved by the Clemson University Institutional Review Board (IRB2021-0879) before procedures were implemented. All participants provided written informed consent before participating in the study. They were given the option to opt-out of participating. All data are deidentified. Participants were incentivized to participate with compensation in the form of course credit, extra credit, or a US $20 Amazon gift card, depending on their choice.

Results

Mental Health Symptoms

Change in Depressive Symptoms

The 2 (conversational vs nonconversational) × 2 (animated vs nonanimated) × 2 (time: baseline vs postintervention) mixed ANOVA results demonstrated a statistically significant main effect of time (F(1, 205)=10.06, P=.002; ηp^2=.05), indicating that depressive symptoms were lower at 2-week follow-up (mean 5.5, SD 4.86) compared with baseline (mean 6.35, SD 4.71) across all 4 experimental conditions. There was no significant main effect of animation condition (F(1, 208)=.02, P=.91; ηp^2<.001), conversational condition (F (1, 208)=.25, P=.62, ηp^2=.001), nor any of the interaction effect (Ps>.05). Multimedia Appendix 3 shows the full ANOVA results.

We note that when the 2 (conversation: present vs absent) × 2 (animation: present vs absent) × 2 (time: pre vs post) analysis is performed separately for those that meet criteria of depressive symptoms at baseline (PHQ-9 scores<6) and those that do not, the results do not differ. Thus, animation and conversation features do not significantly affect change in depressive symptoms for those with or without depressive symptoms.

Change in Stress Symptoms

Mixed ANOVA results showed a significant main effect of time (F(1, 205)=8.09, P=.005; ηp^2=.038), such that self-reported stress levels were lower at 2-week follow-up (mean 15.91, SD 7.67) than baseline (mean 17.02, SD 6.81) across all 4 experimental conditions. The animation condition (F(1, 208)=.007, P=.93; ηp^2<.001), conversational condition (F(1, 208)=.113, P=.74; ηp^2=.001), and all interaction effects, (Ps>.05) were nonsignificant (Multimedia Appendix 4).

Change in Rumination Symptoms

A main effect of time indicated that postintervention rumination scores were significant lower after the 2-week intervention (mean 40.42, SD 12.96) when compared with the preintervention scores (mean 41.92, SD 13.61), (F(1, 205)=4.88, P=.03; ηp^2=.023) across all 4 conditions. No significant effects were ascertained for animation condition (F(1, 208)=.09, P=.76; ηp^2<.001) nor the conversational condition (F(1, 208)=.37, P=.54; $\eta p^{2=}$.002). The interaction effect was also nonsignificant (Ps>.05; Multimedia Appendix 5).

User Experience Results

MAUQ-Ease of Use and Satisfaction

The ANOVA analysis on MAUQ-ease of use and satisfaction scores revealed a significant main effect of animation, $F(1, 201)=102.60$, $P<.001$, $\eta p^2=0.34$. Table 2 shows the mean (SD) values on the MAUQ-ease of use and satisfaction scores, and Table 3 displays the full ANOVA results. The Tukey honestly significant difference posthoc pairwise comparisons indicated that mean MAUQ-ease of use and satisfaction scores was significantly higher when the agent was animated (mean 39.91, SD 9.51) as compared with when the agent was not (mean 23.35, SD 9.81; $P<.001$).

Table . mHealth App Usability Questionnaire scores for ease of use and satisfaction.

Variable	Score, mean (SD)
Animated, n=106	39.91 (9.51)
Nonanimated, n=103	23.35 (9.81)
Conversational, n=105	32.37 (12.53)
Nonconversational, n=104	31.12 (12.93)
Depressed, n=46	32.76 (12.82)
Not depressed, n=163	31.46 (12.71)

Table . Analysis of variance results for the mHealth App Usability Questionnaire-ease of use and satisfaction.

Effect	*F* value	*P* value	Partial Eta squared (ηp^2)
Conversational main effect	1.23	.27	.006
Animation main effect	102.60	<.001	.34
Depressive status main effect	.86	.36	.004
Animated × conversational interaction effect	.32	.57	.002
Conversation × depressive status interaction effect	.024	.88	.0001
Animation × depressive status interaction effect	.024	.88	.0001
Conversation × animated × depressive status interaction effect	.54	.46	.003

MAUQ-System Information Arrangement

As presented in Table 4 and Table 5, ANOVA results for the MAUQ-system information arrangement scores showed a significant main effect of animation, $F(1, 201)=123.12$, $P<.001$, $\eta p^2=.38$. The mean MAUQ-system information arrangement scores was significantly higher (mean 30.97, SD 6.87) when the agent was animated as compared with when the agent was not (mean 17.27, SD 7.43; $P<.001$).

Table . mHealth App Usability Questionnaire scores for system information arrangement.

Variable	Score, mean (SD)
Animated, n=106	30.97 (6.87)
Nonanimated, n=103	17.27 (7.43)
Conversational, n=105	24.35 (9.74)
Nonconversational, n=104	24.09 (10.11)
Depressed, n=46	23.43 (10)
Not depressed, n=163	24.44 (9.89)

Frequency Analysis for Agent Characteristic Selections

Agent Representativeness Selections

In total, 95 participants (45.5% of total sample) indicated that they designed the virtual agent to resemble themselves; of these participants, 55 (57.8%) were experiencing depressive symptoms than those that were not experiencing depressive symptoms ($z=1.54$, $P=.12$). Seventy-seven participants (36.8% of total sample) reported that they designed the virtual agent to resemble someone they know, such as a friend, sibling, parent, or current or former therapist. Of these participants, 40 (51.9%) reported experiencing depressive symptoms ($z=0.33$, $P=.74$). The remaining 37 participants (17.7%) reported making the virtual agent resemble a celebrity (n=3), a doctor or professional (n=2), or did not have a specific reason for their virtual agent design (n=32).

XSL•FO
RenderX

Agent Gender Selections

Of all participants, 84% (n=175) chose a female virtual agent, and 16% (n=34) chose a male. The majority of participants selected an agent's gender so that it aligned with their own gender: all but 3 female participants (98.2%) chose a female virtual agent, 31 of the 39 males (79.5%) selected a male virtual agent, and both nonbinary participants chose a female agent.

Qualitative Results

Participants were asked to explain the reason they selected the gender of their virtual agent. Responses were collected from all 209 participants, but 3 were excluded for failing to supply a usable response. Two key themes emerged: relatability (89/206, 43.2%) and trust or comfort in talking with a particular gender about one's mental health concerns (160/206; 77.7%); note that some participants listed both reasons. Example quotes to illustrate the relatability theme are listed below:

> *I chose a masculine agent because I was making a model of myself.* [p#5]
>
> *Female; I am also female.* [p #116]
>
> *I chose the same gender as mine to connect better with the therapist.* [p #176]

Quotes describing the comfortability preference with a particular gender are included below:

> *I selected a female therapist because I feel more comfortable talking to females about my problems. This is just my personal preference.* [p #161]
>
> *I selected female because I associate women with a more nurturing nature.* [p #76]
>
> *I chose a female because my previous therapist was female and it felt more comfortable.* [p #67]

Suggestions for improving the virtual agent were collected from all 209 participants, but 39 of them failed to provide a viable answer. The 170 responses resulted in 4 different themes: (1) robotic voice or interaction, (2) lack of personalization or customization, (3) more engagement or realism, and (4) technical issues. Similar to the previous free response question, *z* score proportion tests were conducted for the depressive and nondepressive participants in each category. The robotic voice/interaction (z=3.36, P<.001) was the sole categories to reach significance. A frequency data table was created to help visualize this information (Table 8).

XSL•FO
RenderX

Table . Visualization of qualitative data: suggestions for virtual agent improvement.

Themes	Animation versus nonanimation	Conversation versus nonconversation	Examples	Depressive versus nondepressive
Robotic voice or interaction	Animated: 44/102 Nonanimated: 58/102	Conversational: 53/102 Nonconversational: 49/102	"Make it less robotic" (p. 80) "make the voice left stiff-sounds like a robot." (p. 101) "Possibly make the voice more realistic and not as robotic" (p. 177)	Depressive: 63/102 Nondepressive: 39/102
More engagement, interaction, or connection	Animated: 7/19 Nonanimated: 12/19	Conversational: 9/19 Nonconversational: 10/19	"It didn't really feel like we were having a conversation or that she was listening to my responses" (p. 21) "Maybe be more engaging then just talking." (p. 59)	Depressive: 11/19 Nondepressive: 8/19
Lack of personalization	Animated: 23/41 Nonanimated: 18/41	Conversational: 27/41 Nonconversational: 14/41	"… they did not change their answers based on whether or not I responded so it did not feel very real." (p. 83) "It seemed very scripted, and like I was just typing into a box." (p. 150)	Depressive: 23/41 Nondepressive: 18/41
Tech or user interface issues	Animated: 8/16 Nonanimated: 8/16	Conversational: 11/16 Nonconversational: 5/16	"Map wasn't lining up" (p. 54) "I think there should be the opportunity to rewind what the therapist says. If I missed something I would have to restart the whole module and that is frustrating." (p. 139)	Depressive: 10/16 Nondepressive: 6/16
No suggestions	Animated: 21/38 Nonanimated: 17/38	Conversational: 14/38 Nonconversational: 24/38	"No." (p. 30) "NA" (p. 89)	Depressive: 20/38 Nondepressive: 18/38

Discussion

Principal Findings

The current randomized controlled trial sought to investigate how conversational and animated components of a virtual agent within a bCBT-based mental health app might affect change in depressive symptoms and perceived user experience. Given that individuals experiencing depressive symptoms may have negative views of themselves or others and may struggle with anhedonia, low energy, amongst other symptoms [64], it is reasonable that individuals experiencing depressive symptoms may have different intervention needs or preferences compared with those who are not experiencing such symptoms. The results demonstrated that bCBT delivered through a virtual agent within a mental health app significantly reduced symptoms of depression, stress and rumination over a 2-week period, regardless of whether the agent included conversational or animation features. Consequently, these results partially support H1. The animation feature did enhance user experience, while the conversation feature had no significant impact.

While several empirically-evaluated bCBT-based mental health apps like Woebot, Wysa, Tess, and Fido [20-22,65] include virtual agents, these existing mental health apps leverage a text-based chatbot design. Such design does not allow for animation features and certain conversational feature components like natural speech dynamics and nonverbal behaviors. In addition, while Tess displays a static picture of a smiling Caucasian female in the text-based chat dialogue box [22], Woebot, Wysa, and Fido do not feature a human-like graphic and instead use animals or robots [20,21,65]. Furthermore, none of these apps feature a customizable virtual agent. In contrast, the AirHeart mental health app included a human-like, customizable virtual agent, and the conversational animated app condition featured both speech and text-based verbal capabilities, nonverbal behaviors, and dynamic animations.

Small pilot studies on virtual agent-based self-monitoring technologies have shown promise in demonstrating the feasibility and preliminary efficacy in reducing depressive symptoms [66-68]. The current study advances this work by

XSL•FO
RenderX

demonstrating that virtual agent-based bCBT technology can effectively reduce depressive symptoms through a moderate-size randomized controlled trial. While conversational and animation features were expected to enhance the effectiveness of the intervention, particularly among those experiencing depressive symptoms, no added benefit of these features was observed on changes in depressive symptoms, stress, or rumination. Past work has shown that ECA-style virtual agents that mimic human-human interactions may enhance perceived empathy and working alliance with the user [45,69]. The results of the present study suggest that conversational and animation features may not be critical for establishing a meaningful connection between the virtual agent and the user in the context of bCBT mental health apps for depression. Instead, the social presence of the human-like virtual agent alone may be sufficient.

Study results indicated that users in the animated agent conditions reported higher ratings for system information arrangement (MAUQ-system information arrangement), ease of use (MAUQ-ease of use and satisfaction), and usefulness (MAUQ-usefulness) compared with those in nonanimated conditions. There was no significant difference in conversational versus nonconversational conditions; therefore, H2 is partially supported. These results suggest that animation can enhance the user experience in mental health interventions, which aligns with previous research showing that the inclusion of both nonverbal behaviors can create more human-like interactions and improve user impressions in mental health contexts [34,35]. In addition, the inclusion of such animation design has previously demonstrated a strong connection to higher levels of agent acceptance, trust, credibility, and task appropriateness [38]. These findings are crucial for developers of mental health interventions, as they underscore the importance of integrating virtual agents with natural animations, such as body, mouth, and gesture movements, to enhance user satisfaction and foster human-like interactions.

Consistent with the similarity-attraction effect [24,25], most participants (>90%) selected an agent of the same gender as themselves and designed it to resemble themselves or someone familiar, such as a friend, family member, or therapist. This preference aligns with research showing that familiarity provides comfort, particularly during vulnerability [70]. Many participants reported feeling more comfortable discussing mental health with females, citing greater relatability on emotional matters. This increased relatability may be more attributable to similarity than stereotypes of females as more emotionally aware and empathetic than men [71-73]. Indeed, while females often self-report higher empathy, a meta-analysis showed no objective gender differences in empathy [74]. The findings support research demonstrating stronger therapeutic alliances when clients and counselors share the same gender, particularly among female clients [75], and users' preference for same-gender virtual agents [76-79]. In mental health contexts, gender synchrony has been shown to enhance trust in virtual agents, especially when paired with similar age [79]. These results highlight the importance of virtual agent gender customization for relatability in mental health app design. However, past research suggests that developers often rely on stereotypical binary gender cues, which can reinforce societal gender expectations [23]. Thus, mental health app developers and researchers should be cognizant of the limitations of stereotypical binary gender cues and enhance features that support diverse gender representation, especially in verbal and nonverbal animations.

Limitations and Future Directions

The qualitative analysis revealed that most participants found the virtual agent's voice robotic and suggested improvements to voice quality. It is possible that the quality of the virtual agent's voice may have impacted the results of the conversational feature. The app used AmazonWeb Services Polly Standard Voice (iOS) and RTVoice Native (Android) for TTS, both of which can sound synthetic, similar to Siri (Apple) or Google Assistant (android). Previous research has shown that synthetic, artificial voices induce an eerie feeling [80,81], and similar results were found using a TTS agent for CBT-based emotional regulation, where participants also noted the robotic speech [82]. Future studies should explore higher quality TTS or prerecorded human voices to enhance user interactions with the virtual agent.

Furthermore, the study included pre- and 2-week postintervention measurements, but long-term follow-ups assess whether the effects of the intervention are sustained over time were not included in the study design. Additional research is needed to determine the duration of the benefits from the virtual agent-delivered bCBT mental health intervention following the conclusion of app use.

Conclusions

This study is among the first to compare the effectiveness and user experience of a virtual agent bCBT-based mental health app in both users with and without depressive symptoms. The key findings from the study demonstrated that the app intervention was effective in reducing mental health symptoms, regardless of whether the agent included conversational or animation features, but animation features enhanced user experience. These effects were observed in both users with and without depressive symptoms. This work suggests that college students experiencing depressive symptoms may not have unique user experience requirements in mental health apps, and such findings may apply more broadly to wellness apps. The finding that virtual agent animation improves user experience in mental health apps but does not affect the intervention's effectiveness offers valuable insight for optimizing app design, which can help guide future development of digital mental health tools that are both effective and user-friendly.

Abstract

Background: Mental health disorders such as anxiety and depression are common among individuals of childbearing age. Such disorders can affect pregnancy and postpartum well-being. This study aims to study the impact of prenatal mental health on the pregnancy journey and highlights the use of mobile health technologies such as PowerMom for symptom tracking and screening.

Objectives: We collected data in a decentralized digital trial using the PowerMom platform to investigate the impact of maternal mental health throughout pregnancy. The goal was to understand how anxiety and depression influence pregnancy-related symptoms, pregnancy outcomes, and postpartum well-being.

Methods: Survey data were collected via PowerMom, a bilingual mobile research platform that integrates patient-reported outcomes, wearable data, and electronic health records. Participants were divided into 2 cohorts: those who reported receiving treatment for anxiety or depression during pregnancy (n=571) and those who reported not receiving treatment (n=1505). We compared self-reported symptoms, prepregnancy conditions, complications from past pregnancies, delivery outcomes, and postpartum mental health between cohorts, using the Fisher exact test and the Kruskal-Wallis test for statistical analysis.

Results: Participants receiving treatment for anxiety or depression reported higher instances of physical symptoms than those untreated, with significant differences for 13 symptoms including fatigue (80.2% vs 65.4%; adjusted P<.001), nausea and vomiting (69.7% vs 52.7%; adjusted P<.001), and stomach cramping and abdominal pain (64.0% vs 50.4%; adjusted P<.001). Participants receiving treatment also had a higher prevalence of several conditions prior to pregnancy than those not receiving treatment, with significant differences noted in 4 out of 10 conditions: endometriosis (14.0% vs 8.8%; adjusted P=.007), hypertension (10.9% vs 3.9%; adjusted P<.001), eating disorder (7.7% vs 3.1%; adjusted P<.001), and heart disease (2.8% vs 0.5%; adjusted P<.001). Participants receiving treatment also reported a higher prevalence of complications in past pregnancies than those not receiving treatment, with significant differences noted in 2 out of 7 complications: high blood pressure (9.9% vs 5.8%; adjusted P=.016) and preeclampsia (9.2% vs 5.5%; adjusted P=.021). No significant differences were observed in mode of delivery, epidural use, stillbirth, and miscarriage rates between the 2 cohorts. Postpartum, treated participants reported significantly higher mental health composite scores, indicating more severe mental health symptoms. A higher percentage of treated participants were at high risk for having perinatal mood disorder (38/83, 45.8%) than untreated participants (36/196, 18.4%; P<.001).

Conclusions: The PowerMom platform demonstrated its value in facilitating remote, scalable data collection for maternal mental health research. Pregnant individuals reporting treatment for anxiety or depression experienced more physical symptoms and worse postpartum mental health outcomes than untreated individuals. These findings underscore the potential for mobile health technologies to support future interventional studies aimed at improving maternal mental health outcomes during pregnancy.

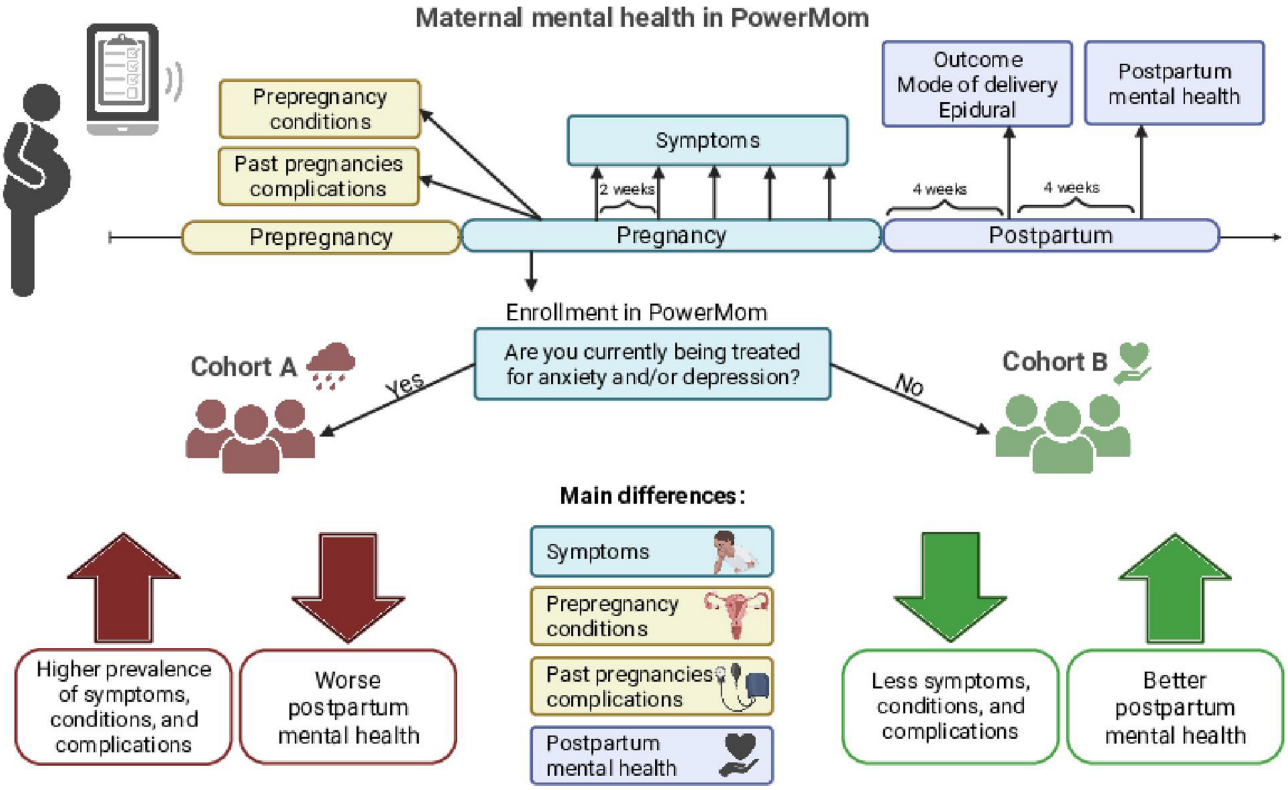
Introduction



Mental health disorders such as anxiety and depression are common among individuals of childbearing age, impacting up to 1 in 5 women [1]. Research on mental health and pregnancy typically focuses on postpartum depression, a common condition that impacts 15% - 25% of those postpartum [2,3]. However, there is limited guidance on the ideal timing, frequency, and method for mental health screening before, during, and after pregnancy [4]. Some studies have identified prenatal depression as one of the strongest predictors of postpartum depressive symptoms, highlighting the importance of systematic screening and care coordination throughout pregnancy [5,6]. Similarly, antenatal anxiety has been associated with perinatal depression, underscoring the need to assess both conditions in research and clinical practice [6]. Nevertheless, studies exploring these issues remain scarce. There have been some limited data showing the association between prenatal mental health conditions and physical symptoms during pregnancy such as nausea and vomiting, as well as with delivery outcomes such as the use of epidurals and cesarean sections, but these also need further exploration [7,8].

We aim to expand this body of literature by using data from the PowerMom mobile research platform [9], which offers a novel digital framework to study and collect data from pregnant individuals from diverse backgrounds. PowerMom was chosen for this study because of its unique ability to facilitate bilingual, decentralized, and scalable data collection.

The platform collects longitudinal health data through participant-reported surveys and integrates psychological, social, and technological inputs related to maternal health. Participants have the option to connect wearable device data, allowing for a multidimensional view of their health throughout pregnancy. PowerMom's decentralized nature enables remote participation, overcoming geographical barriers and expanding the reach to more diverse populations, thereby enhancing the generalizability of the study findings. Moreover, its bilingual capabilities allow participation from both English and Spanish speakers, improving inclusivity and engagement, particularly among underrepresented groups.

By leveraging these features, this study examines the relationships among prenatal mental health, self-reported symptoms during pregnancy, preexisting conditions, complications from past pregnancies, delivery outcomes, and postpartum mental health, offering new insights into the interplay between mental health and pregnancy outcomes (Figure 1).

Figure 1. In PowerMom, participants enroll during pregnancy through their smartphone. At enrollment, they provide demographics information, due date, and answer surveys regarding current well-being, including whether they are being treated for anxiety or depression at that time. If yes, participants are included in cohort A (receiving treatment for anxiety and/ depression); otherwise, they are included in cohort B (not receiving treatment for anxiety or depression). Participants are then prompted to complete surveys regarding their health history, including questions about conditions diagnosed prepregnancy or complications experienced in past pregnancies. During their pregnancy, participants are prompted to complete biweekly surveys to track their pregnancy, such as physical symptoms experienced. Four weeks after their expected due date, participants are prompted with a delivery survey to report their pregnancy outcome, mode of delivery, and so forth. Around 8 weeks postpartum, participants are asked to complete a survey about their postpartum mental health. Participants in cohort A were more statistically significantly more likely to experience symptoms, to have been diagnosed with prepregnancy conditions, to have experienced complications in past pregnancies, and to have worse postpartum mental health than participants in cohort B. Created with BioRender.com.

Methods

Study Design

In March 2021, The Scripps Research Institute expanded upon the Healthy Pregnancy study [10] and launched the PowerMom digital health study. This participant-centered research study is implemented as a bilingual (Spanish and English) mobile research platform.

Eligible participants include birthing people aged 16 years or older, currently pregnant or within 8 weeks postpartum, living in the United States and its territories, and with access to a smartphone. Participants are recruited via direct-to-participant methodologies including public announcements, social media outlets, and others. Those unable to read, speak, or consent in English or Spanish are excluded from the study.

Participants engage with PowerMom through surveys provided via the MyDataHelps app, with the option of sharing wearable device data with the platform. Wearable data, including heart rate, activity levels, and sleep patterns, were collected from participants who opted to sync their devices with the PowerMom platform. While not analyzed in this study, these objective measures will be examined in future research to complement and validate self-reported pregnancy symptoms and mental health outcomes. Surveys are presented to the participants at enrollment, during pregnancy, and postpartum. Data such as age, race and ethnicity, zip code, and pregnancy due date are reported by participants during study enrollment. Reported zip codes are used to determine the participants' Area Deprivation Index (ADI) as defined by the Neighborhood Atlas, which is based on population-level data connecting geographical location to domains such as income, education, employment, and housing quality [11].

Ethical Considerations

The PowerMom study was reviewed and approved by the Scripps Office for the Protection of Research Subjects (IRB-21‐7738). All participants provided informed consent electronically. Both the primary consent specify that the original consent and the institutional review board approval cover secondary analysis without additional consent. Data presented in this paper have been deidentified.

Analytic Methods

PowerMom Survey Data

After consent, participants are asked to complete a series of surveys at preset intervals within the PowerMom research platform. (Methods 1—Participant Flow in Multimedia Appendix 1). After enrollment in the study, they complete a study intake survey to collect demographic information and a "Health and History" survey to provide details on their current and past health status. Throughout the course of their pregnancy, participants are asked to complete a biweekly "Health and Well-being" survey and a bimonthly "Pregnancy Support" survey. Based on self-reported due date, participants are alerted to complete the "Delivery" survey within 4 weeks of their due date and the "Postpartum" and "Postpartum Mental Health" surveys 6‐8 weeks after that date (Methods 2—Surveys in Multimedia Appendix 1).

Self-Reported Mental Health Diagnosis

Participants were asked whether they were currently receiving treatment for anxiety or depression at the time of enrollment in the "Health History" survey. The survey did not collect information on whether they had a prior history of mental health conditions before pregnancy. Cohort A includes participants who reported receiving treatment for anxiety or depression at the time of enrollment, and cohort B includes participants who reported not receiving treatment for anxiety or depression. It is important to note that this classification is based on treatment status rather than the presence or severity of symptoms. While cohort A consists of individuals receiving treatment for anxiety or depression, it does not necessarily include all individuals experiencing symptoms. Similarly, cohort B includes individuals who are not receiving treatment but may still have undiagnosed or untreated symptoms. Future research should incorporate validated symptom severity scales to better disentangle the effects of treatment from the presence of mental health conditions. Differences between the 2 cohorts were determined by analyzing additional survey responses during and postpregnancy, with participation varying by survey.

Self-Reported Symptoms During Pregnancy

Participants report symptoms in the biweekly "Health and Well-being" survey, noting any physical symptoms experienced in the previous 2 weeks by selecting them from a list, or selecting the "None of the above" option. The data capture symptom prevalence across both cohorts throughout pregnancy.

Self-Reported Past Conditions and Past Pregnancies Complications

In the "Health History" survey, participants are asked about any conditions diagnosed before their current pregnancy, accompanied by a selection list, including "Other" and "None of these" options. Participants are asked whether they experienced pregnancies in the past, whether they had any complications in their past pregnancy or pregnancies, and, if so, to select complications in past pregnancies with a list provided, including "Other" and "None of these" options. Participants who answered "Other" or "None of these" to these questions were excluded.

Pregnancy Outcomes

The "Delivery" survey includes questions on pregnancy completion. If the pregnancy concluded with a live birth, the participant is asked several follow-up questions about the mode of delivery, use of epidurals, whether delivery was induced, delivery date, and newborn-related information, such as weight and length. When available, due date, delivery date, and birth weight were used to evaluate the fraction of small for gestational age, appropriate for gestational age, or large for gestational age infants between the cohorts [12,13].

Postpartum Mental Health Symptoms

If participants did not report a miscarriage or pregnancy loss in the "Delivery" survey, they are prompted to complete the "Postpartum Mental Health" survey within 6‐8 weeks of their

XSL•FO
RenderX

due date. The survey is used to evaluate the participant's overall postpartum mental health through a composite mental health score. The survey and the composite score are based on the Edinburgh Postnatal Depression Scale. The Edinburgh Postnatal Depression Scale is a validated screening tool for perinatal mood disorders, with a cutoff score of ≥10 commonly used in clinical and research settings to identify individuals at risk. This threshold has demonstrated good sensitivity and specificity across diverse populations, although variations may exist based on cultural and demographic factors [14,15]. A score of 10 or greater is used to diagnose perinatal mood disorder. Patients with perinatal mood disorder are more likely to being diagnosed with postpartum depression. The survey includes 10 statements (eg, "I have been able to laugh and see the funny side of things"), with 4 possible responses for each statement (eg, "As much as I always could," "Not quite as much," "Definitely not so much now," and "Not at all"), and a point value between 0 and 3 is assigned to each of the responses, with higher point values assigned to responses that signify worse mental health (Table S1 in Multimedia Appendix 1). Inclusion of this survey in our results allowed us to compare prenatal mental health by self-reported anxiety or depression with postpartum mental health scores.

Statistical Analysis

Demographic and Baseline Characteristics

The demographics of participants, including age at enrollment, ADI, enrollment timing relative to conception, and gestational age at delivery, were reported as medians and the first and third IQRs (Q1, Q3). To account for potential confounding by socioeconomic status, we used the ADI, which provides a composite measure of socioeconomic disadvantage based on participants' reported zip codes. The ADI was incorporated in our descriptive statistics and baseline cohort comparisons. While this approach offers an indirect measure of socioeconomic status, future analyses should incorporate additional individual-level metrics such as health care access and insurance status to further refine these findings. The Kruskal-Wallis test was used to determine statistical significance across the cohorts in terms of age, ADI, time of enrollment, and gestational age.

Race or ethnicity and preterm birth (delivery prior to 37 weeks of gestation) were expressed as count and percentage of participants among the ones answering the questions in the cohorts. The chi-square test was used for race or ethnicity and preterm births (Python package scipy; version 1.11.1; Python Software Foundation). Statistical significance was set at $P<.05$ for all results.

Symptoms, Prepregnancy Conditions, and Past Pregnancy Complications

The "Health and Well-being" survey was administered multiple times during pregnancy. Symptom prevalence was defined as the percentages of participants reporting symptoms at least once across all survey responses. The "Health and History" surveys were administered only once. Prepregnancy conditions and past pregnancy complications were reported as percentages of participants reporting the conditions or complication in that survey. For our analysis, we reported all symptoms, prepregnancy conditions, and past pregnancy complications that were presented in the selection lists to the participants for each related survey question. The 95% CIs were calculated using the bootstrap bias-corrected and accelerated method with 10,000 iterations. Statistical significance was assessed using Fisher exact test (Python package FisherExact; version 1.4.2).

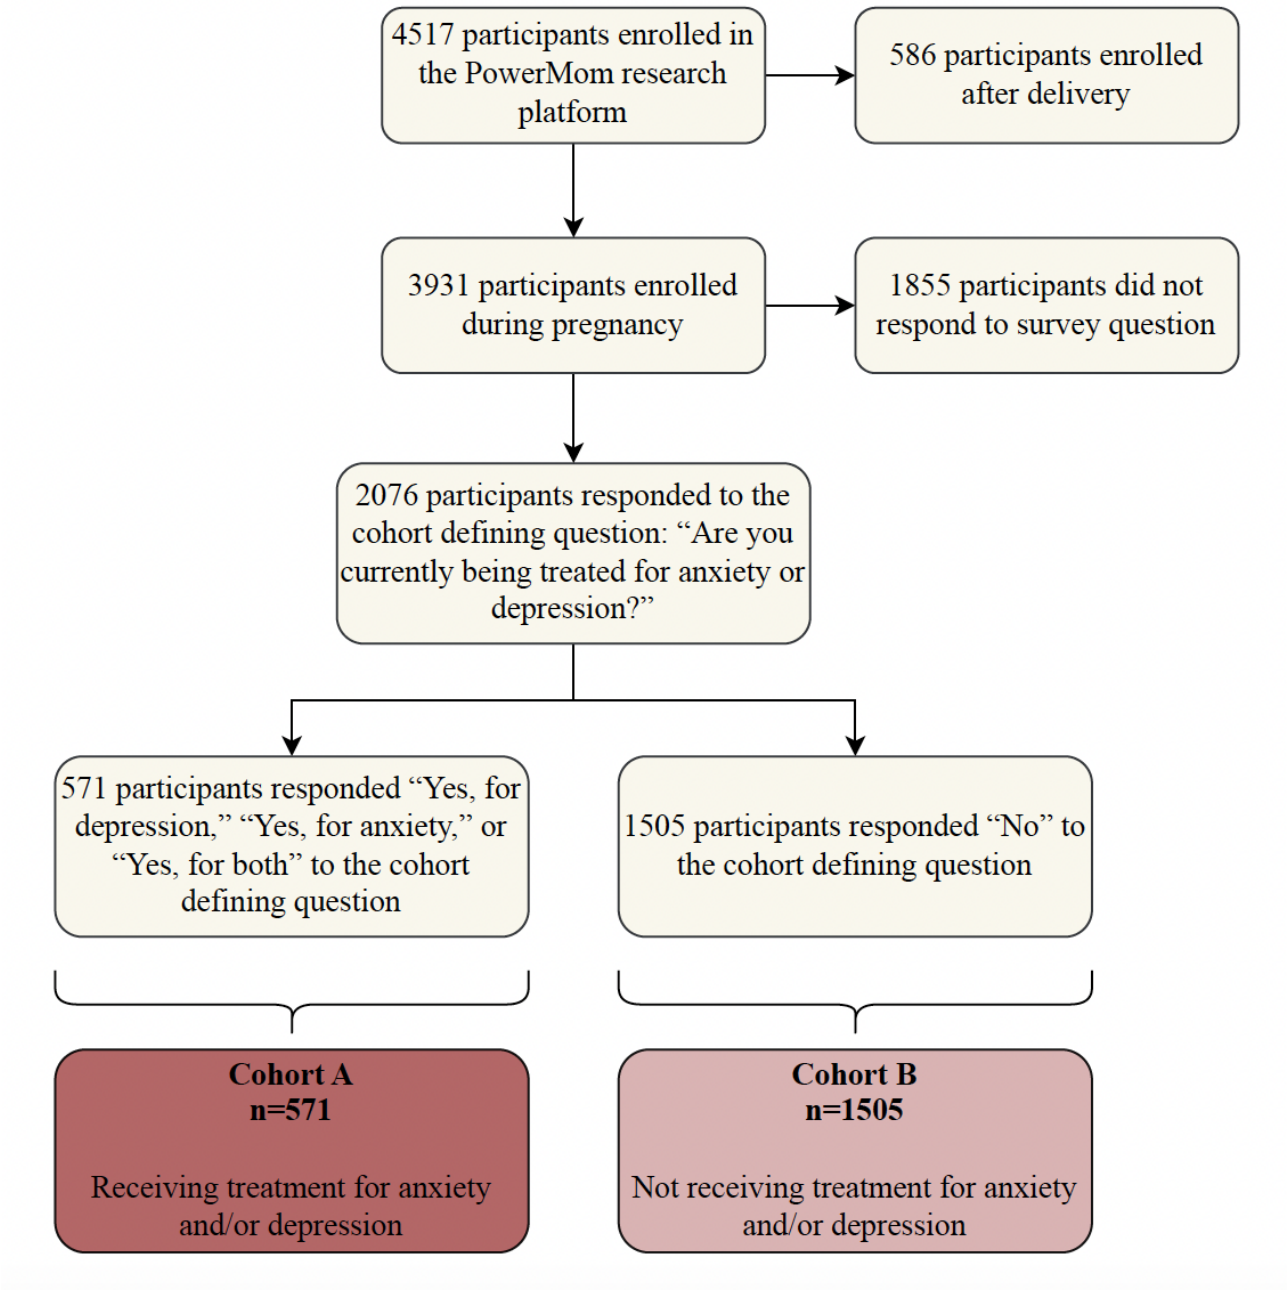
To mitigate the risk of increased false positives due to multiple comparisons, the Holm-Bonferroni correction was applied (Python package Pingouin; version 0.5.4) to compute adjusted P values (P_{adj}) for an alpha significance at .05. This method was selected as it provides a balance between statistical power and control of type I error across multiple hypothesis tests. The correction was applied separately for each category of comparisons (symptoms, prepregnancy conditions, and past pregnancy complications) rather than across all tests combined, ensuring that each domain was adjusted independently. In total, 13 comparisons were corrected for assessing the differences in terms of symptoms between the 2 cohorts, 10 comparisons for prepregnancy conditions, and 8 comparisons were corrected for past pregnancy complications. No additional corrections were applied for multiple comparisons.

Pregnancy Outcomes

For pregnancy outcomes, the percentage and 95% CIs between the 2 cohorts were computed using the bootstrap bias-corrected and accelerated method with 10,000 iterations. Overall significance between the cohorts was evaluated with either a multichoice or binary Fisher exact test.

Postpartum

For postpartum analysis, the mean composite mental health score is computed for the 2 cohorts. The 95% CI is computed using the bootstrap bias-corrected and accelerated method with 10,000 iterations. Postpartum mental health scores differences were evaluated for statistical significance via the Kruskal-Wallis test. In addition, participants were assigned to 2 groups based on the postpartum mental health composite score: higher risk for perinatal mood disorder (score ≥10) or not (score <10) [14,15]. Binary hypothesis test with Fisher exact test was used to evaluate the statistical differences between the cohorts.



Results

Study Population

Data collection through the PowerMom platform spanned from September 15, 2021, to June 18, 2024, with 4517 participants initially enrolled. Of these, 586 participants who enrolled postdelivery were excluded, leaving 3931 participants for analysis. From those, 2076 participants responded to the "Health History Survey" about anxiety or depression treatment: "Are you currently being treated for anxiety or depression?" The 571 participants who answered "Yes, for depression" (n=76), "Yes, for anxiety" (n=132), and "Yes, for both" (n=363) were included in cohort A. A total of 1505 participants responded "No" to the cohort-defining question and were included in cohort B. A total of 1855 participants did not respond to this survey question and were excluded from the analysis (Figure 2).

XSL•FO
RenderX

Figure 2. Participants inclusion diagram and segmentation into cohort A and cohort B. Cohort A (N=571) includes participants who responded "Yes, for depression," "Yes, for anxiety," or "Yes, for both" to the study intake survey question, "Are you currently being treated for anxiety or depression?". Cohort B (N=1505) includes participants who responded "No." Participants who did not respond to the survey question (N=1855) were excluded from this analysis.

Differences in race and ethnicity between cohort A and cohort B were statistically significant (P<.001). A greater proportion of treated participants identified as White compared with those untreated (67.3% vs 49.7%), whereas a smaller proportion of treated individuals identified as Black or African American compared with those reporting not receiving treatment (8.8% vs 19.5%).

In addition, cohort A participants enrolled in the PowerMom study earlier in their pregnancy (P=.003), which might influence symptom reporting due to the frequency of survey administration. This early enrollment may impact the reliability of symptom data. To mitigate this issue, we included all participants who reported symptoms at least once through all the completed symptoms surveys.

The difference between the 2 cohorts in number of preterm births was not statistically significant. However, preterm birth information, including gestational age and delivery date, was available for a small fraction of the 2 cohorts (14.5% vs 14.6%). The 2 cohorts did not differ in terms of age at enrollment, ADI, gestational age, and birth weight (Table 1).

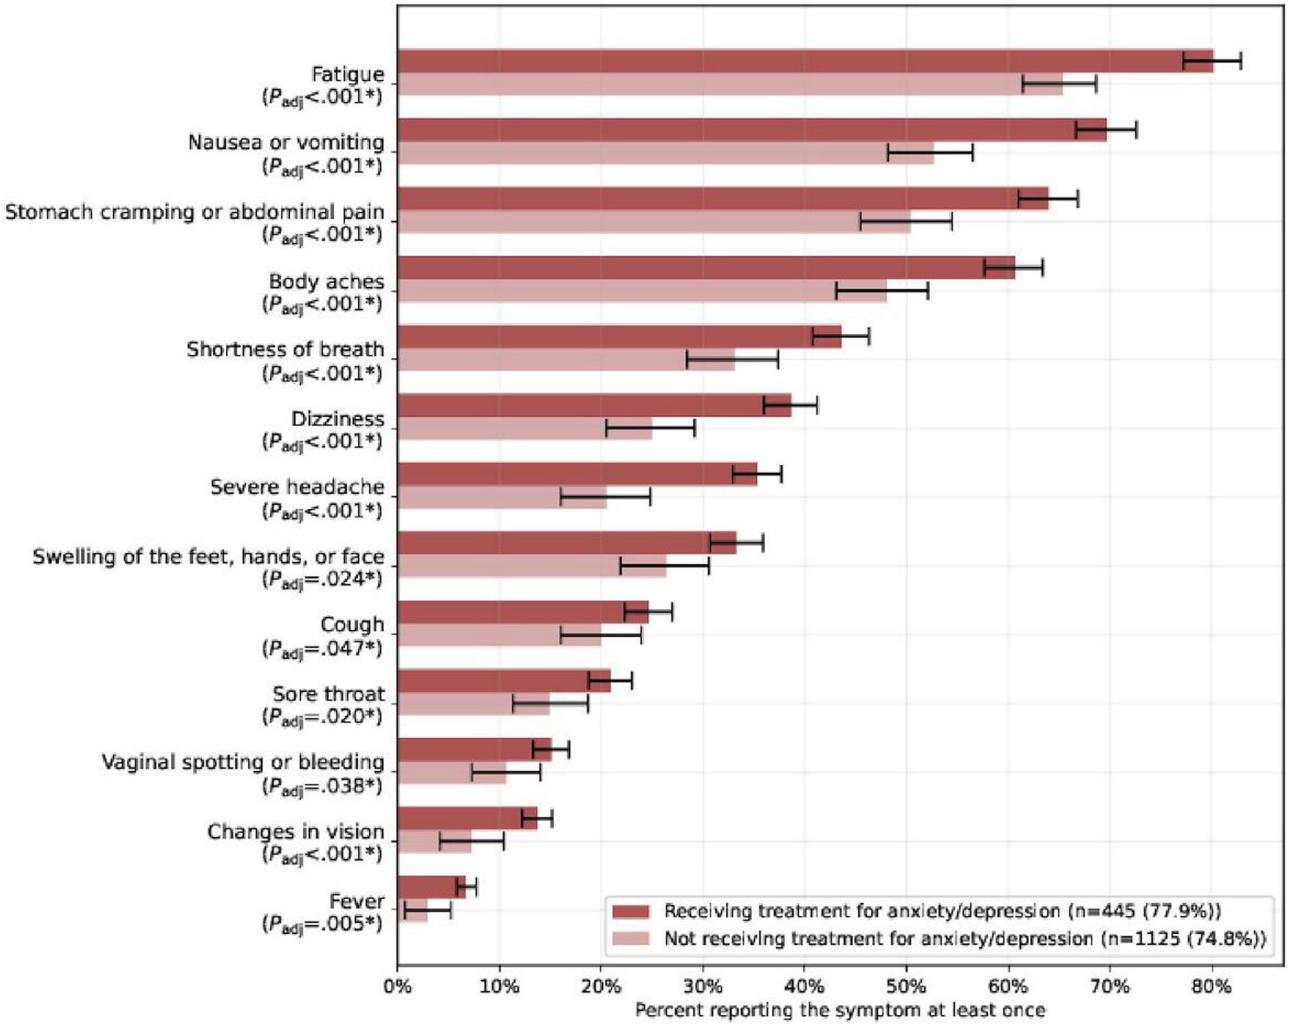
[a]Comparison of demographic characteristics for participants in cohort A (receiving treatment for anxiety or depression) and cohort B (not receiving treatment for anxiety or depression). Age, race or ethnicity, Area Deprivation Index, time of enrollment relative to conception, number of preterm births, gestational age, and birth weight across the 2 cohorts are shown. Preterm births were computed as delivery happening before completing 37 weeks of gestation. Chi-square and Kruskal-Wallis tests were used to determine statistically significant differences across the cohorts.

[b]Statistical significance at the .05 level.



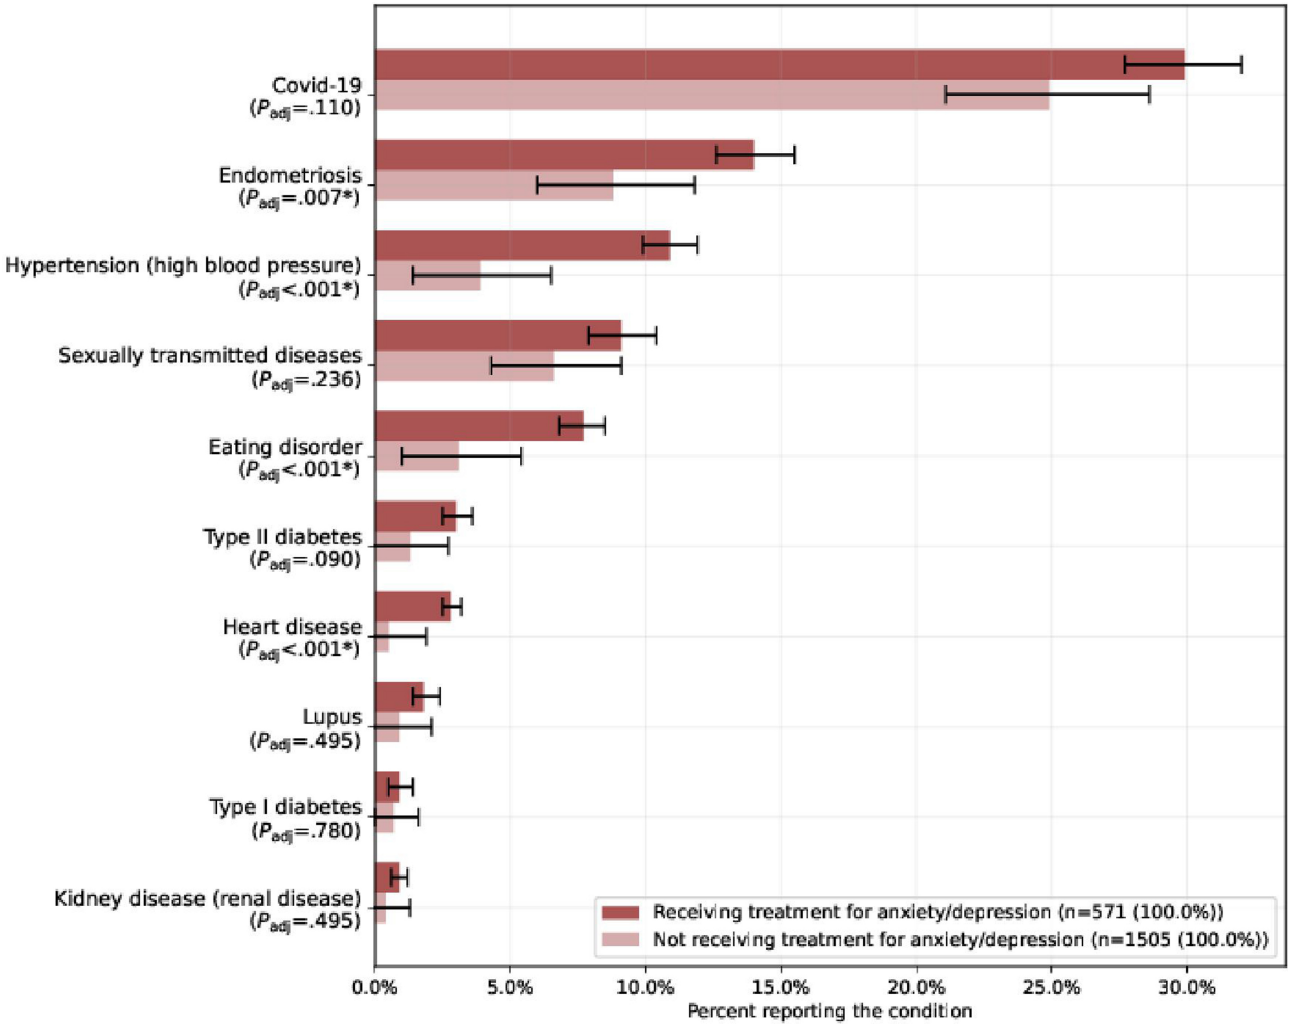
[c]ADI: Area Deprivation Index.

Self-Reported Symptoms During Pregnancy

Participants who reported receiving treatment for anxiety or depression (cohort A) were more likely to report experiencing physical symptoms across all tracked symptoms than untreated participants (cohort B). Applying the Holm-Bonferroni correction (significance at .05), the difference among participants experiencing a symptom across the 2 cohorts was statistically significantly higher for cohort A for all 13 listed symptoms: fatigue (80.2% vs 65.4%; P_{adj}<.001); nausea or vomiting (69.7% vs 52.7%; P_{adj}<.001); stomach cramping or abdominal pain (64.0% vs 50.4%; P_{adj}<.001); body aches (60.7% vs 48.1%; P_{adj}<.001); shortness of breath (43.6% vs 33.1%; P_{adj}<.001); dizziness (38.7% vs 25.0%; P_{adj}<.001); severe headache (35.3% vs 20.5%; P_{adj}<.001); swelling of the feet, hands, or face (33.3% vs 26.4%; P_{adj}=.024); cough (24.7% vs 20.0%; P_{adj}=.047); sore throat (20.9% vs 14.9%; P_{adj}=.020); vaginal spotting or bleeding (15.1% vs 10.7%; P_{adj}=.038); changes in vision (13.7% vs 7.2%; P_{adj}<.001); and fever (6.7% vs 2.9%; P_{adj}=.005) (Figure 3 and Table S2 in Multimedia Appendix 1).

XSL•FO
RenderX

Figure 3. Physical symptoms reported during pregnancy by participants in cohort A and cohort B. The fraction of participants who answered the survey at least once in cohort A (receiving treatment for anxiety or depression) and cohort B (not receiving treatment for anxiety or depression) experiencing each symptom during pregnancy. *Statistical significance at the .05 level. The *P* value (P_{adj}) is calculated with the Holm-Bonferroni correction.



Self-Reported Past Conditions and Past Pregnancies Complications

Treated participants (cohort A) were more likely to report preexisting medical conditions across all tracked conditions than untreated participants (cohort B). Applying the Holm-Bonferroni correction, the difference among participants diagnosed with a condition across the 2 cohorts was statistically significantly higher for cohort A for 4 out of 10 listed conditions: endometriosis (14.0% vs 8.8%; P_{adj}=.007), hypertension (10.9% vs 3.9%; P_{adj}<.001), eating disorder (7.7% vs 3.1%; P_{adj}<.001), and heart disease (2.8% vs 0.5%; P_{adj}<.001) (Figure 4 and Table S3 in Multimedia Appendix 1).

XSL•FO
RenderX

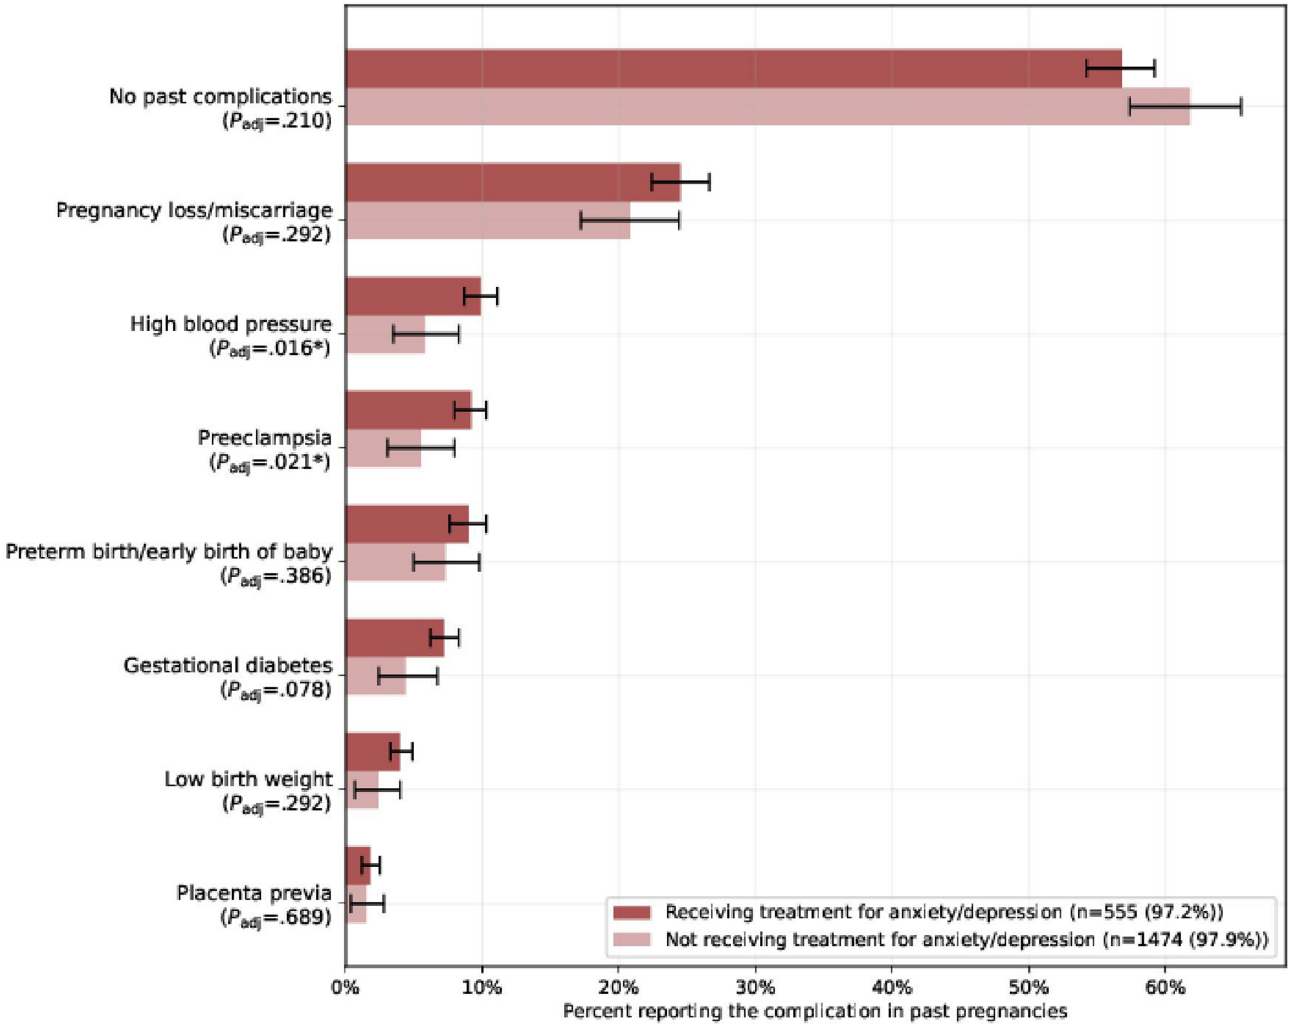


Figure 4. Conditions diagnosed prepregnancy by participants in cohort A and cohort B. The fraction of participants who answered the survey in cohort A (receiving treatment for anxiety or depression) and cohort B (not receiving treatment for anxiety or depression) who were diagnosed with such conditions before the current pregnancy. *Statistical significance at the .05 level. The *P* value (P_{adj}) is calculated with the Holm-Bonferroni correction.

Complications in prior pregnancies were more prevalent in cohort A across all tracked complications than in untreated participants (cohort B). Applying the correction, the difference among participants who experienced a complication in past pregnancies across the 2 cohorts was statistically significantly higher for cohort A for 2 out of 7 listed complications: high blood pressure (9.9% vs 5.8%; P_{adj}=.016) and preeclampsia (9.2% vs 5.5%; P_{adj}=.021) (Figure 5). Gestational diabetes was not statistically significant with the Holm-Bonferroni correction. Participants who had previous pregnancies but did not have complications in past pregnancies were more prevalent in cohort B than in cohort A; however, the difference was not significant with the correction. Results without the correction are available for all conditions and complications presented in the analysis (Table S4 in Multimedia Appendix 1).

XSL•FO
RenderX

Figure 5. Reported complications in past pregnancies by participants in cohort A and cohort B. The fraction of participants who answered the survey from cohort A (receiving treatment for anxiety or depression) and cohort B (not receiving treatment for anxiety or depression) reporting experiencing each complication during past pregnancies. *Statistical significance at .05 level. The *P* value (P_{adj}) is calculated with the Holm-Bonferroni correction.

Pregnancy Outcomes

Treated participants (cohort A) were more likely to experience a miscarriage or a stillbirth (14.8% and 4.3%) than untreated participants of cohort B (11.3% and 1.5%). These differences were not significant (*P*=.142). A higher percentage of participants in cohort A (71/93, 76.3%) received an epidural than in cohort B (151/231, 65.4%); however, the difference was nonsignificant (*P*=.065). No differences were found between the 2 cohorts in terms of labor induction, mode of delivery, and neonatal size for gestational age. Fewer participants for each cohort completed the "Delivery" survey for pregnancy outcomes (cohort A: 115/571, 20.1%; cohort B: 265/1505, 17.6%) and delivery-related questions (cohort A: 93/570, 16.3%; cohort B: 231/1509, 15.3%) (Table S5 and Figure S1 in Multimedia Appendix 1). The response rate was much higher for the surveys on symptoms, prepregnancy conditions, and past pregnancies complications.

Postpartum Mental Health Symptoms

The postpartum mental health composite score was significantly higher for treated participants (cohort A) than that for untreated participants (mean 9.94, 95% CI 8.37-11.63 vs 5.80, 95% CI 5.15-6.53; *P*<.001). The distribution of postpartum mental health composite scores for cohort A and cohort B is available (Figure S2 in Multimedia Appendix 1). Treated participants were at higher risk for perinatal mood disorder based on the survey than untreated participants (45.8% vs 18.4%; *P*<.001) (Multimedia Appendix 2).

Discussion

Principal Findings

We reported strong associations between self-reported prenatal mental health treatment and postpartum mental health outcomes. The significant correlation between prenatal and postpartum mental health, supported by a validated survey, underscores the critical importance of addressing prenatal mental health conditions. Although we did not observe statistically significant differences in pregnancy outcomes between the 2 cohorts, several factors may explain these findings. These include cohort heterogeneity, sample size limitations, or additional unmeasured variables influencing obstetric outcomes. These results align with prior research showing mixed evidence regarding the impact of prenatal anxiety and depression on delivery outcomes. Future studies with larger, more targeted cohorts could help clarify these relationships and identify potential moderating

XSL•FO
RenderX

factors. Regardless, there were notable disparities in physical symptoms, preexisting conditions, and past pregnancy complications. These findings highlight the complex relationships between prenatal mental health and overall pregnancy experiences. While this study provides key insights into prenatal mental health and its associations with pregnancy and early postpartum outcomes, long-term follow-up was beyond its scope. Other research leveraging digital health platforms such as PowerMom could expand on these findings by incorporating longitudinal postpartum assessments to track mental health trajectories over time.

Results in the Context of What Is Known

These findings enrich and expand upon existing research by elucidating the link between prenatal and postpartum mental health [2] and between prenatal mental health and pregnancy-related outcomes. Our longitudinal data reveal that individuals who reported being treated for anxiety or depression during pregnancy reported more physical symptoms, such as nausea and vomiting, consistent with some previous findings [8,16] and contrary to other findings that focused on the usage of antidepressants and physical symptoms [17]. This discrepancy highlights the need for further investigation into the complex relationships between mental health and physical symptoms during pregnancy.

Although differences in pregnancy outcomes between the 2 cohorts were not significant, data showed an increase of miscarriage, stillbirth outcomes, and use of epidural in participants treated for anxiety or depression, aligning our research to previous findings [5-7,18].

Treated individuals reported more complications and preexisting conditions, such as endometriosis, aligning with previous research on the impact of endometriosis on mental health [19]. Previous research showed how COVID-19 may negatively affect postpartum mental health [20], and how complications during pregnancy and at birth are associated with increased risk of postpartum depression, long-term depression, anxiety disorder, and posttraumatic stress disorder [21,22]. Postpartum depression may have harmful consequences on the birthing person and child [23]. Hence, depression should be detected and treated as early as possible [23], and complications and postpartum physical symptoms should be taken into account when screening for postpartum depression [21,22,24].

Clinical Implications

As an observational study, our findings describe associations rather than establish causal relationships. While we observed significant differences in postpartum mental health outcomes between treated and untreated individuals, we cannot determine whether treatment itself influenced these outcomes or whether underlying differences in mental health severity, access to care, or other confounders contributed to the observed patterns. Future research should consider randomized or quasi-experimental study designs to better isolate treatment effects.

Our results validate how digital technology can be effectively used in mental health screening techniques. Current screening methods during pregnancy could be improved by including systematic assessment of physical symptoms and pregnancy outcomes.

In addition, we observed more participants identified as Black in the no-treatment cohort with respect to the treatment cohort, potentially reflecting racial and ethnic disparities in the treatment of anxiety and depression. This distribution supports known access to care issues [25-27] and raises critical questions about access and the influence of structural inequities and medical mistrust [28]. The interpretation of this result is indeed complicated by the fact that participants in cohort B reported fewer symptoms and complications. A further investigation into the intersection of race, treatment access, and health outcomes in pregnancy will be needed to properly interpret this finding.

Research Implications

The use of the PowerMom platform exemplifies how decentralized trials and digital health technology can enhance participant engagement and data collection, extending the reach of maternal health research beyond traditional settings. This approach, demonstrated by our study's alignment with previous findings, confirms the use of digital health platforms in broadening our understanding of maternal health dynamics, supporting the effectiveness of digital health platforms [29]. However, our results also highlight the need for careful consideration of equity in mental health care access. Digital platforms such as PowerMom, while effective for data collection, may exacerbate existing disparities in access to smartphone technology and health care. The digital divide may limit participation among lower-income or marginalized populations [30,31].

Strengths and Limitations

A key strength of this study is the large, diverse sample collected through the PowerMom platform, which allowed us to analyze data across multiple dimensions of maternal health. By integrating these various dimensions, this study offers a comprehensive view of the participants' health, going beyond traditional clinical health records. However, potential clinician bias in diagnosing and treating mental health conditions may have influenced which patients reported receiving treatment, reflecting broader systemic barriers to care for certain racial and ethnic groups [28]. Finally, this study successfully engages a diverse cohort, potentially increasing the generalizability of the findings and providing insights into populations often underrepresented in clinical research.

A key limitation is the reliance on self-reported treatment status, which varies widely from meditation to medication possibly affecting consistency in treatment classification. It is important to acknowledge that our classification was based on treatment status rather than the presence of symptoms alone. While treatment status during pregnancy was self-reported, we cannot determine whether participants had a history of anxiety or depression prior to conception, which may have influenced both their treatment decisions and symptom presentation. Furthermore, treatment status does not directly reflect symptom severity. Some participants in the untreated cohort may still experience significant anxiety or depression symptoms, while others in the treated cohort may have had milder conditions

XSL•FO
RenderX

warranting intervention. This limitation may have introduced heterogeneity in the analysis and highlights the need for future studies to assess both treatment status and clinical symptom severity separately to improve interpretability. Participants undiagnosed or not being actively treated for anxiety or depression were not captured in this analysis. This reinforces the need for future research to explore confounding factors, such as whether participants' anxiety and depression were driven by comorbid conditions, or vice versa. Furthermore, we found differences between the cohorts in terms of race and ethnicity. Future analyses should objectively assess the presence of these conditions and include covariates such as race and ethnicity to further evaluate the relationships between anxiety and depression treatment, race and ethnicity, and measured outcomes. Furthermore, while ADI was used as a proxy for socioeconomic status, it does not capture all individual-level factors influencing mental health and prenatal care quality. Future studies should explore additional confounders, such as direct measures of income, health care access, and social support networks, to enhance causal interpretations.

In addition, we did not report results for conditions identified during the current pregnancy via the "Health and Well-being" survey. While more than 70% of participants in each cohort completed the survey, the prevalence of specific conditions was low (eg, fewer than 4 participants reported preeclampsia), leading to not statistically significant results due to the small sample size. This limitation might stem from the timing of diagnosis, as many conditions manifest later in pregnancy, and not all participants completed the biweekly surveys up to delivery.

Relatedly, this low prevalence of certain conditions reported during the current pregnancy due to timing and incomplete survey responses, coupled with significant attrition as the study progressed, was a limitation.

Conclusions

This study underscores the essential role of early and continuous mental health screenings for expectant individuals, emphasizing the association between prenatal mental health and various maternal outcomes. We found that those receiving treatment for anxiety or depression experienced more physical symptoms and poorer postpartum mental health. However, these findings reflect associations rather than causal relationships, and further interventional studies are necessary to establish causality. Significant disparities in treatment for prenatal mental health across racial groups call for targeted interventions to ensure equitable care. Our findings also demonstrate the potential of digital health technologies to enhance screening and research, laying the groundwork for future studies on the impacts of mental health conditions.

Multimedia Appendix 1

Participant flow, surveys, and results by cohort, including detailed survey instruments and analyses related to postpartum mental health outcomes, pregnancy symptoms, prepregnancy conditions, past pregnancy complications, and obstetric outcomes. Results compare 2 cohorts: cohort A (receiving treatment for anxiety or depression at baseline) and cohort B (not receiving treatment). Statistical significance was evaluated using Fisher exact test with Holm-Bonferroni correction applied. Figures display key obstetric outcomes and the distribution of composite postpartum mental health scores, based on the Edinburgh Postnatal Depression Scale.

[DOCX File, 13705 KB - mental_v12i1e70151_app1.docx]

Multimedia Appendix 2

Postpartum composite mental health scores for cohort A and cohort B. Severity of self-reported postpartum mental health symptoms for participants in cohort A (receiving treatment for anxiety or depression) compared with participants in cohort B (not receiving treatment for anxiety or depression). Postpartum composite mental health scores are determined using the scoring based on the Edinburgh Postnatal Depression Scale (EPDS) [14]. A score of 10 or higher indicates that the participant is at higher risk for perinatal mood disorder and for developing postpartum depression.

Abstract

Background: Strong evidence suggests physical activity (PA) can ameliorate postpartum depression (PPD) symptoms; however, many postpartum individuals do not meet PA guidelines. Electronic health (eHealth) interventions are a promising approach to address common barriers to PA during postpartum.

Objective: To test the effectiveness of a tailored eHealth PA intervention for increasing PA and decreasing depressive symptoms in individuals at high risk for PPD.

Methods: We conducted a randomized controlled trial within the Kaiser Permanente Northern California integrated health care delivery system. From November 2020 to September 2022, individuals 2 - 6 months postpartum at high risk for PPD were randomized to an eHealth PA intervention (n=50) or usual care (n=49). The eHealth PA intervention group received access to an online library of 98 ten-minute workout videos developed for postpartum individuals, including interaction with their infants. At baseline, 3 months, and 6 months postrandomization, surveys were used to assess depressive symptoms, PA, sleep quality, anxiety symptoms, perceived stress, and mother-infant bonding. PA was also measured using a wrist-worn accelerometer for 7 days at each timepoint. Primary outcomes were depressive symptoms and device-measured moderate-to-vigorous intensity PA (dm-MVPA) at 3 months postrandomization. Secondary outcomes were self-reported MVPA (sr-MVPA) at 3 and 6 months postrandomization and depressive symptoms and dm-MVPA at 6 months postrandomization. Intent-to-treat and modified intent-to-treat (excluding participants in the intervention group who did not watch at least 1 video) analyses were conducted using linear regression adjusted for variables used in the randomization procedure and using multiple imputation to account for missing data.

Results: Participants were 4 months postpartum at baseline with moderately severe depressive symptoms (mean PHQ-8 [Patient Health Questionnaire-8] score=12.6), on average. Intent-to-treat analyses indicated no association between the intervention and change in depressive symptoms (mean difference=−0.9; 95% CI −3.3 to 1.5), dm-MVPA per day (mean difference=−4.5 minutes; 95% CI −23.5 to 14.5), or sr-MVPA per week (mean difference=3.8; 95% CI −1.9 to 9.5) at 3 months postrandomization or 6 months postrandomization (depressive symptoms: mean difference=−1.3; 95% CI −3.7 to 1.1; dm-MVPA: mean difference=1.3 minutes; 95% CI −18.9 to 21.5; sr-MVPA: mean difference=−1.8 MET-hours; 95% CI −7.7 to 4.2). Engagement with the intervention was suboptimal; although 52% (n=26) of participants allocated to the intervention group logged on to the intervention website and watched at least 1 video, the median minutes watched per week peaked at 10 minutes 2 weeks postrandomization, then fell to zero for the rest of the follow-up period. Results from modified intent-to-treat analyses were similar to those from intent-to-treat analyses.

Conclusions: An eHealth PA intervention tailored to postpartum individuals did not affect depressive symptoms or PA among those at high risk for PPD. Additional research to develop effective and engaging PA interventions is needed to help alleviate PPD symptoms and decrease PPD risk.

Introduction

Postpartum depression (PPD) is a debilitating and costly condition that affects nearly 20% of postpartum individuals [1,2]. PPD can have long-lasting health consequences for both postpartum individuals and their children, including negative maternal-infant interaction [3], lower likelihood of breastfeeding [4,5], and cognitive and behavioral problems [5-7]. Counseling is the currently recommended approach for prevention of PPD in individuals at high risk [8]; however, stigma and health care system barriers remain a challenge to accessing these mental health services for many postpartum individuals [9,10]. Alternative and complementary strategies are needed for PPD prevention .

There is strong evidence that physical activity (PA) can reduce PPD symptoms [11-15]. The PA Guidelines for Americans [16], the American College of Sports Medicine [17], and the American College of Obstetricians and Gynecologists [18] recommend participation in regular PA (at least 150 minutes of moderate-to-vigorous-intensity PA per week) during the postpartum period for physical and mental health benefits. Despite these recommendations, PA levels remain low in postpartum individuals [19]. Common barriers include lack of time and prioritization of other responsibilities, including parenting and household responsibilities, lack of child care, lack of motivation or social support, and difficulty finding accessible and affordable PA programs or classes [20-26].

Technology-based electronic health (eHealth) interventions may address common barriers to being physically active in the postpartum period, and as such are a promising approach to increasing PA levels in postpartum individuals at high risk for PPD. eHealth PA interventions have demonstrated effectiveness in increasing PA in the general adult population [27,28]. In contrast, most previous PA interventions for postpartum individuals have relied on in-person supervised exercise sessions alone or in combination with individual health coaching [13,29,30].

The objective of this study, the POstpartum Wellness study (POW), was to test the effectiveness of an eHealth PA intervention (MomZing) for increasing PA and decreasing depressive symptoms in individuals at high risk for PPD. MomZing is a web-based library of short, tailored exercise videos developed with and for postpartum individuals to address accessibility (no equipment needed, designed to be done at home), time constraints (10 min videos available on demand), and child care concerns (exercises are designed to incorporate baby as weight), common barriers to PA in postpartum.

Methods

Below we summarize key aspects of the POW study protocol, which has been previously published [31].

Study Design and Setting

We conducted a 2-arm, parallel-group randomized controlled trial among members of Kaiser Permanente Northern California (KPNC), an integrated health care delivery system that provides care for over 66,000 pregnant and postpartum individuals annually. PPD screening is part of standard postpartum care at KPNC [32,33] and also occurs at each pediatric well-baby visit. Results of all PPD screening and diagnosis are captured in KPNC's comprehensive electronic health record database.

Ethical Considerations

This study was approved by the KPNC Institutional Review Board (approval number 1548855) and registered with ClinicalTrials.gov on June 1, 2020 (ID: NCT04414696). All participants provided documented informed consent and could withdraw from the study at any time. All data are deidentified. Participants received gift cards as incentives after completing each assessment: US $20 after the baseline and 3-month assessments, and US $30 after the 6-month assessment (including the infant ASQ screener), for a total of US $70 in incentives.

Recruitment and Eligibility

From November 2020 through September 2022, 12,269 postpartum individuals who met the following inclusion criteria in the electronic health record were invited to participate in the study via letter and email invitations: 2 - 6 months postpartum, no current depression diagnosis, and at high risk for PPD (identified using PPD screening PHQ-9 score 10 - 19 or PHQ-2 score ≥3, or history of depression diagnosis and antidepressant medication prescription prior to delivery date). Additional eligibility criteria (including reassessment of depression symptoms using a PHQ-8 screener) were assessed using online questionnaires prior to the baseline survey. See Table S1 in Multimedia Appendix 1 for detailed inclusion and exclusion criteria.

Randomization and Blinding

Eligible participants completed informed consent documents and baseline surveys through the REDCap website (Research Electronic Data Capture; Vanderbilt University). After survey completion, participants were mailed an accelerometer and were asked to wear the accelerometer for 7 consecutive days, 24 hours per day, and then mail it back. Participants who returned the accelerometer were eligible to be randomized.

Participants were randomized by the study project manager into the intervention group or control (usual care) group using

XSL•FO
RenderX

minimization, implemented using QMinim [34]. Minimization aims to achieve between-group balance in distributions of pre-specified important factors associated with outcomes of interest. Variables included in the randomization procedure included number of children at home (1, 2+), self-reported race and ethnicity category (Asian/Pacific Islander, Hispanic, non-Hispanic Black, non-Hispanic White, other), baseline PHQ-8 score (Patient Health Questionnaire-8; 10-14, 15-19), and PA level prior to pregnancy (below recommendations, at or above recommendations). Investigators and data analysts were blinded to the assigned study group. Research assistants, who informed participants of their assigned study group, and participants were not blinded.

Intervention: MomZing

In addition to usual postpartum care, participants randomized to the intervention group received access to MomZing (Klein Buendel), an eHealth PA intervention tailored to postpartum individuals [35]. MomZing is an online library of 98 ten-minute exercise videos that was developed with and for postpartum individuals. The exercise videos on MomZing instructed postpartum individuals how to safely exercise with their baby based on the infant's weight and developmental stage, did not require exercise equipment, and featured postpartum individuals (who were not fitness instructors) exercising with their own infant. The website also included a page to set a weekly PA goal and visually tracked (via a graph) the number of videos watched per week. Participants randomized to the intervention group received individual login information for the MomZing website via email and up to 6 reminders (text and email per each participant's preference) to log into the MomZing website (73% text and 27% email).

Control: Usual Care

Participants randomized to the control group received usual postpartum care for women at increased risk of depression, which typically is a brief discussion about their depression symptoms with their obstetric provider.

Follow-Up Data Collection

Follow-up surveys were sent via email at 3 and 6 months postrandomization. After completion of each survey, participants were mailed an accelerometer and were asked to wear the accelerometer for 7 consecutive days, 24 hours per day, and then mail it back. An additional assessment occurred when the participant's child was 12 months old; for some participants, this occurred simultaneously with the 6-month follow-up surveys. Follow-up data collection ended in April 2023.

Primary Outcomes

Primary outcomes were depressive symptoms and device-measured moderate-to-vigorous intensity PA (dm-MVPA), measured at 3 months postrandomization. Depressive symptoms were assessed using the validated 8-item PHQ-8 screener [36,37], with higher scores indicating greater symptom severity (range 0‐24). dm-MVPA was measured using the ActiGraph GT3X+ accelerometer (ActiGraph, Pensacola), worn on the non-dominant wrist. Raw accelerometer data were downloaded using ActiLife software (ActiGraph, Pensacola) and counts were summarized for each 1-second and 60-second epoch. Wear time was identified using the Choi algorithm [38-40], and wake (non-bedrest) was identified using the Tracy algorithm [41]. Individuals with at least 4 days (including at least 1 weekend day) of at least 10 hours of waking accelerometer wear were considered to have sufficient accelerometer data for analyses [42]. Waking wear time was categorized into intensity categories using the Hibbing 2-regression model, which was developed for wrist-worn accelerometer data [43]. Average dm-MVPA duration was calculated across valid days.

Secondary Outcomes

Secondary outcomes included self-reported moderate-to-vigorous intensity PA (sr-MVPA) at 3 and 6 months postrandomization, and depressive symptoms and dm-MVPA at 6 months postrandomization. sr-MVPA duration was assessed using the sports and exercise domain of the Pregnancy Physical Activity Questionnaire [44]. In addition, we created a subscale of the sports and exercise domain of the Pregnancy Physical Activity Questionnaire (sr-MVPA-MomZing) limited to activities included in MomZing videos: dancing; yoga or Pilates or stretching or core strengthening exercises, exercise videos, or computer games; aerobic exercise videos or computer games; and weightlifting and resistance exercises (ie, MomZing included workouts where the infant was lifted or carried).

Additional Outcomes

Additional outcomes were measured using validated questionnaires and included sleep quality, anxiety symptoms, and perceived stress at 3- and 6- months postrandomization, mother-infant bonding at 3 months postrandomization, and infant development at 12 months of age. Sleep quality was measured using the Pittsburgh Sleep Quality Index [45], with higher scores indicating worse sleep quality (range 0‐21). Anxiety symptoms were measured using the GAD-7 screener [46,47], with higher scores indicating greater symptom severity (range 0‐21). Perceived stress was measured using the Perceived Stress Scale [48,49], with higher scores indicating higher stress (range 0‐40). Mother-infant bonding was assessed using the Mother Infant Bonding Scale [50], with lower scores indicating better bonding (range 0‐24). Infant development across 5 domains (communication, gross motor function, fine motor function, problem-solving, and personal social skills) was assessed using the Ages and Stages Questionnaire-3 for 12-month-old infants [51], with higher scores indicating more typical ("on schedule") development (range 0‐60).

Adverse Event Reporting

Participants reported injuries or illnesses related to exercise at 3 and 6 months postrandomization.

Participant Feedback About the Intervention

Participants allocated to the intervention group received a feedback survey at 3 months postrandomization that assessed their use of the MomZing website, reasons for not using the website, experience and satisfaction with the MomZing intervention, and qualitative feedback about the intervention. The satisfaction questions were adapted from a validated satisfaction questionnaire for web-based health interventions

XSL•FO
RenderX

with Likert scale responses, with higher scores indicating higher satisfaction (range 12 - 60) [52].

Sample Size Determination

Original sample size calculations were based on a planned sample size of 100 participants per group. With our achieved sample size of 99 participants (50 in the intervention group, 49 in the control group), 80% power, and 5% type I error rate, the minimum detectable difference in means for depressive symptoms and dm-MVPA was 0.57 standard deviation units, which is considered a "medium" effect size [53]. Using the observed outcome distributions (Table 1), this corresponds to 3.2 units for PHQ-8 score and 24.1 minutes for dm-MVPA.

Table . Effect of the MomZing intervention on primary outcomes (measured at 3 months postrandomization).

	Control Mean (SD)	Intervention Mean (SD)	Adjusted mean difference (95% CI)[a]
Intent-to-treat analysis			
Depressive symptoms	11 (5.8)	10.1 (5.4)	−0.9 (-3.3 to 1.5)
dm-MVPA[b] (minutes per day)	58 (44.8)	53.2 (39.9)	−4.5 (−23.5 to 14.5)
Modified intent-to-treat analysis			
Depressive symptoms	11 (5.8)	10 (5.8)	−0.8 (−3.9 to 2.3)
dm-MVPA (minutes per day)	58 (44.8)	52.2 (38.2)	−0.5 (−23.2 to 22.2)

[a]Adjusted for baseline PHQ-8 (Patient Health Questionnaire-8) score, race and ethnicity, number of children at home, pre-pregnancy PA level, and corresponding baseline outcome measure

[b]dm-MVPA, device-measured moderate-to-vigorous intensity physical activity.

Statistical Analysis

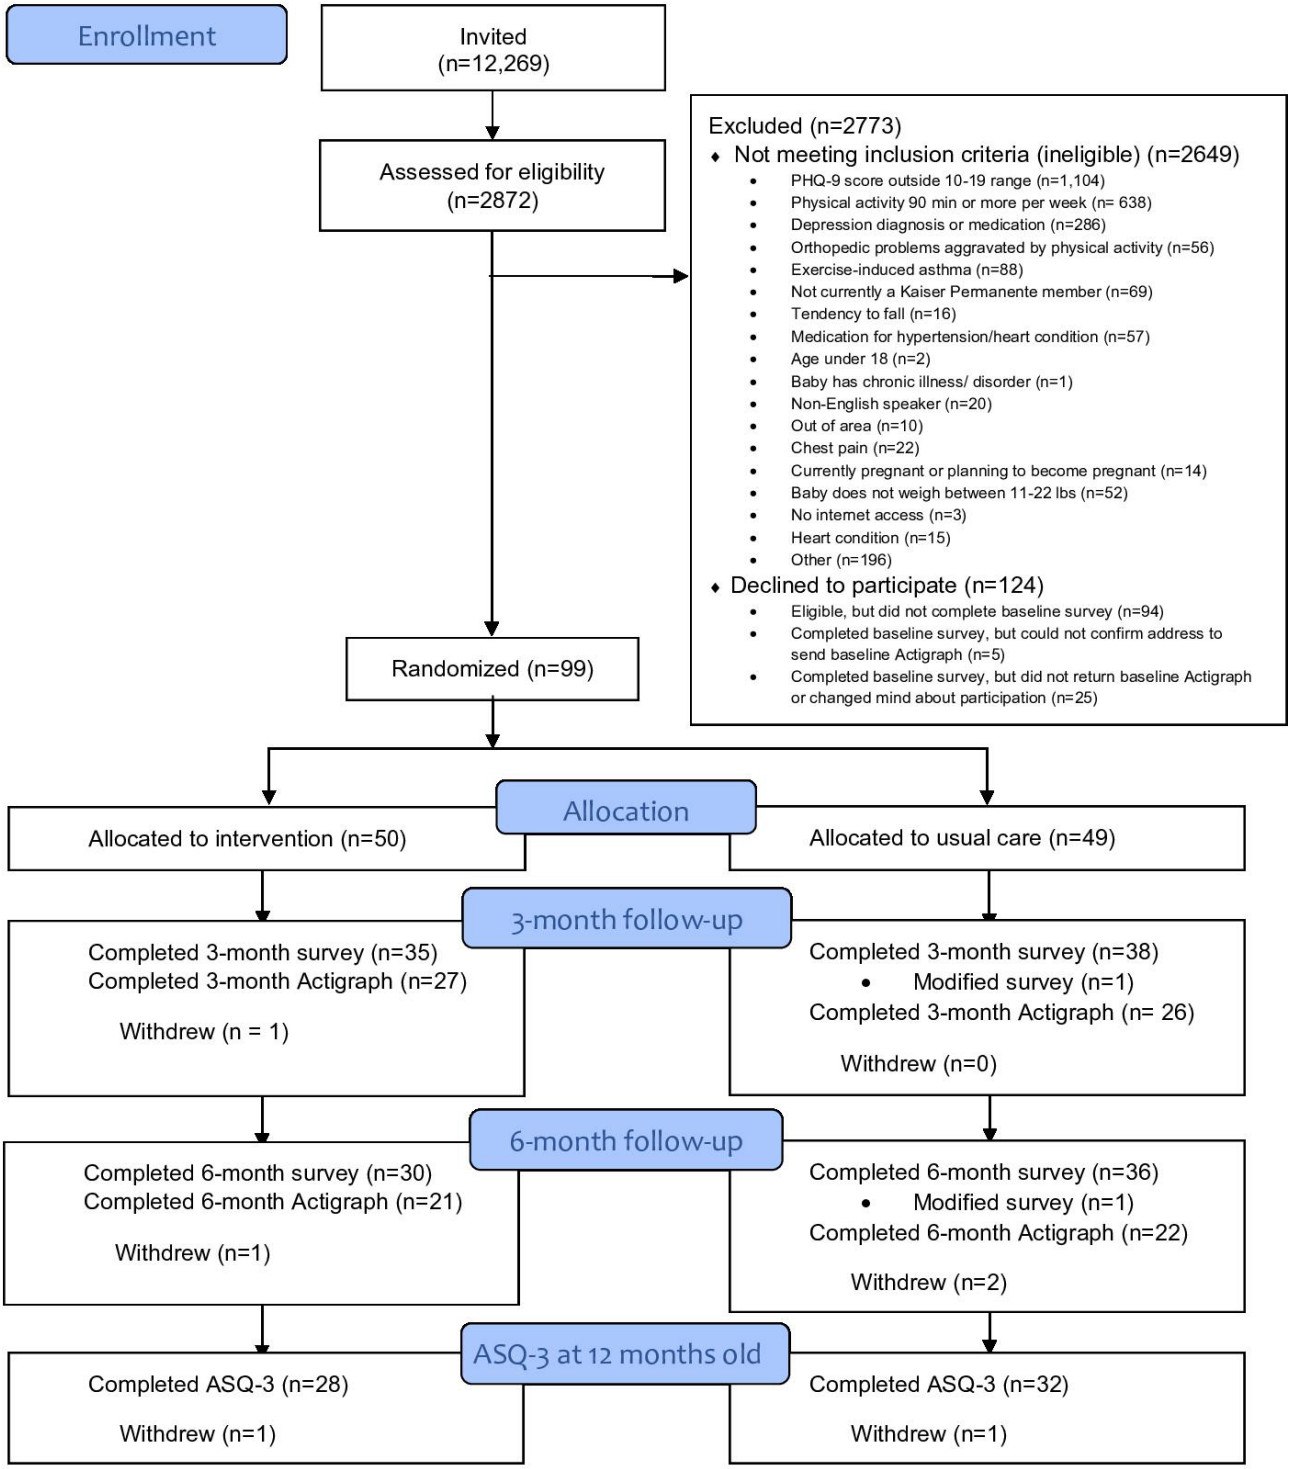
We compared baseline characteristics between the intervention and control groups and between the entire intervention group and the subset of the intervention group who engaged with the intervention (watched at least 1 MomZing video).

Primary analyses followed an intent-to-treat approach. We used multivariable linear regression models, adjusted for variables used in the randomization procedure (number of children at home, race and ethnicity, baseline PHQ-8 score, pre-pregnancy PA level) and corresponding baseline value of the outcome, to estimate mean differences in each outcome associated with the MomZing intervention.

Secondary analyses followed a modified intent-to-treat approach. We excluded participants allocated to the intervention group who did not engage with the intervention (did not watch at least 1 video on the MomZing website during the 3-month period postrandomization).

We used multiple imputation using chained equations to impute missing outcome and baseline MVPA data with 10 imputations. Variables included in imputation models are shown in Table S2 in Multimedia Appendix 1. Regression models were run using each imputed dataset. Results were combined using Rubin's rules [54]. We also conducted complete case analysis as a sensitivity analysis. Analyses were conducted in SAS (version 9.4; SAS Institute Inc.) and R (version 4.3.1; R Foundation for Statistical Computing).

Results



Participant Characteristics

Of the 99 randomized participants, 27 (54%) and 26 (53%) in the intervention and control groups, respectively, completed all 3-month follow-up activities (online surveys and accelerometer; Figure 1). At baseline, participants were 4 months postpartum, on average, and had moderately severe depressive symptoms (mean PHQ-8=12.6; Table 2). Most participants were members of a minoritized racial or ethnic group (63%), not currently working (74%), married or living with their partner (86%), did not meet PA recommendations prior to pregnancy (61%), had a college education or more (80%), and had 2 or more children at home (59%). Baseline characteristics were similar between the intervention and control groups (Table 2).

In total, 52% (n=26) of participants allocated to the intervention group logged in to the MomZing website and watched at least 1 video. The median minutes of videos watched per week peaked at 10 minutes 2 weeks after randomization, then fell to zero for the rest of the follow-up period (Figure 2). Baseline characteristics were similar between participants who engaged with the intervention (watched at least 1 MomZing video) and participants in the control group . Within those allocated to the intervention, characteristics differed somewhat by engagement with the intervention: compared to participants who did not engage with the intervention, those who did were fewer months postpartum, more likely to be non-Hispanic White, more likely to have a household income of US $100,000 or greater per year, less likely to be working, and less likely to meet PA recommendations in pre-pregnancy (Table S3 in Multimedia Appendix 1).

Intent-to-Treat Analyses

Primary Outcomes

There was no association between the MomZing intervention and change in depressive symptoms (mean difference=−0.9; 95% CI −3.3 to 1.5) or dm-MVPA per day (mean difference=−4.5 min; 95% CI −23.5 to 14.5) at 3 months postrandomization (Table 1).

Secondary outcomes

As shown in Table 3, there were no differences between groups in sr-MVPA or sr-MVPA-MomZing per week at 3 months postrandomization and no differences between groups in change in depressive symptoms, dm-MVPA per day, and sr-MVPA or sr-MVPA-MomZing per week at 6 months postrandomization.

Fine motor function	48.5 (9.5)	48.4 (10.2)	0.7 (−4.6 to 6)
Problem-solving	41.1 (13.8)	39.8 (13.4)	0.1 (−7.7 to 7.9)
Personal social skills	36.9 (14)	37.9 (14.6)	2.2 (−6.6 to 11)

[a]Adjusted for baseline PHQ-8 (Patient Health Questionnaire-8) score, race and ethnicity, number of children at home, pre-pregnancy physical activity level, and corresponding baseline outcome measure.

Modified Intent-to-Treat Analyses

Findings from modified intent-to-treat analyses were similar to those from intent-to-treat analyses for primary, secondary, and additional outcomes (Tables 1, 3 and 4).

Sensitivity Analyses

Findings from complete case analyses were similar to those using imputation (data not shown).

Adverse Events

There were no adverse events reported during the study.

Participant Feedback About the Intervention

Among those who reported using the MomZing website (44%, n=22), the mean satisfaction score was 40, indicating moderately high overall satisfaction with the intervention (Table 5). In total, 90% rated MomZing as good or very good or excellent. Over 60% of participants who reported using the MomZing website

XSL•FO
RenderX

found it very or moderately helpful for being more physically active. Qualitative feedback also indicated that participants wanted more frequent reminders to use the MomZing website, more intense workouts, and an app that is accessible on multiple devices. The most common reason for not using the MomZing website was lack of time (77%).

Table . Participant evaluation of the MomZing intervention 3 months postrandomization.

Feedback item	Value
Satisfaction and experience with MomZing[a] (n=22)	
Satisfaction score, mean (SD)	40 (9)
Overall rating of MomZing, n (%)	
Excellent or very good	10 (45%)
Good	10 (45%)
Fair or poor	2 (9%)
How helpful did you find the MomZing workout videos for being more physically active?, n (%)	
Very or moderately helpful	15 (68%)
Of little help or not helpful	7 (32%)
Reasons for not using the MomZing website[b] (n=13), n (%)	
Did not have time	10 (77%)
Was not sure what my login information was	2 (15%)
Did not find the website helpful	2 (15%)
Other: Used other workout program or walked instead	2 (15%)
Did not understand how to use it	1 (8%)
Was not interested in using the website	1 (8%)
Did not have access to the internet	0
Did not like the website	0

[b]Limited to respondents who reported not using the MomZing website.

Discussion

In this 2-arm, parallel-group randomized controlled trial, there were no statistically significant differences in change in depressive symptoms or dm-MVPA over a 3-month period associated with the MomZing eHealth PA intervention in postpartum individuals at high risk of PPD. There were also no differences in change in sr-MVPA, sleep quality, anxiety symptoms, perceived stress, mother-infant bonding, or infant development at 12 months of age associated with the intervention.

Engagement with the intervention was low, with roughly half of intervention group participants logging into the MomZing website and peak weekly engagement of a median of 10 minutes of videos watched at 2 weeks after randomization, which may explain our null findings in both intent-to-treat and modified intent-to-treat analyses. Participants in the intervention group who used the MomZing website rated it highly; however, those who did not use the MomZing website reported that lack of time remained a barrier to PA. Additionally, for some participants the MomZing intervention did not meet their expectations for quality and content, as they preferred higher intensity workouts and accessibility of content via an app. A previous review of behavior change techniques present in efficacious PA interventions among postpartum populations identified goal setting for PA and self-monitoring of PA as important components (ie, these techniques were present in all efficacious interventions) [55]. While the MomZing website did allow for setting a weekly PA goal and visually tracked the number of videos watched per week, there was no promotion of these activities in our study materials, which may also have contributed to our null findings. Providing goal-setting and self-monitoring tools without additional social support is likely not enough to change PA behavior in this population, as previous research suggests that social support is the strongest contributor to PA behavior change in postpartum individuals [56].

Previous randomized controlled trials of eHealth PA interventions in postpartum populations have used various eHealth modalities, including a mobile app alone [57] or paired with free exercise equipment for the home [58], a Facebook group [59], and an exercise DVD [60]; only 1 study was conducted among individuals at high risk of PPD [58], and all reported no associations with mental health outcomes despite higher intervention engagement and retention compared to the present study. Teychenne et al [58] pilot tested whether a 12-week home-based PA intervention, which included a free in-home treadmill or stationary bike, mobile app, and online

XSL•FO
RenderX

forum, changed PA, sleep, and mental health in postpartum individuals at high risk for PPD (n=62). Results showed that the intervention group had less dm-MVPA compared to the control group (−1.3% of the day), and there were no differences in sr-MVPA, depressive symptoms, anxiety symptoms, or sleep quality. Other studies have been conducted among the general population of postpartum individuals. In a pilot study with 35 participants, Tinius et al [57] did not find differences in dm-MVPA or sr-MVPA at 12 weeks postpartum between participants in an attention control group and those who had access to a mobile app to help perinatal individuals (mid-pregnancy to postpartum) meet PA recommendations, which included PA tracking, exercise videos, and educational content. In a trial with 120 participants, Kernot et al [59] did not find differences in dm-MVPA or self-reported walking between participants in a 50-day team-based PA intervention delivered via Facebook and participants in a control group. Finally, Yang et al [61] did not report differences in depressive symptoms, sleep quality, or perceived stress in a pilot study (n=140) of a 12-week aerobic gymnastic intervention designed for postpartum individuals and delivered via DVD. These findings, along with our study results, highlight the need for additional research to develop effective PA interventions for postpartum individuals at high risk of PPD and for the postpartum population in general.

Strengths of this study include using an intervention tailored for postpartum individuals that was developed with key stakeholder input; assessment of dm-MVPA and sr-MVPA; assessment of multiple aspects of mental health; multiple timepoints of outcome assessment; inclusion of participants from a large population sample; and use of statistical techniques for balancing groups. However, several limitations should be noted, which highlight the challenges in PA and research engagement during postpartum, especially in those at high risk for PPD and may explain our null results. We did not meet our recruitment goal, and as a result, our study is underpowered for effect sizes smaller than “medium,” resulting in imprecise estimates of associations (wide confidence intervals). As discussed previously, engagement with the intervention was low, which can lead to underestimation of intervention effects in intent-to-treat analyses [62] and further reduces sample size and power in modified intent-to-treat analyses. Study recruitment occurred from November 2020 to September 2022, during the COVID-19 pandemic when many stressors and barriers to PA were heightened [63], which may have reduced motivation for and interest in PA. This was also when many other online PA offerings were becoming available, which may have been more attractive to participants, resulting in low engagement with the MomZing intervention and highlighting potential needs for improvement in production value and content of the website. Finally, retention for follow-up assessments was a challenge, likewise potentially due in part to the challenges of the COVID-19 pandemic; however, multiple imputation mitigated this limitation.

In conclusion, an eHealth PA intervention tailored to postpartum individuals did not change PA, mental health, sleep quality, perceived stress, mother-infant bonding, or infant development among those at high risk for PPD. Additional research, including qualitative data, to develop effective and engaging PA interventions for this population is needed to help alleviate PPD symptoms and decrease PPD risk.

Acknowledgments

The authors would like to thank Julia Koo for her editorial assistance. The research reported in this publication was supported by the Kaiser Permanente Exercise as Medicine Research Program. The funding organization had no role in the design and conduct of the trial; collection, management, analysis, and interpretation of the data; preparation, review, or approval of the manuscript; or decision to submit the manuscript for publication.

Authors' Contributions

SEB and LAA were responsible for study concept, study design, funding acquisition, and statistical analysis. SEB drafted and revised the manuscript. NO designed the study tracking system, collected data, and conducted statistical analysis. MR was involved in data collection, supervision of the study team, and study design modification. LGC participated in data collection. EK was involved in supervision of the study team. CPQ consulted regarding study design and statistical analysis. CLA designed the eHealth intervention (MomZing) and contributed to study design. SDB and MB contributed to study design. All authors critically reviewed the manuscript for important intellectual content.

Abstract

Background: The prevalence of adolescent mental health conditions such as depression and anxiety has significantly increased. Despite the potential of machine learning (ML), there is a shortage of models that use real-world data (RWD) to enhance early detection and intervention for these conditions.

Objective: This study aimed to identify depression and anxiety in adolescents using ML techniques on RWD and social determinants of health (SDoH).

Methods: We analyzed RWD of adolescents aged 10 - 17 years, considering various factors such as demographics, prior diagnoses, prescribed medications, medical procedures, and laboratory measurements recorded before the onset of anxiety or depression. Clinical data were linked with SDoH at the block-level. Three separate models were developed to predict anxiety, depression, and both conditions. Our ML model of choice was Extreme Gradient Boosting (XGBoost) and we evaluated its performance using the nested cross-validation technique. To interpret the model predictions, we used the Shapley additive explanation method.

Results: Our cohort included 52,054 adolescents, identifying 12,572 with anxiety, 7812 with depression, and 14,019 with either condition. The models achieved area under the curve values of 0.80 for anxiety, 0.81 for depression, and 0.78 for both combined. Excluding SDoH data had a minimal impact on model performance. Shapley additive explanation analysis identified gender, race, educational attainment, and various medical factors as key predictors of anxiety and depression.

Conclusions: This study highlights the potential of ML in early identification of depression and anxiety in adolescents using RWD. By leveraging RWD, health care providers may more precisely identify at-risk adolescents and intervene earlier, potentially leading to improved mental health outcomes.

Introduction

The United States is experiencing a national health emergency as rates of childhood and adolescent mental health conditions, including depression and anxiety, doubled during the COVID-19 pandemic [1,2]. An estimated 49.5% of individuals experience a mental health concern in their lifetime, and nearly half of those cases occur by the age of 14 [3,4]. Mental illnesses with significant impairment affect approximately 1 in 4 adolescents [5]. Consequently, new and innovative strategies for early detection are critical [6]. However, early detection and access to early intervention are often limited due to a lack of specialized knowledge and resources [6]. The United States alone has an estimated deficit of 4.5 million trained mental health clinicians [6]. As a result, about half of the adolescents with mental health problems do not obtain mental health services despite having treatable conditions. Given the shortage of mental health specialists, primary care clinicians are a critical access point for screening and early treatment of pediatric mental health conditions [7]. This increased demand for mental health care, along with the already limited time available in routine primary

XSL•FO
RenderX

care visits, creates the need for innovative approaches to support longitudinal care beyond the clinic.

Machine learning (ML) in health care provides flexibility and scalability in assimilating and evaluating large volumes of complex data, including those found in electronic health records (EHR) [8]. The EHRs span multiple domains beyond clinical tests and diagnoses, including social determinants of health (SDoH) such as education, economic circumstances, and social environment, all of which can significantly impact adolescents' mental health and well-being [9-12]. Growing evidence suggests that ML algorithms can facilitate the early detection of symptoms such as depression [13]. Incorporating SDoH data into the predictive models for depression and anxiety in adolescents can potentially identify those who are at higher risk, which can have a significant impact on the practice of medicine by providing more accurate diagnoses and timely interventions.

Previous research has shown that SDoH are significantly associated with adolescent mental health outcomes [14]. Factors such as socioeconomic status, education, neighborhood environment, and access to health care contribute to disparities that impact mental well-being. Adolescents from low-income families are often affected by stressful environments and limited access to mental health services, driving increased rates of anxiety and depression [15-19]. In addition, educational environments can play a critical role; schools with abundant resources can promote better mental health among students [20]. Studies have also indicated that community factors such as social support and community engagement can improve resilience and mitigate adverse mental health outcomes. For instance, adolescents who experience a sense of belonging and trust within their community are less likely to experience severe mental health issues [21].

Despite this established association between SDoH and adolescent mental health, further research is needed to develop and improve ML models that effectively incorporate these SDoH factors. In the past, mental health research has mainly relied on questionnaires and neuroimaging data. While the use of EHR data shows promise, it has not been widely used in this area of research. This gap emphasizes the necessity for further exploration and innovation in leveraging EHR data to improve the accuracy of ML-driven mental health models for children.

Methods

Study Population and Outcome Variables

This retrospective research study used data from the University of Florida Integrated Data Repository (UF-IDR); it included only adolescents aged 10 - 17 years. Patients diagnosed with anxiety or depression were identified using the *ICD-10* (*International Statistical Classification of Disease and Related Health Problems, 10th Revision*), as shown in Table 1. Controls were matched to targeted cases based on age and sex in a ratio of 3:1.

Table . Description of *ICD-10* codes used to identify the target cohort.

ICD-10 codes	Description
F32	Major depressive disorder, single episode
F33	Major depressive disorder, recurrent
F34	Persistent mood disorders
F40-48	Anxiety, dissociative, stress-related, somatoform, and other nonpsychotic mental disorders
F93	Emotional disorders with onset specific to childhood

Ethical Considerations

The study was reviewed and approved by the Institutional Review Board of the University of Florida (IRB202301144). The study used existing data for secondary analysis, and primary consent was obtained previously. Therefore, additional consent was not obtained in this case. The data was deidentified and the participants were not compensated in any manner.

Predictive Features

Predictive features in this study encompassed a variety of factors, including demographics, prior diagnoses, prescribed medications, medical procedures, and laboratory measurements recorded before the first episode of anxiety or depression. Additionally, SDoH features were incorporated from the National Historical Geographic Information System. These block-level SDoH features included employment rate, poverty level, educational attainment, health insurance coverage, household computer and internet access, and median household income. A comprehensive list of features is provided in Table S1 in Multimedia Appendix 1.

Area Deprivation Index

The area deprivation index (ADI) assesses community deprivation and its impact on health outcomes and helps develop policies and health care utilization strategies [22]. Studies have shown that living in a disadvantaged area may have negative effects on health similar to certain chronic diseases [22]. The Centers for Medicare & Medicaid Services incorporate the ADI in their strategies. In this study, we used the ADI to examine community-level disparities. This index is calculated at the US Census block group level and represents neighborhoods of approximately 6003000 residents. This level of detail provides a localized view of health-related social and geospatial determinants [23]. We assigned ADI ranks to patient addresses based on their Florida residential Census block group, sourced from their 9-digit ZIP codes. Higher ADI ranks indicate greater social disadvantage.

Data Linkage

To integrate EHR data from the UF-IDR with Census data from National Historical Geographic Information System, we followed a systematic process that used geographic identifiers (GEOIDs). First, we used patient addresses from the UF-IDR to acquire geographic coordinates (ie, latitude and longitude). These coordinates were then matched to Census block groups using GEOIDs that are unique numeric codes assigned to all geographic areas tabulated by the Census Bureau. Block Groups are divisions of Census tracts, typically containing 600-3000 people and are identified by the first digit of their four-digit Census block number. To merge the EHR and Census datasets, we made use of GEOIDs. By using the RStudio software (version 2024.12.0+467; R Foundation for Statistical Computing), *tigris* package (version 2.1), the function "call_geolocator_latlon'" converted latitude and longitude into corresponding Census tracts and blocks, providing the necessary GEOID. This GEOID then enabled us to combine patient data with Census block group data; each patient ID was associated with pertinent Census information. The ADI were linked at the block group level using Federal Information Processing Standards codes, equivalent to GEOIDs. This integrated dataset allowed for comprehensive analysis by merging detailed demographic and socioeconomic data from Census blocks with patient health records.

Data Processing

We transformed the original codes of patients' diagnoses and medical procedures into clinically meaningful categories using the Clinical Classification Software; only diagnoses, procedures, and medications present in at least 5% of patients were considered. Categorical variables were encoded to facilitate their inclusion in the analysis, and numerical variables were scaled using a standard scaler to ensure consistency across different scales. We used k-nearest neighbors imputation to address missing data. The SDoH variables had a maximum of 7% missingness per block group, while vital signs data had a substantial 20% missing data rate. We excluded patients with more than 50% missing SDoH variables or those without mapped ADI, resulting in a final dataset of 52,054 patients. Outliers in laboratory values were identified using the IQR method, which is calculated as the difference between the third quartile and the first quartile , was used to define outliers as values below Q1 - 1.5 * IQR or above Q3+1.5 * IQR. These identified outliers were replaced with the median value of the respective laboratory test, as the median is less sensitive to extreme values and provides a more robust measure of central tendency.

Feature Selection

We followed a three-phase feature selection approach to eliminate features that did not significantly contribute to predicting the outcomes. First, we examined the association between each predictor and the target outcome using χ^2 test for categorical features and *t*-test or Wilcoxon rank-sum test for continuous features, depending on normality assumptions. Features that did not exhibit significant differences between the two groups were eliminated. Second, we calculated pair-wise correlations between features and removed highly correlated ones (r>0.7) to mitigate multicollinearity. Finally, we performed the least absolute shrinkage and selection operator regression to further reduce this feature space. We examined different regularization strengths and selected the one that achieved the highest area under the receiver operating characteristic curve (AUC) for predicting the outcome.

Machine Learning Model Development

We used Extreme Gradient Boosting (XGBoost), a robust ML framework known for its efficiency, flexibility, and portability [24]. It is an ensemble learning algorithm based on the gradient boosting framework, in which models are built sequentially to boost (ie, increase) the performance of the previous models by using the gradient descent algorithm to minimize errors [24]. Our selection of XGBoost is based on simplified interpretability and the inclusion of feature selection as part of the model-building process. XGBoost exhibits various advantages that make it a compelling alternative to conventional statistical techniques and other ML algorithms.

To address our research objectives, we developed 9 ML models based on the outcome and the type of predictor included. The first 3 models used all features to predict depression, anxiety, and both anxiety and depression together. The next three models replaced individual SDoH features with the ADI as a single representation of SDoH. The final three models conducted a sensitivity analysis by excluding SDoH entirely to evaluate its impact on predicting anxiety and depression and to assess its effect on the performance of the models for these mental health conditions.

Model Performance and Evaluation

We used a 5×5 nested cross-validation technique to evaluate our ML models. This technique consisted of 5 outer and 5 inner folds. For each outer fold, we set aside one-fifth of the patient records as an independent testing set, while the remaining four-fifths formed the training set. This outer training subset was then split into 5 inner folds for further validation. Each inner fold served as a standalone validation set, while the other 4 functioned as the training set for the inner loop. The inner loop was responsible for training the models and fine-tuning the hyperparameters, using a methodical approach while searching for the model's ideal hyperparameter settings. Meanwhile, the outer loop estimated errors and evaluated generalization capabilities. To optimize hyperparameters, we used a grid search strategy to systematically explore various combinations of predefined hyperparameters to train our models. We calculated and reported the mean and standard deviation for metrics such as AUC, accuracy, sensitivity, and specificity across the five outer folds. This thorough approach boosts confidence in the models' generalizability and scalability.

Model Interpretation and Feature Ranking

We used the Shapley additive explanation (SHAP) method to explain the functioning of our trained ML models. The SHAP is a widely used model-agnostic explanatory approach that helps in understanding the outputs of the ML model. We created a SHAP summary plot to demonstrate the importance of features and their impact on the outcome. This impact is shown through a sign and magnitude, where the SHAP value's sign indicates

XSL•FO
RenderX

the direction of the feature's impact on the outcome (eg, a positive SHAP value indicates that the feature in question increases the likelihood of frailty), while its magnitude reflects the feature's predictive influence.

Results

The study encompassed a total of 52,054 patients, among whom a subset exhibited symptoms of anxiety, depression, or both conditions concurrently. Out of the total cohort, 12,572 patients were identified as experiencing anxiety, 7812 patients were diagnosed with depression, and 14,019 patients presented with anxiety or depression. Using this dataset, 3 distinct models were trained for each condition: anxiety, depression, and anxiety or depression.

Table 2 shows the predictive performance of the ML models. The model predicting both depression and anxiety achieved an AUC of 0.78. The model focusing on depression alone showed an AUC of 0.81, and the model concentrating on anxiety alone recorded an AUC of 0.80. The models built using only the ADI achieved similar performance, as shown in Table 3. When excluding SDoH, the performance of the ML models remained largely unaffected, as shown in Table 4. The model predicting both depression and anxiety achieved the same AUC of 0.78, the depression model maintained the AUC of 0.81. However, the performance of the anxiety model alone slightly decreased to an AUC of 0.78.

A sensitivity analysis was conducted by removing demographic features from the model for predicting the composite outcomes while incorporating SDoH features. The model achieved a slight decline in performance with a mean accuracy of 0.71, balanced accuracy of 0.67 , sensitivity of 0.60 (SD 0.01), specificity of 0.75 (SD 0.01), and AUC of 0.75 (SD 0.01).

Figure 1 shows the distribution of anxiety and depression with respect to ADI. In the lower (advantaged) ADI national rank bins (0-20 and 20-40), the frequency of individuals with depression or anxiety is higher than those without these conditions. As the rank increases (40-60, 60-80, and 80-100), the frequency of both groups increases; however, the proportion of individuals without depression or anxiety becomes more significant. The highest (disadvantaged) ADI national rank bin (80-100) shows the largest frequencies for both groups, with a higher representation of individuals without depression or anxiety.

Figure 2 shows the SHAP summary plot, which identifies various important features contributing to the prediction of anxiety and depression in adolescents. Key predictors include gender (with females being more vulnerable), race (showing a higher likelihood in White adolescents), and educational attainment (both high school diploma or General Educational Development and less than high school education). Additionally, medical indicators such as BMI, systolic and diastolic blood pressure, heart rate, and temperature, along with procedural and diagnostic factors, were found to be influential. Notably, adolescents with neurodevelopmental disorders or connective tissue diseases, along with those undergoing frequent diagnostic imaging or specific vaccinations, displayed a higher propensity for anxiety and depression. Figure 3 shows the SHAP summary plot for the model predicting both depression and anxiety while replacing the individual SDoH features with the ADI, which ranked 14th in importance among other features.

Figure 4 presents the SHAP summary plot for the ML model, which combines both depression and anxiety while excluding SDoH predictors. Overall, there were slight changes in the list of important predictors. Additionally, Figures S1-S3 in Multimedia Appendix 1 display the SHAP summary plots for the individual ML models predicting depression with SDoH, ADI only, and without SDoH, respectively. Figures S4-S6 in Multimedia Appendix 1 display SHAP summary plots for the individual ML models predicting anxiety with SDoH, ADI only, and without SDoH, respectively.

Table . Predictive performance of ML models (presented as mean, SD) by incorporating SDoH features. The reported performance is presented using mean and standard deviation from the five outer folds.

	Accuracy, mean (SD)	Balanced accuracy, mean (SD)	Sensitivity, mean (SD)	Specificity, mean (SD)	AUC,[a] mean (SD)
Depression and anxiety	0.73 (0)	0.70 (0.01)	0.65 (0.01)	0.75 (0.01)	0.78 (0)
Depression	0.76 (0.01)	0.73 (0)	0.68 (0.02)	0.78 (0.01)	0.81 (0.01)
Anxiety	0.75 (0.01)	0.72 (0)	0.66 (0.02)	0.78 (0.01)	0.80 (0)

[a]AUC: area under the curve.

Table . Predictive performance of ML models by incorporating ADI only. The reported performance is presented using mean and standard deviation from the five outer folds.

Discussion

Principal findings

Our study findings show that incorporating SDoH features, or ADI did not improve the predictive accuracy of the ML models for depression, anxiety, or a combination of both. While SDoH factors influence individuals' health, their contribution to the model's predictive performance was limited. Individuals with depression or anxiety were more prevalent in areas with lower (advantaged) ADI rankings. In contrast, in higher (disadvantaged) ADI areas, the overall number of individuals with and without mental health conditions increased, but the proportion of individuals without depression or anxiety was greater. This suggests that area deprivation is associated with mental health issues but is not a sole determinant. The lack of improvement in model performance with the inclusion of SDoH features may be attributed to using community-level data, which does not account for individual differences. Future studies should explore individual-level SDoH data, potentially extracted from clinical notes, to improve the detail and predictive accuracy of ML models.

The results emphasize the significant impact of various factors on adolescents' mental health. The higher prevalence of anxiety and depression among female and White adolescents may reflect the influence of social, cultural, and systemic stressors. For women, societal pressures, gender-based expectations, and hormonal factors may contribute to higher rates of anxiety and depression. For White adolescents, the observed prevalence may be linked to differential access to mental health diagnoses or treatment, health care–seeking behaviors, or unmeasured cultural stressors. Future studies should explore these patterns in detail, accounting for intersectionality and regional differences. The strong effect of educational attainment highlights the importance of supportive educational environments in reducing mental health risks. Medical factors including heart rate, systolic and diastolic blood pressure, and temperature were notable predictors. These physiological measures may indicate stress or comorbid health conditions that influence mental health. The inclusion of variables such as prophylactic vaccinations and inoculations and "routine chest X-ray suggests a potential relationship between health care utilization and mental health outcomes, possibly reflecting access to health care services. Additionally, neurodevelopmental disorders showed a strong impact on mental health predictions, emphasizing the need to address comorbidities in this population.

Furthermore, the ML models performed better in predicting individual mental health conditions (ie, anxiety or depression) than in predicting both conditions combined. This observation could be attributed to the increased complexity and variability when dealing with multiple conditions simultaneously. Overlapping symptoms may lead to reduced overall performance, and predictive features for one condition may not be as relevant for the other. Focusing on a single condition allows the model to optimize its parameters specifically for that condition and improve performance.

Our study differs from previous research that has primarily relied on questionnaires and neuroimaging data as model outcomes by using EHR data, which, though common, is less frequently applied in adolescent mental health research. For instance, Zhang [25] developed a hybrid convolutional neural network and long short-term memory model trained on a large clinical dataset, including neuroimaging data to predict mental

XSL•FO
RenderX

health risks in adolescents. This approach provides valuable insights but focuses on neuroimaging data, which differs from our use of EHR data to address population-level mental health risks. Both approaches contribute uniquely to advancing predictive models in adolescent mental health research. Most studies on adolescent mental health have primarily focused on identifying suicidal attempts or thoughts[26-28], with relatively little focus on addressing conditions such as depression or anxiety in this age group. For example, a study by Sacco et al [29] used EHR data to model suicide risk in the youth but did not specifically address depression or anxiety. Our models achieved AUC values ranging from 0.78 to 0.81, consistent with the 0.8 average reported in a recent review by Nickson et al [30]. Notably, SDoH have not been thoroughly examined in models targeting depression or anxiety in adolescents specifically or in the overall general population.

While our study focuses on data from Florida, USA, it is important to recognize that the prevalence and predictors of depression and anxiety among adolescents vary across different regions and countries. Cultural, social, and health care system differences significantly influence these variations. For instance, a study analyzing data from the Global Burden of Disease Study 2019 found that the prevalence of depression among adolescents and young adults has been rising globally, with notable differences across regions. High-income regions such as North America have experienced significant increases in age-standardized rates for depressive disorders [31]. Additionally, research comparing adolescent mental health in the Nordic countries revealed that socioeconomic inequalities contribute to variations in mental health outcomes. Sweden, for example, exhibited higher rates of mental health problems among adolescents compared to other Nordic countries, potentially due to greater income inequality and higher at-risk-of-poverty rates [32]. These findings suggest that factors such as income inequality, cultural norms, and access to health care services play a crucial role in shaping adolescent mental health outcomes across different regions. Our findings of higher prevalence rates of depression and anxiety among female and White adolescents may align with trends in other high-income countries; however, these patterns can differ in regions with varying socioeconomic structures and cultural contexts.

Limitations

Our study has several limitations. The data on SDoH and ADI were collected at the community level, which may have obscure significant individual-level differences and reduce the accuracy of our model. Additionally, our models were built using data from a specific group of people and health care system, so it is unclear how well they can generalize to other health care systems with different demographics and SDoH characteristics. The data was gathered at a single point in time; therefore, they do not capture the changing nature of mental health conditions. Additionally, we noticed a higher likelihood of anxiety and depression among White and female adolescents, consistent with the distribution in Florida, which could be influenced by biases in the data or health care system. This pattern warrants further investigation to address potential systemic or reporting biases and to understand unique stressors affecting these groups.

Future research should focus on incorporating longitudinal data to better understand the progression of mental health conditions over time. Additionally, leveraging individual-level SDoH data, such as those derived from clinical notes or surveys, may enhance the predictive accuracy of models. Future studies examining a broader range of demographic and regional settings are also necessary to assess the generalizability of findings. Furthermore, exploring multimodal data sources including genetic, behavioral, and social media data may provide deeper insights into the complex interplay of factors influencing adolescent mental health. Incorporating external validation by testing predictive models on independent datasets from diverse populations and health care systems will be critical for ensuring the reliability and robustness of findings. Finally, targeted studies to understand the intersectionality of race, gender, and socioeconomic status in mental health outcomes are essential to designing equitable and effective interventions.

Conclusion

This study emphasized the potential of ML in the early detection of depression and anxiety in adolescents using EHRs. It also examined the additive value of community-level SDoH in improving the model's predictive power. Our models achieved relatively high performance; however, incorporating SDoH did not improve predictive accuracy. This suggests that more detailed, individual-level data may be necessary to enhance predictive power. The implications of this study for clinical practice and decision-making are meaningful; using RWD from EHRs could enable health care providers to more accurately identify at-risk adolescents and intervene earlier, potentially improving mental health outcomes. The ML models that facilitate early detection could allow for prompt mental health interventions, likely enhancing outcomes and lessening the impact of untreated mental health issues. Future studies should focus on integrating individual-level social determinants of health data and validating these models within varied populations to optimize their effectiveness and applicability in clinical and public health environments.

Abstract

Background: Although suicide bereavement is highly distressing and is associated with an increased risk of suicidal behaviors and mental and physical health impairments, those bereaved by suicide encounter difficulties accessing support. Digital resources offer new forms of support for bereaved people. However, digital resources dedicated to those bereaved by suicide are still limited.

Objective: This paper aimed to develop and implement an evidence-based, innovative, and adaptive online resource for people bereaved by suicide, based on their needs and expectations.

Methods: We performed a mixed methods, participatory, user-centered study seeking to build resources from the perspectives of people bereaved by suicide and professionals or volunteers working in the field of postvention. We used the Information System Research framework, which uses a three-stage research cycle, including (1) the relevance cycle, (2) the design cycle, and (3) the rigor cycle, and the Design Science Research framework.

Results: A total of 478 people participated in the study, including 451 people bereaved by suicide, 8 members of charities, and 19 mental health professionals working in the field of postvention. The development stage of the resource lasted 18 months, from October 2021 to March 2023. A total of 9 focus groups, 1 online survey, 30 usability tests, and 30 semistructured interviews were performed. A website for people bereaved by suicide named “espoir-suicide” was developed that includes (1) evidence-based information on suicide prevention and bereavement, (2) testimonies of people bereaved by suicide, (3) a delayed chat to ask questions on suicide and bereavement to a specialized team of mental health professionals, and (4) an interactive nationwide resource directory. The mean system usability score was 90.3 out of 100 for 30 participants, with 93% (n=28) of them having a rating above 80. Since the implementation of espoir-suicide in March 2023, a total of 19,400 connections have been recorded, 117 local resources have been registered nationwide, and 73 questions have been posted in the chat.

Conclusions: The use of a mixed methods, participatory, user-centered design allowed us to implement an evidence-based, innovative, and functional website for people bereaved by suicide that was highly relevant for fulfilling the needs and expectations of French people bereaved by suicide.

Introduction

Each year, approximately 700,000 individuals die by suicide worldwide [1]. Approximately 7 million relatives are bereaved by suicide in the aftermath [2]. Suicide bereavement is highly distressing and is associated with an increased risk for suicidal behaviors, as well as mental and physical health impairments [3,4]. Nevertheless, those affected by suicide bereavement encounter unmet needs, including difficulties accessing informal or formal support after their bereavement [4,5]. The social stigma surrounding suicidal behaviors and bereavement is associated with high levels of loneliness and lack of social support [6]. In France, the suicide rate has been on a downward trajectory for more than 30 years, although it remains higher than the global and European averages [7]. In 2014, the government introduced a national suicide prevention strategy, which has yielded encouraging outcomes. However, the resources available to those who have lost a loved one to suicide remain limited, prompting the exploration of digital resources as a potential avenue for supporting suicide survivors in France.

Digital resources are currently changing the way we experience death and grief by offering new forms of support to people who have lost loved ones [8]. They include online forums, online support groups, mailing groups, online memorials, or online interventions such as online peer-support groups or online psychotherapeutic counseling [9]. A recent systematic review on 11 studies demonstrated that the internet and social networks are frequently used by individuals bereaved by suicide [9], as online resources promote 24×7 access to help and support for everyone, including people who can be far from health care services. Furthermore, it offers some benefits, such as easy and unlimited access, anonymity, a nonjudgmental space, and direct access to other people bereaved by suicide [9]. For example, Kramer et al [10] reported in a longitudinal cohort of 270 participants in the Netherlands a significant increase in well-being and a decrease in depressive symptoms at 12 months after using an online forum for people bereaved by suicide. In Sweden, Westerlund [11] conducted a cross-sectional survey in Sweden on 370 participants to investigate potential predictors of satisfaction with psychosocial health after using an online support group or an online memorial for suicide bereavement. Online support group activity was found to be significantly associated with satisfaction regarding psychosocial health, while memorial website activity showed a tendency to a negative association. A recent German study also reported that completing an online group intervention for the suicide bereaved could significantly reduce trauma-related outcomes [12].

However, resources dedicated to those bereaved by suicide are still limited, and the assessment of their relevance and effectiveness remains scarce [9,13]. In addition, to our knowledge, none of the existing resources have been designed or implemented based on an evidence-based process involving participants with lived experience of suicide bereavement [9]. However, the participation of people with lived experience in research, especially concerning mental health and suicide bereavement, is essential for developing a well-accepted and effective postvention tool reaching the needs and expectations of people bereaved by suicide [14].

Hence, the main objective of our study was to develop and implement an innovative and ergonomic online resource for French people bereaved by suicide, aligned with their needs and expectations toward digital resources after bereavement.

Methods

Overview

The protocol of the study has been exhaustively described in a study by Leaune et al [15]. We conducted a mixed methods, participatory, user-centered study seeking to build resources from the perspectives and needs of people bereaved by suicide and professionals or volunteers working in the field of postvention. We used the Information System Research (ISR) framework to guide the design of the study [16]. The ISR framework uses various design processes to build a product or design an artifact, such as a mental health online resource. According to the literature on the ISR [16], a three-stage research cycle was planned, including (1) the relevance cycle, (2) the design cycle, and (3) the rigor cycle. Our 3-stage research cycle also aligns with the Design Science Research (DSR) framework, which is defined as “a qualitative research approach in which the object of study is the design process, i.e. it simultaneously generates knowledge about the method used to design an artifact and the design or the artifact itself” [17]. The DSR has been demonstrated to be an effective approach for the development of mobile health digital resources. It involves a series of cyclical steps, beginning with the identification of a problem and ending with the communication of the solution [18]. These steps include defining the solution, establishing the solution objective, developing and evaluating the solution, and demonstrating it. Our study aligns perfectly with the DSR methodology. We used a combination of qualitative and quantitative data to identify the needs of people bereaved by suicide; define the solution and its objective; and develop, evaluate, and communicate an adapted solution. The study also aimed to generate insights into the methodology used, the efficacy of a participatory approach, and the challenges encountered in designing an online resource in the context of bereavement and mental health.

RenderX

Mixed Methods Evaluation

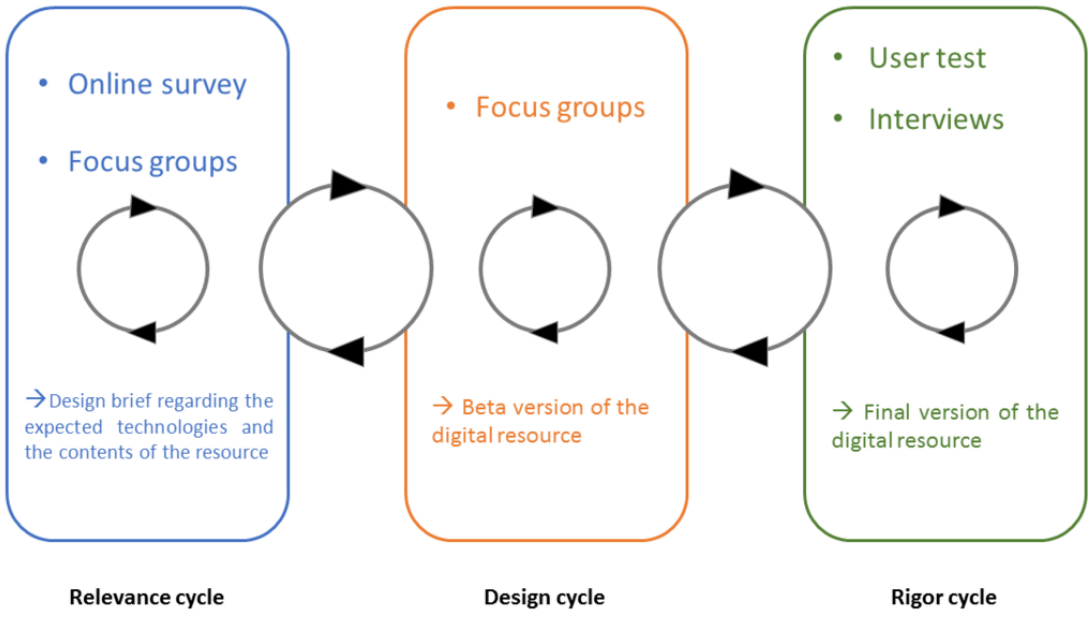
Mixed methods studies have been shown to be effective in evaluating the implementation of new prevention and intervention programs in mental health [19]. A mixed methods design focuses on collecting, analyzing, and merging both quantitative and qualitative data into one study. According to the taxonomy of mixed methods studies described by Palinkas et al [19], the structure of the study relied on a sequential and complementary collection of qualitative and quantitative data.

User-Centeredness

The participation of people bereaved by suicide in the 3 cycles of the study aimed to ensure the user-centeredness of both the resource development and the research process. Their active participation throughout the entire research and design or implementation process was expected to offer a unique means to develop an innovative and adaptive resource that meets their needs and expectations. The participation of the other stakeholders (health professionals, associations, and peers) was expected to offer a better understanding of bereaved people's needs. The coproduction of information on suicide bereavement and digital resources enables users to use and distribute their experiential knowledge, skills, and expertise with researchers and other participants [20]. By interacting, the team inaugurated a culture of empowering practices that let users freely express themselves and make impactful contributions to the research process [21]. The study's participatory design was ensured through the establishment of an environment promoting equality, equity, and empowerment.

Inclusion and Exclusion Criteria

French adults bereaved by suicide were eligible to participate in the 3 stages of the study, whatever the duration since loss and the kinship with the deceased. Health care professionals, social workers, or volunteers working in postvention units or charities dedicated to bereavement were also eligible for participation in stages 1 (excluding the survey) and 2 (focus groups). They should have been at work or volunteering in the field of suicide bereavement and postvention for at least 1 year. People younger than 18 years of age and people bereaved by causes other than suicide were excluded from the study.



The survey (stage 1) and all the focus groups (stages 1, 2, and 3) were administered online to include people nationwide. In stage 3, some of the user tests were conducted on-site, and the other test was conducted under ecological conditions on their own devices from their homes. The tests were conducted either on smartphones or on a computer.

For the 3 stages, participants were recruited through social media and charities dedicated to suicide bereavement. A purposive snowballing recruitment process was used to construct a convenience sample covering a broad range of sociodemographic profiles. No incentive was offered for participation in the study.

Data Collection

According to the mixed methods research design of the study, quantitative and qualitative data were sequentially and complementarily collected through a 3-stage process to obtain an in-depth evaluation of the implementation of the online resource. Quantitative and qualitative data were collected and analyzed during (1) the relevance cycle through an online questionnaire and focus groups, (2) the design cycle through focus groups, and (3) the rigor cycle through an online questionnaire and semistructured interviews (Figure 1).

Figure 1. The Information System Research framework used in the ESPOIR2S study.

XSL•FO
RenderX

Stage 1: Relevance Cycle

The relevance cycle aimed to understand the environment of the end user by determining requirements. The needs and expectations of people bereaved by suicide, professionals, and volunteers working in the field of postvention were collected through an online questionnaire and a series of focus groups.

A 26-item online questionnaire was built according to a recent systematic review of digital resources for suicide bereavement [9] and was hosted on the website Lime Survey. The questionnaire collected sociodemographic characteristics and evaluated four dimensions: (1) perceived needs regarding suicide bereavement, (2) use of online resources associated after suicide loss, (3) needs and expectations regarding the development of online digital resources for people bereaved by suicide, and (4) personal propositions regarding the development of online digital resource for people bereaved by suicide. We determined that the participation of 385 respondents would permit us to estimate a proportion with a 95% CI and a 5% error margin, as determined in a previous study [22]. The questionnaire was subsequently sent to participants through social media and through associations for people bereaved by suicide. Purposive snowballing sampling was used to access the link to the online questionnaire to the maximum number of putative participants.

The focus groups included 3 categories of participants—people bereaved by suicide, postvention professionals, and volunteers working in the field of bereavement and postvention. To obtain the perspectives of all the stakeholder profiles, we adopted a maximum variation recruitment process to constitute our focus groups. To facilitate the participatory process, each focus group was led by 2 researchers (a facilitator and an assistant; KB and PL-T) and organized through the process, such as (1) work objectives, (2) emerging needs and expectations, (3) hypotheses and concepts, (4) putative solutions, and (5) conclusions [23]. No guide was used for the focus groups. The content of the focus group was recorded and anonymized. The needs and expectations of people bereaved by suicide were collected and synthesized to construct a brief overview of digital resources. The data collected during the relevance cycle aimed to inform the design brief regarding the expected technologies and the contents of the resource.

Stage 2: Design Cycle

The design cycle aims to produce digital resources by compiling qualitative and quantitative data collected during the relevance cycle through an iterative process of building and evaluating digital resources.

Focus groups were established with people bereaved by suicide, members of associations for bereaved people, postvention professionals, and web designers from a startup specialized in eHealth solutions. Again, each focus group was led by 2 researchers (KB and PL-T) with no guidance, which led to the redaction of specifications or adjustments of the resource, based upon which the web designers progressively and iteratively designed a prototype of the digital resource. The iterative feedback of participants on the resource and its final validation ensured the incremental design of an online resource adapted to the needs and expectations of people bereaved by suicide and stakeholders. The content of the focus group was recorded and anonymized. A pilot of the online resource was expected to be designed and built at the end of the design cycle before its evaluation during the rigor cycle.

Stage 3: Rigor Cycle

The rigor cycle served as the final evaluation and aimed to evaluate the acceptability and the perceived effectiveness of the online resource by the users.

Quantitative analysis

The French version of the System Usability Scale (SUS) [24] was used to assess (1) satisfaction with the resource and (2) acceptability of its design and content. The SUS is a 10-item Likert-scale questionnaire that provides a global view of the subjective assessment of a system's usability [24]. The SUS scores range from 0 to 100 (scores range from 0 to 10 for each item) [24]. A score above 70 indicates good acceptability of a resource, and a score above 80 indicates very good acceptability [25]. We concluded that acceptability was reached if at least 80% (24/30) of the respondents rated the acceptability of the SUS above 80.

Qualitative analysis

Semistructured interviews were also performed with the participants to qualitatively assess the accessibility and perceived effectiveness of the resources. The participants were questioned about their perception of the online resource (satisfaction, usability, and acceptability) and the putative modifications that they may recommend.

We also used a heuristic evaluation, which offers a quick and methodical way to identify and categorize usability problems. The participants were asked to follow scenarios when using the resource (ie, going back to the main page, finding specific content, and using specific options). To create these scenarios and to analyze the user tests, the Scapin and Bastien [26] ergonomic criteria for human-computer interfaces were used. These criteria, namely guidance, workload, explicit control, adaptability, error management, consistency, significance of codes, and compatibility, were qualitatively assessed during the heuristic evaluation and used to improve the platform.

Sample

According to the previous literature on the SUS [27,28], a total of 30 people bereaved by suicide were expected to participate in the rigor cycle. The combination of quantitative and qualitative analyses of acceptability enabled us to identify the strengths and weaknesses of our online resources to proceed (or not) further with improvements and with a larger-scale effectiveness evaluation study.

The final evaluation of acceptability and usability was based on the combination of SUS results and heuristic evaluation. The final version of the online resource was designed and built at the end of the rigor cycle before its implementation.

Additional Analyses

In order to assess the implementation and use of the online resource, a series of key performance indicators were monitored 18 months after its launch. These included the number of visits

XSL•FO
RenderX

to the online resource, the number of local resource records on the platform, and the number of questions posted on the chat.

Data Analysis

The qualitative results were combined with the quantitative results to provide a detailed overview of the acceptability of the online resources.

Quantitative Analysis

Data manipulation and analyses were performed using R software (version 3.4.1; R Core Team). Categorical variables are summarized using numbers and percentages, and quantitative variables are described using either means and SDs or medians and IQRs. For stage 1, the number of respondents, number of completed questionnaires, characteristics of respondents (age, gender, socioeconomic status, and relation to the deceased), and responses to the questionnaire were analyzed using descriptive statistics. Subgroup analyses of responses according to age category (defined according to the distribution of age of the respondents), sex, and relationship to the deceased were also conducted. A report summarizing the results was produced and presented during the focus groups. For stage 3, the characteristics of the included population were described. The main outcome criterion was the SUS score. The SUS score was described as a continuous variable by its mean (SD) and median (IQR). SUS was dichotomized as SUS>80 (very good usability) versus SUS<80 (moderate or poor usability) [25].

Qualitative Analysis

Based on the verbatims of the focus groups, semistructured interviews, or heuristic evaluation, a content analysis was performed, with several chronological phases (reanalysis, operation of equipment, and interpretation) [29]. Furthermore, 2 authors (KB and PL-T) first looked at the apparent messages through a repeated reading of the transcripts to achieve immersion and obtain a sense of the whole. In addition, this first reading allowed us to define the thematic and formal categories relevant for later coding speeches. Units of meaning were then independently identified, categorized, and put into relation to identify axes of transversal meanings. This process allowed us to classify the elements and construct a simplified representation of the raw data to obtain further quantitative data to better understand their needs.

Merging Quantitative and Qualitative Data

For the relevance cycle (stage 1), the use of qualitative and quantitative analyses provided a comprehensive understanding of the development and evolution of the needs and expectations of people bereaved by suicide and stakeholders. For the rigor cycle (stage 3), the addition of user tests using SUS and semidirected interviews permitted us to observe the problems, if any, encountered on the platform in different concrete situations.

Ethical Considerations

The study received ethical approval from the Ethical Review Board of The University Claude Bernard Lyon 1 (institutional review board approval 2021-01-12-04). The data were anonymized, and compensation was provided for travel expenses in connection with participation in the study.

Results

Total of Participants

A total of 478 people participated in the study, including 451 (94.3%) people bereaved by suicide, 19 (3.9%) mental health professionals working in the field of postvention, and 8 (1.7%) members of charities. The development stage of the resource lasted 18 months, from October 2021 to March 2023.

Relevance Cycle

A total of 417 people participated in the relevance cycle from October 2021 to February 2022; 401 participated in the online survey, and 16 participated in the focus groups.

Online Survey

A total of 401 people bereaved by suicide participated in the online survey. The results of the online survey have been exhaustively described elsewhere [30]. The characteristics of the participants are reported in Table 1. Most of them were women bereaved by the suicide of their child. A slight majority of the participants had been bereaved for less than 3 years and benefited from counseling during their bereavement process. The mean age was 45.7 years; the age range was 18 to 80 years.

XSL•FO
RenderX

Table 1. Characteristics of the participants in the survey of the relevance cycle.

Characteristics	Values (n=401), n (%)
Age (years), mean (SD)	45.7 (12.7)
Gender	
Women	354 (88.3)
Men	46 (11.5)
Nonbinary	1 (0.2)

[a]In France, psychotherapists are neither psychiatrists nor psychologists.

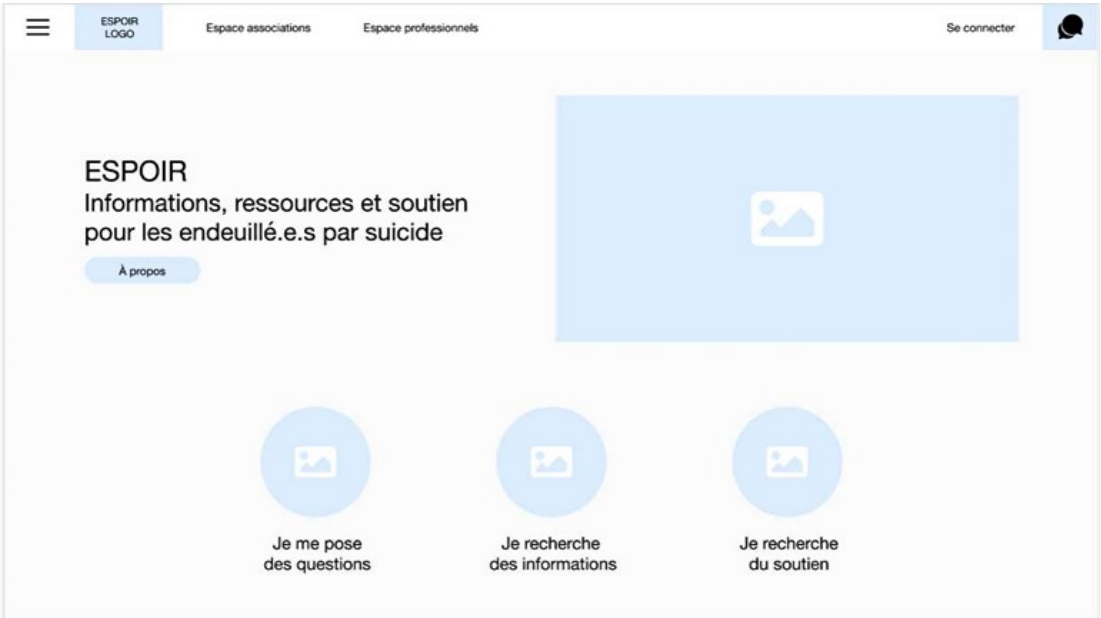
Nearly three-quarters (296/401, 73.8%) of the sample used the internet for their grief process, while nearly two-thirds (247/401, 61.6%) used social media. Regarding social media, Facebook (Meta) was used by the majority of participants (233/401, 58.1%). The participants mostly reported their use of the internet or social media as beneficial or very beneficial after bereavement—33.1% (98/296) for the internet and 31.6% (78/247) for social media. At the same time, few participants reported their use as not beneficial—9.8% (29/296) for the internet and 13.4% (33/247) for social media. The participants mainly used the internet to find information on suicide (286/296, 96.6%) and to access testimonies of other people bereaved by suicide (231/296, 78%). The use of social media was associated mainly with honoring the memories of their relative deceased by suicide (144/247, 58.3%%), accessing testimonies of other people bereaved by suicide (137/247, 55.5%), and discussing with other people bereaved by suicide (116/247, 47%).

A web platform (281/401, 70.1%) or a specific social media platform (232/401, 57.9%) was expected to be developed by the majority of the participants. Information on suicide bereavement (261/401, 65.1%) and suicide prevention (240/401, 59.9%) were the most reported expectations regarding digital

XSL•FO
RenderX

resources. Discussion with a mental health professional was also frequently expected (229/401, 57.1%), while accessing online counseling was the least frequently reported expectation (109/401, 27.2%). Access to testimonies by other people bereaved by suicide was expected by a slight majority of the participants (214/401, 53.4%). When compiling expectations in 4 dimensions, obtaining information on suicide and suicide bereavement (310/401, 77.3%) and reaching peers bereaved by suicide (263/401, 65.6%) were the most frequently reported expectations.

Focus Groups



A total of 3 focus groups were performed, including 16 people, 4 of whom were bereaved by suicide, 8 of whom were professionals working in the field of postvention, and 4 of whom were members of charities. Each focus group lasted 1-2 hours and included 4-8 participants. Through the three focus groups, the participants agreed that an online digital resource for people bereaved by suicide should (1) offer validated and relevant information on suicide, suicide prevention, and bereavement; (2) provide guidance to people bereaved by suicide; (3) be personalized and anonymous; (4) centralize existing and validated knowledge on suicide, suicide prevention, and bereavement; and (5) centralize existing resources for people bereaved by suicide.

Design Cycle

A total of 31 people participated in a total of 6 focus groups during the design cycle from February 2022 to September 2022; a total of 16 people were bereaved by suicide, 11 professionals worked in the field of postvention, and 4 professionals were members of organizations. Each focus group lasted 1-2 hours and included 4-8 participants. The focus groups mainly relied on topics, such as (1) design of the platform—feedback on the mockup of the platform (n=3) and design of the mockup (n=6); (2) content of the platform—naming the different functions (n=4), organizing information on the platform (n=3), and delayed chat (n=6). Some of these focus groups could have more than 1 topic because of the iteration process needed in a user-centered conception.

According to the results issued from the relevance cycle and from the 6 focus groups performed during the design cycle, a website was chosen for people bereaved by suicide, including features such as (1) evidence-based information on suicide prevention and bereavement, (2) testimonies of people bereaved by suicide, (3) a delayed chat to ask questions on suicide and bereavement to a specialized team of mental health professionals, and (4) an interactive nationwide resource directory. The authors selected the website “espoir-suicide” (“ESPOIR” means “hope” in French and is an acronym for People bereaved by Suicide: Platform for Orientation, Information and Resources [*Endeuillés par Suicide: Plateforme d’Orientation, Informations et Ressources*]) and designed it to offer easy access and navigation for people bereaved by suicide at any stage after the death of their relative. It also offers easy access to the national helpline for suicide prevention (3114). The beta version of the platform was built at the end of the design cycle (Figure 2) before it was evaluated by a panel of people bereaved by suicide.

Figure 2. Screenshot of the beta version. English translations: “Informations, ressources et soutien pour les endeuillé.e.s par suicide”: Information, resources and support for people bereaved by suicide; “Á propos”: About; “Je me pose des questions”: I ask myself some questions; “Je recherche des informations”: I'm looking for information; “Je recherche du soutien”: I'm looking for support.

Rigor Cycle

A total of 30 people bereaved by suicide participated in the rigor cycle from September 2022 to March 2023. Participant characteristics are displayed in Table 2. Among them, 26 were women and 20 were bereaved by the suicide of their child. The mean age was 53.5 (SD 14.7) years. The mean SUS score after the user tests was 90.3, with 93% (28/30) of the participants rating the SUS above 80.

XSL•FO

[a]SUS: System Usability Scale (score ranging from 0 to 100).

Each interview and heuristic evaluation lasted between 30 and 60 minutes. The participants reported 3 main strengths of the espoir-suicide platform in terms of guidance, workload, consistency, adaptability, and explicit control:

1. The aesthetics of the website

> *I truly love the colors. I find it sweet, it's calming. It's truly important when you go on a site like this.* [P11]
>
> *The small side springs out on the 3 features; it gives a dynamic feel; there's that bounce-back feel.* [P16]

2. The main functions

> *I cannot wait to read the answers to the chat. It lacked a site like this; it is great that professionals are answering.* [P25]
>
> *It is very, very good. I will not hide the fact that I will go back when it goes online. Looking at it like this, it seems very complete.* [P19]

3. Access to testimonies

> *It's important to see that we are not alone, to see others live the same thing as me.* [P10]
>
> *It is good that there's a little summary so that people can find what they are looking for.* [P11]

XSL•FO
RenderX

Some of the participants also reported the following limitations and needs for improvement, in terms of significance of codes, error management, and compatibility:

1. Access to home page

> *I find there's a problem on all the pages; there's no back button.* [P7]

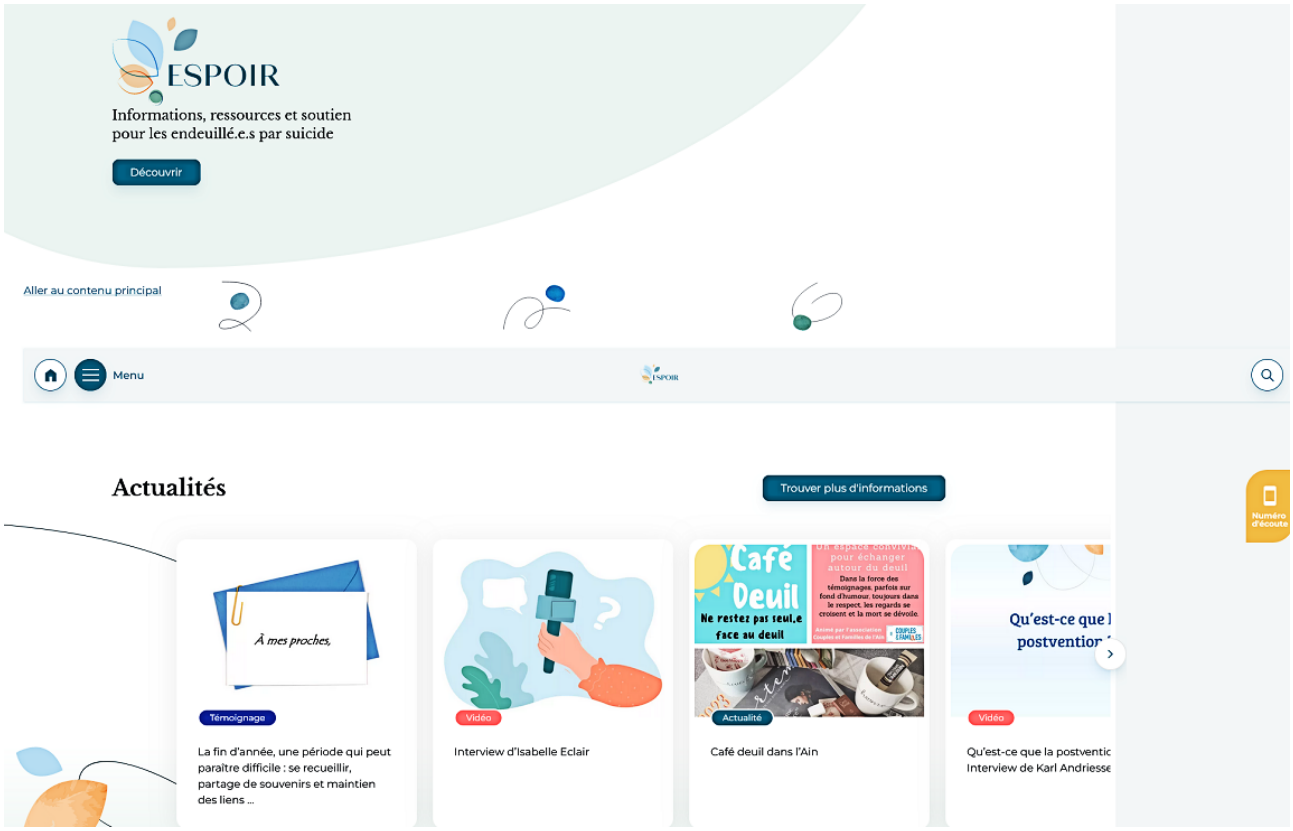
2. Visibility of favorite options

> *I cannot see where to click for the favorite options.* [P8]

3. Presentation of the national helpline for suicide prevention (3114)

> *Maybe mention it too. I'm saying this because we need to be reassured about confidentiality and anonymity. If people need to know more, there should be a small link to the national suicide helpline.* [P14]

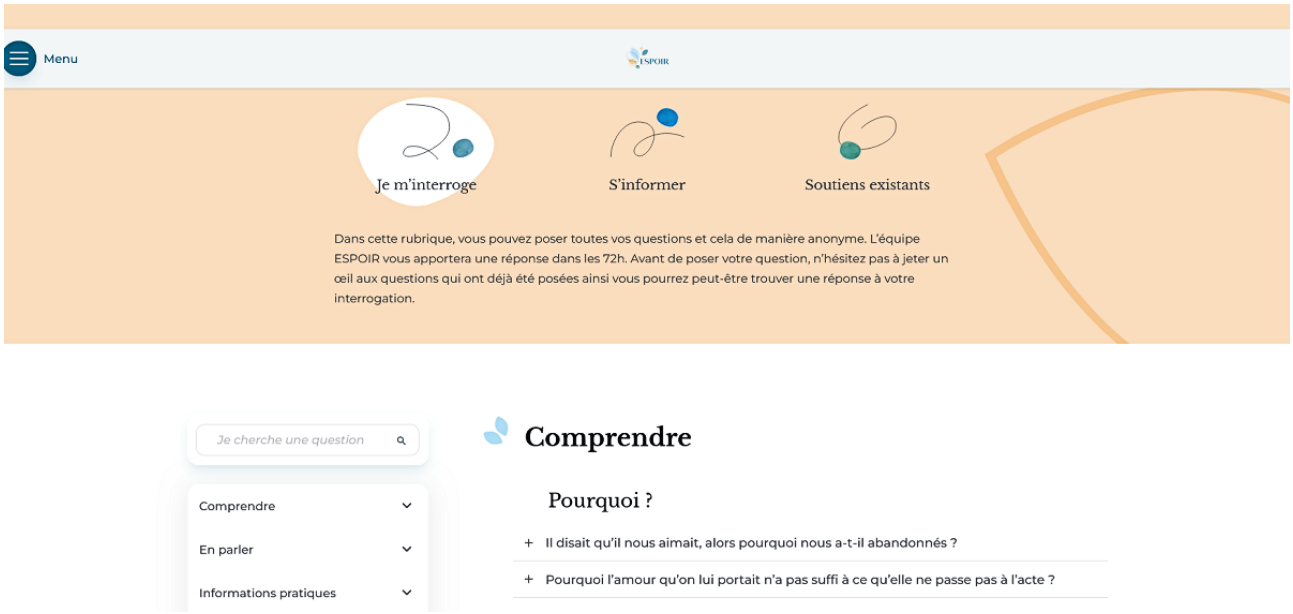
4. Need to simplify the names of some subtopics.



> *I did not understand "risk factors". Maybe put more words. The same goes for "signs of distress"; it is not clear enough.* [P24]

The espoir-suicide website was improved according to their remarks.

Implementation



The online platform "espoir-suicide" was launched in March (Figures 3 and 4). The platform was launched through media, including national newspapers, and through mental health services and charities.

Figure 3. Screenshot of the main page of the espoir-suicide platform. English translations: "Informations, ressources et soutien pour less endeuillé.e.s par suicide": Information, resources and support for people bereaved by suicide; "Découvrir": Discover; "Aller au contenu principal": Go to main content; "Actualités": News; "Trouver plus d'informations": Find more information; "Á mes proches": To my loved ones; "Témoignage"; Testimony; "La fin d'année, une période qui peut paraître diffcile : se recueillir, partage de souvenirs et maintien des liens": "The end of the year, a period that can seem difficult: reflecting, sharing memories and maintaining connections"; "Interview d'Isabelle Eclair": Interview with Isabelle Eclair; "Café deuil dans l'Ain"; Mourning café in Ain.

Figure 4. Screenshot of the chat. English translations: “Je m’interroge”: I'm wondering; “S’informer”: Get informed; “Soutiens existants”: Existing support; “Dans cette rubrique, vous pouvez poser toutes vos questions et cela de manière anonyme. L'équipe ESPOIR vous apportera une réponse dans les 72h. Avant de poser votre question, nhésitez pas à jeter un oeil aux questions qui ont déjà été posées, ainsi vous pourrez peut-être trouver une réponse à votre interrogation”: In this section, you can ask all your questions anonymously. The ESPOIR team will get back to you within 72 hours. Before sending your question, don't hesitate to have a look at the questions that have already been posted, so you may find an answer to your question; “Comprendre”: Understand; “En parler”: Talk about it; “Informations pratiques”: Practical information; “Pourquoi ?”: Why?; “Il disait qu’il nous aimait, alors pourquoi nous a-t-il abandonnés ?”: He said he loved us, so why did he leave us?; “Pourquoi l'amour qu'il nous portait n'a pas suffi à ce qu'elle ne passe pas à l'acte”: Why the love she had for us was not enough to keep her from acting on it.

Since the implementation of the resource, a total of 20,600 visits were recorded. A total of 122 local resources (including health care settings, charities, counselors, and so on) all around the country were registered on the platform to provide help and support to people bereaved by suicide in their department or region. A total of 81 questions were posed, mainly in the evenings, to the mental health team by people who were recently or long-term bereaved, covering a wide range of suicide bereavement issues (emotional effects, disclosure of suicide bereavement with others, discussions about suicide within the family, and so on). Answers were given by the mental health team 72 hours after they were posted. Here are 3 examples of questions posted in the chat:

> *My daughter was also a sister, a companion, a granddaughter, a cousin, a godmother and a friend. Does the mother-child bond and relationship result in a more specific and more tragic form of grief than that experienced in other contexts?*
>
> *My brother died by suicide 13 years ago. There’s a photo of him and me at home when we were little and my daughter, who is 9, has now realized that it was my brother in the photo. She’s started asking questions, and I have answered honestly, explaining that he died by suicide, but she’s asking very specific questions about why he did it, how he did it, who found him (I was the one who found him). I do not know how I’m supposed to answer these questions, how much detail I can give, because it seems violent for a child her age. Thank you for your help.*
>
> *When my friend died by suicide a year ago, I told the people around me that he had died in a road accident because there had already been suicides in my family and I did not want to make things worse. Is there any point in telling the truth? Thank you for your reply.*

Discussion

Summary of Results

We performed the first mixed methods, participatory, user-centered study aimed at developing an online digital resource for people bereaved by suicide. Our findings support the efficiency of codevelopment research through the ISR framework for developing digital resources for mental health, especially for suicide bereavement. Through a 3-stage, user-centered design, merging both qualitative and quantitative data from a large sample of participants with lived or professional experiences, we were able to develop an adaptive and interactive website offered to French-speaking people bereaved by suicide. The results of the SUS during the rigor cycle and the first data regarding the use of the platform since its implementation highlight the relevance of our online resource to fulfilling the needs and expectations of French people bereaved by suicide.

Discussion of Results

First, our results confirmed that a great proportion of people bereaved by suicide used digital resources for their grief process and reported high levels of need and expectation regarding the development of dedicated digital resources. This finding is consistent with previous studies on suicide bereavement [9] and bereavement after other causes [31], which showed high levels of use of digital resources by bereaved people.

XSL•FO
RenderX

Second, it is notable that it was decided to create a website rather than a social media platform, while 57.9% (232/401) of participants reported in the relevance cycle that they would expect dedicated social media to be developed. The choice not to create a social media dedicated to suicide bereavement was based on arguments that (1) more participants expected a website to be developed (281/401, 70.1%) than a social media platform; (2) there was a lack of existing data on the effectiveness of social media for people bereaved by suicide; and (3) there were concerns regarding the moderation of such a resource, including the risk of inappropriate behaviors between members. However, social media offers a new avenue for the grieving process [30-33], and further studies are needed to better understand how to use social media effectively and safely after suicide bereavement. Furthermore, the development of a chat dedicated to people facing suicidal behaviors, including suicide bereavement, is currently ongoing in France.

Third, we did not include any memorial pages on the website, while a substantial number of the participants in our sample reported memorialization as a critical need for digital resources after suicide bereavement [30], which is consistent with previous studies [34]. As proposed by Morley et al [35], experience-based co-design must also be based on scientific evidence from previous literature, which they term "evidence-informed experience-based co-design." In light of the dearth of empirical evidence substantiating the efficacy of online memorials in providing assistance and support to individuals who have lost a loved one to suicide, as well as the emerging literature indicating potential adverse effects of such memorials on the well-being and mental health of those who have experienced such a loss, our decision not to develop a memorial was informed by these considerations. Westerlund [11], for example, reported that higher online support group activity predicted more satisfaction with current psychosocial health, while memorial websites seemed to have the opposite effect in a sample of Swedish people bereaved by suicide. However, other studies on bereavement by all causes have reported some positive effects of participation in online memorials [34,36,37], including the ability to foster emotional expression and continuing bonds with the deceased. Thus, implementing a memorial on the espoir-suicide website may represent an interesting avenue for which a new user-centered study is needed.

Fourth, our development study did not include any effectiveness measures after the implementation of the resources. The next step will be to develop a study aimed at measuring the effectiveness of the espoir-suicide website for fulfilling the needs of people bereaved by suicide and for improving their mental health. Further studies would benefit from examining the use of the website (including user satisfaction and use patterns) and its impact on bereavement experience, grief symptoms, depressive or anxiety symptoms, as well as on well-being and posttraumatic growth. Several questions will be raised regarding the most relevant means to assess the effectiveness of an online platform for people bereaved by suicide, which will also require the active involvement of people bereaved by suicide. According to our results, we can conclude that further studies must further explore codevelopment by identifying people with lived experiences in other domains and stages of the research, such as the design of the study, the definition of the research question, or the identification of the most relevant outcomes. Although our use of a codevelopment and user-centered design showed its relevance, the effectiveness of the website may have been even greater through the implications of people with lived experience in other stages and domains of the study.

Finally, it is notable that the espoir-suicide website was designed as a general resource for people bereaved by suicide that insufficiently considered several specific populations, including children and adolescents, which are known to display specific needs for digital resources after suicide bereavement [38]. While several pages are dedicated to the needs encountered by children and adolescents and their parents and families, after suicide bereavement, no specific space has been developed for them. A focus on specific populations that may display specific characteristics and needs [39] will have to be developed and implemented on the espoir-suicide platform in the future using a user-centered approach.

Limitations

We performed the first user-centered study on the use of a digital resource for suicide bereavement and codeveloped the first evidence-based online resource for French people bereaved by suicide. The large sample of participants, which included a vast proportion of people with lived experience of suicide bereavement, was the main strength of our study.

However, our study has several limitations. First, the study included only French people; therefore, the generalizability of our findings must be considered cautiously. Although the results from the relevance cycle showed similar patterns to those from other countries, further studies should be conducted in low- and middle-income countries. Second, the participants were mainly women in the 3 stages of the study. Although this limitation is frequently observed in research on suicide bereavement, this issue raises the question of the ability of the espoir-suicide website to suit men bereaved by suicide. Third, due to French research legislation, we could not assess the ethnicity, religion, or sexual orientation of the participants; therefore, we cannot conclude on the ability of espoir-suicide to reach people from ethnic, religious, or sexual minority groups. This limitation is also observed for people with disabilities (those who are visually impaired, color blind, and so on). Fourth, selection bias may have occurred in our study, as participants who were bereaved by suicide, volunteers, or professionals who participated may have been particularly interested in the topic and may not have been representative of the overall target population. However, the inclusion of a diverse sample of people with lived experience, professionals, and volunteers provided a unique means of collecting a wide range of perspectives to ensure the reliability of our findings and the relevance of the platform.

Conclusion

While people bereaved by suicide display high levels of need for digital resources, the use of a mixed methods, participatory, user-centered design allowed us to implement an evidence-based, innovative, and ergonomic website for people

XSL•FO
RenderX

bereaved by suicide, showing good relevance for fulfilling the needs and expectations of French people bereaved by suicide. Our findings support the efficiency of codevelopment research through the ISR framework for developing digital resources for mental health, especially for suicide bereavement.

Acknowledgments

The authors would like to thank all the participants of the study. The ESPOIR$_2$S study was funded by the Scientific Research Committee from the Centre Hospitalier le Vinatier under grant CSRN05 and by the National Institute for Public Health Research (Institut de Recherche en Santé Publique) under grant IRESP-RSP2020-230791.

Data Availability

The data that support the findings of this study are available from the corresponding author, EL, upon reasonable request.

Authors' Contributions

EL and BC contributed toward conceptualization, data collection, data analysis, and writing. KB and PL-T contributed toward data collection, data analysis, and writing. HR contributed toward data analysis and writing. LL, PG, MM, GV, JH, and EP contributed toward conceptualization and editing. NL contributed toward conceptualization and data collection. Supervision was handled by GV, JH, and EP.

Abstract

Background: Mood disorders are among the most common mental health conditions worldwide. Wearables and consumer-grade personal digital devices create digital traces that can be collected, processed, and analyzed, offering a unique opportunity to quantify and monitor individuals with mental disorders in their natural living environments.

Objective: This study comprised (1) 3 subcohorts of patients with a major depressive episode, either with major depressive disorder, bipolar disorder, or concurrent borderline personality disorder, and (2) a healthy control group. We investigated whether differences in behavioral patterns could be observed at the group level, that is, patients versus healthy controls. We studied the volume and temporal patterns of smartphone screen and app use, communication, sleep, mobility, and physical activity. We investigated whether patients or controls exhibited more homogenous temporal patterns of activity when compared with other individuals in the same group. We examined which variables were associated with the severity of depression.

Methods: In total, 188 participants were recruited to complete a 2-phase study. In the first 2 weeks, data from bed sensors, actigraphy, smartphones, and 5 sets of daily questions were collected. In the second phase, which lasted up to 1 year, only passive smartphone data and biweekly 9-item Patient Health Questionnaire data were collected. Survival analysis, statistical tests, and linear mixed models were performed.

Results: Survival analysis showed no statistically significant difference in adherence. Most participants did not stay in the study for 1 year. Weekday location variance showed lower values for patients (control: mean –10.04, SD 2.73; patient: mean –11.91, SD 2.50; Mann-Whitney *U* [MWU] test *P*=.004). Normalized entropy of location was lower among patients (control: mean 2.10, SD 1.38; patient: mean 1.57, SD 1.10; MWU test *P*=.05). The temporal communication patterns of controls were more diverse compared to those of patients (MWU test *P*<.001). In contrast, patients exhibited more varied temporal patterns of smartphone use compared to the controls. We found that the duration of incoming calls (β=–0.08, 95% CI –0.12 to –0.04; *P*<.001) and the SD of activity magnitude (β=–2.05, 95% CI –4.18 to –0.20; *P*=.02) over the 14 days before the 9-item Patient Health Questionnaire records were negatively associated with depression severity. Conversely, the duration of outgoing calls showed a positive association with depression severity (β=0.05, 95% CI 0.00-0.09; *P*=.02).

XSL•FO
RenderX

Conclusions: Our work shows the important features for future analyses of behavioral markers of mood disorders. However, among outpatients with mild to moderate depressive disorders, the group-level differences from healthy controls in any single modality remain relatively modest. Therefore, future studies need to combine data from multiple modalities to detect more subtle differences and identify individualized signatures. The high dropout rates for longer study periods remain a challenge and limit the generalizability.

digital health; mental disorders; depression; digital phenotyping; smartphones; mobile devices; multisensor; mobile phone

Introduction

Background

Mood disorders, including major depressive disorder (MDD) and bipolar disorder (BD), are substantial contributors to the worldwide disease burden and impairment, bearing important implications for public health [1,2]. They also have an increased association with premature mortality [3,4]. Mood disorders are usually recurring and often chronic conditions that typically require long-term treatment [5]. Currently, the diagnostic landscape and assessment of symptom severity for mood disorders are primarily based on clinical evaluations, interviews, and questionnaires, which are predominantly reliant on subjective interpretations and retrospective recollections by patients and only conducted when the patient visits the mental health professionals. This framework is susceptible to memory bias and may not capture the dynamic symptomatology inherent in mood disorders [6,7]. Compounded by the lack of clear biomarkers and a worldwide shortage of adequate mental health resources, the treatment of these conditions has long posed challenges.

In recent years, the ubiquity of digital technologies, particularly wearables and personal digital devices, has facilitated their integration into different fields of medicine. These devices can measure various physiological metrics, such as heart rate, heart rate variability, and respiration rate [8]. Moreover, through interactions with these devices, significant amounts of digital traces are generated, which can be collected, analyzed, and transformed into valuable information regarding their users' behavior and activities. In the case of psychiatric disorders, particularly mood disorders, leveraging digital traces and the associated information holds the potential to introduce greater objectivity in diagnosing and treating these conditions as well as the possibility for continuous monitoring of patients. The emerging field of digital phenotyping harnesses real-time indicators of human behavior to uncover behavioral markers that objectively quantify, monitor, and assess mental health conditions continuously [9-14].

Several digital phenotyping studies have used data collected from personal digital devices to extract behavioral features. These studies typically use clinically validated scales, such as the 9-item Patient Health Questionnaire (PHQ-9) [15], to measure symptoms of the disorder, using them as a reference point. Most digital phenotyping studies aim to determine which passive behavioral features, gathered as participants interact with their devices, are most indicative of clinical scores. A recent review [16] examined 45 articles and found that most of these studies focus on a single modality. In contrast, a multimodal approach could provide a more accurate understanding of an individual's life and behaviors. In addition, many of the studies involve nonclinical cohorts or individuals who self-identified as experiencing depression through self-administered questionnaires, rather than individuals formally diagnosed with depression.

Objectives

In response to significant challenges in digital phenotyping, we designed and conducted the Mobile Monitoring of Mood (MoMo-Mood) study. These challenges include the scarcity of research involving patients with clinically diagnosed mood disorders, the necessity for prolonged observation periods to identify behavioral precursors to recurrent episodes in mood disorders, and the requirement for a multimodal approach to capture behaviors from various data streams. This multimodal digital phenotyping study focused on different types of patients who were receiving treatment for major depressive episodes, including (unipolar) MDD, BD, or borderline personality disorder (BPD), as well as healthy controls. Before MoMo-Mood, we conducted a smaller pilot study (MoMo-Mood Pilot) to test the feasibility of our study design before scaling it to a larger number of participants and patients with less prevalent disorders. In this work, we explore the potential and effectiveness of personal digital devices in capturing clinically significant behavioral indicators from patients with diagnosed conditions over (a maximum of) a period of up to 1 year. The unique combination of patient subcohorts, a wide range of data streams from different devices, and an extended study time allows us to, for the first time, test the feasibility of such a study design at a larger scale and gain insights into what works and what needs to be improved for future studies.

While study adherence has been recognized as a challenge in digital phenotyping studies [17], how different groups of patients comply with long-term passive data collection remains understudied. Similarly, while past research has suggested that patients with serious mental disorders have similar or even higher rates of smartphone use compared to others [18,19], the frequency and quantity of smartphone use in different groups of mood disorders need to be better examined. To this end, we measured adherence based on the time each person has remained in the study (maximum 1 year). Furthermore, we used smartphone screen activity (on, off, lock, and unlock) time stamps as a proxy for general smartphone use and smartphone apps used for specific types of use.

XSL•FO
RenderX

In addition to that, we hypothesized that patients (compared to healthy controls) exhibited differences when comparing activities and behaviors that were relevant for assessing mood disorder symptoms or associated psychosocial disability. Here, we focused on 4 domains: social activity, mobility, physical activity, and sleep. Depression is known to be associated with social isolation [20], which can potentially be reflected in a person's communication pattern. Fatigue and loss of energy are among the diagnostic criteria for depression [21,22], which can be reflected in mobility and physical activity data. Past research has used passively collected location data from smartphones. It has identified variables such as location variance, location entropy, and time spent at home to be associated with symptoms of depression [23-25]. Finally, both increased and decreased sleep are symptoms of depression [26]. In our study, as a proxy of social activity, we used time stamps for incoming and outgoing calls and SMS text messages through the phone network provider. Location and mobility were measured through the smartphone's GPS and Wi-Fi data, and the variables shown to exhibit significant differences between patients and healthy controls in other studies were investigated. We measured physical activity in 2 ways: first, through actigraphs, and second, through smartphone accelerometers. Sleep timing and duration were measured by actigraphs and bed sensors.

Moreover, to assess several different behaviors, we focused on their temporal patterns by exploring activity rhythms and how patients and controls allocated their time to a particular activity throughout the week. The timing of different activities may contain important behavioral markers linked to mood disorders. Previous research in studying temporal rhythms of activity inferred from different personal digital devices has shown that people tend to have persistent activity rhythms over time [27-30]. However, these rhythms and their consistency are linked to personal and sociodemographic characteristics [31,32]. A recent study [33] suggests that daily activity rhythms inferred from smartphone GPS data are associated with anxiety levels in patients with MDD and BD. While we know that mood disorders impact daily activity and sleep rhythms, the activity rhythms of patients with mood disorders inferred from passively collected data from their smartphones are not well studied [34]. This work investigates the different activity rhythms inferred from smartphones and evaluates the differences between patients and healthy controls.

We specifically aim to answer the following research questions (RQs):

- RQ1: Does study adherence, that is, how long the participants remain in the study, vary between patient subcohorts and healthy controls?
- RQ2: Do the quantity and temporal patterns of smartphone use, in terms of phone screen and app use, vary between patients and controls?
- RQ3: Do differences exist between patients and healthy controls when comparing social activity, mobility, physical activity, and sleep, as measured by passively collected data?
- RQ4: To what degree do people within the same subcohort show similar temporal rhythms of smartphone use, social activity, and physical activity?
- RQ5: Is the severity of depression symptoms during the follow-up associated with social activity, mobility, physical activity, and sleep?

Methods

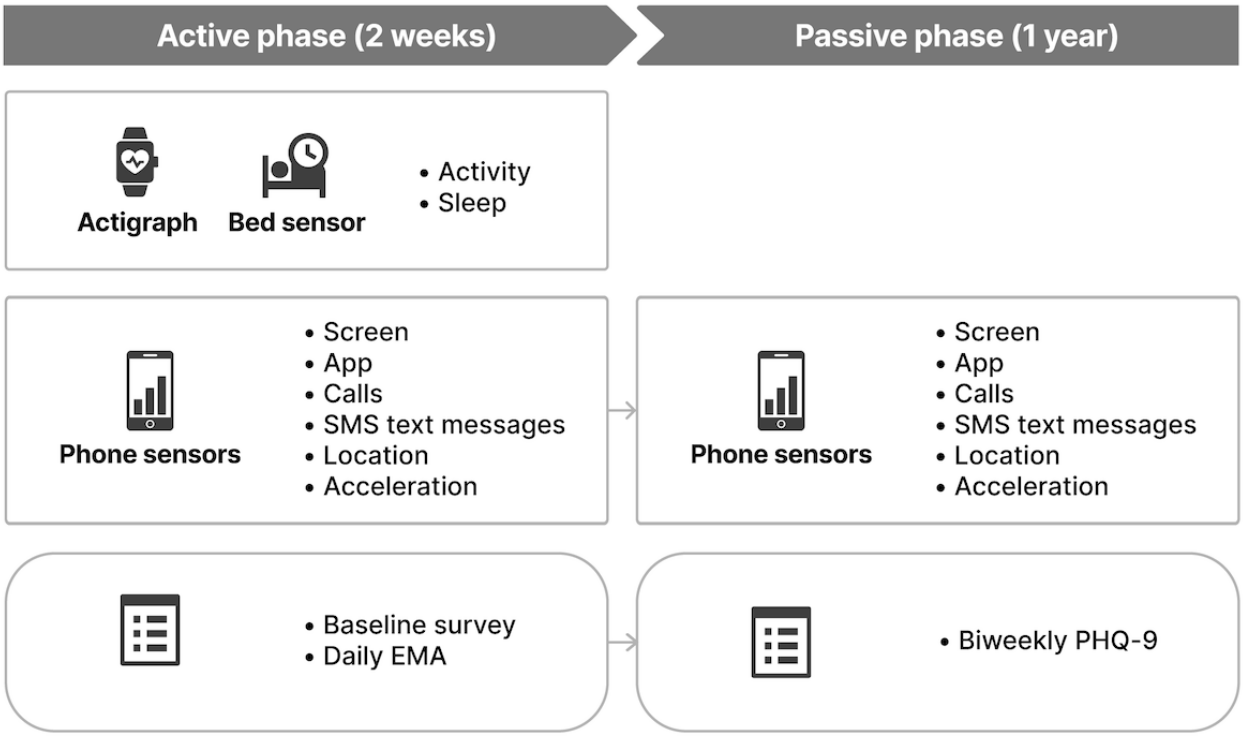
Setting

We initially conducted a smaller-scale pilot study, the MoMo-Mood Pilot, to test our study design. Once the study was deemed feasible, we moved on to a larger-scale study, namely, MoMo-Mood. Other than the number of participants, the main difference between the 2 studies was that for the pilot study, participants were either patients with MDD or healthy controls, as opposed to the main study, where 2 additional patient subcohorts were recruited. The recruitment of all the cohorts for the main study was performed independently from the pilot study. In addition, the pilot study had a shorter maximum data collection period from patients (6 months) than the MoMo-Mood study (1 year).

Both studies were conducted in Finland. Patients who had already been diagnosed using structured clinical interviews were recruited on a voluntary basis from the mood disorder outpatient treatment facilities at the Helsinki University Hospital Mood Disorder Division, Turku University Central Hospital Department of Psychiatry, and City of Espoo Mental Health Services. The Mini International Neuropsychiatric Interview [35] was used for the diagnosis of MDD and BD, and the Structured Clinical Interview-II [36] was used for BPD. The patients with any psychotic features, concurrent substance use disorder, or imminent risk of suicide were excluded.

The studies had an active phase that lasted 2 weeks, during which we collected data from actigraphs and bed sensors loaned to study participants. Different types of data were passively collected (passive data) from smartphone sensors through a smartphone app. Passive data are a byproduct of the participants' use and engagement with personal devices; they do not need to change their behavior or actively engage with the study. During the active phase, we also did ecological momentary assessment (EMA) [37] 5 times a day. In the second phase of the study, the passive phase, which lasted for up to 1 year, passive data were collected from smartphones (Textbox 1). However, actigraph, bed sensor, and EMA data were no longer collected. Participants received a prompt every 2 weeks on their smartphones to fill out a PHQ-9. They were also presented with PHQ-9 at baseline. The division of the study into active and passive phases was implemented to minimize the risk of study fatigue and burden on participants.

XSL•FO
RenderX



Textbox 1. Raw features description.

Sensors and raw features

- Accelerometer: x-axis, y-axis, z-axis, and accuracy
- App: foreground use, notifications, and crashes
- Battery: battery level, battery status, and battery health
- Call: type (incoming, outgoing, and missed) and duration
- SMS text messages: type (incoming and outgoing)
- Location: latitude, longitude, speed, and accuracy
- Screen: status (on, off, lock, and unlock)
- Actigraph: activity count and status (active, rest, and sleep)
- Murata bed sensor: heart rate, heart rate variability, respiration rate, and stroke volume

The actigraphs we used did not need to be recharged for 14 days, allowing us to provide fully charged devices to participants without recharging during the active phase. In addition, PHQ-9 asks about depression symptoms in the past 2 weeks, which made the 2-week period a natural choice for the length of our active phase. Given the time frames of when people typically change their smartphones or the operating system on the smartphones, we chose the length of 1 year for the passive phase of the study. The participants could withdraw from the study at any time. Figure 1 demonstrates the study's timeline.

Figure 1. Data collection procedure of the Mobile Monitoring of Mood study. EMA: ecologic momentary assessment; PHQ-9: 9-item Patient Health Questionnaire.

Participants and Recruitment

MoMo-Mood Pilot

A total of 23 healthy controls and 14 patients with MDD were recruited. One control was excluded from the study for having a baseline PHQ-9 score that fell in the subclinical depression range. The healthy control group included 17 female participants and 5 male participants, with an average age of 30.5 (SD 10.4) years. The patient group consisted of 8 female participants and 5 male participants. The average age for the patients was 32.4 (SD 12.2) years. One patient had not entered their age and sex information in the forms. In the pilot study, for practical reasons, we asked patients to stay in the study for 6 months, and we asked the healthy controls to stay in the study for 1 year.

MoMo-Mood

In this study, a total of 151 participants were recruited from four different groups: (1) healthy controls (n=30), (2) patients with MDD (n=76), (3) patients with BPD (n=24), and (4)

XSL•FO
RenderX

patients with BD (n=21). The participants were invited to stay in the study for a maximum of 1 year. The length of involvement differed; therefore, data provided by each participant varied widely, from days to the entire year. Participants were enrolled continuously, entering and leaving at different times. This work refers to the MoMo-Mood study as the *main study*.

Participants received 4 movie tickets for participation in the study, 2 at the time of enrollment and 2 after completing the active phase. They did not receive any further compensation or feedback.

Data Collection Platform

The Non-Intrusive Individual Monitoring Architecture is a data collection platform designed for MoMo-Mood Pilot and other digital phenotyping studies [38]. This platform allows for the design of studies with various parameters and links data from different sensors. It also provides basic cleaning and preprocessing to standardize data into tabular formats for easy handling and analysis. The Non-Intrusive Individual Monitoring Architecture platform was used to conduct both studies.

Data Sources

Smartphone

We used the AWARE phone app [39] to collect data from the smartphone sensors. Our team modified and adapted this open-source framework to cater to the needs of our studies. Data collected from smartphones included communication (call and text) time stamps, an anonymous identifier for contacts, time stamps of smartphone screen events (on, off, lock, and unlock), GPS data, app use, and battery status. Each record included the user's ID, the device's ID, and a time stamp. The smartphone also served to ask participants several questions multiple times a day during the active phase of the study and to present them with the PHQ-9 every 2 weeks during the passive phase. Textbox 1 summarizes all the raw features gathered from each sensor.

EMA Technique

In clinical studies, EMA measures real-time emotional states [37]. In this method, participants respond to questions about their current state on their smartphones multiple times daily. In our studies, a prompt appeared on each participant's smartphone once in the morning, once in the evening, and 3 times at random intervals during the afternoon, within specific time ranges. These questionnaires asked participants about their psychological and physical states, physical activity, behavior, and sleep. This paper focuses on the behavioral patterns measured objectively through passive data. Results from the EMA data are reported elsewhere [40].

Actigraph

Actigraphs are wrist-worn devices commonly used in clinical studies (including psychiatric studies) to measure activity levels and sleep. We used Philips Actiwatch 2 devices. The data were aggregated at 30-second intervals.

Bed Sensor

We used ballistocardiography-based Murata SCA11H nodes (bed sensors) to measure bed acceleration. Participants were provided with these sensors and a preconfigured Wi-Fi router, enabling data transmission directly to the study server. The sensors locally analyzed data, providing heart rate, heart rate variability, respiration rate, stroke volume, and signal strength at 1 Hz frequency.

Data Preprocessing

Communication and Smartphone Screen Use

The number of incoming or outgoing calls, SMS text messages, and screen use episodes were extracted hourly. The mobile app did not transfer any message content or contact identities from the device. To ensure equal evaluation of event volume and temporal patterns, we retained participants with at least 8 weeks of communication and smartphone use data for further analyses. Records from the first and last day were excluded to avoid incomplete data capture. No additional outlier filtering was performed. To analyze the weekly temporal patterns or "rhythm" of events, we aggregated these events into 1-hour bins across 8 weeks, resulting in 168 bins for weekly frequency. One event is 1 instance of a particular data type, such as 1 call or smartphone screen-on data point. The aggregated values were normalized to sum up to 1, providing a proportionate measure of event distribution over time.

Apps

The frequency and duration of smartphone apps use were collected based on time stamps when apps were actively used in the foreground. Each app was manually categorized to reflect its function, including "sports," "communication," "leisure," "social media," "work," "news," "shop," "transport," and "utility." The categorization of smartphone apps was performed after data collection was completed. App use durations >10 hours (132 instances) were removed as they might represent an error in the system rather than actual app use. Similar to communication and screen use features, we limited the data time frame to 8 weeks in the analyses that used these data. The weekly rhythm of app use was then computed using the same approach applied to communication and screen time.

Accelerometer

Accelerometer data were recorded every 30 seconds. The magnitude was computed as the Euclidean norm of the acceleration vectors (x-axis, y-axis, and z-axis) and normalized to center around the 0 value. We used the SD of accelerometer data at hourly intervals as a proxy for physical activity, similar to prior work [41,42]. In addition, physical activity was estimated using actigraph data described in the Sleep and Activity Detection section.

Sleep and Activity Detection

Sleep variables were derived from actigraph and bed sensor data. For actigraph, sleep-wake epochs were scored using the algorithm proposed by Oakley [43]. Each epoch was assigned a status indicating whether the user was active, at rest, or asleep. The active hours for each day were calculated based on the total number of epochs labeled as "active." Bedtime was determined as the first occurrence of a continuous 3-minute sleep period.

Similarly, wake time was determined as the first instance of the first 3-minute span of activity observed in a day. For bed

XSL•FO
RenderX

sensors, each 1-second epoch was given a status indicating whether the bed was occupied or free. The sleep period was defined as the longest duration during which the bed was occupied. For both sensors, records on the first and last nights were excluded due to a high likelihood of being incomplete. Nights with <3 or >13 hours of sleep were omitted, similar to previous work [44]. The preprocessing step resulted in 862 actigraph days and 841 bed sensor nights.

Location and Mobility

Several mobility features were extracted from the GPS sensor using the Niimpy behavior data analysis toolbox [45] which we have created. The choice of features was motivated by previous studies [23,24]. Preprocessing details and feature descriptions are provided in Table S1 in Multimedia Appendix 1 [46-48].

Statistical Analyses

Descriptive statistics were used to summarize the demographic characteristics of participants. Survival analysis was performed using the Kaplan-Meier curve [49] to assess the likelihood of staying in the study over time for different groups. The log rank test was used to compare the differences in adherence between groups. This nonparametric test is commonly used in survival analysis in the presence of censored data.

The comparative analysis of the quantity of communication and smartphone use among different groups was performed using the Mann-Whitney *U* (MWU) test. Results with a *P* value <.05 were considered significant.

Linear mixed models were used to examine the association between passive sensor data and depression severity, as measured by the PHQ-9 score. The model incorporated behavioral features derived from sensor measures as predictors of PHQ-9 scores. Mean values of sensor data were calculated over the 14-day window preceding each PHQ-9 measurement. Continuous predictors were within-person centered to ensure comparability.

Temporal Analysis

To determine how an individual distributes a specific activity temporally, we built *weekly activity rhythms.* The rhythm was computed as the normalized distribution of the aggregated volume of variables for 8 weeks. Intradifference of rhythm was defined as the cosine distance between the average rhythm of individuals belonging to the same cohort:

$R_i \cdot R_j$ represents the dot product of the activity distributions of individuals *i* and *j*, and $||R_i||$ and $||R_j||$ are these distributions' Euclidean norms (or magnitudes).

Intuitively, individuals with similar rhythms will share a smaller distance. The MWU test was conducted to compare mean differences in intragroup distances, assessing the diversity of rhythms between groups. Post hoc correction using the Benjamini-Hochberg procedure [50] was used to control for the false detection rate during multiple tests.

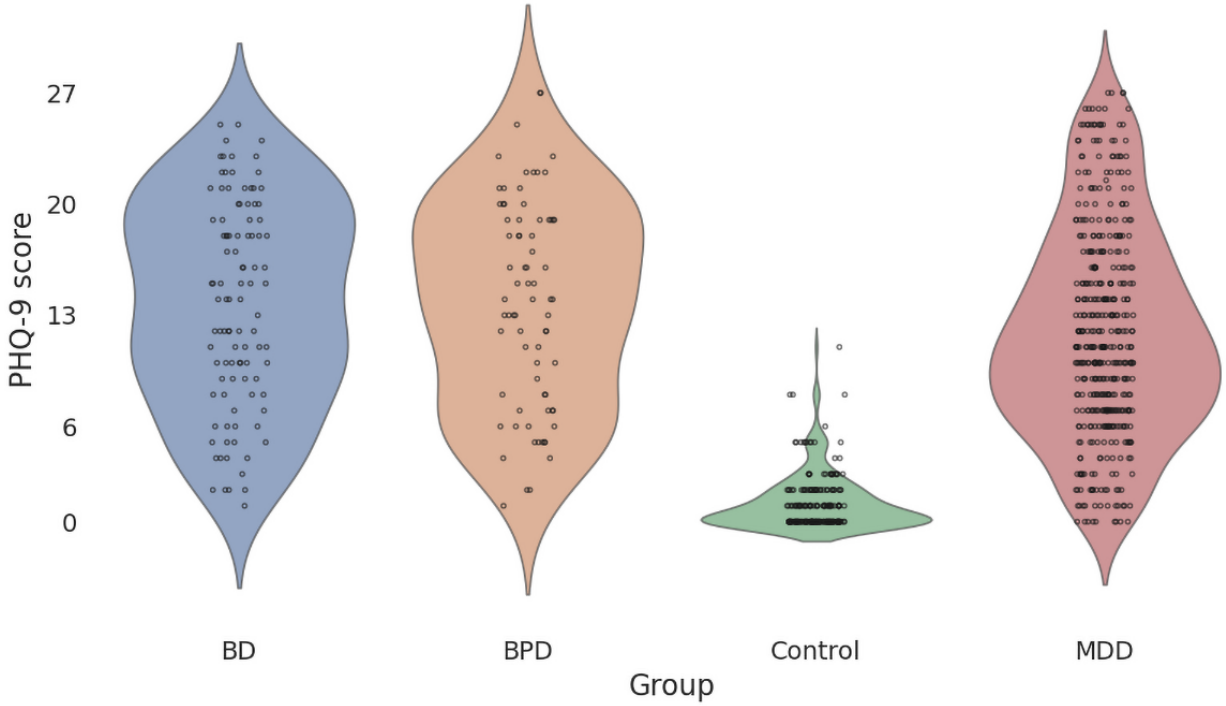
Ethical Considerations

The research protocol for both MoMo-Mood Pilot and MoMo-Mood was approved by the Helsinki and Uusimaa Hospital District's Ethics Committee and was granted research permits by Helsinki and Uusimaa Hospital District Psychiatry (approval number § 125/2018). The approvals covered data streams, data collection platform security, and participant consent information. All data in transit were encrypted, and participant privacy was a key design value. Local IT support and the research ethics committee approved the written data security statement. Participants received detailed information about the study and the data to be collected before enrollment. All participants provided written consent. Participants were informed that they could withdraw from the study at any time. The only compensation they received was 4 movie tickets each.

Results

Overview

The main goal of the MoMo-Mood Pilot study was to prove the feasibility of our study design. This study had no significant issues, which led us to continue to the main study with minimal changes overall. The results presented here focus on the main study. We present the information about the participants and the population-level behavioral features from the pilot study in Table S2 in Multimedia Appendix 1.



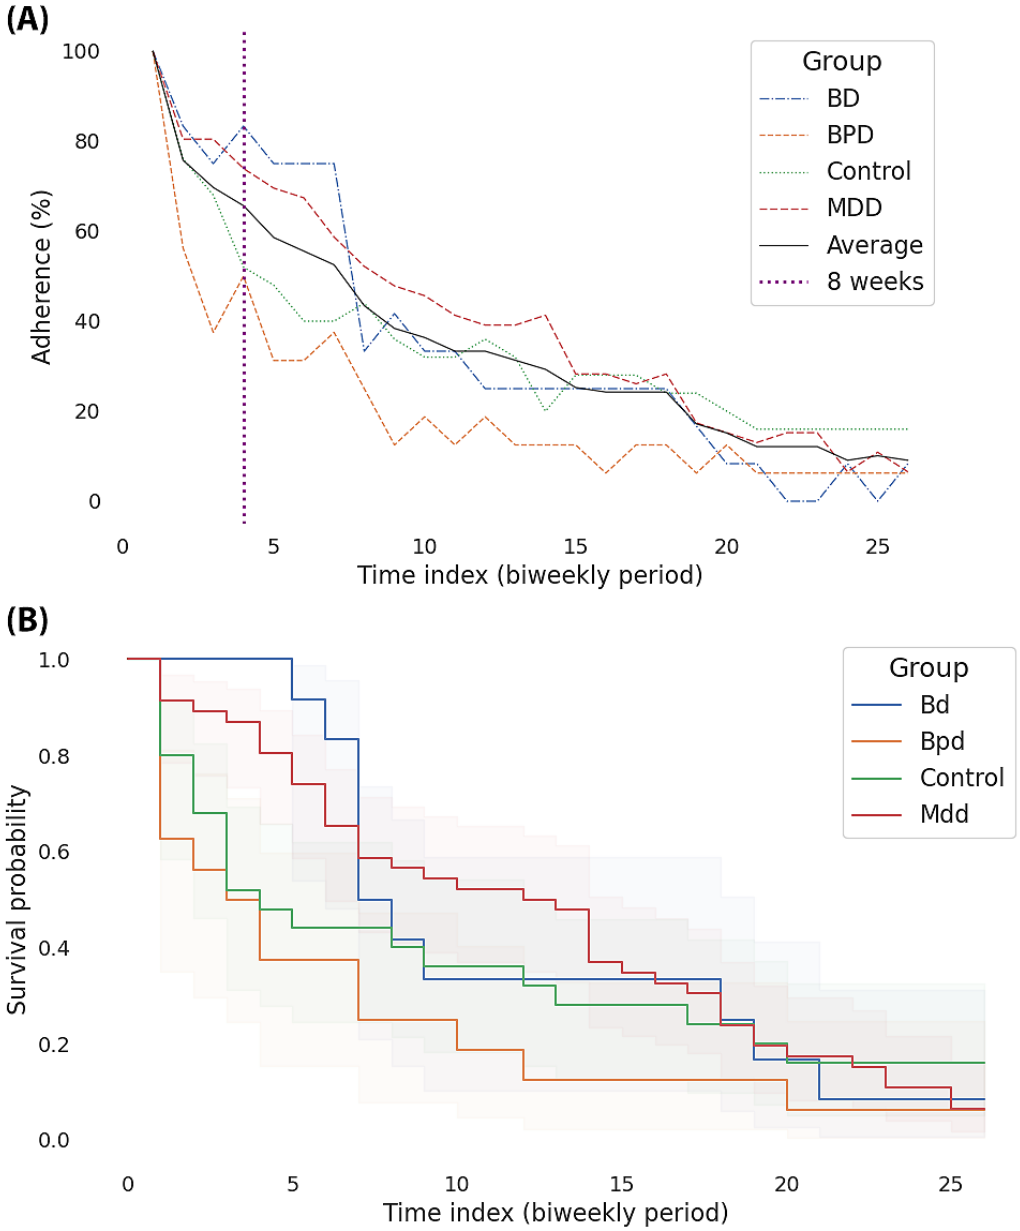
Participants

In the main study, a total of 164 participants were recruited. Due to technical challenges or other issues, of the 164 participants, 13 (7.9%) provided no passive data and were excluded from all analyses. Further analyses included 30 control participants and 121 participants diagnosed with major depressive episode. Among 121 patients, 76 (62.8%) were diagnosed with MDD, 21 (17.4%) with BD, and 24 (19.8%) with BPD. The pilot study included 23 controls and 14 MDD patients. All participants diagnosed with a major depressive episode were collectively categorized into a single "patient" group for clarity in the following analyses unless otherwise noted.

The mean age of the control group was 42 (SD 14.07) years, and the mean age of the patient group was 34.7 (SD 12.71) years. A total of 77% (23/30) of the control group were female, compared to 71.1% (86/121) in the patient group. Regarding employment, 83% (25/30) of the control group were employed full time, compared to only 9.9% (12/121) of the patient group. At baseline, the mean PHQ-9 score of the control group was 1.7 (SD 1.49). For the patient subcohorts, the baseline PHQ-9 scores were 14.6 (SD 5.41) for patients with MDD, 14.57 (SD 5.62) for patients with BPD, and 13.53 (SD 4.73) and 13.53 (SD 4.73) for patients with BD. Figure 2 shows PHQ-9 distribution for the control and patient groups. More detailed information about group-level PHQ-9 score distributions and trajectories for the active phase are reported elsewhere [14].

XSL•FO
RenderX

Figure 2. Main study 9-item Patient Health Questionnaire-9 distributions show clear differences between the control and patient groups, while differences between patient subcohorts are less prominent. BD: bipolar disorder; BPD: borderline personality disorder; MDD: major depressive disorder.



RQ1: Participation Adherence

For this work, we defined participation adherence as the availability of the PHQ-9 responses. Adherence declined over time throughout the study; by the end of study week 8, in total 65.7% (99/151) of enrolled participants were still providing questionnaire answers and were thus considered active in the study. At this point in time, the adherence rates for different subcohorts were as follows: 50% (12/24) for patients with BPD, 52% (16/30) for controls, 74% (56/76) for patients with MDD, and 83% (17/21) for patients with BD. Figure 3A shows the adherence rates and proportion of PHQ-9 answered across the groups throughout the study's passive phase. In addition, survival analysis using the log rank test did not reveal significant differences in adherence levels between all groups. Figure 3B shows the survival curve depicting the adherence rate assessed with PHQ-9 data. Supplementary survival analysis using smartphone battery data is presented in Figure S1 in Multimedia Appendix 1.

XSL•FO
RenderX

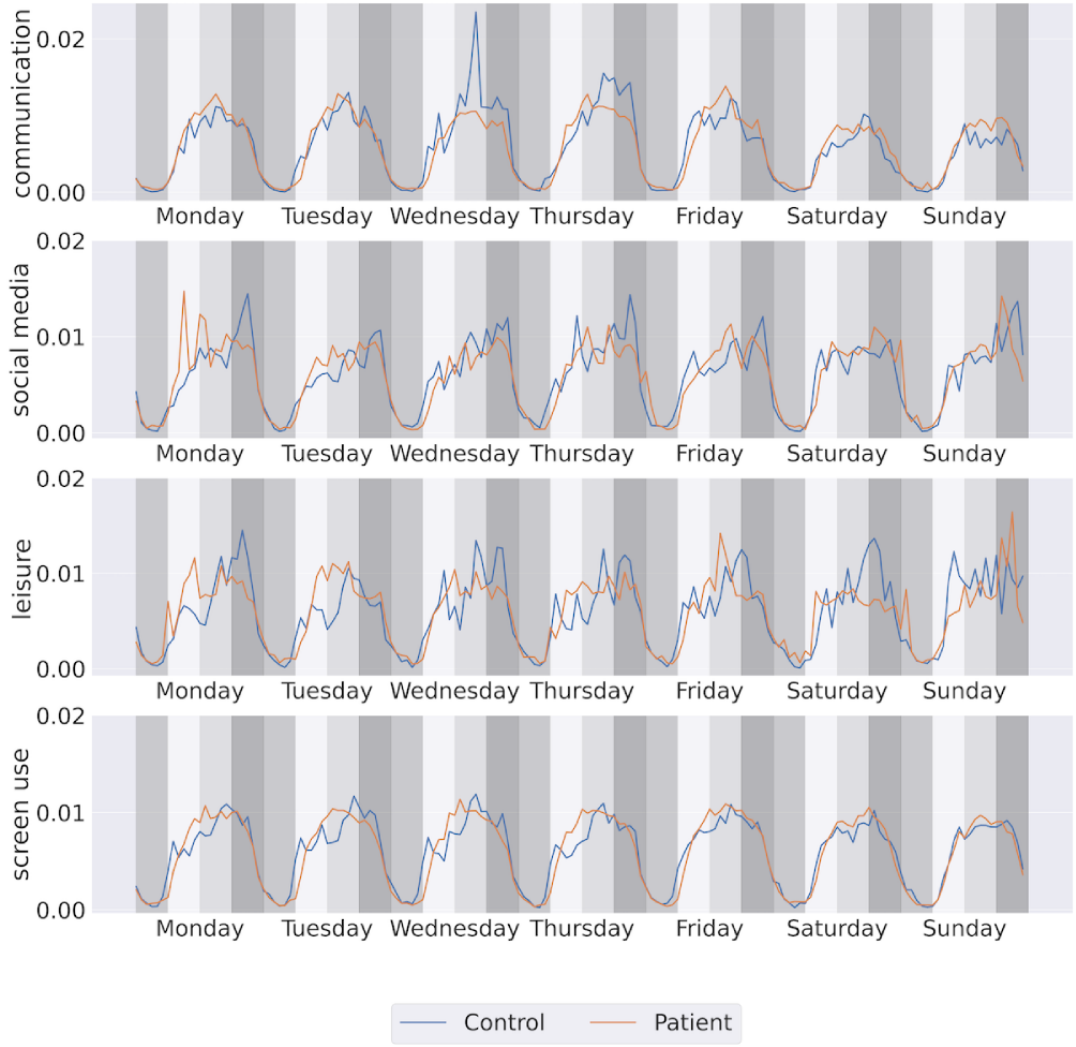
Figure 3. Study participants' group average adherence proportion across the study's passive phase. (A) Adherence was assessed by answers to the biweekly (14 days) 9-item Patient Health Questionnaire. After 8 weeks, approximately 65.7% of participants were still active in the study. The subcohort adherence rates were 50% for borderline personality disorder (BPD), 52% for controls, 73.9% for major depressive disorder (MDD), and 83.3% for bipolar disorder (BD). The adherence rates show some fluctuation due to the intermittent missing responses. (B) Kaplan-Meier survival curves depicting the probability of continued participation (survival) among different groups in the study. A participant is considered adherent if they provide biweekly period (14 days) 9-item Patient Health Questionnaire answers, starting from the beginning of the study. Notably, the curves indicate no statistically significant difference in adherence between the groups.

As an additional data quality assessment, we evaluated the data completeness by counting the proportion of missing intermittent daily passive data. We used battery data availability as a proxy for passively sensed data, considering the day as missing if no battery data were available. Combining the active and passive phases, the average passive data missingness across all participants is 10.5%, and more specifically, 4.5% for BD, 20.4% for BPD, 1.2% for control, and 14.1% for MDD groups. For each participant we calculated the total number of days with no battery data divided by the number days that participant was in the study. We then calculated the average of these percentages for all participants in a given group to derive the average percentages of passive data missingness.

RQ2: Quantity and Temporal Patterns of Smartphone Use

To assess the difference between patients and controls in smartphone use, we measured the quantity of smartphone interaction for each group by analyzing the daily average duration of smartphone screen use and time spent on the top 5 most-used app categories. To quantify the temporal patterns of smartphone use, we used the normalized amount of interaction with the screen and these top 5 categories of apps. For both analyses, we restricted the data to an 8-week period to ensure a comparable data volume across participants and to minimize potential bias from participant dropout.

XSL•FO
RenderX



The daily average use of the top 5 app categories and overall screen time are presented in Table 1. No significant differences were observed in the amount of time spent on each category or the overall volume of smartphone use between the groups. However, noticeable differences emerged when examining the temporal patterns of app use. As illustrated in Figure 4, controls tend to use leisure apps more frequently during the weekend, with a peak on Saturday. This pattern suggests that controls prefer to engage with entertainment apps during their free days.

Table 1. Daily average duration of top 5 app use categories and total time spent using the smartphone[a].

Duration of use (min)	Control, mean (SD)	Patient, mean (SD)	*P* value
Communication	18.46 (11.65)	29.06 (36.18)	.87
Social media	31.62 (22.59)	39.41 (41.23)	.90
Leisure	18.62 (18.30)	29.20 (50.92)	.87
Games	11.50 (15.73)	13.81 (25.26)	.87
News	16.12 (42.73)	7.36 (15.33)	.90
Screen use	225.91 (113.68)	178.18 (130.92)	.55

[a]*P* values from the Mann-Whitney *U* test, adjusted to correct for multiple testing.

Figure 4. Weekly pattern of app interaction and smartphone use. The y-axis represents the normalized count of events within each 4-hour time bin over an 8-week period. Each color region denotes a 4-hour daily bin representing night (midnight to 6 AM), morning (6 AM to noon), afternoon (noon to 6 PM), and evening (6 PM to midnight).

XSL•FO
RenderX

RQ3: Between-Group Difference in the Quantity and Temporal Patterns of Behaviors

We used the same strategy to quantify daily communication and location patterns from smartphone sensors, sleep patterns from bed sensors, activity patterns from actigraphs, and weekly temporal communication patterns.

Communication

We used call and SMS text message data collected by smartphones as a proxy of social activity. We collected 46,788 incoming and outgoing calls, of which 39,491 (84.4%) were longer than 0 seconds, with an average daily incoming call duration of 6.9 (SD 17.2) minutes and average daily outgoing call duration of 7.4 (SD 19.3) minutes. In addition, we collected 46,031 SMS text messages within the same period. Again, we restricted the data to an 8-week period for this analysis to ensure comparable temporal patterns. Table 2 presents the mean (SD) of the 2 groups' daily calls and SMS text messages. A comparison of the daily average communication between groups did not show significant differences.

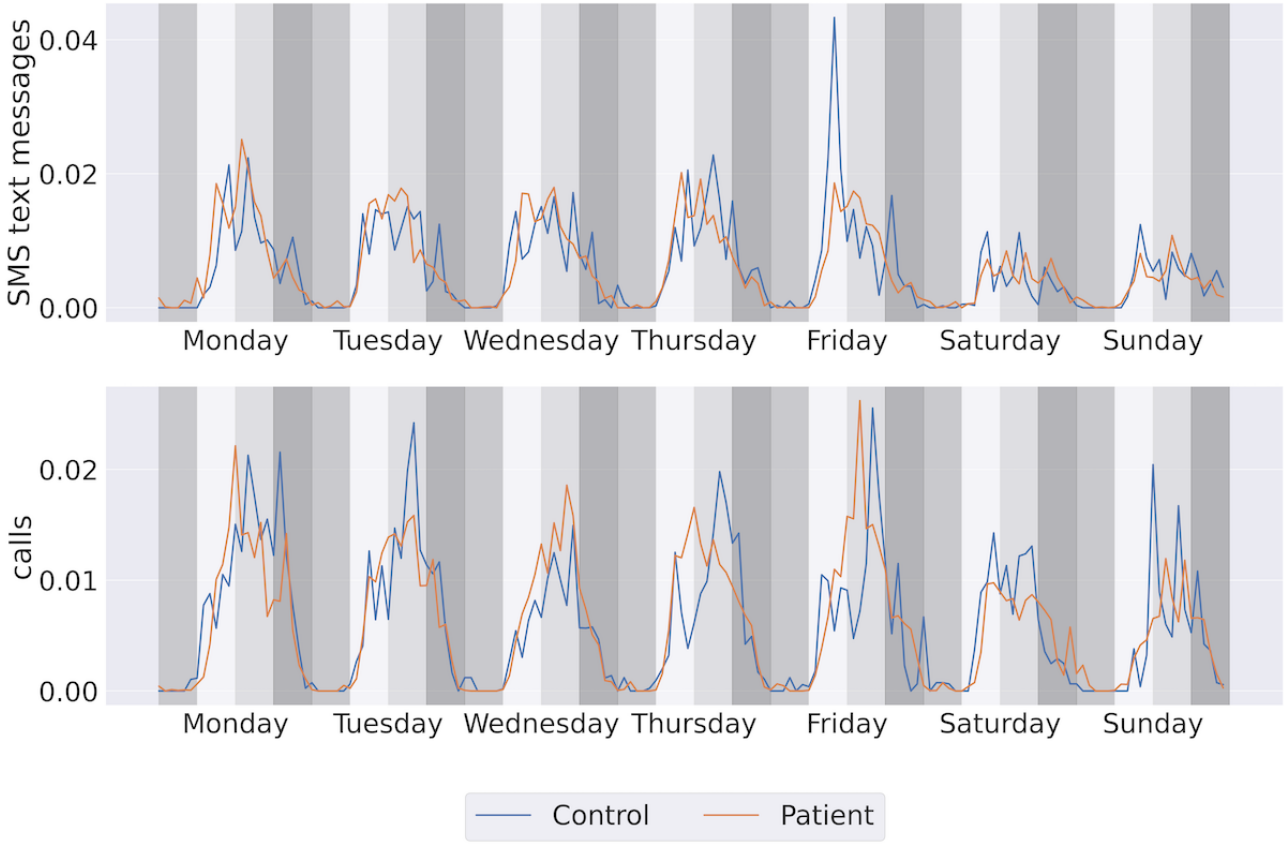


Figure 5 displays the weekly communication rhythms for both groups. A visual inspection reveals that both groups tended to have a decreased communication volume during the weekend. Within the control group, call events were more frequently observed in the afternoon bins (noon to 6 PM).

Table 2. Daily average calls and SMS text messages per group for each study[a].

	Control, mean (SD)	Patient, mean (SD)	*P* value
Number of incoming calls	0.67 (0.58)	1.26 (1.17)	.64
Number of outgoing calls	1.26 (1.21)	1.59 (1.37)	.90
Incoming call duration (min)	4.87 (6.08)	7.89 (7.36)	.64
Outgoing call duration (min)	5.55 (5.48)	7.67 (9.94)	.94
Number of incoming SMS text messages	1.24 (0.79)	1.48 (1.23)	.94
Number of outgoing SMS text messages	0.66 (0.98)	0.95 (1.27)	.69

[a]*P* values from the Mann-Whitney *U* test were adjusted for multiple tests.

Figure 5. Weekly pattern of communication. The y-axis represents the normalized count of events within each 4-hour time bin over an 8-week period. Each color region denotes a 4-hour daily bin representing night (midnight to 6 AM), morning (6 AM to noon), afternoon (noon to 6 PM), and evening (6 PM to midnight).

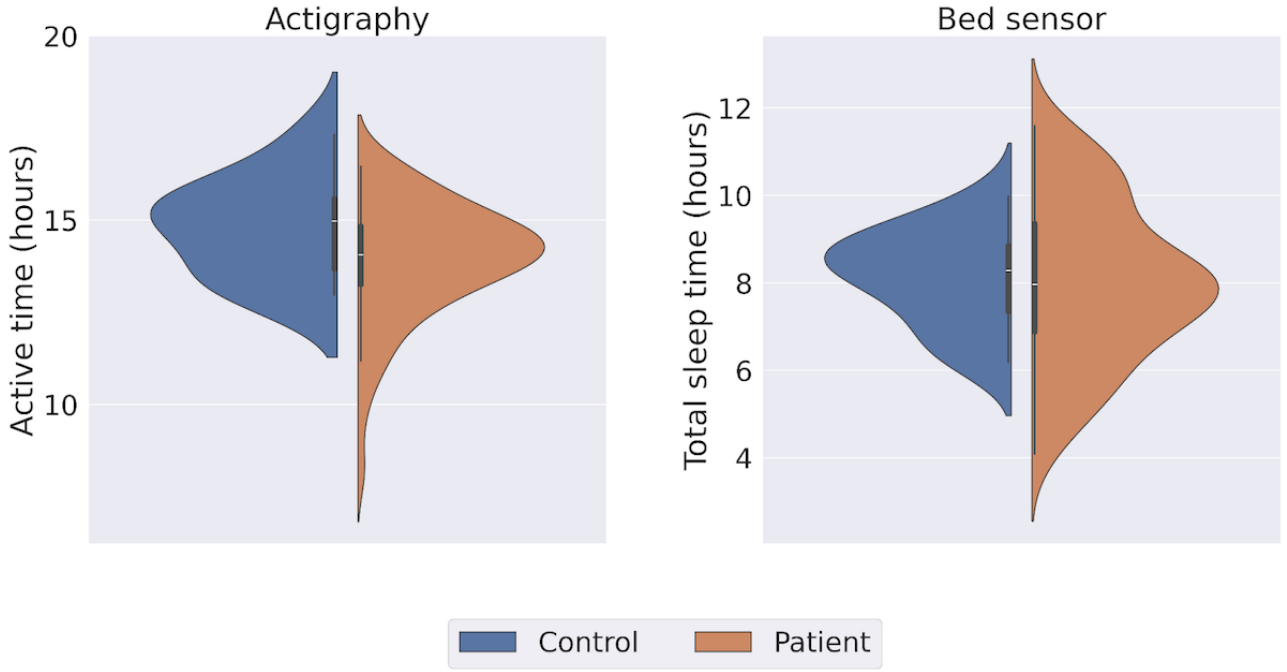
XSL•FO
RenderX

Sleep and Physical Activity

We examined all participants' sleep and physical activity patterns via features extracted from the actigraph and the bed sensor. We look at these 2 behaviors together as they complement each other throughout the day. We measured the sleep duration from the bed sensor and the active hours from the actigraphy. The daily average active hours and sleep duration of each group in each study are presented in Figure 6. We found no between-group difference in sleep duration (patient: mean 7.99, SD 1.80; control: mean 8.13, SD 1.05; MWU test *P*=.57). Similarly, active hours showed no significant difference between groups (patient: mean 13.93, SD 1.57; control: mean 14.80, SD 1.30; MWU test *P*=.14).

We measured the intensity of physical activity using the SD of the phone's magnitude computed from the accelerometer sensor. Again, we found no significant difference in daily physical activity intensity between the groups (patient: mean 0.60, SD 0.32; control: mean 0.58, SD 0.34, MWU test *P*=.35). The temporal trend (Figure 7) showed a general decrease in activity intensity toward the weekend. This reduction is more noticeable in the control group.

Figure 6. Sleep variables extracted from actigraph and bed sensor.



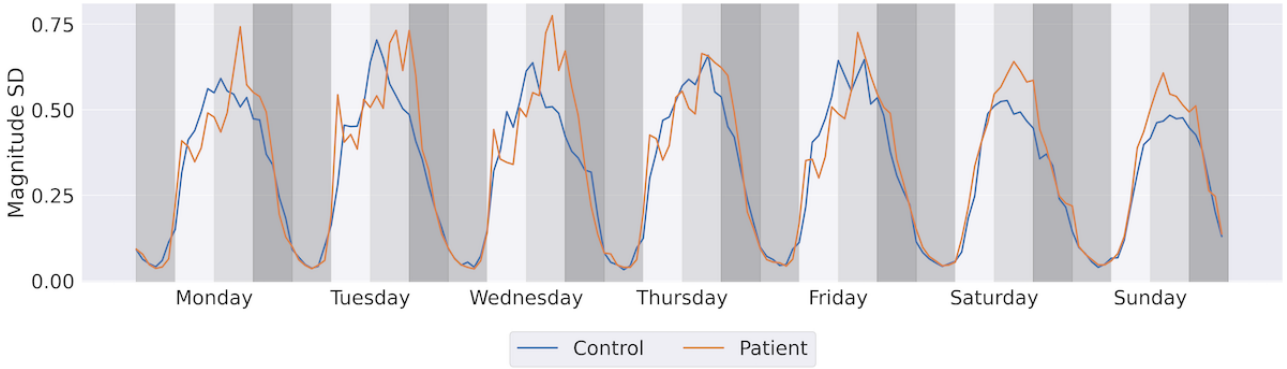


Figure 7. Weekly pattern of physical activity intensity measured by the SD of the accelerometer's magnitude.

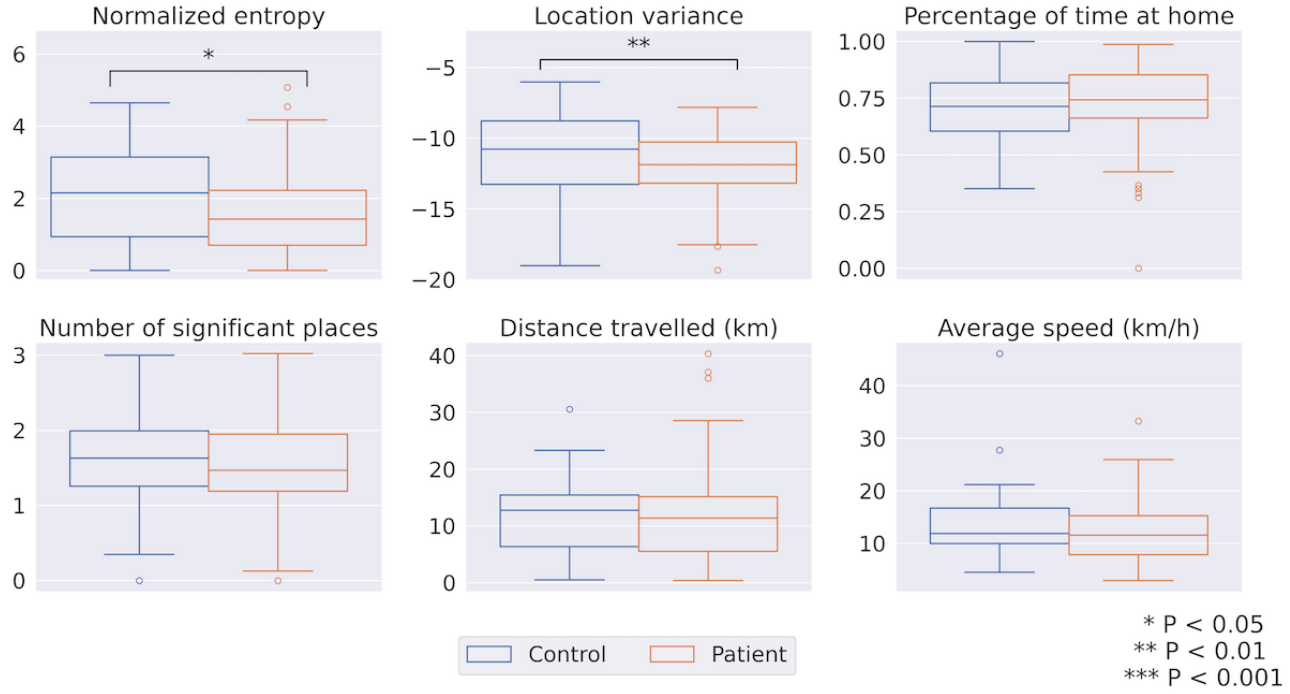

Mobility and Location

Due to the inherent difference in mobility patterns during workdays and weekends, we separated the features for these 2 time frames. Figure 8 demonstrates the weekday location features of the 2 groups. Significant differences were observed in weekday location features. Specifically, both location variance (patient: mean –11.91, SD 2.50; control: mean –10.04, SD 2.73; MWU test *P*=.004) and normalized entropy (patient: mean 1.57, SD 1.10; control: mean 2.10, SD 1.38; MWU test *P*=.05) were lower in patients. However, no significant differences in weekend location features were detected. When the analysis was restricted to participants with work duties, only the weekday location variance remained significant (patient: mean –11.14, SD 2.08; control: mean –10.00, SD 2.80; MWU test *P*=.05). Weekend-weekday location features' values are presented Table S3 in Multimedia Appendix 1.

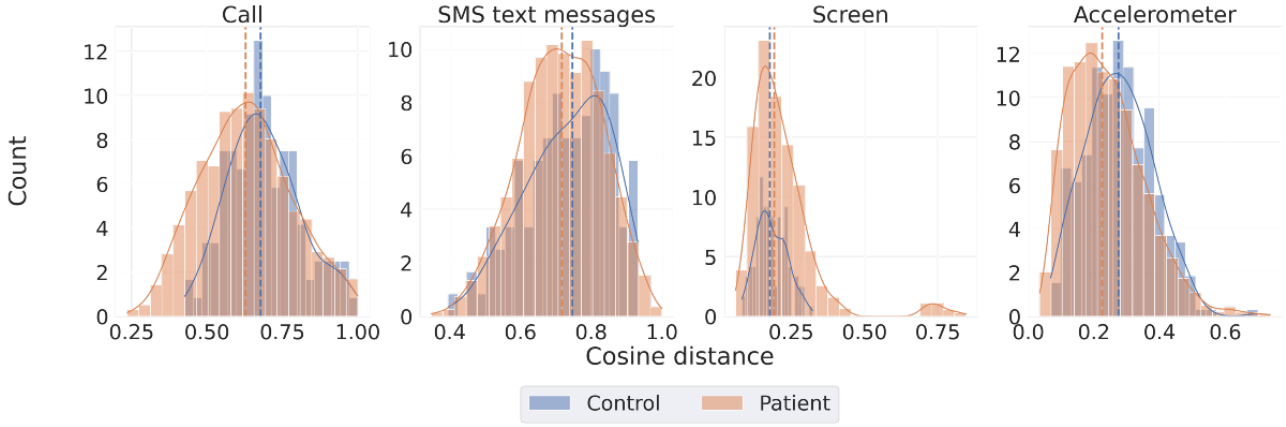
Figure 8. Weekday location features. Asterisks denote significance.



RQ4: Similarity in Temporal Rhythms of Smartphone Use, Social Activity, and Physical Activity Within Subcohorts

We examined the extent to which participants within the same group exhibited similar temporal rhythms of smartphone use patterns. Higher homogeneity of behavior within a group indicates that members exhibit similar behaviors. To compare within-group similarity, we calculated the cosine distance between individuals' average weekly rhythms within each group (patients-patients and controls-controls). We applied the MWU test to determine significant differences between groups' mean distances, thus evaluating internal group consistency. The analysis timeframe was limited to 8 weeks to ensure a consistent evaluation of temporal patterns.

Figure 9 shows the relative within-group distance for each of the groups. Patients established a more homogenous communication rhythm than the controls, meaning that their time allocation for communication was more similar to one another compared to how the healthy controls compared to each other (MWU test, call: P<.001; SMS text message: P=.04). Because most patients did not have full-time jobs at the time of the study, we also examined the potential confounders by composing the same analysis only on the participants who had full-time jobs. Nonetheless, the previous results persisted, meaning employment did not play a significant role in maintaining communication rhythms.

Figure 9. Histogram representing the intradifference of weekly rhythm measured by cosine distance. Smaller distances indicate more intraindividual similarity.

By contrast, patients exhibited less consistent smartphone use rhythms compared to controls (MWU test P=.002). However, among participants with full-time jobs, controls displayed less consistency in smartphone use than patients (MWU test P=.002). Patients exhibited more consistency in activity rhythms captured by accelerometers than controls, across both the entire sample and the group of full-time employed individuals (MWU test P<.001).

RQ5: Sensor Measures as Predictors of Depression Severity

In addition to analyzing the differences in sensor measures between participant groups, we also examined the association between these measures and the severity of depressive symptoms. To this end, we fitted a linear mixed model with each sensor-derived feature as a predictor, the raw PHQ-9 score as the response variable, and participant ID as the grouping factor. Model estimates are presented in Table 3.

Table 3. Behavioral factors predicting the severity of depression symptoms[a].

	Estimates (95% CI)	*P* value
Model 1: communication		
Incoming call duration—W	–0.08 (–0.12 to –0.04)	*<.001*
Outgoing call duration—W	0.05 (0.00-0.09)	*.02*
Number of incoming SMS text messages	0.31 (–0.11 to 0.77)	.14
Number of outgoing SMS text messages	–0.13 (–0.59 to 0.31)	.56
Model 2: location		
Location log variance—W	–0.10 (–0.44 to 0.18)	.48
Normalized entropy—W	0.55 (–0.03 to 1.11)	.08
Distance traveled—W	–0.00 (–0.00 to 0.00)	.12
SPs	–0.11 (–1.33 to 1.19)	.87
Percentage of time at home	0.67 (–2.71 to 4.06)	.68
Model 3: duration of phone and app use		
Social media—W	–0.01 (–0.02 to 0.00)	.24
Communication—W	0.00 (–0.01 to 0.02)	.88
Games—W	–0.01 (–0.03 to 0.01)	.34
Leisure—W	–0.01 (–0.02 to 0.00)	.14
Screen use time—W	0.01 (–0.00 to 0.01)	.10
Model 4: accelerometer		
Magnitude SD morning	–2.05 (–4.18 to –0.20)	*.02*
Magnitude SD afternoon	0.30 (–1.49 to 2.15)	.82
Magnitude SD evening	0.29 (–1.94 to 2.32)	.78
Magnitude SD night	–0.94 (–6.77 to 3.65)	.66

[a]Within-person mean-centered predictors are suffixed with *W*. The unit for duration variables is minutes.

Our analysis of sensor data revealed notable associations in communication and physical activity patterns related to depression symptoms. For communication patterns, the duration of incoming calls was negatively associated with depression symptoms (β=–0.08, 95% CI –0.12 to –0.04; *P*<.001), indicating that shorter incoming call durations were linked to higher depression severity. In contrast, the duration of outgoing calls was positively associated with depression symptoms (β=0.05, 95% CI 0-0.09; *P*=.02), suggesting that longer outgoing call durations were associated with greater depression severity. For physical activity data, the SD of activity magnitude in the morning was negatively associated with depression symptoms (β=–2.05, 95% CI –4.18 to –0.20; *P*=.02).

Discussion

Principal Findings

In the MoMo-Mood study, there were no significant differences in adherence between patients and healthy controls. However, the overall adherence rates for all groups were low. Our analysis of smartphone use patterns did not reveal significant differences between the groups in terms of the daily quantity of smartphone use. However, the weekly temporal patterns revealed distinct preferences, such that the control group typically made or received calls in the afternoon. Furthermore, we initially hypothesized that patients would exhibit notable differences in activities and behaviors crucial for assessing mood disorder symptoms or associated psychosocial disability across 4 domains: social activity, sleep, physical activity, and mobility. Our findings partially supported this hypothesis, as we found significant differences in mobility and location patterns, particularly in terms of normalized entropy and variance of locations during weekdays. However, the groups showed no notable differences in sleep, social, and physical activity patterns.

The within-group temporal rhythm analysis revealed more nuanced findings. The patient group demonstrated more similar communication and physical activity rhythms to one another

XSL•FO
RenderX

than the control group. By contrast, patients showed more varied rhythms in smartphone screen use. Interestingly, this trend for the smartphone screen patterns reversed when we took employment status into account.

Using passive data to predict the severity of depression symptoms, we found that depression severity was negatively associated with the duration of incoming calls and accelerometer magnitude variability but positively associated with the duration of outgoing calls.

Implications

The similarity in smartphone engagement between patients and controls validates the potential of smartphone data as a reliable source for finding new behavioral markers. Notably, despite being mildly to moderately clinically depressed, the patients remained actively engaged with their smartphones. Furthermore, the analysis supports the value of smartphone data in capturing temporal behavioral patterns and reveals differences in behavioral rhythms, including communication and screen use patterns. However, low adherence rates limit the generalizability of this methodology.

In contrast to prior research [10], our study did not confirm the significance of sleep duration in detecting depression symptoms, although it is well known that both insomnia and hypersomnia are symptoms of depression [21]. In the future, we will conduct a more fine-grained analysis focusing on the disturbances and individual differences in sleep.

Our exploration of weekday and weekend mobility patterns and location features revealed a significant difference in weekday normalized entropy and location variance between the groups. These findings are consistent with prior research, such as the studies by Saeb et al [23,24], which identified a significant correlation between depression scores and location features, including location variance and location entropy. The importance of mobility and location data is also supported by previous literature [10,51,52], recognizing these data as crucial components in modeling depression severity.

When examining the similarity of behavior among patients and among healthy controls, we found that, across 3 different activity types—communication via calls and SMS text messages, and smartphone acceleration—patients displayed more similar behaviors to one another. These results persisted even when controlling for the participant's employment status. This highlights the importance of temporality and temporal behavioral features as behavioral markers for mood disorders. The tendency for patients to engage in communication efforts or physical activities at similar times of the day or week may suggest common behavioral trends among patients. For example, this could manifest as an increased number of calls in the morning or a noticeable reduction in physical activity during that time compared to the control group. Such patterns might indicate shared disruptions in circadian rhythms, where patients struggle with energy and motivation early in the day. Alternatively, it may reflect a more structured or predictable routine as a coping mechanism, helping patients manage their symptoms.

It is essential to keep in mind that digital phenotyping studies aim to capture subtle differences and patterns in the behavior of patients and healthy controls, which can possibly be missed even by trained clinicians. Any major behavioral differences between these groups have naturally already been noticed and studied by experts in psychiatry. Our study adds to the body of knowledge in digital phenotyping. It points out essential yet subtle features that need further research and can potentially be used to expand the behavioral symptomology of mood disorders.

Our findings provide valuable longitudinal insights and generalizability by representing different types of patients with major depression. It is important to note that most of our patients experienced from mild to moderate clinical depression, representing the range of severity of most outpatients with depression in health care. However, the inclusion of psychiatric inpatients with severe or psychotic depression, or individuals with BD experiencing manic episodes, might have revealed more marked deviations from standard behavioral patterns. Furthermore, patients were receiving treatment, and it is likely that, for example, the observed sleep symptoms were influenced by ongoing pharmacotherapy.

Our results can help future studies improve their designs, increase adherence, and focus on the most promising digital traces and meaningful features. Ultimately, these findings, combined with insights from future similar studies, may lead to the development of tools for monitoring and in-time intervention for patients with mood disorders.

Limitations

The research is limited by incomplete data, declining participant adherence, and increasing dropout rates as the study progresses. These are common challenges in digital phenotyping studies that may decrease the study's analytical power, introduce bias, and obscure longitudinal patterns and interactions in the data. The sources of poor adherence and incomplete data collection may stem from technical issues, participant burden, lack of motivation, or health status. Other digital phenotyping studies have similarly reported adherence of various degrees, ranging from 65.3% smartphone data completeness (a study with 334 patients with MDD monitored for 12 weeks [53]) to 99% completeness (a study with 29 patients diagnosed with BP monitored for 1 year [54]). The adherence may also vary between the study cohorts. For example, a study [52] reported average adherence levels of 84.8% for patients with BD and 66.8% for the healthy controls for daily smartphone-reported self-assessments collected over 9 months. However, in our study, adherence remained similar for different subcohorts. Our participants were not followed up on or engaged with after they completed the active phase of the study (approximately 2 weeks after the enrollment). The lack of further follow-up or feedback to the participants has likely played an essential role in our dropout rates.

Our study does not include patients with severe depression, inpatients, and patients with psychotic depression. This limits the applicability of our findings for these cases.

This study is limited by the data types that we could collect. Thus, it does not capture the full extent of a person's communication (eg, communication via social media or messaging apps). Furthermore, for devices such as bed sensors

XSL•FO
RenderX

and actigraphs, we relied on the preprocessed data provided by the manufacturer, which can potentially introduce unknown errors and biases.

Future Research

We have collected a very rich dataset that requires much more extensive exploration. This paper provides an overview of the study and compares behavioral patterns at the group level for the passively collected data from smartphones, bed sensors, and actigraphs. Future research should include more detailed analysis at the individual level, a deeper exploration of the parameters highlighted in this study, and an examination of the relationship between passive data and subjective data collected through validated clinical questionnaires.

The results of this study show that the mobile behavioral data, including features from smartphone use, communication, location, mobility, and sleep, collected within this study can be further used to predict and monitor the patients' depression. The group-level differences observed in this study, based on the comparison of rhythms, suggest the importance of focusing on extracting temporal features from behavioral data. Therefore, further studies are required to validate these findings. We have released an open-source behavioral data analysis toolbox, Niimpy [45], to facilitate the studies and encourage researchers to use and further develop it. Furthermore, we propose that future analyses use personalized statistical and machine learning models, accounting for the differences in behavior and sociodemographic information (eg, participant' age, sex, and work status). In the future, we will extend our analyses and explore the possibility of predicting the future mood state and severity of depression from features extracted from the passively collected data.

Conclusions

This study demonstrates the feasibility of harnessing data from a cohort of patients with different types of clinically diagnosed depressive syndromes. It also shows the important features and data streams for future analyses of behavioral markers of mood disorders. However, among outpatients with mild to moderate depressive disorders, the group-level differences from healthy controls in any of the modalities remained relatively modest, despite the demonstration of within-individual variations in behavioral patterns linked to the severity of depression. Overall, the sensors used in passive monitoring may more readily detect gross observable behavioral abnormalities, which may emerge only in the epidemiologically rarer severe range of depression or in mania. Therefore, future studies need to be able to combine data from multiple domains and modalities to detect more subtle differences, identify individualized signatures, and combine passive data with clinical ratings.

Abstract

Background: Smartphones could enhance access to effective cognitive behavioral therapy (CBT). Users may frequently and flexibly access bite-size CBT content on personal devices, review and practice skills, and thereby achieve better outcomes.

Objective: We explored the distribution of actual interactions participants had with therapeutic content in a trial of smartphone CBT for depression and whether interactions were within assigned treatment modules or revisits to prior module content (ie, between-module interactions).

Methods: We examined the association between the number of within- and between-module interactions and baseline and end-of-treatment symptom severity during an 8-week, single-arm open trial of a therapist-guided CBT for depression mobile health app.

Results: Interactions were more frequent early in treatment and modestly declined in later stages. Within modules, most participants consistently made more interactions than required to progress to the next module and tended to return to all types of content rather than focus on 1 skill. By contrast, only 15 of 26 participants ever revisited prior module content (median number of revisits=1, mode=0, IQR 0-4). More revisits were associated with more severe end-of-treatment symptom severity after controlling for pretreatment symptom severity (P<.05).

Conclusions: The results suggest that the frequency of use is an insufficient metric of engagement, lacking the nuance of what users are engaging with and when during treatment. This lens is essential for developing personalized recommendations and yielding better treatment outcomes.

Introduction

An estimated 21 million US adults experienced at least 1 major depressive episode in 2021; yet, only 61% of these individuals are expected to have received any past-year treatment [1]. Mental health care providers caution that waitlists already far exceed what can be addressed by the current workforce and demands for treatment are expected to continue to rise [2]. Smartphone-delivered psychotherapies offer increased access to care in the face of limited clinician availability by reducing clinician hours or duration of treatment. Promisingly, cognitive behavioral therapy (CBT) treatments delivered fully or in part via smartphone apps have demonstrated efficacy for depression [3-5].

App-delivered CBT can be implemented as a standalone, self-guided treatment or alongside varying degrees of human support (eg, asynchronous messaging or teletherapy sessions). Apps can ideally offer users "bite-size," high-quality psychoeducation and empirically supported treatment tools that can be unobtrusively accessed on their personal smartphone when and where it would be most helpful. For example, a user might return to an earlier lesson on cognitive restructuring for a quick reminder about the skill when feeling upset at work; later that day, they might open their ongoing activity scheduling log when feeling unmotivated. By serving as an on-demand "pocket therapist," app-delivered CBT might even stand to improve treatment response rates, which are only around 42% for face-to-face CBT for major depressive disorder (MDD; see [6] for meta-analytic review). Indeed, a core tenet across CBTs is that reviewing and practicing skills is necessary for recipients to benefit and see long-term gains; this effect has been shown in traditional face-to-face formats as well as single-session interventions and digital formats [7-11]. The CBT model aims to equip patients with the ability to recognize patterns in their own thoughts, feelings, and behaviors and routinely apply new approaches to emotional situations. To do so requires repetition; at minimum, identifying a pattern necessitates multiple data points, and new thought or behavioral patterns must replace old ones [12]. Thus, the unique benefit of flexible, real-world treatment integration may depend on users engaging with app content frequently and accessing a range of different skills that are well-matched to their needs.

In reality, however, app-based treatments often struggle with high user dropout [13,14] and little is known about how users actually interact with app content throughout treatment [15]. Indeed, app-delivered interventions for depression are commonly completed by fewer than 50% of research participants [16] and 1 study of high-fidelity smartphone CBT treatments showed the modal number of sessions is one [17]. These sobering findings undermine the assumption that providing treatment material at one's fingertips will translate into frequent use of that material.

Of those who stay in app-supported treatments, questions remain regarding the dose (both per access and frequency of access) needed for clinical benefit [16]. In general, meta-analysis suggests that greater engagement with digital interventions is associated with improvement in mental health symptoms [18]. However, this conclusion is complicated by the fact that operationalizations for app engagement vary widely (ie, time spent on an app, number of messages sent, number of logins, number of modules completed, frequency of self-monitoring, days used, and self-reported frequency of use) [19,20] as do strength and direction of results. In this vein, some work suggests that the relationship between app use and depression treatment outcomes is nonlinear [21], which further contradicts the belief that users who engage more with app content will necessarily benefit most.

CBT models assume that by building up a person's repertoire of skills, they will be better able to handle the diverse challenges faced in life [22]. It is perhaps unsurprising, then, that one systematic review found that higher module completion rates—more so than frequency of app use—are associated with better depression outcomes [23]. Thus, the nonlinear relationship between the frequency of app use and outcomes may suggest that differences in how a user engages with app content (what content they use rather than how often they use the app overall) predict intervention outcomes. It is also possible that building mastery in one or two specific skills (ie, repeating frequently) will be most beneficial [24]. For example, 1 study found that participants who used behavioral activation content within the provided CBT for MDD app were more likely to benefit than participants who did not use this content [25]. Moreover, focusing on content or skills practice solely during the treatment module in which it is introduced or formally assigned may be less beneficial than practicing those skills the same number of times but spaced throughout treatment and thus integrating a greater range of skills. Indeed, data from internet-delivered interventions show wide variability in how much different users look at content within versus across treatment sessions [26], suggesting that similar between-user differences may emerge during app-based interventions. The impact of such heterogeneity remains an open question. More clarity may be gained by homing in on what material or skills users return to and when, rather than treating all bouts of app use as interchangeable. Specifically, we introduce a novel dimension of engagement, differentiating between skills review or practice that occurs within a treatment step (akin to rehearsing what a person learned from their therapist that week) from that which occurs across steps (akin to going back to old lessons or skills to sustain gains or implement in new situations). The latter is particularly compelling given how flexibly treatment developers imagine their tools will be used and the field's lack of data on how users navigate them in practice.

This study therefore investigates how users accessed therapeutic content throughout an 8-week therapist-guided CBT for depression smartphone treatment [27] to test two predictions: (1) users will access content more than required within modules and will revisit content from previous modules; and (2) more frequent within- and between-module content review will be associated with better outcomes. Specifically, we visualized and quantified the degree to which users accessed various app content both within and across 8 different treatment modules. We then explored whether different use patterns were associated with baseline characteristics and treatment outcomes.

Methods

Ethical Considerations

The study was approved by the institutional review board of Massachusetts General Hospital (2020P001958). All participants provided informed consent before the initiation of study procedures and were given the ability to opt out at any point. Data were deidentified to protect participants' privacy. Participants were compensated US $25 at mid-treatment, end of treatment, and 3-month follow-up assessments.

Study Design

This is a secondary analysis of a recent trial of Mindset for Depression (Mindset) [27]. Participants completed an 8-week trial of app-led CBT for MDD with therapist support (through brief weekly video-conferencing appointments and asynchronous in-app secure messaging). Assessments used in this project were conducted at baseline (pretreatment) and week 8 (posttreatment). Self-report measures were administered via web-based survey during the aforementioned assessment visits. Study staff monitored for measure completion and were able to confirm with participants whether any measures were left blank intentionally or required completion. App use data were collected continuously via the Mindset app.

Participants

A total of 28 adults enrolled in an open trial of Mindset [27]. Further, 2 participants completed the trial but were excluded from the present analyses due to a technical issue resulting in missing app use data. Additionally, 2 further participants did not complete the trial and were lost to follow-up; however, as app use data were available for these participants, they were retained in these analyses. This resulted in a final sample of 26 adults. To be included in the trial, individuals were aged at least 18 years, living in Massachusetts, presenting with a current primary *DSM-5* (*Diagnostic and Statistical Manual of Mental Disorders* [*Fifth Edition*]) diagnosis of MDD and at least moderately severe symptoms (Patient Health Questionnaire-9 [PHQ-9] score ≥10; [28]), and, if taking psychotropic medication, were on a stable dose of those medications for at least 2 months before enrollment and throughout the trial. Potential participants were excluded if they had already completed 4 or more prior sessions of CBT for depression; presented with current severe substance use disorder, lifetime bipolar disorder or psychosis, or acute and active suicidal ideation (as indicated by either clinical judgment or a score ≥2 on the past month suicidal ideation subscale of the Columbia-Suicide Severity Rating Scale [29]); were engaged in concurrent psychological treatment; or were unable to engage with treatment (eg, did not own a supported mobile smartphone). See Table 1 for a summary of demographics. Table 2 includes baseline clinical characteristics.

About Mindset

The Mindset app delivers core CBT for MDD psychoeducation and skills practice organized into 8 modules and designed to be used with therapist support over 8 weeks. See Table 3 for a summary of app content. Treatment includes psychoeducation, cognitive restructuring and core beliefs, behavioral activation, mindfulness, and relapse prevention [27,30,31]. Modules, and activities within each module, unlock one at a time after users have either completed the requisite didactic material (eg, users can practice "catching" cognitive distortions after they learn about what cognitive distortions are) or completed sufficient practice (eg, users begin scheduling weekly activities after monitoring their habits and associated mood for 1 week). This pacing is intended to reinforce regular practice and allow skills to build. Therapists supported participants' progress in the app-led treatment through 8 weekly video-conferencing appointments (16-25 minutes each) and were available via asynchronous in-app secure messaging. Sessions were intended to monitor risk (eg, the emergence of suicidal ideation or adverse events), enhance motivation, clarify and practice the skills learned via the Mindset app, and problem-solve treatment barriers. Therapists were licensed, doctoral-level clinicians with training in CBT for MDD. They had access to a therapist dashboard that displayed patient progress in the app. Weekly supervision from the principal investigator (expert in CBT) was also provided. Therapists were instructed to focus on whatever content patients had engaged with in the app and not to introduce additional therapeutic skills or modalities. Fidelity was monitored in weekly supervision, via therapist self-checks included within session records, and via adherence ratings (ie, the degree to which forbidden content was introduced). Notably, 100% (40/40) of rated session tapes (40/212, 19%) were rated to be completely adherent. Participants attended an average of 7.6 (SD 1.5) of 8 available therapist appointments and sent a median of 0 (IQR 0-4) between session messages to their therapist through the app.

Table 3. Mindset for depression content.

Content	Module	Activities
Psychoeducation on major depressive disorder and cognitive behavioral therapy	1	• Read and watch videos of didactic material
Cognitive restructuring	1	• Read didactic material • Practice identifying cognitive distortions • Practice constructing alternative thoughts
Understanding the relationship between behavior and mood	2	• Read didactic material • Record activities and associated mood
Behavioral activation	3-8	• Read didactic material • Schedule activities • Record activities and associated mood
Mindfulness	4-6	• Read and watch videos of didactic material • Listen to guided mindfulness exercises
Modifying core beliefs and building self-esteem	7	• Read didactic material • Practice identifying and challenging negative core beliefs
Relapse prevention	8	• Read didactic material • Implement strategies to consolidate skills and maintain gains

Measures

Overview

Independent evaluators (ie, Master's and doctoral-level clinicians) assessed participants for study eligibility at baseline using the MINI (Mini International Neuropsychiatric Interview, version 7.02 [32]), which is a semistructured diagnostic assessment of the *DSM-5* psychiatric disorders.

Depression Symptom Measures

To measure clinician-rated depression symptom severity, trained independent evaluators administered the Hamilton Depression Rating Scale (HAM-D; [33]). The HAM-D consists of 21 items rated on a mixture of 3- and 5-point Likert scales, with the total score equaling the sum of the first 17 items. Scores can range from 0 to 52, with higher scores indicating greater depression severity. The HAM-D has demonstrated substantial reliability and validity as a measure of depression severity across many populations (see [34] for review).

To measure self-reported depression symptom severity, participants completed the PHQ-9. The PHQ-9 is a widely validated measure (see [35]) consisting of 9 Likert scale items ranging from 0 (not at all) to 3 (every day) that map onto the *DSM-5* symptom criteria of MDD. Higher scores indicate greater depression severity. The HAM-D and PHQ-9 were both administered at baseline and posttreatment (week 8) to establish change in depression severity throughout treatment.

Mindset Belief Measures

Participants' beliefs about the credibility of Mindset and their degree of optimism regarding the treatment having a positive effect on them were measured at baseline using only the self-report Credibility/Expectancy Questionnaire (CEQ; [36]). The CEQ has good psychometric properties [36] and includes 2 subscales that can range from 3 to 27. Higher scores correspond to higher treatment credibility and higher outcome expectancy, respectively. Participants' satisfaction with the Mindset intervention was assessed using the 8-item Client Satisfaction Questionnaire (CSQ; [37]) at week 8 only. This self-report questionnaire has excellent psychometric properties [37]. Scores on the CSQ can range from 8 to 32, with higher scores indicating greater satisfaction.

Internal reliability for all scale measures in the present sample is provided as McDonald Omega (ω_t) values in Table 2.

Mindset App Use Measures

The Mindset app passively logged every user interaction concerning the date and time that it occurred, what element of the Mindset app was opened (eg, home screen, library, or exercise), what type of action was automatically registered as occurring (eg, app opened, app paused, or exercise complete), the specific type of app content engaged with, and device information (eg, operating platform). The app also automatically logged the date that each participant unlocked each intervention module. We measured app use by counting the number of app interactions that each participant initiated throughout the entire intervention. We further identified how many overall app interactions were to app content from previous modules and how many were to app content associated with the module they were currently assigned to complete. We obtained these app interaction count variables according to the steps described in the Data Analysis section. Participants were additionally asked to answer 1 question at week 8 to capture their perceived treatment use off the app. Specifically, participants were asked how much time they spent practicing treatment skills off the app. Responses were considered in the number of minutes in integer format. More self-reported time spent practicing on and off the app corresponds to greater treatment use.

XSL•FO
RenderX

Data Analysis

Identifying App Interactions

To quantify repeated engagement with app-based content, we identified each time a participant opened a unit of content (eg, video about the nature of depression, cognitive restructuring practice, or mindfulness audio) during the 8 weeks of their active treatment. This action was counted as long as the content or app was not subsequently closed in fewer than 5 seconds. We set this 5-second threshold a priori to remove instances when a person spent so little time on the content page that we could reasonably assume that they had clicked into the page without meaningfully engaging with it (while not being so restrictive as to remove potentially meaningful interactions when a participant may have been briefly reminding themselves of a principle taught in an earlier exercise). We consulted with the app developers who confirmed that there was no other way to identify errant app openings than to set a time threshold. An exercise did not have to be completed to be counted (eg, repeating 3 minutes of a 5-minute mindfulness audio or using some, but not all, of the challenging questions within a cognitive restructuring exercise). We also identified all logging behaviors (ie, scheduling activities, recording completed activities, and associated mood), counting only those that had not been submitted within 30 minutes of other logged content of the same type. We set this 30-minute threshold a priori to address logging bursts (eg, a participant who scheduled 26 activities in 1 sitting). From our perspective, a logging burst does not represent many unique interactions; returning to log throughout the day, by contrast, suggests separate attempts to integrate the app into daily life. As such, a participant who logged 26 activities within 30 minutes would be given credit for 1 activity scheduling interaction (not 26). We chose to set this threshold to 30 minutes to be conservative after comparing the number of removed surveys using candidate thresholds of 10 minutes, 20 minutes, and 30 minutes. These sensitivity tests found that the 30-minute threshold only removed an additional 31 observations than the 10-minute threshold. We elected to use the 30-minute threshold before running analyses. We refer to these retained actions as "interactions" moving forward.

Overall Use

We first computed the overall and per-person total number of interactions across this study (8-week treatment) and the distribution across modules. To describe between-person differences in the frequency of app interactions, we calculated the median number of interactions logged by each participant, as well as the IQR (presented as the 25th and 75th percentiles in the data).

Within-Module Use

We next examined the number and proportion of interactions that occurred within each treatment module during a participant's progression through the treatment (eg, completing a module 1 cognitive restructuring exercise while in the module 1 treatment stage; listening to a module 4 guided mindful breathing exercise while in the module 4 treatment stage).

Between-Module Use

We then considered the number and proportion of interactions for which a participant "revisited" prior content within a module different from the stage they were currently in (eg, completing a module 1 cognitive restructuring exercise while in the module 3 treatment stage and listening to a module 4 guided mindful breathing exercise while in the module 8 treatment stage). For modules that were revisited, we examined which activities within that module were most frequently revisited.

Exploratory Analyses

Exploratory analyses were conducted in R (version 4.3.3, R Foundation). First, to explore which baseline characteristics (user age, PHQ-9, HAM-D, CEQ-credibility, or CEQ-expectancy) and treatment-focused self-report features (CSQ or perceived treatment use) predicted number of app interactions (overall, within-module, and between-module), we conducted a series of univariate quasi-Poisson regression models with robust SEs. Quasi-Poisson models were fit using the "glm" function in the base R *stats* package. Robust SEs were implemented using the *sandwich* package [38,39]. The number of overall interactions, within-module interactions, and between-module interactions were treated as dependent variables in separate models. Only 1 baseline or treatment-focused predictor variable was included in each model. This resulted in 21 total models. All predictors were grand mean-centered, apart from perceived treatment use, which was log-transformed due to its right-skewed distribution. We fit these count models with a quasi-Poisson distribution given our interaction counts evidenced overdispersion on a small sample, rendering Poisson regression and negative binomial models less appropriate, respectively. We used a robust SE estimating procedure given our small sample.

To explore whether different app use patterns predicted better treatment outcomes on PHQ-9 and HAM-D measures, we conducted a series of univariate residual change score models using robust linear regression. Specifically, week 8 PHQ-9 and week 8 HAM-D were treated as dependent variables in separate models. Baseline PHQ-9 and baseline HAM-D (both grand mean centered) were entered as independent variables in their respective models, along with the specific app use count variable under investigation. This resulted in 6 additional models. These models were fit with the "rlm" function from the *MASS* package [40]. Robust *P* values were obtained for all models with the *repmod* package [41]. We fit these models with robust methods to relax model assumptions to retain all participants in this limited sample; robust models are better able to handle outliers without biasing estimates, allowing for all participants' data in this present sample to be included.

To reduce the risk of type I error, we applied a Benjamini and Hochberg false discovery rate (FDR) correction to all models using the "p.adjust" function in the base R *stats* package.

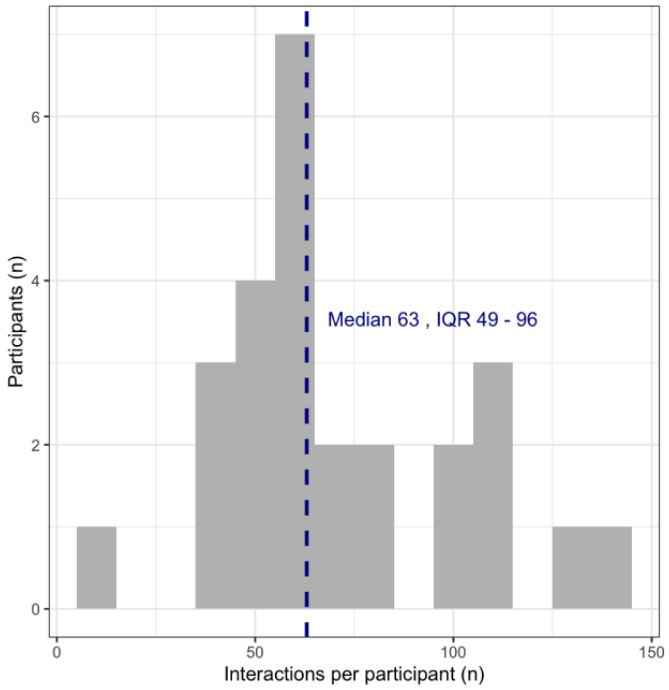
Results



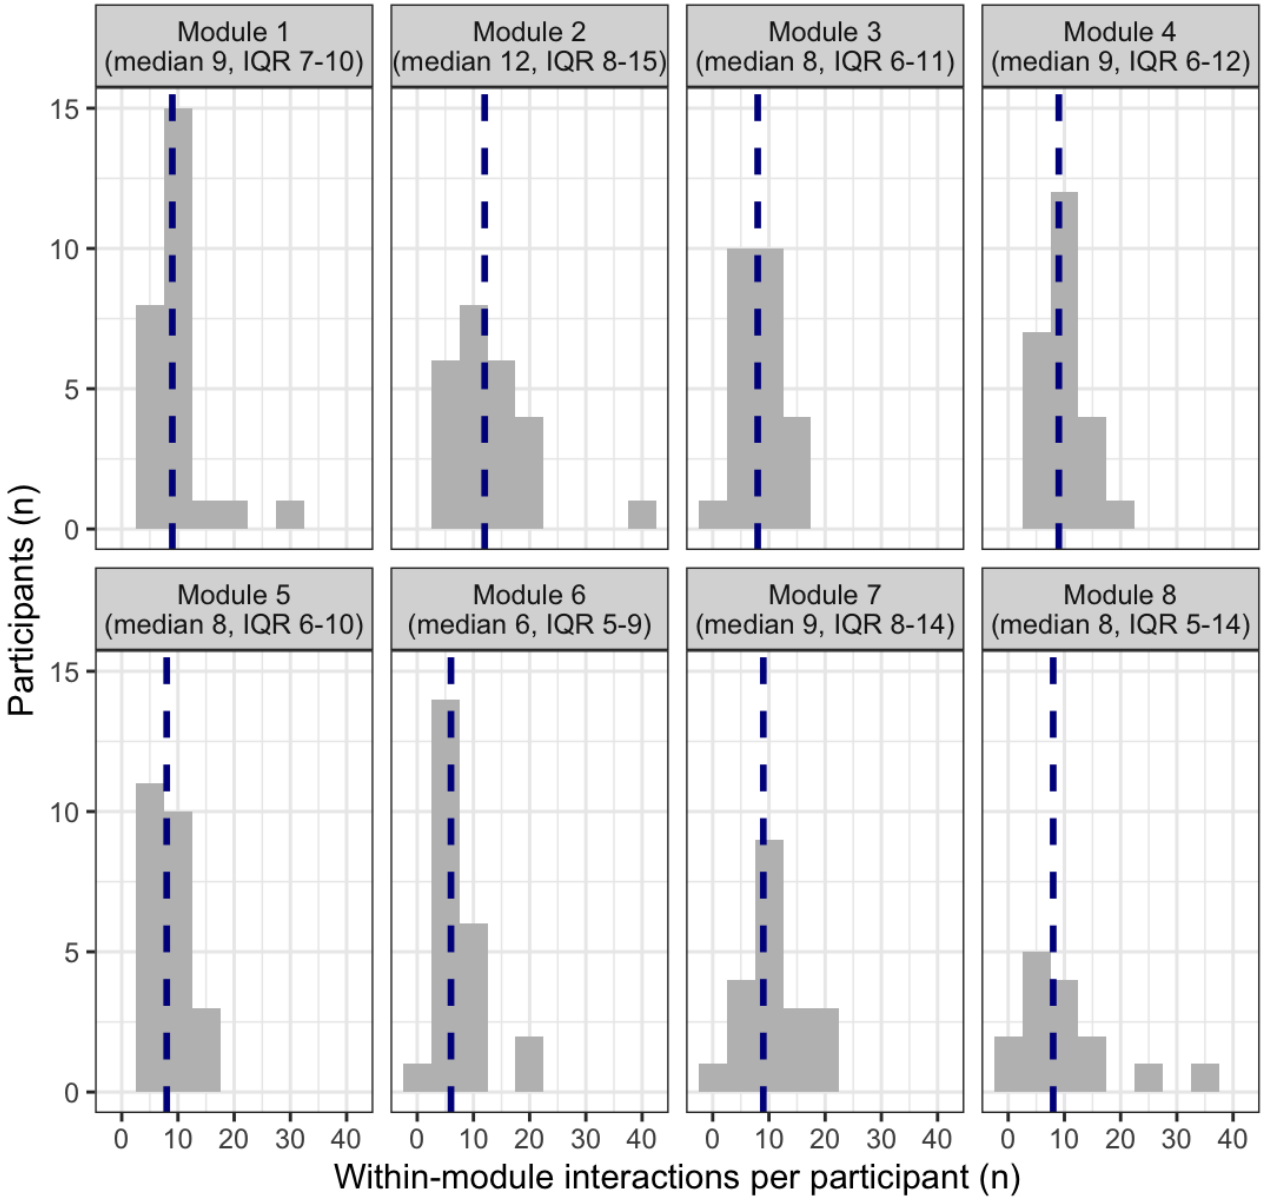
Overview of Previously Reported Intervention Outcomes

A total of 24 of the 26 participants included in the analyses completed the 8-week trial. A detailed summary of app development and clinical outcomes is reported in the study by Wilhelm et al [27]; key findings are shared here. As described in the primary trial paper [27], participants self-reported using the app or practicing CBT skills (on or off the app) for a median of 50 (IQR 30-60; week 4) or 60 (IQR 30-90; week 8) minutes per week; participants accessed the app on an average of 36.8 (SD 10) days. Participants' depression symptoms (HAM-D scores) decreased from, on average, moderate severity (mean 19.1, SD 5) at baseline to mild severity at week 8 (mean 10.8, SD 6.1; g_{ave}=1.47; P<.001). By week 8, a total of 13 participants were classified as responders (HAM-D score reduction ≥50%) and 10 as in remission (HAM-D score ≤7). Further, 18 (69%) participants completed all 8 modules during the 8-week treatment period, 3 (11%) completed 6 modules, 3 (11%) completed 5 modules, 1 (3%) completed 2 modules, and 1 (3%) did not complete any modules.

Overall Use

Across the 26 participants with available app use data, we retained 1860 interactions across learning activities (n=254 interactions; didactic material presented via readings or videos), practice activities (n=500 interactions; active skills practice, eg, restructuring a thought or mindfulness practice), and scheduling activities and tracking associated mood (n=1106 interactions). The highest proportion of interactions occurred in modules 1 and 2 and interaction rates declined modestly across subsequent modules: 339 (18.2%) in module 1, 327 (17.6%) in module 2, 220 (11.8%) in module 3, 230 (12.4%) in module 4, 199 (10.7%) in module 5, 175 (9.4%) in module 6, 213 (11.5%) in module 7, and 157 (8.4%) in module 8. At the participant level, the number of unique interactions ranged from 8 (the participant who dropped within the first week and before completing module 1) to 144 (median 63, IQR 49-96). Note that the minimum number of interactions required to complete the full program is 62. See Figure 1 for a distribution of participant-level interactions.

Figure 1. Histogram of person-level total interactions with the Mindset app. The dashed vertical line represents the median value of interactions.



Within-Module Use

Out of all 1860 interactions retained, 94.3% (n=1754) comprised activities within a participant's current module. At the participant level, within-module interactions also ranged from 8 to 144 (median 60.50, IQR 49-80). Figure 2 visualizes the distribution of within-module interactions across treatment modules. Most participants made more interactions than were necessary across all modules and they tended to return to all types of available content (eg, revisiting a psychoeducational video a few times and logging more activities than necessary to progress). Moreover, there were no "clear winners" for which specific pieces of app content participants tended to use at higher than required rates. The one exception is concerning activity logging; for example, 1 participant entered 30 logs throughout module 8, even after log bursts were removed. This also explains the right skew to the distributions seen in some modules, which otherwise tended to be relatively tightly clustered. See Figure 3 for a visualization of participant-level behavior.

Between-Module Use

A total of 106 (5.7%) interactions comprised activities that met our a priori definition of "revisiting" a previous module. At the participant level, between-module interactions ranged from 0 to 36 (median 1, IQR 0-4). Figure 4 visualizes the distribution of person-level between-module interactions. Although recommended, between-module use was not required to progress through treatment content; in practice, between-module use was very rare in these data. Further, 11 (42.31%) participants never revisited any previous module. Of the between-module uses observed, over three-quarters were to a module 1-associated activity (82 out of 106, which were registered by 12 participants). Of the 82 revisits to module 1, a total of 12 (14%) were to psychoeducational content (10 revisits to general CBT overview, 2 revisits to psychoeducation on the nature of depression), 33 (40%) were to a practice exercise accessed through the module 1 page (eg, "catch the thinking trap" and "evaluating your thoughts"), and 37 (45%) were to the "check in with your thoughts" practice tool accessed through the library. The higher likelihood of returning to module 1 is reflected in Figure 5, which visualizes the distribution of between-module interactions across treatment modules. Participant-level behaviors are visualized in Figure 3.

Exploratory Analyses

Spearman correlations between individuals' number of overall, within-, and between-module interactions and baseline (HAM-D, PHQ-9, CEQ-Credibility, and CEQ-Expectancy) and end-of-treatment (HAM-D, PHQ-9, CSQ, and perceived treatment use) features are provided in Table 2. Although the total number of interactions and the number of within-module interactions were significantly positively correlated with each other, neither of these 2 app use features were significantly associated with any of the clinical features examined. The number of between-module interactions was not significantly correlated with overall or within-module interactions, nor with any clinical or treatment-focused self-reported feature.

Analyses exploring potential predictors of treatment use patterns found that age was significantly positively associated with the number of between-module interactions (b=0.07, SE 0.03, z=2.70, 95% CI 0.011-0.129; P=.007, rate ratio=1.07); baseline treatment credibility was significantly positively associated with the number of between-module interactions (b=0.17, SE 0.09, z=2.01, 95% CI 0.0014-0.34; P=.04, rate ratio=1.19); and week 8 treatment satisfaction was significantly positively associated with the number of overall (b=0.05, SE 0.02, z=2.27, 95% CI 0.01-0.09; P=.02, rate ratio=1.05) and within-module app interactions (b=0.04, SE 0.02, z=1.97, 95% CI 0.001-0.08; P=.049, rate ratio=1.04). Rate ratios can be used to interpret effect sizes within count models. For example, the rate ratio of 1.07 above suggests that, holding all other predictors constant, for each 1 unit increase in age the expected count of within-module logins increases by a factor of 1.07. Residual change score models found that the number of between-module interactions was significantly positively associated with week 8 PHQ-9 scores, even after accounting for baseline PHQ-9 scores (b=0.23, SE 0.11, t=2.10, 95% CI 0.014-0.446; P=.049). No other explored effects were significant at an α level of .05. None of the above effects survived FDR correction.

Discussion

Principal Findings

In this study, we quantified how participants engaged with didactic content and guided skills practice within and across treatment modules of Mindset, an 8-week therapist-guided CBT smartphone app for MDD. Our goal was to investigate to what degree people repeated and revisited content, and whether more repetition promoted better treatment outcomes. We found that 18 (69%) individuals completed all content within the app and 14 (78%; 53% of the total sample) of those individuals engaged with content more times than was required to complete the treatment protocol. The number of interactions logged varied widely across the sample (median 63, IQR 49-96), and only 106 (5.7%) of those interactions were to revisit content from a previous module. Before FDR correction, exploratory analyses found that older participants tended to log more app revisits; participants who saw the treatment as more credible at baseline tended to log more app revisits; participants who were more satisfied with the treatment at week 8 tended to log more overall and within module app interactions; and participants with worse self-reported depression symptoms at week 8, after controlling for baseline self-reported depression symptoms, tended to log more app revisits.

Despite the ease of access, mental health app use rates are generally low in clinical trials for depression [13,42] and are even worse outside of research contexts [13,43]. Yet, there remains meaningful variability. For example, a recent scoping review of digital mental health interventions for depression reported attrition rates across 11 studies ranging from 7% to 85.6% and only 50% or fewer participants completed their given digital intervention as intended [16]. This suggests that important differences in user characteristics, app content, and app design may be differentially associated with engagement. The present data extend this literature by not only reporting completion rates but also by highlighting the degree to which some users repeated content (ie, beyond typical criteria for adherence or completion). Indeed, approximately half of the present sample engaged with the app more times than was strictly necessary—even with regular appointments with a therapist, which offers modest support for the hope that providing treatment material at users' fingertips will translate into frequent, personally driven use of that material. That said, the number of overall interactions with the app was unrelated to any baseline or end-of-treatment variables. This further motivates a more nuanced look at how patients use available content and whether they naturally gravitate toward the types of content and cadence of app use that are most likely to be beneficial to them [44].

Although just over half of the users in this study reviewed the content of all types more than was required (eg, reread psychoeducation or logged more than the minimum number of activities required to progress in the app), 11 (42%) participants did not revisit content from previous modules at all. Moreover, 10 of the 15 participants who did revisit a previous module did so fewer than 5 times. Participants instead tended to focus on whatever content was delivered within a given module. This suggests that most users may rely on the program to suggest the type of work that would be most beneficial for them at a given point in treatment. Thus, if developers intend for users to review old content throughout a trial, the typical user may require explicit reminders to return to previous content, repetition built into future modules, or a feature allowing for bookmarked exercises to be highlighted and easily found. This also presents a clear opportunity for user-centered and co-design methods as well as more effective collaboration with designers [45]. This would allow greater insight into how users navigate digital mental health tools and what product modifications could have the greatest impact.

Of the participants who returned to previous app content, they most often revisited foundational content such as psychoeducation (regarding depression and the CBT model) and cognitive skills (eg, identifying and challenging maladaptive thoughts) in particular. This may simply be due to their being introduced earliest in treatment and thus more likely to be forgotten later on, necessitating a revisit. This pattern could also align with past work on user preference; in a survey-based study interviewing smartphone owners (n=119) with depression, anxiety, or both, 64.7% of respondents endorsed interest in psychoeducation as a specific feature of a mental health app and 72.3% were interested in a module on cognitive restructuring [46]. Mastering psychoeducational content may be advantageous given known associations between health literacy—or understanding one's condition—and treatment options, adherence, and outcomes [47,48]. Many participants in this study had never received treatment for MDD before and could thus have relied more heavily on these components to gain insight and to better understand their progress. Interestingly, although there is a lack of research comparing engagement with psychoeducation or cognitive skills versus other content within the same app, studies comparing engagement across mental health apps suggest that individuals typically engage with these elements less than others; for example, apps using psychoeducation as the primary tool have lower rates of engagement in terms of daily minutes when compared to apps with other tools, such as mindfulness or meditation and peer support [13]. This again, however, highlights the importance of examining what users are engaging with; it may simply require fewer minutes to consume brief psychoeducational material than to complete a 10-minute mindfulness exercise. Similarly, stand-alone cognitive apps seem to have sharper drop-offs than behavioral activation-focused programs. Taken together, present results highlight the need to consider the interaction between treatment components; for instance, individuals may be more likely to return to foundational content when it is integrated with more actionable accompanying skills such as behavioral activation. Helping users to understand the personal relevance of the content and the anticipated effect on their mood may increase engagement. Again, bringing users into this process is essential to truly understand the observed patterns, their impact on outcomes, and the desired program changes.

Before FDR correction, baseline treatment credibility was positively associated with revisiting prior modules. In other words, participants who entered this study with more positive views of CBT or mHealth approaches were more likely to revisit

XSL•FO
RenderX

material during treatment. This finding may suggest that participants with more initially positive views of Mindset were more motivated to return to foundational skills to glean more from treatment. Yet, revisits were overall very infrequent, and using the app more overall—within-module in particular and again before FDR correction—was ultimately associated with more satisfaction with the program. As causality cannot be determined presently, it is possible that individuals who found the program less helpful or personally relevant chose to engage less; it is also possible that engaging more—particularly with the activities that the program assigned each week—led participants to feel that they were benefiting or connecting more with the materials. Both app use and satisfaction could also be explained by third variables, such as perceived fit (ie, how well the treatment aligns with a person's symptoms and preferences) or motivation. Replication in a larger sample is required to tease apart this association.

Surprisingly though, more revisits in the present sample were associated with more severe end-of-treatment self-reported depressive symptoms, after controlling for pretreatment self-reported depressive symptoms. Although we expected more frequent revisits to boost treatment efficacy, it could be that participants with relatively elevated symptoms after 8 weeks had good insight into their need for extra support throughout the intervention, which prompted them to return to foundational materials more often. This pattern could also be because people with higher levels of depression may have had greater difficulty remembering or required more repetition due to the cognitive symptoms of MDD (eg, poor concentration), felt less confident in their knowledge about the foundational psychoeducational content, or may have felt frustrated by lack of progress; as such, their revisits may have represented lesser mastery of the information or cycling back through the material to see if anything critical may have been missed. Yet another potential explanation is that stronger clinical response is associated with greater independent skills use off the app (ie, enactment in daily life); thus, sustained reliance on the app could suggest lesser comprehension of skills or difficulty integrating skills into daily life. However, we did not see any association between the perceived number of minutes reportedly spent practicing off-app and any clinical or app use feature in the present sample.

That said, our finding is interestingly misaligned with another trial of app-based CBT for MDD, which found that participants with better treatment response completed more in-app cognitive restructuring and behavioral activation experiments than peers with lesser response [25]. Of note, participants in the trial were supported by prescribing physicians, rather than CBT therapists, and with variable frequency, making it more challenging to directly compare the studies. It is also possible that our finding is an artifact of a small sample with low variance—again, few people revisited any content, and those who did usually did so infrequently—or the availability of a CBT therapist for skills review. Moreover, this effect did not survive FDR correction, so it is similarly possible our finding is a false positive in need of replication in a larger sample. However, this potential discrepancy highlights broader questions in the field; evidence for how best to capture the use of digital treatments (guided and self-guided; for depression and other targets) and whether use patterns relate to outcomes remains mixed [18]. While some studies have found significant positive associations between engagement and outcomes [49], others have not [50]. Such heterogeneity encourages moving away from one-size-fits-all approaches; recommending the same dose or pace for all patients is likely inefficient and is possibly reducing overall efficacy.

Indeed, researchers have begun to favor "effective engagement" over simply more engagement [51] and highlighted the need for greater integration of evidence-based engagement strategies in addition to cognitive behavioral ones [52]. Users would likely benefit from more personalized recommendations that offer greater insight into their own behaviors. Increased insight facilitates deeper user engagement with digital mental health interventions [53] and is itself associated with better treatment outcomes [54]. One example of personalization is providing ongoing feedback on progress to bolster motivation and guide users to where they could benefit from additional review or continued practice [55]. Additionally, individual characteristics may be informative; in this sample, older participants were more likely to revisit content from earlier modules than their younger counterparts. Although this requires replication in a larger sample this pattern could reflect different learning needs. Tailoring interventions to each user's individual needs has been shown to reduce attrition [42,56] and lead to improved mental health outcomes [57,58]. Moreover, research suggests that too frequent engagement with certain aspects of mental health apps may inadvertently lead to fatigue and could thus contribute to worse outcomes [50]. Thus, continuing to examine what people are engaging with and how, rather than mere frequency of use, is critical for optimizing digital interventions. In particular, it will be critical to partner with users and other stakeholders to better clarify, operationalize, and evaluate the malleability of subjective aspects of engagement that appear to have an outsized impact on treatment response [59].

Limitations

First, our sample size from this pilot trial is small and has limited demographic heterogeneity (ie, n=21, 80.8% identified as women; n=21, 80.8% identified as non-Hispanic; n=18, 69.2% identified as White); as such, demographics could not be examined as predictors of app interactions or outcomes. Moreover, no effects remained significant after the FDR correction. The present data were powered as an acceptability and feasibility intervention pilot study without respect to app use patterns, potentially rendering these analyses underpowered. Replication in larger, more generalizable samples is therefore needed. However, these data highlight that heterogeneity in-app use, even among a small sample, is high and warrants continued investigation. Second, given the design of the Mindset app, we were only able to consider the use of "pull" components, or content that is available for access in the app and with which the user must initiate engagement. Digital therapies more broadly are also able to deliver content via "push" components, or content sent to users with the hope of providing treatment when it is most likely to be received and effective (eg, "just-in-time" interventions). They do not require participants to be aware of their need for support or even remember that the tool exists [60]. It is possible that participants would have revisited content more or in different ways had there been

XSL•FO
RenderX

pushed suggestions or activities, and engagement with push components may relate differently to demographic or clinical variables than the pull interactions we investigated. Similarly, it will also be important to consider Mindset app use in the absence of therapist check-ins that were available to all patients in this study (ie, self-guided app-based treatment). We were also only able to objectively capture "on-app" behaviors when it is likely that "off-app" behaviors are also powerful for symptom change. Of course, a foundational assumption is that more frequent skills review and app use contribute to better outcomes by facilitating off-app change; although perceived time using skills "off-app" was not associated with app interaction patterns, it remains possible that more rigorous assessment of how often participants were thinking about or implementing CBT skills without the aid of the Mindset app or the quality of the "off-app" work would reveal different associations (eg, daily diary method rather than end-of-treatment measure). Indeed, it remains plausible that higher responders in this trial were going "off-app" more and earlier than others. As with any effort to quantify behavior, we necessarily made assumptions about users and what constituted a meaningful interaction with CBT content (eg, <5 s indicated an erroneous action; multiple logs within 30 minutes indicated one practice session). Addressing all of these limitations and doing so in a larger and more diverse sample is an important next step. Finally, treatment adherence in this study was high and attrition was very low compared to the typical smartphone CBT; a larger, real-world trial would likely provide greater variance and thus further insights.

Conclusions

Some degree of treatment use is important for outcomes [61]. However, it is oversimplified, if not incorrect, to argue that more use is necessarily better. Instead, more nuanced conceptualization and measurement are needed and will hopefully lead to more personalized recommendations for app use [19]. Indeed, whereas 1 person may benefit from frequent reminders to be mindful or require repeated exposure to a concept for it to resonate, others may respond quickly, benefit most from fewer massed exposures, or benefit from content unlocking at a faster or slower rate than others. Past work on engagement has suggested that module completion, rather than volume of use, is a more clinically relevant metric of engagement; this recommendation aligns with our finding that repetition was not associated with better outcomes [18]. Minimum requirements or recommendations for engagement were thoughtfully developed and may on average be sufficient. At the same time, response and remission rates in this trial—similar to other trials—could be much stronger. These data underscore the high degree of heterogeneity that exists in users' app use patterns. More work such as this—particularly in larger and more representative samples—which aims to explain this heterogeneity in what users engage with and how they do so is essential for driving more flexible therapies, more personalized dosing and sequencing, and better outcomes.

Abstract

Background: Over 80% of trials worldwide fail to complete patient recruitment within the initially planned time frame. Over the past decade, the use of social media for recruitment in medical research has become increasingly popular. While Google and Facebook are well established, newer social media channels such as Instagram and TikTok garner less research attention as recruitment tools. Although some studies have investigated the advantages and disadvantages of using social media for recruitment, a considerable gap still exists in understanding the precise mechanisms and factors that make different social media platforms most effective and cost-efficient for patient recruitment in mental health studies.

Objective: This study evaluates the effectiveness of recruitment strategies implemented during the investigative phase of a validation study for a new suicidality assessment questionnaire optimized for primary care.

Methods: We describe how online recruitment contributed to the enrollment of patients with depressive symptoms for the validation of a suicidality questionnaire (Suicide Prevention in Primary Care), which required over 500 participants. To this end, we analyzed differences in sample demographics between traditionally recruited and online participants, compared advertising metrics and conversion rates, and conducted a cost-benefit analysis.

Results: We found online recruitment to be a fast and efficient method of securing the required number of participants with depressive symptoms for the study and increasing patient diversity. Considering the distribution of gender, age, and Patient Health Questionnaire-9 scores, participants recruited offline and online were equally eligible for the study. Online recruitment demonstrated high advertising efficiency. For example, the study population responded well to video advertisements on social media; these performed 50% to 70% more cost-efficiently than the best image advertisements. Moreover, a long website copy proved slightly better than a short version. Pixel tracking for improved advertisement targeting reduced advertising costs per suitable participant by 83.3%, making the advertisements 6 times more cost-efficient.

Conclusions: Social media recruitment increased the diversity of patients in the studies and proved suitable for vulnerable and hard-to-reach populations. The total cost per patient recruited online was comparable to that achieved using offline methods, but overall recruitment progressed faster. In this study, implementing video advertisements and pixel tracking resulted in significant cost savings.

Introduction

Background

In primary care, approximately 10% of patients experience suicidal ideation [1]. Studies indicate that these individuals often seek contact with their general practitioners (GPs) during suicidal crises [2-5] but rarely report their suicidal thoughts on their own initiative [6,7]. Moreover, GPs often feel overwhelmed when interacting with patients with suicidal tendencies [8,9]. Thus, a new short questionnaire for suicidal assessment, Suicide Prevention in Primary Care (SuPr-X), was designed and validated in various treatment settings, optimized for primary outpatient care, and aimed at guiding health care professionals when interacting with patients with suicidal tendencies. Detailed information about the development [10,11] and validation [12] of the questionnaire can be found elsewhere.

However, recruiting the required number of patients for the SuPr-X validation study proved to be a significant obstacle. In medical and psychological research, generating valid study results by collecting data from large representative samples is essential [13]. For many research teams, recruiting the number of participants needed on time and within budget limitations becomes a major challenge [14]. Over 80% of trials worldwide fail to complete patient recruitment within the initially planned time frame, with insufficient case numbers being the primary reason for discontinuing 55% of all studies [15].

Studies in outpatient care rely on physicians' practices to recruit patients. Conventionally, the first step involves finding collaborative practices that are interested in the research topic [16]. Participating physicians then screen suitable patients and recruit them for the study using leaflets, posters, or directly approaches to potentially eligible patients. Here, two worlds often collide: the interest and willingness of medical practices to actively recruit and the constant pressure to provide care coupled with a lack of time [16]. In studies specifically within the primary care setting in the United Kingdom, less than a third of the studies managed to meet the recruitment time frame: recruitment challenges mainly stem from the GP having to shoulder the responsibility of handling patient consent and inclusion [17]. To alleviate this bottleneck, researchers need to identify different solutions.

In the last 10 years, the use and popularity of social media recruitment in medical research has gained popularity [18]. Targeted advertisements on commonly used search engines such as Google are also often used to extend visibility and cover a more extensive outreach to potential participants to complement traditional recruitment methods, such as email or phone lists, prints, and leaflets [19-21]. Despite the growing use of social media for patient recruitment in mental health studies, the effectiveness and cost-efficiency of Instagram and TikTok remain underexplored. While Google and Facebook are well-established methods, studies on newer platforms such as Instagram are limited and primarily focus on younger audiences [22,23]. Social media provides the opportunity to reach a broad and diverse target audience and is helpful for highly focused recruitment approaches in a hard-to-reach population [18]. The time and costs involved are generally significantly lower than those associated with traditional recruitment methods [18,24-26]. However, potential limitations in representativeness must be considered [27]. When explicitly focusing on mental health studies (n=176), social media recruitment is indeed a cost-effective approach [28]: It was primarily used in studies including substance abuse (43.8%), mood disorders (15.3%), general mental health (11.9%), trauma and stress-related disorders (8.9%), and suicidal ideation and self-injurious behaviors (4.5%). In around two-thirds of the studies, social media performance was just as good or superior to traditional strategies such as mailing lists or referrals [28]. Moreover, participant characteristics from patients recruited online only differ minimally compared to those recruited from general practices, as a study on urinary incontinence found [29]. A web-based mental health program study showed that social media had the highest reach, lowest cost per participant, and similar adherence rates compared to general practice and pharmacies [30]. Although some studies have explored the advantages and disadvantages [18,24-28], there is still a notable gap in understanding the precise mechanisms and factors by which various social media platforms can be most effectively and cost-efficiently used for patient recruitment in mental health studies.

At the beginning of the SuPr-X study in 2022, we could not motivate GPs to cooperate due to the increasing spread of the highly contagious COVID-19 Omicron variant [31]. Conducting research on other topics became increasingly challenging [32]. It was not until spring 2023 that the situation improved, and study recruitment accelerated, resulting in some patients being included in practices. However, by this time, any buffer for recruitment delays had been exhausted, making the recruitment target of 500 seem no longer achievable by the previously used conventional method. Starting in September 2023, we used an online recruitment strategy to support the project.

Objective

This study aims to evaluate the effectiveness of recruitment strategies in validating a suicidality assessment tool for primary care settings.

Methods

Study Design

This study used a cross-sectional observational design. For the SuPr-X validation study, we recruited adult patients with depressive symptoms from outpatient settings (GPs and psychotherapeutic or psychiatric practices) and from partial or full inpatient settings and online (subsequently enrolled on-site). The inclusion criteria required a Patient Health Questionnaire-9

XSL•FO
RenderX

(PHQ-9) score >5 and the ability to complete a 30-minute German-language questionnaire. Suicidal thoughts were not mandatory. People were excluded from the study if they had cognitive impairment, had significant positive psychotic symptoms (eg, hallucinations or disorganized thinking), or were minors.

Measures

PHQ-9 Score

The PHQ-9 assesses depression severity over the past 2 weeks using 9 items (on a scale from 0=not at all to 3=nearly every day). The instrument has been validated in German, including evaluation for primary care use, and exhibits strong psychometric properties [33,34]. The PHQ-8 is a short form that does not contain the item related to death wishes or suicidality from the PHQ-9 [35]. PHQ-9 severity can be classified as minimal (>0), mild (≥5), moderate (≥10), moderately severe (≥15), and severe (≥20) [36].

Beck Suicide Ideation Scale

The Beck Suicide Ideation Scale (BSS) is based on a self-assessment of the past week using 19 items and a 3-point scale. Part 1 (items 1-5) serves as a screening tool. All further items are completed if the patient expresses active suicidal ideation (item 4=desire to kill oneself) or passive suicidal ideation (eg, if they prefer not to make apparent attempts to save themselves in the event of a life-threatening situation; item 5) [37].

SuPr-X Scale

The preliminary version includes 17 items. Four items (a-d) inquire about lifetime risk factors, such as family history of suicides. The response options are dichotomous (yes or no), and if a question is answered affirmatively, it prompts a brief open follow-up. Four items (1-4) explore protective or moderating aspects, such as confidence. Moreover, 7 items (5-11) assess current suicidal tendencies, such as ideation, plans, or suicidal behaviors. The response options for these are provided on a 4-point scale ranging from 0 to 3, with 0 indicating “strongly disagree,” 1 indicating “somewhat disagree,” 2 indicating “somewhat agree,” and 3 indicating “strongly agree.” The final item (item 12) asks a dichotomous question about whether there has been a suicide attempt in the last 2 weeks (yes or no). If the answer is no, it is followed up with multiple-choice options detailing reasons that prevented a suicide attempt (item 12.1). This structure situates the risk scale between protective items, facilitating a supportive start and conclusion to the interview by offering a perspective [12].

Patient Recruitment Settings and Strategies

Overview

We used traditional recruitment strategies (direct approach by physician or therapist, leaflets with subsequent enrollment in collaborating practices and clinics) from July 2022 to February 2024, as well as social media and online advertisement (via Facebook [Meta Platforms, Inc]; Instagram [Meta Platforms, Inc]; TikTok [ByteDance Ltd]; and Google Ads [Google LLC] with subsequent enrollment at the Institute of General Practice and Family Medicine in Munich, Germany), starting from September 2023 to February 2024. Traditional recruitment took place in 20 general practices in Germany and Austria and 12 psychotherapeutic practices. In addition, recruitment occurred in 4 inpatient psychiatric wards and 2 daycare clinics. We contacted practitioners at events and conferences via telephone lists or email to raise awareness about the ongoing study. If there was interest, we delivered the study materials for implementation. The practitioners recruited suitable patients with depressive symptoms themselves. For this purpose, we provided them with leaflets and posters for waiting rooms. Patients who became aware of the study through an online campaign and met the inclusion criteria (online prescreening questionnaire PHQ-8) had the opportunity to schedule an appointment at the Institute of General Practice and Family Medicine either through a publicly shared calendar or with the help of a telephone patient service. Study psychologists or medical physicians performed an informative consultation on the study appointment and repeated the inclusion criteria check. Afterward, participants received the questionnaire from a study employee to complete independently on-site. The results were subsequently reviewed and discussed with the patients, particularly concerning questions on current suicidal tendencies. Further details about the recruitment process are given in Multimedia Appendix 1.

Sample

The sample included in the study through traditional recruitment methods (n=282, 54% of the total study population) consisted of patients recruited by GPs (n=105, 37.2%), patients recruited by psychotherapists (n=50, 17.7%), patients from a psychosomatic day clinic (n=74, 26.2%) and patients from an inpatient psychiatric setting (n=53, 18.8%).

Patients recruited online and subsequently invited to the Institute of General Practice and Family Medicine to participate in the study (recruited online but enrolled on-site) were questioned about their treatment and whom they consider their main physician or therapist. Of the 239 online recruited patients (46% of the total study population, N=521), we divided them into 4 groups: 230 (96.2%) patients reported having a GP, with 106 (46.1%) indicating that their GP was their main practitioner and was most familiar with their medical history. In total, 131 (54.5%) of the 239 online recruited patients were connected to psychiatric services, of whom 51 (38.9%) regarded the psychiatrist as their main practitioner. Moreover, 118 (49.4%) of the 239 online recruited patients received psychotherapy, with 66 (55.9%) viewing the psychotherapist as their main practitioner. Furthermore, 51 (21.3%) of the 239 online recruited patients regularly interacted with other physicians and therapists (eg, neurologists and pain specialists), of whom 17 (33%) considered these professionals as their primary medical contact.

Technical Setup of Online Advertising, Study Website, and Online Prescreening Questionnaire

We used Google Ads Manager, AdEspresso (Facebook and Instagram advertisements management), and TikTok Ad Manager to set up the online campaigns targeted at Munich and nearby areas (a radius of 40 km). We implemented tracking pixels as described by the respective advertisement platforms.

XSL•FO
RenderX

The advertisements forwarded interested users to the study website [38]. As per the General Data Protection Regulation, we implemented a cookie consent management platform (Borlabs Cookie). Only if users explicitly consented to advertising cookies did we track and include them for website statistics analysis. On the study website, the online prescreening questionnaire was embedded via HTML iframe (survey provider: Lamapoll [Lamano GmbH & Co KG], all data stored on German servers). Website visitors were screened with the PHQ-8 to ensure study participants showed at least mild depressive symptoms (cutoff >5). Three distinct questionnaire exit pages measured the outcomes of the prescreening questionnaire. They were used for conversion tracking of participants who (1) were eligible and left their contact data ("eligible opt-in"), (2) were eligible but did not leave their contact data ("eligible no opt-in"), and (3) were not eligible ("not eligible").

We defined the desired conversion action as a user passing the prescreening questionnaire and providing their contact details (tracking done using the web page "eligible opt-in"); hence, a conversion represented an eligible patient lead. Throughout answering the online survey, participants remained entirely anonymous. Only the outcome page was then tracked again. Thus, end-to-end tracking from click to enrollment was not possible without the user's consent; their data were transferred to Trials24's system only when the participants passed the prescreening questionnaire, explicitly consented to the data protection declaration, and entered their contact details. We calculated the number of eligible patient leads passing the prescreening questionnaire to fill in their contact details by the respective tracking pixel's measurement ("tracked" leads) or counting the entries in our database ("DB" leads). For some advertisement experiments, for example, pixel versus no pixel, additional versions of the website and the prescreening questionnaire were created so traffic from online advertisements could be directed to a specific version of the web page and prescreening questionnaire, allowing distinct measurements even without conversion tracking.

The online prescreening questionnaire did not include a special captcha question for participants to prove they were human, but the contact center manually checked every contact in the database.

Creative Material Used for Online Advertising

Images

The following images were used (details are given in Multimedia Appendix 2): (1) a sad woman lying on the bed looking into the camera—gray theme with an orange textbox ("together against depression"); (2) a sad man sitting on the couch looking downwards—sepia theme with an orange textbox ("together against depression"); (3) a senior male physician looking into the camera with folded arms—white and blue theme with an orange textbox ("together against depression"); (4) couple 1, a couple with a woman in front looking concerned and sad—gray theme with an orange textbox ("together against depression"); (5) couple 2, a couple with a man in front looking concerned and sad—gray theme with an orange textbox ("together against depression");

Video

We used 2 versions of the same video: (1) a female influencer dressed in everyday clothes explaining the study and (2) a female influencer dressed as a medical physician explaining the study. The person who recorded the video is a medical influencer who talks about medical topics, for example, on TikTok. The influencer has neither published the video on her personal channel nor mentioned her profession to ensure that only the visual impression differs.

Statistical Analysis

The association between the recruitment method and gender distribution within the different samples was analyzed using the ϕ coefficient for nominally scaled items. With a 2-tailed *t* test, we determined if there were group differences regarding the recruitment method (traditional versus online) and age. Nonparametric tests are widely recommended when the assumptions of parametric tests are violated, such as interval scaling and normal distribution. Therefore, they are particularly suitable for ordinally scaled data, which are often found in psychological or medical questionnaires [39]. Data were not normally distributed for each online recruitment channel (Shapiro-Wilk test, $P<.05$); therefore, we chose a nonparametric test: the Kruskal-Wallis test was performed to examine whether age differences exist depending on the online recruitment channel. A nonparametric Mann-Whitney *U* test for ordinally scaled items was conducted to assess possible group or subgroup differences regarding depression symptoms measured by PHQ-9. We also used the Mann-Whitney *U* test to determine possible differences in reported suicidality between recruitment methods measured by the SuPr-X Risk scale (sum score of items 5-11) and BSS screening (sum score of items 1-5). For pairwise comparisons and post hoc tests, Bonferroni-adjusted *P* values were reported to account for multiple testing. For nonparametric tests, the rank-based effect size *r* was used, calculated by dividing the test statistic's *z* statistic by the square root of the total number of observations (N), with divisions into small (0.1-0.3), medium (0.3-0.5), and large (>0.5) effects [40]. To compare the effectiveness of recruitment methods, a linear regression analysis was performed to estimate the monthly participant enrollment rates (slopes) for the traditional and online recruitment methods. We quantified the magnitude of differences between slopes using Cohen *d*, calculated as the difference between group means or slopes divided by the pooled SD, with Cohen $d=0.2$ (small), Cohen $d=0.5$ (medium), and Cohen $d=0.8$ (large) [40]. Any *P* value <.05 indicated statistical significance. We used SPSS (version 29; IBM Corp) for all calculations.

Ethics Approval

The study and all recruitment activities received ethics approval from the medical ethics committee of Ludwig-Maximilians-Universität München (Munich) on May 9, 2022 (project number 22-0028) and were performed in accordance with applicable guidelines and regulations. The amendment for additional online recruitment was approved on August 8, 2023. All participants signed the informed consent on-site after an informed prestudy briefing with the respective clinician from the cooperating practice or, in the case of online

XSL•FO
RenderX

recruitment, on-site at the Institute of General Medicine with the responsible study physicians or psychologists. All data were securely stored, and access to data storage was restricted to authorized personnel only. All participants received a €25 shopping voucher as compensation. The conversion rate (CR) at the time of the study was €1=US $1.074.

Results

Sample Characteristics

From July 2022 to February 2024, a total of 521 patients with depressive symptoms (inclusion criteria: PHQ-9 >5 “mild depression”) were included in the study: 67.8% (n=353) women, 31.7% (n=165) men and 0.38% (n=2) nonbinary participants (n=1 missing, 0.19%). The mean age was 40.89 (SD 14.32) years, and the average PHQ-9 score was 14.8 (SD 4.97), indicating moderate severity [36].

After presenting the overall sample characteristics, we examined how traditional and online recruitment strategies influenced differences within the sample.

Differences in Sample Characteristics Based on Traditional Recruitment Strategies Versus Online

The online recruitment strategy focused on outpatient demographics. For reasonable comparative analysis of sample characteristics using traditional versus online recruitment methods, the inpatient psychiatric cohort was excluded to avoid biases. However, online recruitment included an *outpatient* psychiatric group, which did not have a corresponding comparative group within the traditionally recruited cohort (only the previously mentioned excluded *inpatient* psychiatric group). As a result, a feasible comparison of sample characteristics among the subgroups “traditional” versus “online” could only be conducted within the GP and psychotherapist samples, as detailed in Table 1. Moreover, 74 (14.2% of the 521 patients) from the psychosomatic day clinic were considered for the *total* result but are not separately reported in the table.

Table 1 shows gender, age, depressive symptoms mean scores (PHQ-9), and suicidality mean scores (SuPr-X risk: 5-11; BSS screening: 1-5) of the traditional sample in comparison to the online recruitment sample. Subgroup comparison of participants are attributed to GPs and psychotherapists.

In summary, we recruited participants through traditional methods and online (Table 1), with neither significant difference in gender distribution across recruitment methods (ϕ=0.051; P=.54) nor age differences (t_{465}=–0.1886; P=.06). Depression scores also did not vary significantly between groups (U=26,314.500; Z=–.479; P=.63). We observed an increased suicide risk in the online recruitment group (SuPr-X: U=22,969.500; Z=−3.025; P=.002 and BSS screening: U=23,611.500; Z=–2.323; P=.02) with small effect sizes (SuPr-X: r=0.140; BSS screening: r=0.108), as reflected in significantly higher scores on SuPr-X by 1.04 (95% CI 0.41-1.68) points and on BSS screening by 0.53 (95% CI 0.13-0.94) points. However, no significant difference was found in subgroup comparisons (GP and psychotherapist), indicating that the higher rates of suicide risk in the online recruitment sample were attributable to the psychiatric outpatient sample.

Building on the comparison of traditional and online strategies, we further explored differences in sample characteristics across specific online recruitment channels.

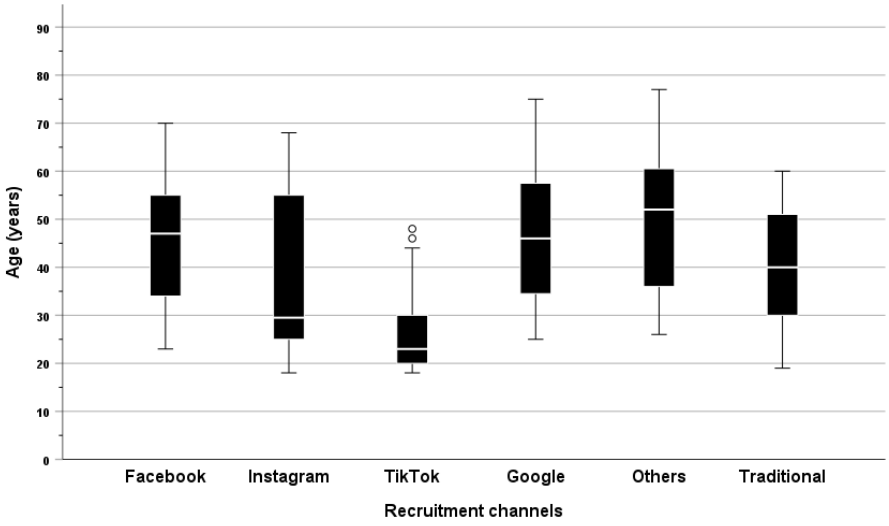
[e]BSS: Beck Suicide Ideation Scale.

Differences in Sample Characteristics Based on Online Recruitment Channels and Search Engines

Online recruitment channels were classified as (1) Facebook, (2) Instagram, (3) TikTok, (4) Google, (5) internet, and (6) others. The category "internet" included all responses from participants that could not be attributed to a specific online platform or search engine. "Others" included responses from participants indicating they learned about the study through people in their networks who had seen the study advertised online.



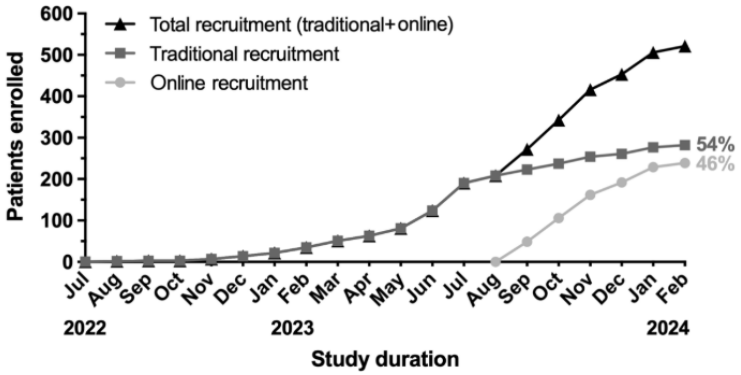
There was no statistically significant association between online recruitment platforms and gender distribution (ϕ=0.188; *P*=.21). The group recruited via TikTok (median 23, SD 9.238) was significantly younger than those recruited through Facebook (median 47, SD 11.479; Z=5.410; *P*<.001); Google (median 46, SD 15.005; *Z*=–4.670; *P*<.001); and other internet sources (median 52, SD 14.614; *Z*=–5.308; *P*<.001), with medium (Facebook *r*=0.489) to strong (Google *r*=-.704; internet *r*=0.766) effect sizes.

The mean age differences were –18.26 (SD 11.479, 95% CI –22.80 to –13.72) years for Facebook, –20.40 (SD 15.005, 95% CI –27.70 to –13.10) years for Google, and –21.94 (SD 14.614, 95% CI –28.72 to –15.16) years for other internet sources. Age did not differ significantly from Instagram (median 29.5, SD 16.796; *Z*=2.038; *P*=.62). These age differences suggested that TikTok may attract a younger demographic for online study recruitment (Figure 1). The severity of depression symptoms did not depend on the online recruitment platform (Kruskal-Wallis H_5=8.773, *P*=.12).

Box plots illustrate the median age and the lower and upper quartiles, minimum, and maximum values across all online recruitment channels compared to the traditional recruitment sample.

XSL•FO
RenderX

Figure 1. Age distribution across recruitment channels.



Enrollment Timeline

The comparison of recruitment methods revealed a highly significant difference in participant enrollment rates (Figure 2). Linear regression analysis estimated a slope of 17.95 (95% CI 15.44-20.46) for the traditional recruitment method and 41.54 (95% CI 32.74-50.33) for the online campaign. The difference between the slopes was 23.59 (SE 3.62), which was highly significant (P<.001; Z=6.51). The effect size, expressed as Cohen d, was 0.22, indicating a small to moderate practical effect. In addition, the correlation coefficient r=0.79 reflects a strong relationship between the recruitment methods and their differences in performance.

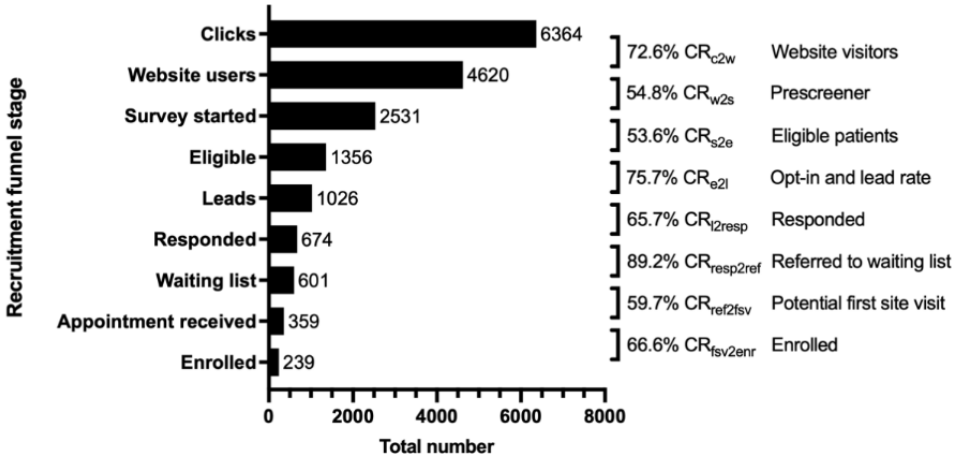
Building on the timeline analysis, we illustrate the process of converting clicks into enrolled participants, noting that comparable data for the traditional setting were not collected.

Figure 2. Number of participants included in the study. The black line displays the total recruitment timeline. Traditional recruitment (dark gray line, squares) was active from July 2022 to February 2024. Online recruitment was activated in September 2023 and is shown as the light gray line (with circles).

CRs in Online Recruitment

Figure 3 describes the typical patient journey during online patient recruitment, the "patient journey to enrollment." The advertisements were displayed 890,145 times (impressions), and 6364 (0.7%) people showed interest by clicking on the study advertisement. In addition, 72.6% (4620/6364; CR from click to website) of website users landed on the study website, and 54.8% (2531/4260; CR from website to survey) individuals started the online prescreening survey. In addition, a 53.6% (1356/2531) CR from survey to eligible respondents was met for the study-specific inclusion criteria, making them potentially eligible and reaching the end of the questionnaire. Of those 1356 individuals, 1026 individuals (75.7% opt-in rate; CR from eligible to lead=opt-in rate) left their contact data, becoming an eligible "lead." When the patient companion service—a dedicated contact center for interested patients—reached out to them, 65.7% (674/1026) CR from lead to people responded, and an 89.2% (601/674) (CR from response to referral=potential referral rate) were placed on the study waiting list because there were only limited slots available for participation.

Overall, 59.7% (359/601) of individuals (CR from referral to first site visit=potential first site visit rate) received an appointment slot. There were reminders 2 days and 1 day before the appointment so participants could cancel their appointment in time if they could not attend (appointments were rescheduled, and open slots were given to the next person on the waiting list). Only 5.3% (19/359) of individuals were listed as "no-shows." Of those who attended their appointment, 66.7% (239/359; CR from first site visit to enrolled) of individuals were subsequently enrolled.



The patient journey to enrollment in the online recruitment funnel starts with the first click on the study advertisement and

XSL•FO
RenderX

then continues to the website visit, before qualification via the online prescreening questionnaire, making an appointment with the patient companion service, and finally ends with participation in the study by signing the informed consent form and being enrolled. The following conditions apply: clicks=registered click on a study advertisement; website users=people on the study website; survey started=people who have started the online prescreening questionnaire; eligible=people who showed potential eligibility online; leads=people who have provided their contact details after being potentially eligible; responded=people who responded when the patient companion service reached out to them; waiting list=all people who wanted to receive an appointment for the study; appointment received=people who received an appointment slot; enrolled=people who completed the study according to the study protocol.

Beyond CRs, we also presented detailed online advertising efficiency metrics to comprehensively assess cost-effectiveness.

Figure 3. The patient journey to enrollment in the online recruitment funnel for Suicide Prevention in Primary Care. CR: conversion rate; CRc2w: CR from click to website user; CRe2l: CR from eligible to lead; CRfsv2enr: CR from first site visit to enrolled; CRl2resp: CR from lead to responded; CRref2fsv: CR from referral to first site visit; CRresp2ref: CR from response to referral; CRs2e: CR from survey to eligible; CRw2s: CR from website to survey.

Online Advertising Efficiency Metrics

Overview

We chose Google, Meta (Facebook and Instagram), and TikTok as advertising platforms. We launched 13 distinct advertisement campaigns (8 in Facebook, 2 in Instagram, 2 in TikTok, and 1 in Google) to perform experiments regarding different advertisement settings or creative material. The advertisement campaigns were set up to create maximum leads (details described in the Methods section). Table 2 shows the key metrics and costs per channel for study recruitment.

When comparing traditional and online recruitment, the overall recruitment cost per enrolled patient (CPE) were €30 and €29.21, respectively. However, online patients still needed to be screened on-site. The CPEs between different online platforms varied between €23.08 and €52.49.

Three metrics can be used to compare advertisement efficiencies of different channels: cost per lead (CPL) tracked as measured by the advertisement platform (but sensitive to cookie consent, browser tracking blockers, user settings, etc), CPL calculated as the cookie consent corrected CPL tracked, and CPL database as the cost per registered person based on their reported source. In theory, CPL calculated and CPL database should be the same, as they reported the same metric but were based on different data sources. For Google and Facebook, this seemed accurate, as the CPLs only differed by approximately 10%. Instagram and TikTok CPLs fluctuated by 60%, indicating that numbers from conversion measurement and participant-reported advertisement channels did not match.

XSL•FO
RenderX

Table 2. Overview of advertising metrics for study recruitment.

	Cost (€[a])	Leads tracked[b], n	Leads calculated[c], n	Leads database[d], n	Enrolled[e], n	Cost per lead tracked	Cost per lead calculated (€)	Cost per lead database (€)	Cost per enrollment (€)
Google[f]	750.20	38	53	59	16	19.74	14.04	12.72	46.89
Facebook	4346.75	351	529	470	116	12.38	8.22	9.25	37.47
Instagram[g]	600	72	112	187	26	8.33	5.38	3.21	23.08
TikTok	1049.81	103	162	97	20	10.19	6.46	10.82	52.49
Other[h]	—[i]	—	—	182	53	—	—	—	—
Total online	6746.76	564	856	995	231	11.96	7.88	6.78	29.21
Traditional: practitioner's compensation	8460	—	—	—	282	—	—	—	30.00

[a]The conversion rate at the time of the study was €1=US $1.074.

[b]Leads (tracked)=conversion defined as eligible patient lead measured by advertising platforms

[c]Leads (calculated)=calculated number of participants that left their contact details when conversions are corrected by the overall cookie consent rate,

[d]Leads (database)=participants that left their contact details in the database and reported to have clicked on a particular advertisement

[e]Enrolled=reported advertisement source by enrolled participants of the study.

[f]First 3 days of the Google advertising campaign were excluded from the metrics (incorrect settings).

[g]Instagram advertisements were run only with the best-performing creative material.

[h]Other=participants in the database that could not be attributed to Google, Facebook, Instagram, or TikTok.

[i]Not available.

Additional Expenses

For online recruitment, the average time per participant was approximately 24 minutes, including 9 minutes for telephone services and prescreening interview (€3 in personnel expenses) and 15 minutes for on-site inclusion and debriefing by the psychologist and doctoral researcher (€6.66 in personnel expenses). This totals 24 minutes and €9.66 per participant, plus advertising costs for the social media campaigns.

In comparison, traditional recruitment by practitioners involved a flat compensation of €30 per participant. On the basis of typical German fee schedules (German Uniform Assessment Standard EBM code 03230 [41], €14.74 per 10 minutes, adjusted for fee increase between quarter 4 of 2022 and quarter 1 of 2024), a minimum time investment of 30 minutes per patient is estimated, resulting in a total cost of €44.22 per patient, including €14.22 in additional opportunity costs.

In summary, the estimated time and personnel costs per participant were 24 minutes and €9.66 for online recruitment, compared to 30 minutes and €14.22 for traditional recruitment. It should be noted that these are rough estimates, as the actual time spent in routine practice during traditional recruitment was not documented.

In addition to overall efficiency, we examined gender-specific differences within the target population to identify potential disparities in recruitment outcomes.

Gender-Specific Differences in the Target Population

We used Facebook advertisements to compare the gender-specific differences in online campaigns. The advertisement spent on men and women was equal, but CPLs and CPE for women were only half as expensive. Metrics for women were as follows: CPL tracked=€9.17; CPL calculated=€6.20; CPL database=€6.32; and CPE=€26.48. The metrics for men were as follows: CPL tracked=€17.87; CPL calculated=€11.92; CPL database=€14.78; and CPE=€55.53. This matched the overall 2:1 ratio of women and men enrolled in the study (Table 1). The total online numbers for women were 725 leads and 160 enrolled, and the totals for men were 302 leads and 79 enrolled.

As we found gender differences in the recruitment of participants, we also wanted to find out whether there were key factors related to the creative material that influenced recruitment.

Impact Factors on Online Patient Recruitment Efficiency

Use of Different Images

Most advertisements used a central image. First, we tested 5 different images on Facebook for their general performance. Initial results showed that the photos of the couples performed the least and thus were excluded from subsequent testing. The remaining 3 images were tested in an A/B split test, meaning they ran simultaneously, in the same audience, with the same advertisement budget. CPL tracked results for the male audience were €19.84 (sad woman), €24.79 (sad man), and €28.43 (senior male physician), while the female audience resulted in a CPL tracked of €7.76 (sad woman), €25 (sad man), and €13.44 (senior male physician). The image of the sad woman performed best in both audiences and achieved 20% to 30.2% and 42.3%

XSL•FO
RenderX

to 69% lower costs in the male and female audiences, respectively.

Image Versus Videos

Furthermore, 3 images (sad man, sad woman, and senior male physician) and 2 videos (physician and layperson) were A/B tested on Facebook and Instagram (Table 3). On Facebook, CPL tracked was €16.21 (images) and €9.52 (videos), showing that image-based advertisements were 70.2% more expensive than video-based advertisements. When looking only at the best-performing image or video asset, the image of the sad woman performed best with a CPL tracked of €11.11, and the layperson video performed best with a CPL tracked of €8.

Table 3. Image versus video advertisements. We compared a standard image-based advertisement with a more modern video-based advertisement (N=1011).

Social media site	Cost per eligible patient lead (€[a])
Facebook	
Image	16.21
Video	9.52
Instagram	
Image	10.53
Video	6.90
TikTok	
Image	—[b]
Video	9.26

[a]The conversion rate at the time of the study was €1=US $1.074.

[b]Not applicable.

On Instagram, the image of the sad woman and the video asset resulted in a CPL tracked of €10.53 for the image and a CPL tracked of €6.90 for the best-performing video (overall video CPL tracked of €7.55). Thus, also on Instagram, the video assets outperformed the best image by 52.6%.

TikTok exclusively allows videos as creative material; therefore, we could not test any images. Here, the overall video performance showed a CPL tracked of €9.26.

We saw that the 2 video variants performed differently on each social media channel, so we wanted to highlight this in more detail.

Appearance of the Influencer in the Video: Medical Physician Versus Layperson

On Facebook, Instagram, and TikTok, both videos—medical physician versus layperson—were tested against each other (Table 4). On Facebook, the video with the physician's outfit was 47.1% more expensive than the layperson's (CPL tracked physician €11.76 and layperson €8). Interestingly, the same video resulted in 17.2% and 15.9% lower CPLs on Instagram and TikTok, respectively (Instagram: CPL tracked physician €6.9 and layperson €8.33 and TikTok CPL tracked physician €8.52 and layperson €10.13).

Table 4. Appearance of the influencer in the video: medical physician versus layperson. We compared a video showing the influencer in a physician's and a layperson's outfits (N=176).

Social media site	Cost per eligible patient lead (€[a])
Facebook	
Physician	11.76
Layperson	8.00
Instagram	
Physician	6.90
Layperson	8.33
TikTok	
Physician	8.52
Layperson	10.13

[a]The conversion rate at the time of the study was €1=US $1.074.

XSL•FO
RenderX

Besides the visuals, the structure and length of the landing page copy seem to play a critical role in converting potential participants after the initial advertisement engagement.

Long Versus Short Landing Page Copy

We compared the performance of a long intro text (4 paragraphs, 199 words) against a short intro text (2 paragraphs, 133 words). Both versions included the same key messages but were phrased differently. In this experiment, the algorithm was not forced to use the budget equally on both versions, resulting in sending more traffic to the better-performing long copy. Overall results for the long copy were €506.7 advertisement spent, 72 conversions, and CPL tracked of €7.04, while short copy showed €243.4 advertisement spent, 33 conversions, and a CPL tracked of €7.37. Even though 90% of website traffic came from mobile devices, the long copy version achieved 4.5% lower CPLs.

In addition to the obvious influencing factors, such as texts and design, we also aimed to determine the effect that technical settings can have.

Using the Facebook Tracking Pixel to Improve Advertisement Targeting and Lower CPLs

Tracking pixels enable conversion tracking, feeding these data back to the advertisement platform's algorithms and allowing them to create artificial intelligence–based anonymous user group profiles that are more likely to convert, thus optimizing advertisement targeting and lowering the CPL. We wanted to know exactly how much this tracking technology lowers lead costs. Two similar advertisements with a budget of €300 each were A/B split tested, with 1 advertisement not using the Facebook tracking pixel and the other one using it (Multimedia Appendix 3). The cost per click (CPC) on the advertisements was €0.53 (n=561 clicks) without and €1.45 (n=206 clicks) with the tracking pixel, showing the advertisement algorithms targeted specific users that are more expensive to reach. Interestingly, the CPL database showed the opposite: the advertisement without the tracking pixel produced n=3 leads, resulting in a CPL database of €99.81, while the advertisement with the tracking pixel produced 18 leads, resulting in a CPL database of €16.63 (Multimedia Appendix 3 right graph). The tracking pixel improved the advertising algorithm's targeting, which reduced the CPL by 83.3%, making the advertising 6 times more cost-efficient.

Discussion

Principal Findings

This study aimed to evaluate the effectiveness of recruitment strategies while validating a suicidality assessment tool optimized for primary care. We found that online recruitment accounted for 46% (239/521) of participants, and they were recruited within a short time frame, demonstrating its potential for reaching vulnerable populations. The samples recruited online and using traditional methods were comparable regarding key demographic and clinical characteristics. Recruitment costs for online methods were similar to traditional approaches, while enrollment was significantly faster. In addition, impact factors such as advertisement formats, landing page design, and pixel tracking substantially influenced recruitment efficiency.

Representativeness of Our Sample

In our analysis, age, gender, and the inclusion criteria for depressive symptoms did not differ among patients based on different recruitment methods (traditional vs online). For ethical reasons, online advertising for the study only mentioned depression and not suicidal ideation. Both groups showed an overrepresentation of women compared to men in a ratio of 2:1, which, however, corresponds to the general gender-specific distribution of depression [42].

Regarding the representativeness of demographic factors (age and gender) and the inclusion criterion (depressive symptoms), patients recruited online were comparable to traditional strategies. Analysis of online recruitment channels showed that TikTok, in particular, targeted younger audiences and could be used strategically to attract a younger sample.

An argument in favor of using social media recruitment in mental health studies is an observed correlation between time spent on social media (r=0.11), addictive use (r=0.29), and depressive symptoms [43], as well as anxiety, low sleep quality, and reduced self-esteem in adolescents. This correlation appeared to be stronger within the female sample [44]. These findings align with our study, where a significant proportion of participants were recruited through social media, including younger people and women, highlighting the platform's potential to engage vulnerable populations effectively. Consistent with previous suicide prevention studies, Facebook was excellent in generating a broad and favorable reach to attract participants for a survey [45]. However, similar to the findings by Whitaker et al [27] and Tang et al [46], young women were overrepresented. This aligns with broader research indicating that female participants may be more responsive to social media recruitment campaigns, potentially due to higher engagement with mental health–related content [43,44]. A frequently cited limitation when using social media is the representativeness of the collected data. Because targeting can be adjusted to a certain extent in these campaigns, social media advertising can specifically address underrepresented groups to increase patient diversity. Yet, advertising costs would have become more expensive.

Online-recruited patients appeared especially suitable for the validation study, as they reported higher average levels of (self-reported) suicidality than the traditionally recruited cohort, thus providing valuable data for validating our new suicidality questionnaire. The online cohort also included 10 individuals of the "under-the-radar" population, defined in suicidology as those who are mentally distressed and suicidal but have minimal or sporadic contact with the health care system and hence are often missed by preventive measures [46]. We identified this group as patients who confirmed suicidal ideations or behavior in the questionnaire but also stated they were not receiving medical treatment and had not reached out for help due to mental stress. Clinical services often face challenges in reaching individuals most in need of mental health care. A systematic review [46] found that nonreceipt of services was linked to factors such as being male, younger or older age, rural residency, and minority ethnicity. Those without access were also less likely to have a psychiatric diagnosis, a history of suicidal

XSL•FO
RenderX

behavior, or contact with health services but more likely to use violent suicide methods. These findings highlight the need for tailored, multifaceted strategies to overcome barriers and engage diverse at-risk groups effectively [46]. However, no clear associations could be derived from our data in this regard. Nevertheless, the campaign successfully reached out to them, and they were enrolled in the study. Suicidality was not mentioned in social media advertising, yet it appeared to have reached a demographic that traditional methods might have missed. Enrolling such underrepresented patients underlines the role of social media campaigns to increase patient diversity in research studies and clinical trials.

Costs

Raising awareness is not an issue when recruiting patients online, as you can use paid advertising to display your messages to a broad audience. The critical part is to find participants who click on the advertisement, complete the survey, and provide their contact information. A meta-analysis by Brøgger-Mikkelsen et al [47] showed that online recruitment costs were generally lower than offline recruitment, but costs varied greatly: the median price per enrollment for online recruitment strategies was US $72 (range US $4-$251), and the median price per enrollment for offline recruitment strategies was US $199 (range US $19-$839). In our study, both recruitment strategies—online and offline—resulted in similar costs of approximately €30 per enrollment, positioning them in the lower range of reported online and offline recruitment costs. This highlights the cost-efficiency of both approaches in our specific context. Even if additional expenses for personnel costs are included (approximately €9 to €15), the overall recruitment costs are still in the lower to middle range. Furthermore, enrollment was completed before we could fully use the optimized advertisements. This means using only the most cost-effective creative material and the advertising platform's artificial intelligence–based targeting algorithm without our restrictions regarding A/B split tests. If we had recruited for a longer period and only run the most optimized and efficient advertisements, we estimate that it would have been 40% to 60% more cost-effective. Furthermore, our appointment slots were limited. Actual online recruitment costs might have been half the reported or even less if every participant on the waiting list could have been included. Surprisingly, only 5.3% (19/359) of individuals did not show up, indicating that the target population was eager to participate in the study. Given that depression primarily occurs with symptoms such as a lack of energy and motivation, the observed low no-show rate was a pleasant surprise.

Impact Factors

When specifically looking at clinical trial recruitment, little is known about which factors impact advertisement efficiencies. These advertisements require ethically correct phrasing and must align with country legislation regarding advertising in health care. In Germany, this is, for example, the Heilmittelwerbegesetz (translating to "Health Services and Products Advertising Act," a law that prohibits advertising for prescription drugs). You can apply some strategies from online marketing; however, the overall toolbox is restricted.

One factor influencing advertisement efficiency was the social media platform used for advertising, as each platform has its predominant age group [48]. A rule of thumb with social media platforms is that teenagers and young adults mainly use the newest and trendiest platforms. At the same time, older people only switch to these platforms later or do not switch at all, resulting in social media platforms "aging up." We also saw this effect with the TikTok population being significantly younger, followed by a slightly older group on Instagram, and Facebook having the oldest users.

When comparing the images, it was interesting to see that even in the male audience, the image of the woman performed best. It must be mentioned that the stock photos of the sad woman and man did not display the same posture and color scheme, so comparability was somewhat limited. Yet, the observed effect could be a result of increased self-stigmatization in male depression [49].

The use of negative imagery, such as depictions of sad individuals, in participant recruitment raises ethical and methodological concerns. Research suggests such portrayals may perpetuate stigma, deter help-seeking behaviors, and reinforce harmful stereotypes [50,51]. Bennett [52] highlights the limitations of visual clichés, noting they oversimplify mental health conditions and may influence who participates in studies.

When looking at image and video advertising for clinical trials, we did not find any reference that specifically showed insights into how the creative material was designed and which effects resulted from it. In our case, videos outperformed classical image advertisements, even though we used a relatively simple video setting of a person explaining the content. All our texts and scripts followed established conversion copywriting rules adapted to the advertising platforms and legal and ethical compliance guidelines. Therefore, the information flow was always the same, only presented in a different format. Because clinical trials are a medical topic, we were interested in how well a video featuring a medical physician performs compared to a layperson. A systematic review analyzing the impact of a physician's attire on patient perceptions discovered that 60% of patients preferred a white coat, especially among older patients [53]. However, in our study, older patients seemed to prefer casual outfits, at least on social media. We assume that young adults may already be used to seeing medical influencers on social media, as this generation is also informing itself more and more about health topics online [54].

A well-researched fact is that the online attention span is extremely short, with the first 10 seconds being crucial as to whether a user continues reading or leaves the website [55]. We were interested in which effect might be stronger: condensing the information to a minimum word count so users could see all relevant information without needing to scroll much on their mobile phones or having a longer version with each paragraph spanning one topic. In the small sample we tested, the longer copy worked slightly better for finding potentially eligible participants for the study, indicating it was not the number of words but the text quality that made a difference.

Finally, we gained a technical but essential insight regarding advertising efficiencies when comparing advertisements with

XSL•FO
RenderX

and without a tracking pixel. CPC is often used as an indicator of the advertisement's cost-efficiency, even though it does not show whether the generated traffic is indeed quality traffic [56] that leads to conversions (which is the actual study leads). The CPC without a tracking pixel was lower, but the CPL—the more critical outcome—was 6 times as high. Ethics committees assessing study recruitment materials sometimes struggle to permit this kind of tracking, even though users in the European Union can opt out of being tracked via cookie consent options. Our data clearly show the need to allow this pixel-based tracking technology; otherwise, researchers must invest significantly more capital to find eligible study participants. This creates an additional financial burden, especially for small research organizations or universities with limited resources and delays the studies. Patients may have to wait longer for potential treatment to be approved, or studies may be prematurely terminated due to not reaching recruitment goals.

Having discussed the key factors influencing recruitment outcomes, we now acknowledge the limitations of our study to provide a balanced interpretation of the findings.

Limitations

In the traditional recruitment setting, clinicians approached patients during routine practice but did not document the total number of patients approached. Only data for included patients were submitted, making it impossible to calculate precise CRs compared to online recruitment. In the online setting, small sample sizes often constrained the subanalyses of the considered impact factors, precluding generalized recommendations concerning image versus video materials, pixel tracking, and how much informational content should be provided. Variations in the images' graphical design may also contribute to whether a picture gains user attention (Multimedia Appendix 2). Stereotypical imagery may have introduced selection bias by attracting participants who identified with these portrayals while deterring others, limiting sample diversity.

The metrics CPL tracked and CPL calculated are influenced by each user's tracking blockers and technical settings, while CPL database relies on the accuracy of the individual's statement. As a result, both technical measurements and human assessment may be prone to error. The low no-show rate may be attributed to our reminders and a common selection bias of motivated participants by the patient companion service. Furthermore, it remains unclear to what extent the results would change in other settings, for example, due to cultural influences on the perception of a person with or without a physician's coat in an advertisement.

Conclusions

Online recruitment demonstrated high efficiency, enrolling 46% (239/521) of the study patients quickly and providing a diverse sample representative of the study's objectives. This approach proved particularly effective in reaching vulnerable, hard-to-access populations and enhancing patient diversity. The comparable costs and faster recruitment rate relative to offline methods highlight the practical advantages of online campaigns. While key insights from tested impact factors—such as the superior cost-efficiency of video advertisements, longer landing pages, and pixel tracking—offer promising strategies for optimizing recruitment efforts, these findings are preliminary and based on limited data. Further research with larger datasets is necessary to generalize these results and refine recommendations for future studies.

Acknowledgments

The POKAL-Group (PrädiktOren und Klinische Ergebnisse bei depressiven ErkrAnkungen in der hausärztLichen Versorgung [POKAL, DFG-GrK 2621]) consists of the following principal investigators: Tobias Dreischulte, Peter Falkai, JG (also a listed author), Peter Henningsen, Markus Bühner, Caroline Jung-Sievers, Helmut Krcmar, KL (listed author), Gabriele Pitschel-Walz, and Antonius Schneider. The following doctoral students are members of the POKAL-Group: Katharina Biersack, Vita Brisnik, Christopher Ebert, Julia Eder, Feyza Gökce, CH (listed author), Lisa Hattenkofer, Lukas Kaupe, Jonas Raub, Philipp Reindl-Spanner, Hannah Schillok, Petra Schönweger, Clara Teusen, Marie Vogel, Victoria von Schrottenberg, Jochen Vukas, and Puya Younesi. The authors give special thanks to Birgit Schouren from Trials24 GmbH, who contributed her linguistic skills to the paper. They also want to thank Marja Krings-Fehlauer, Laura Harreiß, and Jessica Lange from Trials24's Patient Companion Service for scheduling appointments with participants.

Data Availability

The data supporting this study's findings are available from the DFG-GrK 2621/POKAL studies but, due to licensing restrictions, are not publicly available. However, the data are available upon reasonable request. Data requests concerning the study population may be directed at Stiftung Allgemeinmedizin—The Primary Health Care Foundation [57]. Data requests concerning the results of online recruitment efficiency and the following may be directed to Trials24, a SubjectWell Company [58].

Authors' Contributions

CH and LK contributed equally. TK and KL provided joint supervision. JG, CH, LK, TK, and KL were responsible for conceptualization. CH, MH, LK, and TK were responsible for the investigation. CH, LK, TK, and KL were responsible for methodology. CH, LK, and TK were responsible for data curation. CH was responsible for the formal analysis in study population and LK and TK were responsible for the patient journey to enrollment. CH and LK were responsible for writing the original draft.

Abstract

Background: Psychological distress becomes more common during adolescence, yet many young people struggle to access clinic-based mental health care. Digital, self-help single-session interventions (SSIs) could extend current provision and overcome barriers to help seeking.

Objective: This study aims to pilot Project Care UK, a self-compassion–focused SSI, to examine its feasibility, acceptability, and preliminary efficacy for UK adolescents aged between 13 and 18 years.

Methods: We used a single-arm, within-subjects pre-post intervention program evaluation. Consenting participants completed a demographic survey and clinical measures at baseline. Self-assessments of hope, hopelessness, negative beliefs about self-compassion, and help seeking were measured immediately before and after the intervention. Acceptability and feasibility were measured after the intervention using the Program Feedback Scale and study completion metrics. Preliminary efficacy was evaluated using linear mixed-effects models. The study protocol was preregistered on the Open Science Framework before publication.

Results: Of the 813 individuals who gave consent for the study, 714 (87.8%) initiated the preintervention assessment survey, 610 (75%) initiated the intervention, 341 (41.9%) initiated the Program Feedback Scale, and 329 (40.5%) initiated the postintervention assessment survey. The sample consisted of adolescents (mean age 15.38, SD 1.58 y) who were predominantly assigned female sex at birth, were White, and were nonheterosexual. Intervention completers widely endorsed the intervention as acceptable. Significant, favorable pre- and postintervention changes were observed across all outcome measures, including increased hope (Cohen d=0.72, P<.001), decreased hopelessness (Cohen d=–0.73, P<.001), and reduced negative beliefs about self-compassion (Cohen d=–0.64, P<.001). No significant changes were observed for help-seeking intentions.

Conclusions: Although not all participants completed the study, our findings show that recruiting adolescents in the United Kingdom is feasible; completers indicated that the intervention was acceptable, and they showed improvements in the proximal outcomes of hope, hopelessness, and beliefs about self-compassion. More extensive follow-up over time and comparator intervention analyses would allow more robust conclusions to be drawn.

Introduction

Background

Adolescence is a critical period of marked physical, cognitive, social, and emotional development [1], during which psychological distress (eg, depression and anxiety) becomes increasingly common [2]. However, many adolescents will never access treatments [3,4]. In the United Kingdom, a large-scale school-based survey study found that approximately one-third of adolescents had a perceived unmet need for mental health help [5]. Adolescents from underserved groups (eg, adolescents with disabilities; those identifying as lesbian, gay, bisexual, transgender, queer, intersex, and asexual; and ethnic minority adolescents) are particularly less likely to access treatments [6]. There are many potential barriers to accessing mental health services, such as stigma, long waiting lists, inconvenient appointment times, the requirement of parental permission, and a lack of knowledge about where and how to seek help [7-10]. If untreated, psychological distress can escalate, and short- and long-term functioning can be negatively impacted [11,12]. Furthermore, UK adolescents have emphasized through priority-setting exercises the importance of receiving timely support at the onset of mental health challenges [13,14]. To expand upon current mental health provision in the United Kingdom, this study seeks to evaluate the feasibility, acceptability, and preliminary efficacy of a scalable solution, a web-based self-help self-compassion–focused single-session intervention (SSI) for adolescents in the United Kingdom.

SSIs are intentionally designed as stand-alone encounters, which do not assume or preclude repeat use [15,16] and offer a means of providing evidence-based content at scale. SSIs can be offered in a self-help delivery format, without the need for any therapist or human supporter involvement. Self-help SSIs can be completed at any time (ie, on demand or when the user wants to access them) and, if online, from any device that connects to the internet. Self-help SSIs can be accessed anonymously. Importantly, self-help SSIs can be designed to include the key takeaway messages of therapeutic interventions necessary for change within 1 session [17] and thereby are a means of delivering active ingredients from evidence-based treatments (eg, behavioral activation). For adolescents, digital self-help SSIs overcome many known barriers to accessing treatment, such as stigma, long waiting lists, and inconvenient appointment times [7] while not assuming repeat attendance or use, which have been problematic for other approaches to digital and self-help therapeutic interventions [18,19].

Growing evidence indicates that digital self-help SSIs are feasible, acceptable, safe, and effective in reducing depression symptoms and improving quality of life and other outcomes for adolescents [20]. Several of the best-evaluated SSIs have been developed by the Lab for Scalable Mental Health in the United States. Their suite of open-access SSIs [21] includes Project Care (also known as the Teen Goals Project), which aims to develop self-compassion and reduce self-hate. Two open platform trials in the United States have provided evidence that Project Care appears to be feasible and acceptable to American adolescents, with positive proximal outcomes, including decreases in hopelessness and improvements in perceived agency, which yielded large and medium within-subjects effect sizes (Cohen d_z=1.01 and Cohen d_z=0.65), respectively, immediately after the intervention [22,23]. Project Care has not been evaluated in a randomized controlled trial, but 2 other digital self-help SSIs from the suite have been subject to this level of scrutiny [24]. In comparison to an online activity control condition, both Project Personality (growth mindset–based SSI) and Project ABC (behavior activation–based SSI) were effective in reducing depression symptoms 3 months later in a large sample of individuals aged between 13 and 16 years around the time of the COVID-19 pandemic. Moreover, existing studies found that the uptake of SSIs by adolescents from underserved groups is higher than in traditional clinic-based services [24,25], and existing SSIs appear to be effective across demographic groups [26]. Thus, digital self-help SSIs, such as Project Care, could be a useful addition to existing provisions in the UK context, but they have yet to be extensively implemented and tested. Many questions remain regarding implementation strategies and adaptations to existing SSIs, which may be required for this context.

Despite the existing evidence being strongest for 2 other SSIs from the suite [24], we opted to pilot Project Care UK in the United Kingdom first. The rationale for this was that in our formative work with adolescent advisors from 3 different groups, they consistently told us that self-kindness is a challenge for the current generation of adolescents. Furthermore, Project Care received favorable ratings on the Program Feedback Scale (PFS) in terms of its helpfulness and message, as compared to the other SSIs tested within the suite [22]. Therefore, we sought to leverage Project Care as an existing self-kindness and self-compassion SSI from the United States for use in the United Kingdom. In addition to this being a desired focus, the evidence indicates that this activity was well received by American adolescents and addressing self-hate and self-criticism may help to alleviate psychological distress as these are known risk factors for the onset and persistence of various emotional problems [27,28]. Learning to be more self-compassionate might support adolescents to achieve more positive outcomes as compared to completing cognitive and behavioral therapeutic tasks alone [29]. This learning can help people generate feelings of safety and contentment while reducing shame, self-criticism, and self-hate that might underlie and exacerbate negative cognitive processes and behaviors [30].

There has been 1 previous pilot study of a digital SSI that included both growth mindset and compassion principles and was delivered through schools in the United Kingdom [31]. The feasibility and acceptability outcomes were promising, with young people offering positive feedback about the intervention. In addition, in the treatment group, preintervention and post intervention changes in personality mindset, psychological flexibility, self-compassion, and self-esteem were observed, and small reductions in anxiety and depression were observed at the 4-week follow-up. However, the study did not assess the efficacy of the SSI; the intervention was a video, and it was only piloted in 80 UK adolescents aged between 16 and 18 years.

XSL•FO
RenderX

Objectives

We aimed to pilot Project Care UK in a larger sample of adolescents, aged between 13 and 18 years, living in the United Kingdom. Specifically, we sought to test the feasibility, acceptability, and preliminary efficacy of the SSI to see whether this brief, scalable intervention based on evidence-based treatment is suitably promising to warrant a larger-scale randomized controlled trial in the United Kingdom. We were also keen to explore how and where to let adolescents know about Project Care UK to inform future scale-up efforts. Specifically, our research questions were as follows:

1. How do adolescents find out about Project Care UK?
2. How many adolescents complete each stage of the study, including informed consent, preintervention measures, the intervention, and postintervention measures?
3. Do adolescents view Project Care UK as an acceptable intervention?
4. Do adolescents who complete the Project Care UK intervention show improvements in short-term proximal outcomes, including hope, hopelessness, negative beliefs about self-compassion, and attitudes toward help seeking?

While research questions 1 to 3 were exploratory, for research question 4, we hypothesized preintervention to postintervention improvements across all outcome measures, including increased hope and more positive attitudes toward help seeking, as well as reductions in hopelessness and negative beliefs about self-compassion.

Methods

Design

We used a community-based, single-arm, pre-post intervention program evaluation within-subjects design. Thus, all participants were offered the same intervention immediately following baseline measures without a control group or randomization.

The study was reported in accordance with CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) guidelines [32]. Web-based survey elements were reported in line with the CHERRIES (Checklist for Reporting Results of Internet e-Surveys) guidelines [33] (Multimedia Appendix 1).

The study protocol was preregistered on the Open Science Framework (OSF) before data collection [34], with a statistical analysis plan [35] and subsequent revisions submitted before formal analysis [36].

Recruitment

Adolescents aged between 13 and 18 years who were living in the United Kingdom and could communicate in English were eligible to take part in our study, Project Care UK. Recruitment spanned from June 2023 to July 2024.

Potential participants found out about Project Care UK via advertisements, which were created by young adults who were undergraduate students with input from our young people's advisory group. These advertisements were shared in several ways. First, the research team posted the advertisements regularly (several times a week) on various social media channels (eg, Instagram [Meta Platforms, Inc], X [formerly known as Twitter; X Corp], and Threads [Meta Platforms, Inc]), with most activity focusing on Instagram (including a paid boost post for a few days during August 2023). Social media activity continued throughout the duration of recruitment. Second, the advertisements were also shared via email mailing lists of local community-based organizations that supported adolescents, particularly during the first 3 months of recruitment. Third, from September 2023 onward, Project Care UK was advertised to participants in Merseyside on the Young Person's Advisory Service (YPAS; a charitable organization that provides mental health support to young people aged between 5 to 25 years) website, in their support hub, and from January 2024, through 3 schools within the Liverpool Learning Partnership. Project Care UK was signposted as an additional resource by 2 UK-wide organizations that offer free mental health support to adolescents. Kooth commenced signposting in February 2024, and Shout 85258 commenced signposting in March 2024. Project Care UK was an open survey, and no contact was made with potential participants before recruitment.

Procedure

Project Care UK was an online, anonymous, open survey hosted on Qualtrics (Qualtrics International Inc; which specializes in the distribution of online surveys) and could be completed in any location and on any internet-connected device. Participants volunteered to participate by clicking on an anonymous link or scanning the QR code in study advertisements. First, they completed screening questions (ie, age, living in the United Kingdom, and English language ability) and ticked a box to indicate where they had found out about the study. Those who did not meet the eligibility criteria were filtered out by branch logic and displayed an ineligibility message, which signposted other sources of support. Additional measures of fraud detection were also incorporated into the study, including a built-in reCAPTCHA score and a function to prevent multiple submissions, though no cookies or IP address checkers were used. These were used as part of the data cleansing protocol to determine eligibility.

All eligible potential participants advanced to the information sheet and consent form process, with branch logic applied to route them toward the appropriate consent process based on their age (refer to the Materials section). In the information sheet, participants were informed of the purpose of the study, how long it would take, how their data would be stored, and who the principal investigator was. Participants were also reminded that their participation was voluntary and that they could withdraw at any time without giving a reason. Consenting participants then completed the preintervention measures, followed by the intervention itself. Within this, they could choose to read the information and testimonies or use the audio voice-over (this played automatically, but if participants did not want it, they could mute the sound on their device), and they completed the activities. Immediately after completing the intervention, participants completed a program feedback questionnaire and postintervention measures. Participants did not have the option to go back and review their answers. Finally,

XSL•FO
RenderX

participants received debriefing information on sources of support they could access. The entire study, including the intervention, was completed within a single sitting and took approximately 30 to 40 minutes to complete (5-10 min for the preintervention measures, 15-20 min for the intervention, and 5-10 min for postintervention measures and debrief). The minimum number of questions that participants completed (eg, participants aged 16-18 y) was 136 across 68 pages, while the maximum number of questions that participants completed (eg, participants aged 13-15 y who failed to complete the Gillick competence multiple-choice questions twice and provided parental consent) was 153 questions across 74 pages. All survey questions were presented in a nonmandatory format, meaning participants were not required to respond to continue with the survey. All measures were presented in a set order (ie, questions were not randomized), and all data collected as part of the survey were stored in accordance with general data protection regulations in online drives dedicated to the project.

For those who found out about Project Care UK from YPAS and schools in the Liverpool Learning Partnership, we created a separate Qualtrics project as a copy of the main Project Care UK project. The full project used the same design, layout, and measures as Project Care UK, and the intervention itself was identical; however, participants could opt in to the research study (requiring them to complete the pre- and postintervention measures) or just access the intervention only. Therefore, this version used different branching logic to allow participants to choose which pathway they would like to complete. Additional changes were also made to debrief materials so that local sources of support (specific to the local Merseyside area) were listed for participants. In addition, the eligibility criteria to access the intervention were widened to allow individuals aged between 11 and 25 years to complete the intervention (which is more reflective of the age group that YPAS offers support and services to). Of those, for the current analysis, we only included those who opted in and provided consent to the research study and were aged between 13 and 18 years. All participants who accessed and completed the full study within the YPAS version of Project Care UK completed the same steps as earlier. Those who chose to complete the intervention only completed this and received a debrief (including local sources of support), and their data were not recorded.

Ethical Considerations

Ethics approval was granted by the University of Bath Psychology Research Ethics Committee in May 2023 (23-061), with subsequent amendments approved by the University of Bath Research Ethics Committee. To participate in Project Care UK, informed consent was sought through a detailed information sheet and consent process (refer to the Procedure and Materials sections for further details), and participants were reminded of their right to withdraw through closing their internet browser at any point if they wished to stop taking part. All data provided were anonymous. Data safety has been ensured through adherence to General Data Protection Regulations, storing all data online, on password protected drives, and data being made accessible to members of the research team only. In addition, participants were offered the opportunity to enter a prize draw for a £50 (US $62.87) Amazon voucher. To maintain their anonymity, those who wanted to be included in the prize draw clicked a link to a separate Qualtrics project where they could leave their contact details.

Materials

The Intervention: Project Care SSI

Project Care teaches adolescents about self-compassion and how being kinder to themselves could have a positive impact on their well-being, social, and academic outcomes [22,23]. Project Care was designed with input from adolescents using the BEST design elements, which are as follows: B stands for brain science or psychoeducation to teach the key concept in the program, E stands for empower the adolescent by asking them to take a “helper” or “expert” perspective, S stands for saying-is-believing exercises to consolidate learning, and T stands for testimonials and lived experience accounts from valued others [37].

Thus, Project Care SSI contains evidence-based information about how self-kindness can be helpful as well as real-world testimonies from adolescents and experts who had struggled with self-compassion and how they have achieved better outcomes since learning to be more self-compassionate. The intervention also incorporates evidence-based strategies to help overcome common barriers to self-compassion, such as recognizing that compassion extended to others can also be directed inward [30,37]. It includes activities designed to encourage reflection, support the development of a personal action plan, and consolidate learning by having participants summarize key ideas as if teaching them to someone else.

For the version we used in this study, which we refer to as “Project Care UK,” we obtained the American version of Project Care or Project Teen Goals as a Qualtrics project, which has been tested before in American adolescents [38]. With input from our young people’s advisory group and undergraduate students, we made several surface-level adaptations to the content to make it more suitable for UK adolescents (eg, changes to American language, spelling, and references such as “school grades”). Refer to Multimedia Appendix 2 for a copy of our intervention.

Consent Materials

For those who met the eligibility criteria, branch logic in Qualtrics was used to create consent procedure pathways for different participants based on their age. From June 2023 to January 2024, there were 2 branches: (1) all participants aged between 13 and 15 years required parental consent, and (2) participants aged between 16 and 18 years provided consent for themselves. Subsequently, to give those aged <16 years an option that did not require asking for parental consent, given that this could be a barrier to participation [39], we added an additional option whereby those aged 13 to 15 years could opt to complete additional questions to demonstrate Gillick competence and thereby consent for themselves (Multimedia Appendix 3).

XSL•FO
RenderX

Measures

Overview

All measures were self-reported. In the preintervention phase, we measured demographic and clinical characteristics, including self-reported depression and anxiety symptoms, as well as hope, hopelessness, beliefs about self-compassion, and attitudes toward help seeking. Immediately, in the postintervention phase, measures of hope, hopelessness, beliefs about self-compassion, and attitudes toward help seeking were reassessed. Participants also reported views on the acceptability and feasibility of the intervention.

Demographics

Participants completed demographic questions related to age, sex assigned at birth, gender identity, sexual orientation, ethnicity, and subjective socioeconomic status. The item related to age allowed participants to report their age in a free text box, while all other questions asked participants to choose a response from a list that best represents their identity and circumstances. Participants completed demographic questions on sex assigned at birth, gender identity, sexual orientation, and ethnicity. Sex assigned at birth had 4 response options: "male," "female," "prefer not to say," and "other"; only a single response was allowed. Gender identity included 16 options representing a range of masculine, feminine, trans, and nonbinary identities, along with "unsure" and allowed multiple selections. Sexual orientation offered 10 response options based on the UK 2021 census, along with options for those unsure or who preferred not to use a label; this question allowed 1 response. Ethnicity included six subcategories, namely White (4 options), mixed or multiple ethnic backgrounds (4 options), Asian (5 options), Black (4 options), Arab, and others, comprising 19 options in total, with 1 response permitted. Options reflected the listed categories of the 2021 census [40]. Finally, subjective social status was measured on the MacArthur Scale of Subjective Social Status–youth version (MacArthur SSS Scale–youth version) [41]. Participants responded by placing themselves on the ladder (scored 1-10) based on where they perceived their social status in the country and within their school. Scores were summed and averaged to give an overall perceived MacArthur SSS-youth scale score for each participant.

Measures of Mood and Internalizing Symptoms

The Patient Health Questionnaire–2 items (PHQ-2) [42] is a brief self-report screening tool for depressive symptoms over the previous 2 weeks. Items (eg, "little interest or pleasure in doing things") are rated on a 4-point Likert scale ranging from 0 ("not at all") to 3 ("nearly every day"). A higher score on the PHQ-2 indicates greater depressive symptoms. Furthermore, this measure appears to have acceptable internal reliability and validity in adolescents [42-45].

The Generalized Anxiety Disorder–2 items (GAD-2) checklist [46] is a brief self-report screening tool for generalized anxiety over the previous 2 weeks. Items (eg, "feeling nervous, anxious, or on edge") are scored on a 4-point Likert scale ranging from 0 ("not at all") to 3 ("nearly every day"). A higher score on GAD-2 indicates greater generalized anxiety symptoms. In addition, this measure has been found to have good internal reliability and validity [46].

The State Hope Scale (SHS) [47] is a 6-item self-report scale that measures hope and optimism around one's goals. Items are split into 2 subscales, *agency* items (eg, "at present, I am energetically pursuing my goals") refer to one's ability to start and complete actions, and *pathway* items (eg, "I can think of many ways to reach my current goals") refer to the routes available to reach one's goals. Items are rated on an 8-point Likert scale ranging from 0 ("definitely false") to 8 ("definitely true"). Higher scores indicate greater hope. In addition, the SHS appears to have good internal reliability and concurrent and discriminant validity [47]. It must be noted that participants were presented with all 6 items before intervention, while after intervention, they were presented with items 1, 3, and 5, which make up the "pathways" subscale.

The Beck Hopelessness Scale (BHS) [48] is a 4-item self-report scale that measures hopelessness as a cognitive trait of depression. Items pose statements about the self, world, and future (eg, "I look forward to the future with hope and enthusiasm") and ask participants to rate their agreement with each statement on a 4-point Likert scale ranging from 0 ("absolutely disagree") to 3 ("absolutely agree"). This measure has been shown to have excellent internal reliability and good validity [48].

The Beliefs About Self-Compassion Scale (BSCS) [49] is a 10-item self-report measure that assesses an individual's beliefs about self-compassion and how it might have a negative impact on them if they were to show self-compassion. Items (eg, "When I am kind to myself, I will behave more self-indulgently") are rated on a 5-point Likert scale ranging from 1 ("strongly disagree") to 5 ("strongly agree"). A higher score suggests greater negative beliefs about self-compassion.

An adapted version of the General Help-Seeking Questionnaire (GHSQ) [50] was used. This contains 1 item, which asks participants to rate how likely they are to seek mental health support from the 9 listed sources. This was rated on a 7-point Likert scale from 1 ("extremely unlikely") to 7 ("extremely likely"). To make the questionnaire culturally and developmentally relevant for UK youth, "online (eg, social media, forums)" was added as an optional source, while "intimate partner" and "minister or religious leader" were omitted. Participants could also identify other sources of support that are not listed. The original measure has been shown to have satisfactory internal reliability and validity [50].

Measures of Intervention Satisfaction

The PFS [51] used in this study has been adapted from existing validated feedback scales and is routinely used to evaluate the acceptability and feasibility of SSIs. Items (eg, "would recommend to a friend") are rated on a 5-point Likert scale ranging from 1 ("really disagree") to 5 ("really agree"). Participants could also offer additional feedback and opinions about the activity in 3 open-ended questions.

Statistical Analysis

Data were cleaned according to the study's eligibility criteria and analyzed using the R programming language (version 4.3.1; R Foundation for Statistical Computing) [52] within the RStudio integrated development environment (version 2024.09.1) [53]. The statistical analysis plan was preregistered on the OSF [35], with minor revisions made during the analysis phase [36].

Feasibility was examined by calculating counts (n) and proportions (percentages) of participants completing each stage of the study, including informed consent, preintervention measures, the intervention, and postintervention measures. Completeness checks, which defined participant flow, were conducted following the submission of each questionnaire. No statistics on view rate were collected.

Reach and adoption were assessed by summarizing demographic variables (age, sex assigned at birth, sexual orientation, ethnicity, and perceived social status) and clinical characteristics (GAD-2 and PHQ-2). Continuous variables were reported using means and SDs, while categorical variables were summarized using counts and percentages.

Implementation, in terms of recruitment sources, was evaluated by calculating the number and percentage of participants recruited through each channel (eg, well-being organizations, social media platforms, community email lists, and schools).

Acceptability was assessed using central tendency (means) and dispersion (SDs) for the full-scale and item-level scores on the PFS. A score of ≥3.0 (or ≥21.0 total) was preregistered as the threshold for "at least acceptable," corresponding to a neutral average response. A higher threshold of ≥3.5 (or ≥24.5 total), commonly applied in previous literature [51], was used to indicate a "favorable" rating. The proportion of participants meeting each threshold was reported at both item and scale levels.

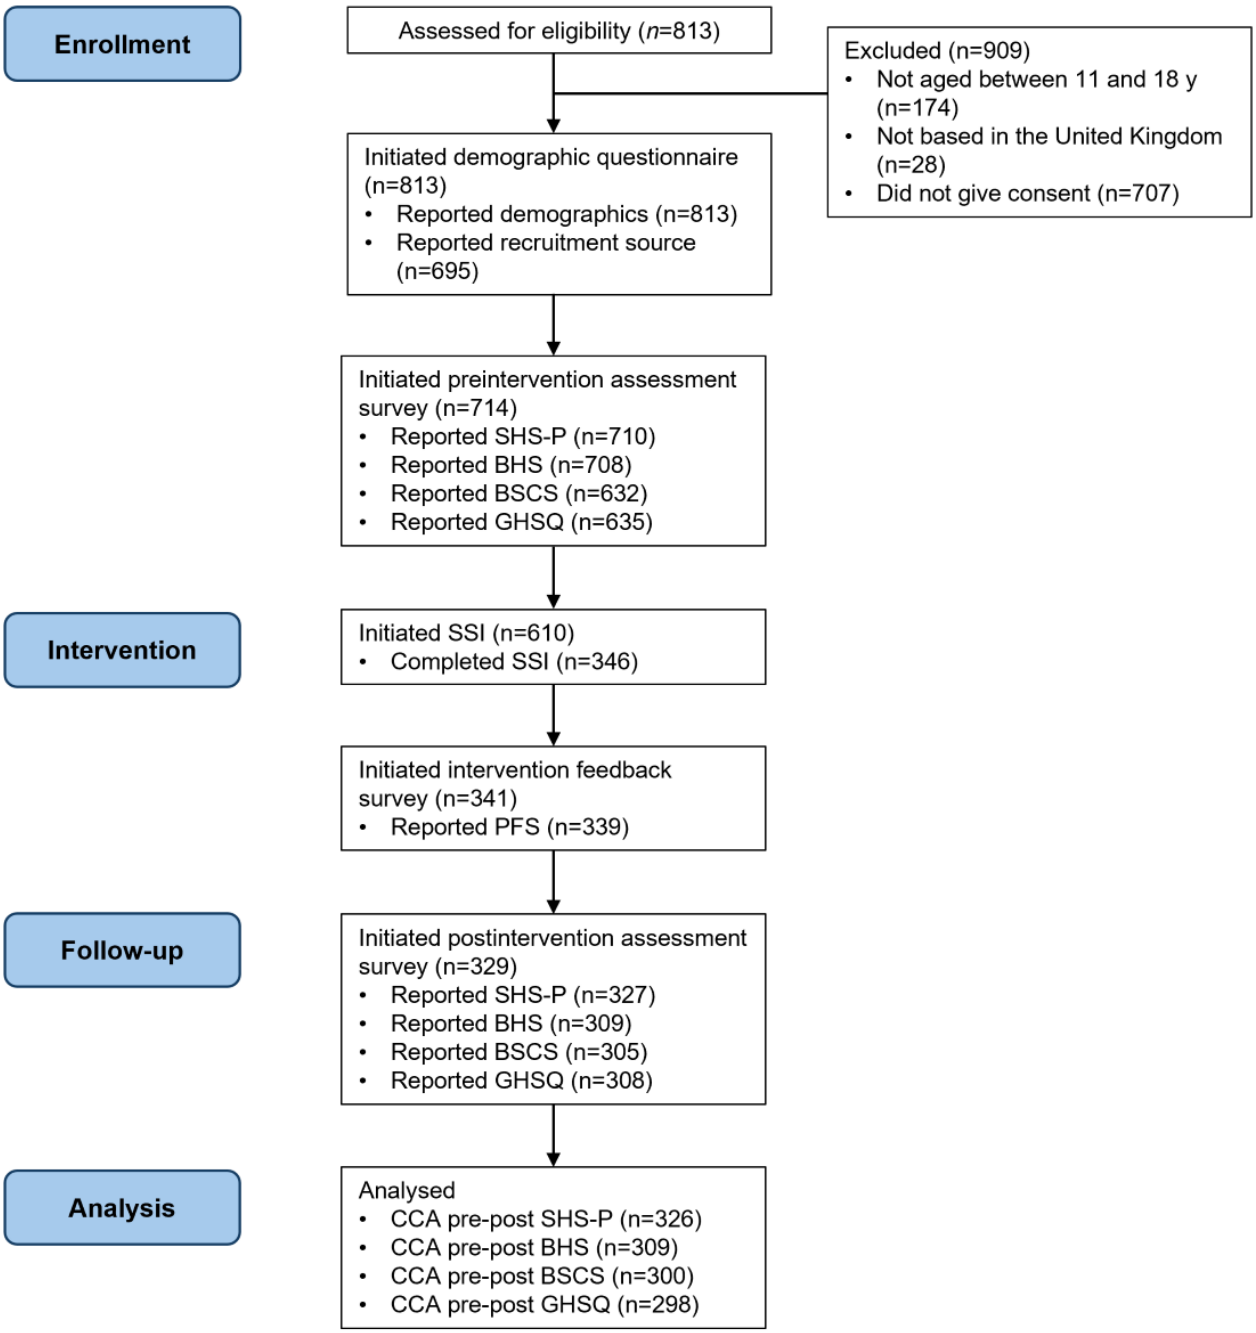
Preliminary efficacy examined the preintervention to postintervention changes in well-being outcomes, including the SHS pathways subscale, BHS, BSCS, and GHSQ. While the original preregistered analysis plan [48] specified the use of 1-tailed paired *t* tests, an unexpectedly large recruited sample, combined with substantial attrition and variability in data completeness, warranted the use of linear mixed-effects models as a more appropriate and robust analytic approach. The revised analysis plan is available on OSF [36], and results from the original paired *t* test analyses are reported in Multimedia Appendix 4 for transparency.

For the revised analysis plan, linear mixed-effects models were fitted using the *lme4* package in R [54]. Models included a fixed effect of time (before intervention vs after intervention) and a random intercept for participant ID to account for within-subject variations. Outcomes included the SHS pathways subscale, BHS, BSCS, and GHSQ.

Using the *MissMech* package in R [55], a nonparametric test for missing completely at random indicated that the missingness mechanism was not related to either observed or unobserved variables (P=.28). This supported the use of complete case analysis for the primary models, which included only participants with both pre- and postintervention data. To assess robustness, a sensitivity analysis was conducted using an intention-to-treat (ITT) approach, where missing postintervention data were imputed using the *mice* package in R [56].

For all models, β coefficients, P values (significance set at P<.05), and standardized effect sizes (Cohen d) were reported. Effect sizes were interpreted according to standard benchmarks: small (0.2), medium (0.5), and large (0.8) [57]. The proportion of participants showing improvement from before intervention to after intervention was reported, with improvement defined as increased scores on the SHS and GHSQ and decreased scores on the BHS and BSCS.

It should also be noted that, although the original analysis plan included all 6 items from the SHS, only the pathways subscale (items 1, 3, and 5) was administered. This reflected a focus on proximal cognitive outcomes likely to change within an immediate pre-post design, whereas agency items (2, 4, and 6), which assess behavioral goal pursuit, may require longer-term follow-up to detect change. In the GHSQ, the "Shout85285" help-seeking source was incorrectly encoded and therefore excluded from pre-post comparisons. In addition, the gender identity variable was omitted from analyses due to a survey coding error that rendered the data unusable.



Results

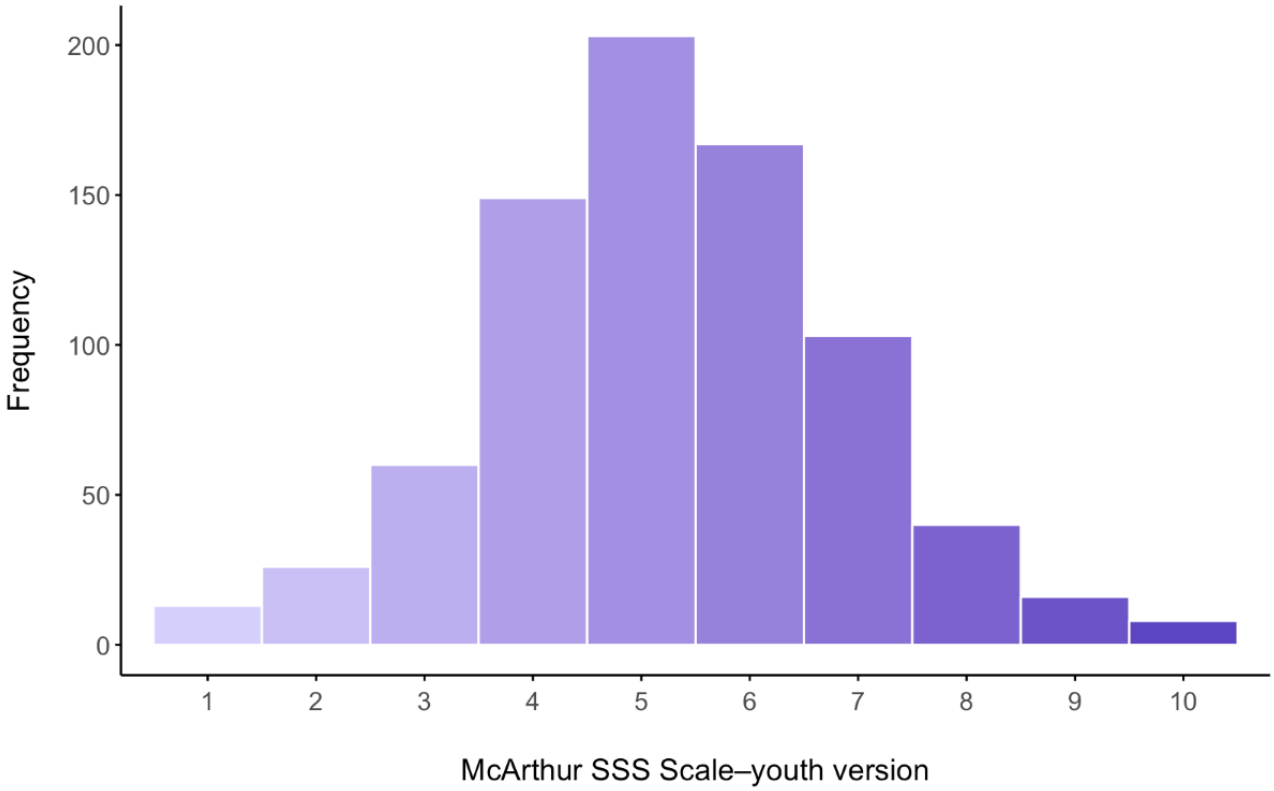
Feasibility

A total of 1722 individuals were assessed for eligibility, of whom 813 (47.21%) met the criteria and provided consent to participate. Among these, all 813 (100%) participants initiated the demographic questionnaire, 714 (87.8%) initiated the preintervention assessment survey, 610 (75%) initiated the SSI, 341 (41.9%) initiated the intervention feedback survey, 329 (40.5%) initiated the postintervention assessment survey, and 304 (37.4%) completed the study. For the preliminary efficacy analysis, complete case data were available for 326 (40.1%) participants for the SHS pathways subscale, 309 (38%) participants for the BHS, 300 (36.9%) participants for the BSCS, and 298 (36.7%) participants for the GHSQ. Participant flow is detailed in Figure 1.

XSL•FO
RenderX

Figure 1. Participant flow diagram. This modified CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) flow diagram depicts the number of participants at each study phase, including enrollment, intervention allocation, follow-up, and analysis. BHS: Beck Hopelessness Scale; BSCS: Beliefs About Self-Compassion Scale; CCA: complete case analysis; GHSQ: General Help-Seeking Questionnaire; PFS: Program Feedback Scale; SHS-P: State Hope Scale pathways; SSI: single-session intervention.

Dropout was relatively high in terms of both *overall study attrition* (509/813, 62.6% of the participants left the study early) and *intervention attrition* (264/610, 43.3% of the participants left the SSI early).



There was substantial variability in SSI completion times, from 9 minutes 17 seconds to 173 minutes 39 seconds (mean 23 min 39 s, SD 15 min 11 s).

Reach and Adoption

A total of 813 participants initiated the demographic questionnaire. They were aged between 13 and 18 years (mean 15.38, SD 1.58 y), with most being assigned female sex at birth (n=699, 86%), White (n=611, 75.2%), and not identifying as heterosexual (466/809, 57.6%). Participants indicated that their family's subjective social status was average relative to other UK households (mean 5.25, SD 1.67; Figure 2).

XSL•FO
RenderX

Figure 2. Histogram depicting the distribution of subjective social status (SSS). This histogram illustrates the distribution of subjective social status scores as measured by the MacArthur Scale of Subjective Social Status–youth version. Each bar represents the frequency of respondents with a specific score ranging from 1 to 10. Gradient color indicates the progression of scores from light purple ("low subjective social status") to dark purple ("high subjective social status").

Mental health difficulties were evident among the participants, with 71.5% (537/751) of the participants meeting or exceeding the threshold for elevated depression symptoms (ie, PHQ-2 scores ≥3) and 75.8% (560/739) of the participants for elevated anxiety symptoms (GAD-2 scores ≥3).

Demographic distributions were broadly similar between those who initiated the demographic form and those who completed the full study. However, while missing completely at random analyses did not indicate systematic sources of selective attrition, there was a noticeable descriptive drop in the proportion of participants identifying as heterosexual (from 343/809, 42.4% to 110/302, 36.4%). Comprehensive demographic information is provided in Table 1.

Implementation: Recruitment Sources

A total of 695 (85.5%) of the 813 participants reported where they had heard about the Project Care UK study. For these 695 participants, third-party well-being organizations were the most common recruitment sources, accounting for 662 (95.3%) participants, with Kooth being the largest individual contributor (n=603, 86.8%). In contrast, recruitment via social media platforms was minimal (n=14, 2%), while community email distributions (n=1, 0.1%) and secondary education institutions (n=0, 0%) contributed few to no participants. In addition, 18

XSL•FO
RenderX

(2.6%) participants reported discovering the study through alternative sources. Recruitment source distributions were similar between those who initiated the survey and those who progressed to the end of the study. A detailed summary of the study's recruitment sources is provided in Table 2.

Table 2. Recruitment sources of the Project Care UK study.

Recruitment source	Initiated (n=695), n (%)	Completed (n=258), n (%)
Well-being organizations		
Kooth	603 (86.8)	230 (89.1)

Acceptability

Of the 813 participants, 341 (41.9%) initiated the intervention feedback survey and 339 (41.7%) completed it. Summed scale scores of these 339 completers indicated that the SSI was well-received, with 313 (92.3%) participants endorsing it as "at least acceptable" (ie, PFS full-scale scores ≥21.0) and 271 (79.9%) endorsing it as "favorable" (ie, PFS full-scale scores ≥24.5). For individual PFS domains, 299-324 (88.2%-95.6%) of participants endorsed each domain as "at least acceptable" (ie, PFS domain scores ≥3.0) and 200-282 (59%-83.2%) endorsed each domain as "favorable" (ie, PFS domain scores ≥3.5; Table 3 and Figure 3).

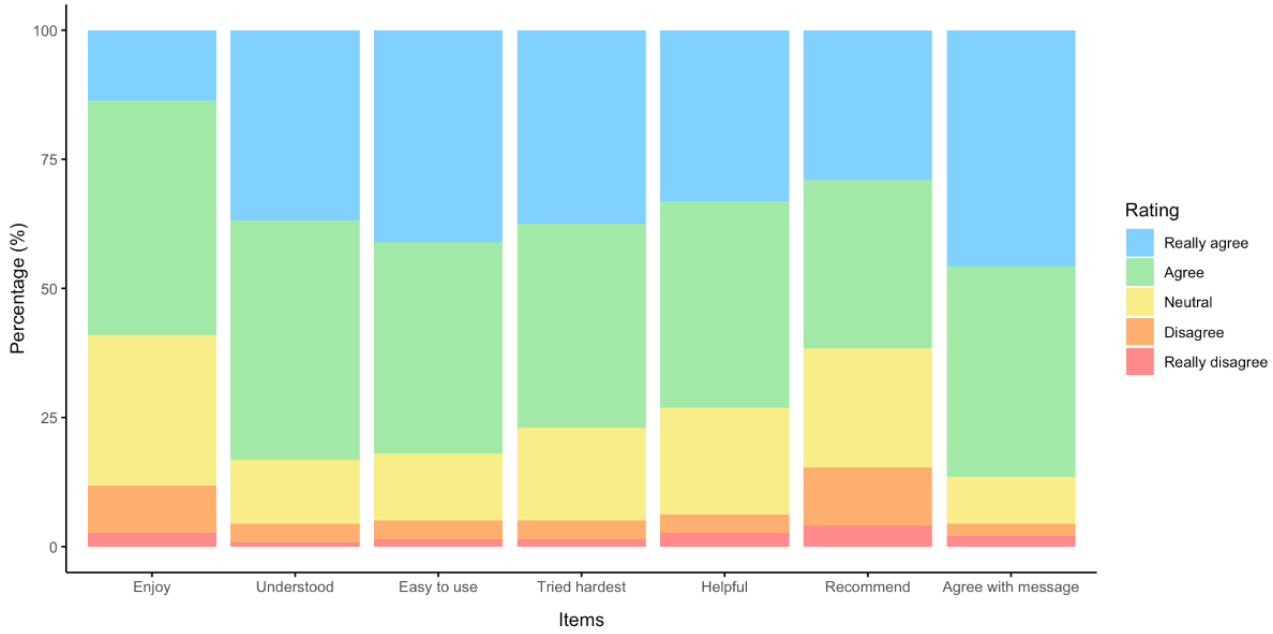

Table 3. Ratings for each item on the Program Feedback Scale (PFS; N=339)[a].

Item content	Ratings, mean (SD)	"At least acceptable" endorsement (≥3.0), n (%)	"Favorable" endorsement (≥3.5), n (%)
Enjoy	3.58 (0.93)	299 (88.2)	200 (59)
Understood	4.15 (0.83)	324 (95.6)	282 (83.2)
Easy to use	4.17 (0.89)	322 (95)	278 (82)
Tried hardest	4.08 (0.91)	322 (95)	261 (77)
Helpful	3.97 (0.96)	318 (93.8)	248 (73.2)
Recommend to a friend	3.71 (1.12)	287 (84.7)	209 (61.7)
Agree with the message	4.26 (0.87)	324 (95.6)	293 (86.4)
Full scale	27.91 (4.74)	313 (92.3)	271 (79.9)

[a]This table presents the mean scores and their corresponding SDs for the full scale and each individual item of the (PFS). In addition, it reports the counts (n) and percentages of individuals who endorsed Project Care UK as "at least acceptable" and "favorable." The intervention is endorsed as "at least acceptable" overall if the full-scale score is ≥21.0 and per domain if individual item scores are ≥3.0. The respective cutoffs for a "favorable" endorsement are ≥24.5 for the full scale and ≥3.5 for each item.

XSL•FO
RenderX

Figure 3. Stacked bar chart depicting the distribution of ratings across each item of the Program Feedback Scale. Together, blue (ie, “really agree”), green (ie, “agree”), and yellow (ie, “neutral”) denote an endorsement of the given item as “at least acceptable.”.

Preliminary Efficacy: Main Analyses

Of the 813 participants, 329 (40.5%) initiated the postintervention assessment survey. Statistically significant improvements were observed for 3 of the outcome measures, including increased hope (326/813, 40.1%; *P*<.001; Cohen *d*=0.72), decreased hopelessness (309/813, 38%; *P*<.001; Cohen *d*=–0.73), and decreased negative beliefs about self-compassion (300/813, 36.9%; *P*<.001; Cohen *d*=–0.64).

For those cases with complete data, rates of individual-level improvement were also significant, with 69.9% (228/326) of the participants showing an improvement in hope, 88% (272/309) of the participants showing an improvement in hopelessness, and 77% (231/300) of them showing an improvement in negative beliefs about self-compassion. Help-seeking tendencies did not exhibit any significant change (298/813, 36.7%; *P*=.13; Cohen *d*=0.09). Detailed pre- and postintervention comparisons are presented in Table 4 and Figure 4.

XSL•FO
RenderX

Table 4. Pre- and postintervention comparisons of hope, hopelessness, self-compassion, and help-seeking[a].

Scale	Preintervention assessment, mean (SD)	Postintervention assessment, mean (SD)	β (SE)	*t* test (*df*)	*P* value	Cohen *d* (95% CI)	Improved cases, n (%)
SHS[b] pathways subscale	12.30 (4.55)	15.02 (5.02)	2.72 (0.21)	13.07 (325)	<.001	0.72[c] (0.60 to 0.85)	228 (69.9)[d]
BHS[e]	2.54 (1.07)	1.99 (1.13)	–0.56 (0.04)	–12.92 (308)	<.001	–0.73[c] (–0.86 to –0.61)	272 (88)[f]
BSCS[g]	3.23 (0.78)	2.65 (0.90)	–0.58 (0.05)	–11.12 (299)	<.001	–0.64[c] (–0.77 to –0.52)	231 (77)[h]
GHSQ[i]	3.30 (0.75)	3.35 (0.86)	0.05 (0.03)	1.54 (297)	<.13*	0.09[j] (–0.02 to 0.02)	133 (44.6)[k]

[a]Preintervention and postintervention comparisons for hope (State Hope Scale pathways subscale), hopelessness (Beck Hopelessness Scale), beliefs about self-compassion (Beliefs About Self-Compassion Scale), and help-seeking (General Help-Seeking Questionnaire). Values represent the number of cases, percentages, means, SDs, fixed effect estimates (β), *df*s, *t* test values, *P* values, effect sizes (Cohen *d*) with 95% CI, and percentages of participants who improved (improved cases). Participants showing improvement in outcome measures (improved cases) were also reported, defined as increased scores on the State Hope Scale and General Help-Seeking Questionnaire and decreased scores on the Beck Hopelessness Scale and Beliefs About Self-Compassion Scale. Effect sizes are classified as small, medium, or large. Pre-post changes in hope, hopelessness, and beliefs about self-compassion were significant.

Figure 4. Modified rain cloud plots depicting pre-post intervention comparisons of hope, hopelessness, self-compassion, and help seeking. The integrated plots comprehensively display pre-post data for hope, hopelessness, self-compassion, and help seeking. Graphs include pre-post trajectories for each participant (ie, individual data points and connecting lines), central tendencies (box plots), and frequency distributions (rain cloud plots). BHS: Beck Hopelessness Scale; BSCS: Beliefs About Self-Compassion Scale; GHSQ: General Help-Seeking Questionnaire; SHS: State Hope Scale.

Preliminary Efficacy: Sensitivity Analyses

To assess the robustness of the main findings for preliminary efficacy, a sensitivity analysis using an ITT approach was conducted. In this analysis, missing postintervention values were imputed using multiple imputation procedures as outlined in the revised statistical analysis plan [36]. Results from the ITT analyses were consistent with the complete case analyses: statistically significant improvements were observed in hope (709/813, 87.2%; *P*<.001), hopelessness (708/813, 87.1%;

XSL•FO
RenderX

P<.001), and negative beliefs about self-compassion (632/813, 77.7%; *P*<.001), with no statistically significant change in help-seeking intentions (635/813, 78.1%; *P*=.19). Full inferential results are presented in Multimedia Appendix 5.

Discussion

Principal Findings

Our single-arm pre-post program evaluation of a minimally adapted version of the American SSI Project Care in the United Kingdom showed that recruitment through large-scale third-party well-being organizations was the most effective implementation strategy. In total, 37.4% (304/813) of our participants completed the study, and most participants who discontinued did so during the SSI. Most of our participants were assigned female sex (699/813, 86%) at birth, were White (611/813, 75.2%), and did not identify as heterosexual (466/809, 57.6%). Overall, participants viewed Project Care UK as acceptable and offered favorable ratings for the SSI. In addition, participants reported significant improvements in hope, hopelessness, and self-compassion. No significant differences were found in help seeking.

A key uncertainty that we need to address to capitalize on digital self-help SSIs, such as Project Care, at the public health level in the UK context is how to let adolescents know about the availability of these interventions. In our study, we piloted several different recruitment routes. As previous research studies and open-access trials in the United States by the Lab for Scalable Mental Health have predominantly reached adolescents via posts and targeted advertisements on social media, particularly Instagram [24], we anticipated that most adolescents would be recruited via social media [58]. This is also consistent with evidence that adolescents look for health information generally [58,59] and mental health information specifically online [60]. Furthermore, in our formative work in the United Kingdom, adolescents identified that they tend to look for support on the internet and social media when they first begin to struggle with their mental health [61]. However, contrary to our expectations, only a very small number of our participants (14/695, 2%) were recruited via social media. There are several potential explanations for this. It may be because our social media accounts do not have the adolescent following that those from the Lab for Scalable Mental Health do, and therefore our advertisements did not reach the intended target audience or that there has been a shift away from social media since the US-based studies. It could also be that in the United Kingdom, where health care, including mental health care, is free to access, the offer of free mental health help is less persuasive and attractive than in the United States, where health care is generally charged to the user. While adolescents spend time on social media, they may doubt the trustworthiness of information they find there [62] and might therefore be cautious about taking part in studies advertised there.

During the recruitment phase of our study, we introduced several alternative recruitment routes and found that most of our participants (603/695, 86.8%) heard about Project Care UK through a large-scale third-party mental health organization. Kooth is commissioned in most of England to provide free, anonymous online mental health help on demand, such as activities to manage emotions, psychoeducation, and crisis support, which is largely used by adolescents who may be struggling with mental health difficulties [63]. Adolescents in the United Kingdom have previously identified that they would prefer to use reputable and trusted sources of mental health support [50,51]. Therefore, they may have been more likely to engage with Project Care when it was listed as a resource in organizations that they already knew of and trusted, and this trust appears to have been extended to Project Care when it was signposted there. There are multiple similarities between self-help SSIs such as Project Care and organizations such as Kooth and Shout, which offer on demand, convenient, and anonymous information and support, and users are not necessarily required to seek adults' permission (eg, parental consent and general practitioner referral), all of which are known barriers to accessing mental health support [7,10]. Hence, those seeking help from these organizations might also be particularly likely to view SSIs favorably due to these shared characteristics in terms of how help is provided. Thus, embedding SSIs within the support offered by these organizations could be a way to extend on what they currently provide.

Limitations and Future Directions

Many (509/813, 62.6%) participants did not complete the study. It may be that while the Project Care UK SSI did not fit with what some adolescents were looking for, offering a choice of SSIs to enable adolescents to select the one that they feel best fits their needs could keep them better engaged. Notably, in open platform trials where Project Care was offered as one of 3 SSI options, only some adolescents selected it (19% of the individuals aged 13-18 years in Project YES [23] and 29% of the individuals aged 11-17 years in Project YES San Antonio) [23]. It is also possible that the type of support that adolescents are looking for is bite-sized information (eg, TikTok-style short videos) that is easy to consume rather than longer, activity-based support (such as Project Care UK). A recent narrative review [19] reported that some of the program features that facilitate engagement in digital interventions are efficient (eg, bite sized) and interesting content (eg, interactive content or videos). A briefer version of an SSI embedded in Tumblr has been found to be feasible and acceptable in the United States [64] Alternatively, it may be that some participants discontinued because they had received what they wanted from the SSI, a pattern which has been found in a subgroup of adolescents with depression who discontinue in-person, multisession psychological therapy [65], and which does not necessarily predict unfavorable outcomes [66]. Exploring barriers to and facilitators of SSI completion using process evaluation [67] could shed light on these possibilities to guide further developments of SSIs to better meet adolescents' needs and preferences.

Similar to samples from SSI studies in the United States [22-24], our sample was diverse, particularly regarding sexual orientation and ethnicity. For example, 9.2% (75/803) of the participants identified their ethnic group as Asian or Asian British, closely matching UK population estimates of 9.3% [68]. In addition, 57.6% (466/809) of the participants did not identify as heterosexual, which exceeds national estimates of approximately

XSL•FO
RenderX

10% [41,68], reflecting strong engagement with sexual minority adolescents. While previous research has often struggled to reach these populations [6,69], our SSI, through multiple recruitment strategies, successfully engaged both ethnic minority groups and young people who identified as nonheterosexual. Thus, SSIs, offered anonymously and on demand online, could be a promising method of reaching underserved groups and providing them with reputable, evidence-based mental health support, as an expansion on traditional clinic-based provision.

Despite this promising finding, most of our sample (ie, 699/813, 86%) were assigned female sex at birth, which is in line with figures from SSI acceptability and feasibility studies conducted in American adolescents [21]. Previous research has suggested that stigma and societal expectations of masculinity are potential barriers to male adolescents engaging with therapeutic support [70], and interventions such as Project Care UK could transcend these barriers by providing online, anonymous support. However, it remains largely unclear whether online SSIs that are offered anonymously are acceptable and feasible for male individuals, and future research that considers how to leverage this type of support among them would be beneficial.

Ours is the first evaluation of the Project Care SSI, which included a self-compassion measure. Promisingly, 77% (231/300) of our sample reported improved beliefs about self-compassion after intervention as an immediately measurable change, and future studies could look at whether this translates over time into changes in self-compassionate thinking and responding.

Even though our evidence of effectiveness on proximal outcomes and preliminary efficacy is promising, it is important to acknowledge the possibility that for some adolescents, SSIs may not be helpful, indicated by several responses (26/339, 7.7%) to the PFS in our study. Future studies could more explicitly explore adverse events and harms to understand more about those who indicate that it is unhelpful. Studies could include adverse events and harm measures such as the Negative Effects Questionnaire [71].

The overall study attrition rate (62.6%) and the SSI attrition rate (43.3%) were quite high, which could potentially limit the validity of our findings. While our data suggested that Project Care was feasible overall and across different groups of young people (eg, across ethnic groups, genders, and sexual orientations), it is unclear why some participants discontinued, and it will be important for future studies to explore this. Our conclusions apply to those participants who did complete measures but cannot be assumed to apply to those who did not. As noted in other SSI evaluations [72], about half (346/813, 42.6%) of the eligible participants who accessed Project Care UK completed the SSI.

In addition to the proximal outcome measures we used, future program evaluations of SSIs could also measure general state affect using the Positive and Negative Affect Schedule [73] as an additional proximal outcome measure. In our study, as we did not conduct a follow-up, we were unable to draw any conclusions about short- and long-term changes in mental health symptoms or self-compassion, and future studies would benefit from additional follow-up points to address this.

As this was a pilot study without a control group, it is unclear whether the observed effects were due to the effects of the intervention or the specific content of this SSI. Future work could compare the outcomes for participants randomly allocated to the Project Care SSI to those allocated to an online activity control condition to account for the time spent doing activities online, for instance, to enable more robust conclusions about the effectiveness of the specific Project Care SSI. Although given our findings of significant pre-post increases in hope and reduced hopelessness and negative beliefs about self-compassion, the Project Care intervention appears to have been effective. While it is possible that young people were able to use the intervention to learn about the value of self-compassion and how they could implement this into their lives, as demonstrated through significant pre-post reductions in negative beliefs about self-compassion, it is ultimately unclear whether the intervention achieved these pre-post changes through its intended mechanisms. Nevertheless, our findings suggest that it would be appropriate to disseminate the Project Care UK intervention, particularly as it would make free, online, evidence-based support about self-compassion widely available to UK adolescents, which they have highlighted as a priority.

Conclusions

SSIs such as Project Care could offer a scalable solution for expanding access to early help and overcoming some of the existing barriers that adolescents face. Through leveraging large-scale third-party mental health organizations whose primary users are adolescents [63], it appears to be feasible to make SSIs such as Project Care widely available, although activities must align with the organization's primary offers of support. Adolescents from racial and sexual minority backgrounds who are underserved by traditional clinic-based services seem to be better represented in studies of SSIs, including our own and previous studies in the United States [21], although more work is needed to establish how to engage individuals identifying as male in using these kinds of scalable supports. Our findings provide initial indications of the preliminary efficacy of Project Care in the UK context. Additional work is needed to more robustly test it by comparing it to other interventions and following up with participants over time to explore whether the effects are maintained and translated into mental health benefits beyond the proximal outcomes reported in this study.

Acknowledgments

MEL (advanced fellowship 302929) is funded by the National Institute for Health and Care Research for this research project. Research Council (project reference 2912026). We particularly valued the advice from young people about how and where to share the recruitment materials for this study, specifically the spotLight on Adolescent Mood Problems Young Person's Advisory Group, and the Camhelions Young Person's Advisory Group. We also particularly appreciated the support of research assistants Beatrice Sung, Melanie Luximon, Christy Chiu, and Chloe Payne-Cook, who supported recruitment to Project Care UK, and colleagues from the Liverpool Learning Partnership and the Liverpool-based Young Person's Advisory Service who signposted the study.

Authors' Contributions

MEL was responsible for conceptualization, methodology, writing the original draft, supervision, and project administration. GP was responsible for software development, data curation, project administration, validation, and writing the original draft. NM was responsible for visualization, data curation, formal analysis, and writing the original draft.

Abstract

Background: Just-in-time adaptive interventions (JITAIs) aim to provide psychological support during critical moments in daily life.

Objective: This preregistered study aims to evaluate the feasibility of a social support JITAI for individuals with subclinical and clinical levels of depressive symptoms awaiting psychotherapy. Triggered by ecological momentary assessment (EMA) reports, the intervention encouraged participants to activate their (digital) social support networks.

Methods: A total of 25 participants completed 2689 EMA surveys and received 377 JITAIs over an 18-day intervention period, including a microrandomized trial, to compare 4 strategies to trigger an intervention: fixed cutoff points of distress variables, personalized thresholds (through Shewhart control charts) of distress variables, momentary support need, and no intervention.

Results: The results showed high feasibility, with participants completing 85.37% (2689/3150) of the EMA surveys, exhibiting a low study-related attrition rate (7%; total attrition rate was 17%), and reporting minimal technical issues. Engagement and perceived helpfulness were heterogeneous and moderate, with participants seeking support in one-third of the instances after an intervention was triggered instances. JITAIs triggered by self-reported need for support were rated as more appropriately timed, helpful, and effective for promoting support-seeking behavior compared to those based on distress indicators, despite being triggered less frequently. Barriers, such as time constraints and perceived unavailability of support providers, likely affected support-seeking behavior, as indicated by additional qualitative analyses. Exploratory effectiveness analyses indicated Cohen *d* effect sizes between 0.06 and 0.14 in reducing distress after JITAIs were received.

Conclusions: The findings of this study demonstrate that a social support JITAI is feasible to implement, with high compliance and minimal technical issues. However, further research is needed to evaluate the JITAI's effectiveness and optimize trigger strategies in addressing individual needs for and barriers to engagement.

Introduction

Background

Mental health problems, such as depression, are becoming increasingly prevalent in today's societies [1,2]. Despite the resulting need for mental health care systems, many countries are struggling to meet the demand for treatment. A large number of individuals around the globe report that their mental health needs are not sufficiently met [3-5] or are left untreated [6]. One reason for this is restricted access to mental health care because of long waiting times for outpatient psychotherapeutic treatment [7-9]. For example, depending on the area in the United States, the average waiting time for outpatient psychotherapeutic treatment is estimated to be between 19 days and 3 months [10-12]. In Germany, for example, the waiting time is estimated to be 16 weeks [13]. Long waiting times can have serious public health consequences. A delay in receiving psychotherapeutic treatment can exacerbate mental health conditions and may prolong distress [14,15].

One promising way to support individuals during this waiting period in coping with, for example, depressive symptoms is through digital mental health interventions delivered via the smartphone [11]. Digital mental health interventions have low entry barriers, can be cost-effective, and have the potential to reach a wide range of individuals, including those reluctant to seek psychotherapy due to stigma [16,17]. Examples of digital mental health interventions aiming to alleviate depressive symptoms include mindfulness training, self-monitoring reports, or elements of cognitive behavioral therapy (CBT) [18,19]. However, these static interventions often do not take into account the dynamic emotional experiences of participants' daily lives, which could be used to determine optimal intervention time points.

The particularly promising forms of digital intervention in this context are just-in-time adaptive interventions (JITAIs) [20]. These interventions use sensor data or responses from repeated smartphone-based surveys, such as the experience sampling method or ecological momentary assessments (EMAs) [21-23], to trigger timely and contextually relevant interventions. JITAIs are designed to provide support precisely when and where it is needed most in daily life settings, allowing them to reach vulnerable individuals in critical moments [20,24]. Therefore, they represent a powerful approach that allows for real-time and personalized delivery of psychological interventions [25,26]. For instance, interventions can be triggered at critical moments when a particular individual is experiencing high levels of negative affect, stress, or rumination [27,28].

Despite the potential of smartphone-based JITAIs, current implementations often overlook one of the smartphone's most obvious functions: connecting individuals to their social support networks. Social support is conceptualized as "a social network's provision of psychological and material resources intended to benefit an individual's ability to cope with stress" [29]. Because of this coping functionality, the availability of social support networks is a key determinant of mental health and a protective factor against the development of depression [30-32]. Socially supportive relationships protect from social isolation and its adverse effects on mental and physical health [29,33]. Seeking social support can be a major hurdle, especially for individuals experiencing depressive symptoms [34,35]. However, to the best of our knowledge, no mental health JITAI exists that aims to aid participants in seeking social support during vulnerable moments. Thus, there is a need to explore how JITAIs can be used to help individuals activate their (digital) social support networks.

When Is "Just-in-Time"?

When designing a JITAI, a critical factor for its effectiveness is ensuring that it is provided at moments in participants' daily lives when they need support and are receptive to it [20,36]. However, identifying these moments is challenging and requires a balance between accurately detecting distress and ensuring timely delivery. The decision rules that trigger the interventions thus need to be systematically studied when designing a JITAI, as these are assumed to affect proximal outcomes, such as intervention engagement [20].

Initially, interventions were triggered based on predefined, fixed cutoff points, such as scoring 4 or more on a 7-point negative affect scale [27,28]. While these cutoff points can capture general patterns, they fail to account for individual differences in what constitutes a "high" or "low" score. What may be normal for one person could represent significant distress for another. Moreover, the cutoff points do not consider natural fluctuations in individuals' experiences over time, limiting their ability to identify meaningful deviations from a person's usual state.

A newer approach that addresses these challenges is the use of *statistical process control* (SPC) methods, specifically *Shewhart control charts* (SCCs), to personalize the timing of interventions [37]. SPC charts track personal variability in key psychological indicators (eg, distress levels) and can be used to identify when someone deviates from their usual emotional state [37]. As interventions are triggered based on real-time changes, this method makes the timing more personalized.

However, a completely different approach may be effective as well, namely directly asking participants about their need for social support at any given moment. Many definitions of social support highlight the anticipation or mobilization of help from others during times of need, typically characterized by elevated stress [38]. Thus, assessing support need can serve as a pragmatic proxy for vulnerability and aligns with the theoretical accounts, emphasizing that support is most effective when individuals need it and are able to express their needs [39]. Hence, we assume that asking individuals directly about their current need for support may offer a more accurate and tailored strategy than relying solely on fixed cutoff points or inferred dynamics of distress variables. This assumption was preregistered on the Open Science Framework (OSF) [40].

The Social Support JITAI

With the aim of helping individuals activate their (digital) social support networks, we designed a social support JITAI based on current best practice and research on social support. The intervention we proposed is designed to facilitate social support through JITAIs by sending prompts and reminders to connect with identified support figures during moments of distress, based

XSL•FO
RenderX

on real-time data and responses gathered through EMAs. We identify moments of distress by assessing (fluctuations in) self-reported negative affect, stress, loneliness, and rumination. On the basis of a microrandomized controlled trial design [41] at each EMA assessment moment, it is randomly determined which condition the current assessment falls under: (1) after a participant's distress level surpasses a fixed cutoff point (condition 1), (2) when the distress level surpasses a critical threshold based on SCCs (condition 2) [42], or (3) when participants indicate that they need support (condition 3). In condition 4, no intervention is triggered. In other words, at each EMA time point, participants were randomized to 1 of the 4 intervention-triggering conditions, making each assessment a distinct randomization unit in the microrandomized trial design. If triggered, the intervention includes prompts and messages designed to encourage participants to reach out to their (digital) social networks for support. Specifically, in line with the JITAI framework [20], when a vulnerable state is detected, the intervention is triggered. In the first step, participants are encouraged to reflect on what type of social support they would find helpful. This reflection is intended to activate problem-solving and coping strategies [43]. In the next step, participants are shown a list of past interaction partners, thereby highlighting potentially available support resources. Because states of vulnerability may be accompanied by narrowed thinking, seeing a list of possible support contacts may help broaden participants' awareness of their social environment [44,45]. Finally, the JITAI encourages participants to seek social support from the available support provider in a way that is helpful for them, which is important for effective support seeking [39]. Participants were not limited to digital channels; they could choose to call, message, video chat, or meet in person based on their own preference and situational constraints. A detailed description of the social support JITAI can be found in the Methods section and Multimedia Appendix 1 and on the project's OSF repository [40].

In line with the skilled support framework [46] and the optimal matching theory [47], this JITAI assumes that when social support is sought in the right moment, from the right person, and in the right way, it can help individuals to cope with distress-related adversity. Receiving social support in critical moments can help individuals by facilitating the feeling of belongingness, activating self-worth, receiving practical aid, developing coping strategies, and providing opportunities to express and regulate emotions or reinforcing positive behavior, thereby contributing to getting out of dysfunctional, depressed states [48,49]. Findings from correlational studies capturing social support behaviors and affective responses in daily life indeed suggest that higher received social support in crucial moments within everyday life contributes to a reduction of felt distress [50-52]. Furthermore, studies on social prescribing, a process where health care professionals refer patients to nonclinical social support interventions, may be effective in improving mental health [53,54]. However, no mental health JITAI has made use of the social support process.

This Study

This study aims to address the gap in understanding the feasibility, acceptability, and initial intervention effects of a social support JITAI among individuals seeking psychotherapy. Feasibility studies are crucial, as they provide valuable insights into how well an intervention works in a real-world setting before proceeding to larger-scale trials. They help identify potential facilitators of and barriers to implementation, ensuring that the intervention is practical and effective [55,56]. In addition, high compliance rates and valid, high-quality data are essential for the JITAI to be triggered at appropriate moments, ensuring its effectiveness in real-world settings.

The first aim of this study is to examine various feasibility and proximal outcomes, specifically how participants report on (1) appropriateness of the interventions' timing, (2) helpfulness, (3) behavior adoption (ie, whether they seek social support), (4) intervention engagement, (5) burden, (6) technical functioning, and (7) negative effects of the social support JITAI in general and specifically of the different triggering conditions. We expect that participants rate these aspects of feasibility and proximal outcomes in general as high. Other feasibility outcomes include the compliance rate with the EMA surveys and the data quality, measured through the rate of careless responses.

Second, we aim to evaluate which of the applied triggering strategies (ie, decision rules) is rated highest by the participants with regard to the perceived appropriate timing, helpfulness, and JITAI behavior adoption. We expect these outcomes to be the highest when the intervention is triggered after participants indicate they need support (condition 3), followed by interventions triggered based on fixed cutoff points (condition 1) or the SPC method (condition 2), as preregistered [40].

Third, we aim to explore the intervention effects of the social support JITAI on self-reported social support sought and momentary distress. We expect that participants are more likely to have sought social support and show a larger reduction in distress variables (negative affect, stress, loneliness, and rumination) between T (previous EMA time point; EMA time point that triggered the JITAI) and T+1 (subsequent EMA time point) after a JITAI (conditions 1, 2, or 3) compared to when no JITAI is triggered (condition 4).

Methods

Participants

Participants were individuals seeking outpatient psychotherapy who reported subclinical and clinical levels of depressive symptoms on the Beck Depression Inventory-II (BDI-II) with scores more than 9, indicating at least minimal depressive symptoms [57,58]. All participants were actively seeking outpatient psychotherapy at the time of study enrollment. While some were reported to be on waiting lists, many Swiss psychotherapists do not maintain explicit waiting lists; thus, some of the participants were seeking psychotherapy while not being on a waiting list. Other inclusion criteria were owning a smartphone and micro randomized providing informed consent. Exclusion criteria included individuals with a scheduled psychotherapy session within 4 weeks, suicidal ideation (values >2 on BDI-II item 9), manic symptoms (determined by the Mood Disorder Questionnaire) [59,60], or aged <18 or >70

XSL•FO
RenderX

years. Inclusion and exclusion criteria were assessed with a screening questionnaire.

Our sample consisted of 25 individuals. Of these, 22 (88%) self-identified as women and 3 (12%) identified as men. No other gender identification categories were reported. The mean age was 35.12 (SD 11.42) years. Most (n=21, 84%) participants self-reported their ethnicity as White. A detailed report of the demographic variables (including the level of education, employment status, living situation, and number of children) can be found in Table S1 in Multimedia Appendix 1.

Procedure

All participants were led through the same procedure. Participants interested in this study, either by referral from psychotherapists who had to reject or put new clients on a waiting list or through our social media posts, were directed to a screening questionnaire. If eligible, participants were invited to an in-person meeting in which participants received information about the study (refer to the information sheet on OSF [40]), signed the informed consent form, completed a baseline survey assessing demographic information and depressive symptoms, installed the m-Path smartphone app for EMA surveys and JITAI delivery, and took part in a semistructured qualitative interview about social support seeking and smartphone-based interventions. Subsequently, EMA surveys were administered over a 21-day period using the m-Path software [61]. During this period, participants received 6 daily EMA surveys (randomly prompted between 8 AM and 10 AM, 10 AM and noon, noon and 2 PM, 2 PM and 4 PM, 4 PM and 6 PM, and 6 PM and 8 PM). After 3 days, JITAIs were additionally delivered through the m-Path app. The details on the intervention procedure are described in the Intervention section. Supplementary to the 6 EMA surveys, participants received an end-of-the-day survey via m-Path every evening (between 8 PM and 9 PM) and every 7 days (between 9 PM and 11 PM). After the 21-day EMA period, participants were again invited for a qualitative interview on their experiences during the study and a debriefing.

Ethical Considerations

The study was approved by the ethics committee of the faculty of arts and sciences of the University of Zurich (23.04.11). All 25 participants provided informed consent. Participants were compensated with CHF 160 to 250 (US $197 to US $308), depending on their participation rate in the surveys delivered through the m-Path app (CHF 160 corresponded to 50%; CHF 250 corresponded to 100%). Ten days into the study, participants received information about their personal participation rate and were motivated to sustain or increase it by reminding them of their compensation.

Measures

Distress Variables

The distress variables measured through EMAs included negative affect, stress, loneliness, and rumination. The original item formulations in German can be found on OSF [40]. In this study, we present their English translations. Negative affect was measured with a single item “to what extent do you experience negative emotions at the moment?” rated on a 7-point Likert scale ranging from 1 (I do not experience negative emotions) to 7 (very negative) [62]. Stress was measured with the item “I feel stressed at the moment” rated on a 7-point Likert scale ranging from 1 (disagree completely) to 7 (agree completely). Loneliness was measured with the item “I feel lonely at the moment” rated on a 7-point Likert scale ranging from 1 (disagree completely) to 7 (agree completely). Rumination was measured with the item “I realize that I am thinking the same negative thoughts over and over again” rated on a 7-point Likert scale ranging from 1 (disagree completely) to 7 (agree completely) [63].

Support Need

Support need was measured with the item “would it help you right now to talk to someone about your worries or negative feelings?”—which could be rated either as “yes,” “no, it would not help me,” or “I have no worries or negative feelings.”

Feasibility and Proximal Outcome Measures

A range of feasibility outcome measures was assessed using postintervention, evening, and weekly survey questions.

Postintervention Questions

The 2 questions mentioned subsequently were prompted at the beginning of the subsequent EMA survey after the intervention was triggered. They were embedded at the start of the next completed EMA survey, regardless of whether one or more scheduled EMAs had been missed in between. In our analyses, we used only those instances where a follow-up EMA was actually completed. JITAI ratings without a subsequent EMA were excluded from the analyses. Furthermore, no EMA lags that spanned overnight were considered. The appropriateness of the timing of the intervention was measured with the item “the last time the app made me aware that I could seek social support, it was just at the right time” rated on the 7-point Likert scale ranging from 1 (disagree completely) to 7 (agree completely). Whether the participant adopted the social support intervention was measured with the question “did you ask others for support because of the app’s advice?” which could be rated as “yes” or “no.”

Evening Questions

The perceived helpfulness of the intervention was measured with the item “the app’s instructions for activating social support were helpful” rated on a 7-point Likert scale ranging from 1 (disagree completely) to 7 (agree completely).

Weekly Questions

The intervention engagement was measured with the question “I have asked others for social support because of the app advice” on a 7-point Likert scale with the same anchors as earlier. The burden of completing the EMA surveys was also measured on a 7-point Likert scale with the question “I don’t mind completing the questionnaires for another week.” Technical problems were measured with the question “I had technical problems using the m-Path app,” also on a 7-point Likert scale. Negative effects of using the app were measured with the question “answering the questionnaires of this study has worsened my mental health” and the question “asking my

XSL•FO
RenderX

social contacts for help has worsened my mental health." These questions were rated on a 7-point Likert scale ranging from 1 (disagree completely) to 7 (agree completely).

Other Outcome Measures

Data quality was assessed with the attention check question "to ensure data quality, please select the value 5 for this question" on a 7-point Likert scale. This item was presented with a probability of 1 out of 7 to reduce the likelihood of participants learning when this item appears. Support seeking was measured with the question "I have asked someone for social support (since the last m-path questionnaire)" rated on a 7-point Likert scale ranging from 1 (disagree completely) to 7 (agree completely).

Baseline Survey

All demographic variables reported in Table S1 in Multimedia Appendix 1 were measured during the baseline survey. For detailed item formulations, refer to the OSF repository of this project [40].

Intervention

Overview

The intervention designed in this study aimed to support individuals in activating their social support networks during critical moments of distress. When the JITAI was triggered, participants received personalized prompts on their smartphones through the m-Path app, encouraging them to reach out to members of their social network for support. The intervention included three core components: (1) specifying the type of support needed, (2) identifying who within the available network could provide this type of social support, and (3) receiving 1 of the 6 evidence-based strategies to facilitate effective support seeking. These strategies, including scholarly references, are described in detail on the OSF and aimed to encourage participants to clearly articulate their feelings and needs, reframe the situation, express gratitude, foster support reciprocation, and to diversify support providers [39,46,64,65]. Intervention delivery was randomized into 4 triggering conditions with a microrandomized trial design [41]. Participants were randomly assigned to 1 of the 4 conditions at each EMA measurement time point. In condition 1, the intervention was triggered when one of the items measuring distress (ie, negative affect, stress, loneliness, or rumination) was ≥5, which is the fixed cutoff value (on a 7-point Likert scale). We used a disjunctive decision rule, issuing an intervention when any 1 of the 4 distress indicators reached the cutoff of ≥5, to ensure that each distinct manifestation of distress, as captured by these variables, could independently trigger the intervention. In condition 2, the intervention was triggered when 1 of the items measuring distress surpassed a personalized upper control limit (UCL) of an SCC [37,42]. The calculation of SCCs is described in the subsequent subsection (Calculation of SCCs). In condition 3, the intervention was triggered when participants responded with a "yes" to the question "whether it would help them right now to talk with someone about their worries or negative feelings?" In condition 4, no intervention was triggered. The intervention was also not triggered when it was already triggered twice or more on the same day. All decision rules (fixed cutoff, SPC, and support need) were evaluated continuously (ie, in real time) during the EMA response on the participant's device. If any rule was satisfied at the end of the EMA questions, the JITAI was delivered immediately.

Calculation of SCCs

We computed univariate SCCs for each distress indicator (negative affect, stress, loneliness, and rumination) as outlined by Schat et al [37]. Our implementation followed a classical 2‐phase SPC design. During the baseline phase (days 1-7), we estimated natural variability of each distress variable by computing the moving range per person (i) for each pair of successive observations at time points (j):

Next, we calculated the average moving range per person and divided this number by the constant (d_2=1.128; defined by Montgomery [66]) to obtain the person-specific moving range–based estimate of the SD, denoted as  [67]. Unlike the conventional sample SD, this computation was based on changes between subsequent observations and thus represented a dynamic SD measure. The personalized UCL was then defined as follows:

where  is the phase 1 mean, and the multiplier (L=2) corresponds to an approximate 1‐sided type I error rate of 2.28% per observation [66].

The intervention phase began on day 4, once each participant had completed at least 7 baseline EMA assessments (all met this criterion on day 4). From that point onward, each new EMA distress score was compared against the participant's UCL. The JITAI was triggered if the score exceeded the UCL and the participant had received fewer than 2 interventions that day. UCLs remained constant after the "learning" phase ended (after day 7), consistent with standard SPC practice [37,66]. Consequently, the intervention time points were personalized as the computation of the UCL thresholds took into account the person-specific mean and the dynamic estimate of the SD.

Given the EMA intensity and ethical concerns around delaying support, we opted for a short baseline phase, in which interventions were available after 3 days and the SPC algorithm "learned" from the previous observations up to the first 7 days. Extending the baseline further may have improved the estimation of individual variability but would likely have reduced adherence in a sample of psychotherapy-seeking individuals. Unfortunately, there are currently no established standards for JITAI baseline durations in mental health, as this research is still in early stages [68,69].

Data Analysis

To examine the feasibility and proximal outcomes of the social support JITAI, data were analyzed in 3 main steps. First, descriptives on feasibility and proximal outcomes were described based on grand means (across all participants), person-specific means (mean values per person), between-person

XSL•FO
RenderX

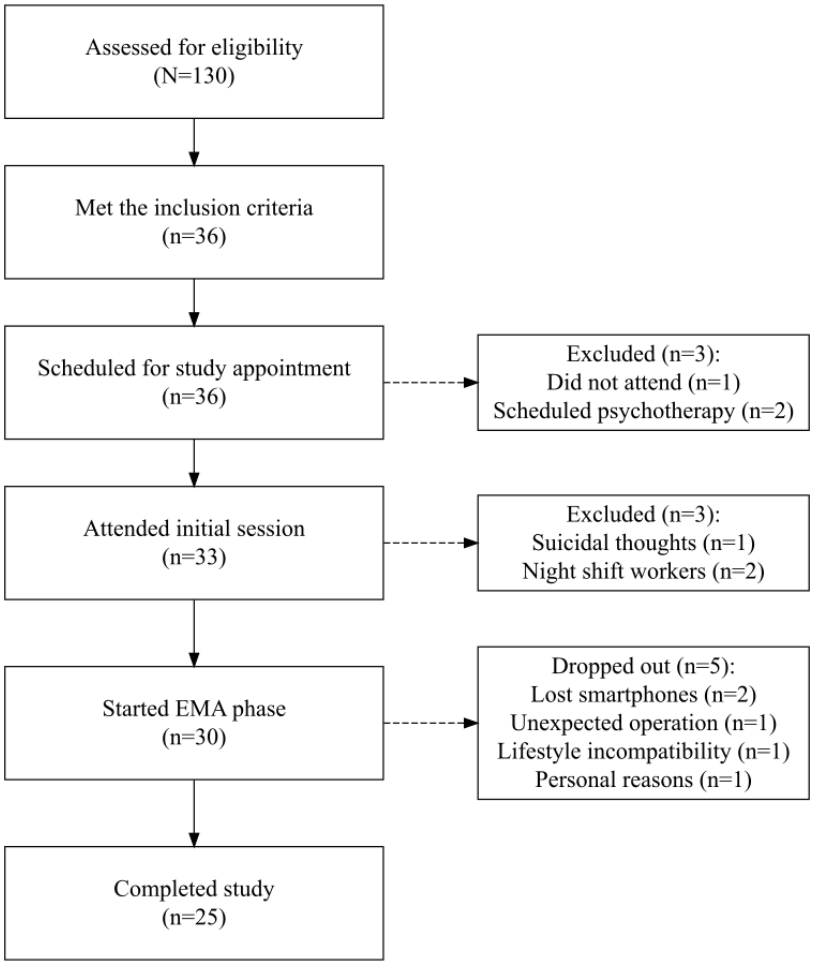
SDs (SDs computed based on the person-specific means), and mean within-person SDs (mean of the SDs computed per person). Furthermore, compliance and careless responding were assessed. Compliance was defined as the proportion of completed EMA surveys out of the total scheduled surveys (126 surveys per participant across 21 days), with ≥70% of participants completing ≥70% of surveys considered sufficient. Data quality was evaluated by calculating the percentage of careless responses to an attention-check item, with high data quality defined as having <5% of responses being careless.

For aim 2, we tested whether the outcomes of appropriate timing, helpfulness, and behavior adoption differed across the 3 JITAI triggering strategies (fixed cutoff, SPC, and support need). We chose these variables because they were measured on the EMA level (appropriate timing and behavior adoption) or daily level (helpfulness). Differences were analyzed using Welch 2-sample 2-tailed *t* tests, comparing pairs of conditions, with Cohen *d* effect sizes to quantify the magnitude of differences. Analyses for helpfulness were restricted to days where only 1 intervention was triggered, as it was measured only in the evening.

Finally, for aim 3, the intervention effects on subsequent social support seeking and changes in momentary distress (negative affect, stress, loneliness, and rumination) were evaluated. Changes in distress variables were computed by subtracting the values from T+1 from the values of T. Pairwise *t* tests were conducted to compare JITAI-triggered time points to the control condition (ie, omitted JITAIs). JITAI-triggered time points included reports from conditions 1, 2, and 3, where the intervention was delivered. In contrast, the control condition (condition 4) was where no intervention was triggered, despite participants meeting at least 1 of the predefined triggering criteria (conditions 1, 2, or 3). In other words, a JITAI was considered as part of the control condition when participants (1) reported distress score more than 5 on at least 1 distress item (condition 1), (2) exceeded their personalized SPC cutoff (condition 2), or (3) indicated a need for social support (condition 3), but no JITAI was delivered because the time point was in condition 4. Cohen *d* was calculated to determine the effect size. Given the exploratory nature of this feasibility study, no formal hypothesis testing was conducted. All tests were 2-tailed with the type I error rate set to $\alpha<.05$.

Results

Overview



The flowchart of this feasibility study is presented in Figure 1. Of the 130 participants who were assessed for eligibility, 36 (27.7%) individuals met the inclusion criteria and were scheduled for a study appointment. Of these, 1 (3%) did not attend, and 2 (6%) scheduled a psychotherapy intake appointment within 2 weeks and were thus excluded from the study. During the initial session, 1 (3%) participant had to be excluded due to expressing suicidal thoughts, and 2 (6%) were excluded due to working night shifts. Over the 3-week EMA phase, 3 (8%) participants dropped out, with reasons including lost smartphones (n=2, 6%) and an unexpected operation (n=1, 3%). A total of 2 (6%) participants decided not to continue the study due to study-related factors such as lifestyle incompatibility (n=1, 3%; the person who left the study by choice indicated that the EMA content and schedule were not adapted to her lifestyle and that they found the items too impersonal) and other personal reasons (n=1, 3%). No participants were excluded based on the second interview or the minimally required EMA completion rate of 50%. Ultimately, 25 (69%) participants were included in the feasibility study.

In total, participants completed 2689 EMA reports, with an average of 107.56 (SD 20.46) reports per participant. Evening assessments yielded 232 valid responses overall, corresponding to a mean of 9.28 (SD 4.98) reports per participant. Finally, weekly reports resulted in 75 entries, with all 25 (100%) of the 25 participants completing all 3 weekly reports. The intervention was triggered 377 times in total, corresponding to n (14%) of all 2689 collected EMA time points—221 (58.6% of intervention time points) times by the fixed cutoff condition, 110 (29.2%) times by the SPC condition, and 46 (12.2%) times by the support need condition. In total, 76 JITAIs were not triggered because there were already 2 JITAIs triggered on a given day. This was the case for 15 (60%) of the 25 individuals on 55 (10%) different intervention days. The mean trigger count per person was 15.08 (SD 8.62; range 2-34). Figure S1 in Multimedia Appendix 1 shows the overlap between potential trigger moments by condition, indicating a strong overlap between potential fixed cutoff time points with SPC and support need time points. Figure S2 in Multimedia Appendix 1 exemplifies the loneliness trajectories with possible trigger time points for the fixed cutoff and the SPC condition.

Preintervention BDI-II scores ranged from 9 to 30 (mean 19.12, SD 5.87). The 25 participants fell into the following depression categories [57,58]: minimal (n=3, 12%; scores 9-13), mild (n=12, 48%; scores 14-19), moderate (n=7, 28%; scores 20-28), and severe (n=3, 12%; scores 29-63). Hence, most participants (n=19, 76%) reported either mild or moderate depressive symptoms. Postintervention scores ranged from 1 to 27 (mean 14.48, SD 8.17).

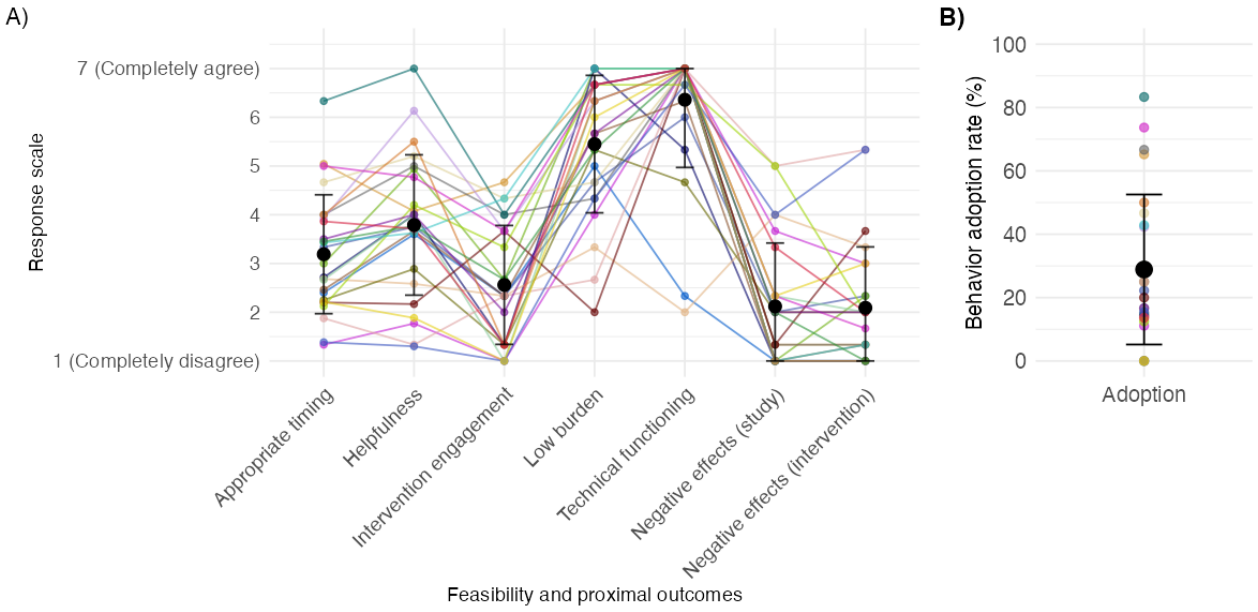
Figure 1. Study flowchart. EMA: ecological momentary assessment.



Aim 1: Feasibility, Proximal Outcomes, and Data Quality

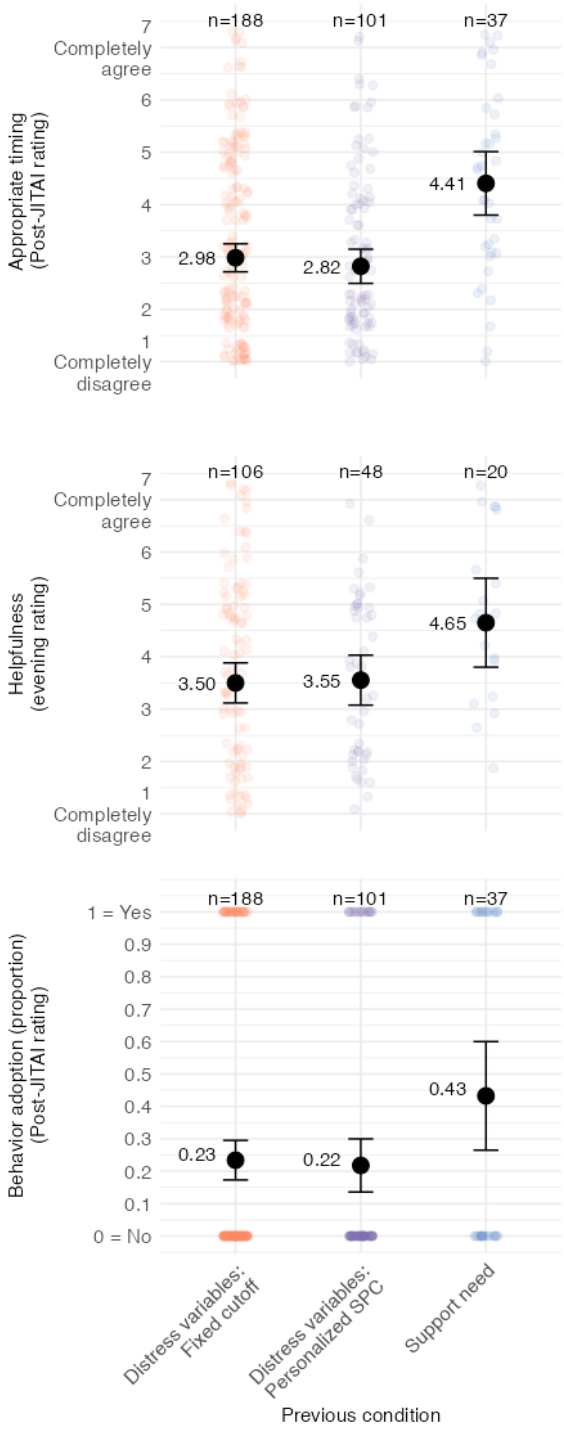
The first aim of the study was to examine various feasibility and proximal outcomes, specifically how participants perceived the following: (1) appropriate timing, (2) helpfulness, (3) adoption, (4) acceptability, (5) burden, (6) technical functioning, and (7) negative effects of the social support JITAI. Figure 2 presents the grand mean and between-person SDs of the items across all participants and time points as well as the person-specific means indicated by colored data points and lines (refer to Table S2 in Multimedia Appendix 1 for the means, between-person SDs, and within-person SDs). The appropriate timing and helpfulness were rated moderately high with means of 3.19 (between: SD 1.22, within: SD 1.22) and 3.79 (between: SD 1.44, within: SD 1.00), respectively (Figure 2A). Participants reported having adopted the suggested intervention behavior to seek social support in 29% on average (between: SD 23.68) of the situations when asked at the next EMA time point (Figure 2B). If they indicated no behavior adoption, we asked for the reasons why they did not seek social support (results of a qualitative content analysis of these reports are presented in Table S5 in Multimedia Appendix 1). Intervention engagement rated on a weekly level was relatively low, with a mean of 2.56 (between: SD 1.22, within: SD 1.22). Low burden was rated with a mean of 5.45 (between: SD 1.41, within: SD 1.15) across the 3-week observation period, indicating most participants would not mind if the study went longer. The means for the low burden item on a weekly level were 2.32 (between: SD 1.95), 2.24 (between: SD 1.54), and 3.08 (between: SD 1.82), respectively. Technical functioning was rated high with a mean of 6.36 (between: SD 1.39, within: SD 0.31). Participants reported low levels of negative effects because of the study participation (mean 2.12, between: SD 1.30, within: SD 0.57) or the intervention (mean 2.09, between: SD 1.25, within: SD 0.70). However, as can be seen in Figure 2A, 2 (8%) of the 25 participants reported relatively high negative effects (above the scale midpoint of 4). In sum, in most feasibility variables, the range of person-specific means was relatively high, suggesting that our social support JITAI was perceived positively by some individuals while being perceived less positively by others.

XSL•FO
RenderX

Figure 2. Feasibility and proximal outcome variables with person-level mean data points of (A) Likert-scale responses and (B) binary responses. In total, 25 colored data points show person-specific mean values. The technical functioning item was inversely formulated and recoded to present positive values.

To further evaluate the feasibility of the study, we examined the compliance rate and data quality of participants' responses. Participants were expected to complete 126 EMA surveys over the 21-day period, with 6 surveys per day. A compliance rate was considered sufficient if ≥70% of the participants completed ≥70% of the EMA surveys. The average compliance rate across participants was 85.37% (SD 16.24%). A total of 80% (20/25) of the participants met the compliance threshold, completing at least 70.6% (89/126) of the EMA surveys.

Data quality was assessed by examining the rate of careless responses, defined as responses to an attention-check item. Out of 389 total responses, only 6 (1.5%) were classified as careless. This percentage is small, indicating that participants generally provided reliable responses.



Aim 2: Differences Between Triggering Strategies

We further investigated differences in the triggering conditions based on appropriate timing, helpfulness, and behavior adoption. Figure 3 shows the raw data points and grand means of these 3 variables by condition of the previously triggered JITAI. These exploratory results indicate that the appropriate timing was perceived differently depending on the triggering strategy. Specifically, appropriate timing ratings were significantly higher for the support need strategy (condition 3) compared to both the SPC strategy (condition 3: mean 4.41, SD 1.82; Cohen d=–1.21; $t_{59.13}$=–4.64; P<.001) and the fixed cutoff strategy (Cohen d=–0.77; $t_{51.95}$=–4.33; P<.001). Similarly, the support need strategy was associated with higher helpfulness ratings compared to both the SPC strategy (condition 3: mean 4.65, SD 1.81; condition 2: mean 3.56, SD 1.63; Cohen d=–0.65; $t_{32.63}$=–2.33; P=.03) and the fixed cutoff strategy (condition 1: mean 3.49, SD 1.95; Cohen d=–0.60; $t_{28.29}$=–2.60; P=.02). Regarding the adoption of support-seeking behavior when presented the JITAI, behavior adoption ratings were higher in the support need condition compared to both the SPC strategy (condition 3: mean 43%, SD 0.50%; condition 2: mean 22%, SD 0.42%; Cohen d=–0.49; $t_{55.01}$=–2.32; P=.02) and the fixed cutoff strategy (condition 1: mean 23%, SD 0.42; Cohen d=–0.45; $t_{46.66}$=–2.25; P=.03). These results suggested that participants perceived the timing and helpfulness of JITAI interventions as more appropriate and were more likely to adopt the behavior when interventions were triggered based on the support need item compared to the other strategies.

Because in this analysis we did not differentiate between different participants, in Figure S3 in Multimedia Appendix 1, we compare the person-level means of appropriate timing, helpfulness, and behavior adoption, indicating high between-person variability in these outcomes. In additional exploratory analyses, we examined whether timing appropriateness differed by distress indicator (negative affect, stress, loneliness, and rumination) under the fixed cutoff and SPC conditions. These comparisons are shown in Figure S4 in Multimedia Appendix 1. The figure shows that there is a tendency toward JITAIs triggered by stress and rumination to be rated higher in appropriate timing and behavior adoption than those triggered by negative affect and loneliness, independent of whether triggered by a fixed cutoff or SPC condition.

XSL•FO
RenderX

Figure 3. Outcomes with raw data points and means with 95% CIs by condition. Appropriate timing and behavior adoption (n=25) were assessed at the next ecological momentary assessment time point following a just-in-time adaptive intervention (JITAI). Helpfulness was rated in the evening when at least 1 JITAI was triggered. SPC: statistical process control.

We additionally estimated multilevel models for appropriate timing, helpfulness, and behavior adoption while accounting for the nesting of repeated observations within participants, controlling for age, gender, and baseline depressive symptoms (Table S4 in Multimedia Appendix 1). Differences between support need and the distress-based conditions remained significant for appropriate timing (fixed cutoff: b=–0.82, SE 0.28; *P*=.004; SPC: b=–0.92, SE 0.31; *P*=.003) and behavior adoption (fixed cutoff: odds ratio 0.45; 95% CI 0.448-0.453 and 0.448-0.453, *P*<.001; SPC: odds ratio 0.52; 95% CI 0.516-0.522; *P*<.001) but not for helpfulness (fixed cutoff: b=–0.57, SE 0.30; *P*=.06; SPC: b=–0.52, SE 0.34; *P*=.14).

Aim 3: Intervention Effects on Support Seeking and Changes in Distress

As this study is a feasibility study rather than a full-scale effectiveness trial, the primary aim was to assess the feasibility of implementing the JITAI and participants' perceptions of its usability and acceptability rather than to test its impact on mental health outcomes. Nonetheless, we explored the intervention effects of the social support JITAI on the proximal outcomes of (1) sought social support and (2) changes in momentary distress measured at the subsequent EMA time point by comparing the intervention conditions (1, 2, or 3) against the control condition when the JITAI that should have been triggered by 1 of the conditions was omitted (condition 4). Figure 4 shows the raw data points and grand means of sought social support and changes in distress measures split by whether the JITAI was triggered (conditions 1, 2, or 3), not triggered, or omitted (control condition) at the previous EMA time point (ie, instances where participants met the triggering criteria but no JITAI was delivered). Figure 4A shows that support seeking at T+1 was rated higher when the JITAI was triggered (mean 3.20, SD2.13) compared to the control condition (when it was omitted) at T (mean 2.72, SD 1.99; Cohen d=0.24; t_{272}=2.06; P=.04), indicating that the intervention had a positive effect on subsequent support seeking. Figure S5 in Multimedia Appendix 1 shows these comparisons additionally split by condition (fixed cutoff, SPC, and support need). These results indicated that subsequent support seeking was not rated higher in the fixed cutoff condition when the JITAI was triggered (JITAI: mean 3.50, SD 2.42; control: mean 2.82, SD 2.26; Cohen d=0.29; $t_{51.93}$=1.11; P=.27), in the SPC condition (JITAI: mean 3.38, SD 2.24; control: mean 3.28, SD 2.18; Cohen d=0.05; $t_{106.99}$=0.25; P=.81), or in the support-need condition (JITAI: mean 3.04, SD 2.01; control: mean 2.78, SD 2.02; Cohen d=0.13; $t_{210.61}$=0.94; P=.35). Figures 4B-4E show the raw data points and mean changes in momentary distress variables between T and T+1 split by JITAI status (ie, not triggered, triggered, or omitted). Figures 4B-4E present the changes in negative affect, stress, loneliness, and rumination between T and T+1, comparing when the JITAI was not triggered, triggered, and omitted (ie, no JITAI condition but at least 1 criterion met for conditions 1-3). More negative change values represented larger reductions in distress. While descriptive trends suggest slightly larger reductions in these variables when the JITAI was triggered, the differences were not statistically significant in pairwise comparisons. Specifically, for negative affect (Figure 4B), changes were not significantly different between the JITAI-triggered time points (mean –0.50, SD 1.71) and the control condition (mean –0.37, SD 1.56; Cohen d=–0.08; t_{546}=–0.92; P=.36). Similarly, for stress (Figure 4C), the change scores did not differ significantly (JITAI: mean –0.54, SD 1.83; control: mean –0.42, SD 1.94; Cohen d=–0.06; $t_{503.95}$=–0.70; P=.48). Regarding loneliness (Figure 4D), participants showed a slightly larger reduction when the JITAI was triggered (mean –0.35, SD 1.39) compared to the control condition (mean –0.16; 1.41), but this difference was not statistically significant (Cohen d=–0.14; $t_{518.18}$=–1.60; P=.11). Finally, for rumination, the difference in change scores approached significance, with larger reductions observed in the JITAI-triggered condition (mean –0.36, SD 1.51) compared to the control condition (mean –0.16, SD 1.30; Cohen d=–0.14; $t_{556.18}$=–1.71; P=.09). Overall, the JITAI-triggered time points did not significantly differ from the control condition reducing negative affect, stress, loneliness, or rumination. Figures S6-S9 in Multimedia Appendix 1 show these comparisons additionally split by condition (ie, fixed cutoff, SPC, and support need). In addition, Figures S10-S14 in Multimedia Appendix 1 show the effects of the intervention split by whether the participants reported having sought social support because of the intervention. These figures descriptively show that the intervention effects are larger or only apparent when participants seek social support due to the JITAI as opposed to not seeking support or the intervention not being presented.

We further explored whether reductions in momentary distress differed depending on which distress variable triggered the intervention (negative affect, stress, loneliness, or rumination). Figure S16-S19 in Multimedia Appendix 1 shows these detailed comparisons. No clear pattern emerged in how conditions or triggering distress variables were associated with changes in distress variables. Furthermore, for comparisons between triggering strategies in changes in distress variables, refer to Figures S6-S9 and Table S3 in Multimedia Appendix 1.

Figure 4. Raw data points and means with 95% CIs for sought support and changes in distress by previous triggering status. Just-in-time adaptive intervention (JITAI; n=25 individuals) triggered by either fixed cutoff, statistical process control, or support need conditions. Omitted JITAI refers to the control condition with fixed cutoff, statistical process control, or support needs condition met, but JITAI was not offered. T: previous ecological momentary assessment time point; T+1: subsequent ecological momentary assessment time point.

Discussion

Principal Findings

This feasibility study explored the practical implementation of a social support JITAI delivered via the smartphone for psychotherapy-seeking individuals with subclinical and clinical levels of depressive symptoms. We assessed participants' perceptions of the intervention's feasibility and proximal outcomes while also comparing the effects of different JITAI triggering strategies on proximal outcomes, such as support-seeking behavior and changes in affective states. Exploratory analyses examining the potential intervention effects

XSL•FO
RenderX

should be interpreted with caution, as the study was not designed or powered to establish efficacy.

The results suggest that the social support JITAI is practically feasible. High compliance rates were observed, with participants completing an average of 85.37% (2689/3150) of the EMA surveys. Most (20/25, 80%) participants also exceeded the preregistered compliance threshold, and the data quality was high, with a negligible proportion of careless responses (6/389, 1.5%). In addition, participants reported minimal technical issues, and burden scores indicated that completing the EMA surveys was not overly demanding. These findings are encouraging, particularly given the challenging nature of intensive data collection in real-world settings, and suggest that JITAI-based interventions can be effectively integrated into participants' daily routines.

Despite the intervention's technical feasibility, participants rated the overall helpfulness and appropriateness of the JITAI as moderate. Similarly, the subjective experiences of the intervention were mixed. Participants scored low on engagement in the intervention and adopted the intervention (ie, sought social support) in about 1 out of 3 times after the intervention was triggered. Barriers to seeking support, such as time constraints (ie, not having time to seek support) or perceived unavailability of support providers, may have contributed to the lower adoption rates (refer to Table S5 in Multimedia Appendix 1 for reasons provided by participants). At the same time, it is difficult to judge what the acceptable behavior adoption rates would have been for this type of intervention, given that a few more high-quality interactions may have helped to reduce depressive symptoms [70-72]. Another factor that might influence adoption rates may lie in the assumptions about what good intervention time points are, which is something that we addressed by randomizing different intervention-triggering conditions.

When zooming in on differences between triggering conditions, it seems that the JITAIs triggered based on participants' explicit self-reported need for support ("support need" condition) were rated as more appropriate, helpful, and effective in encouraging behavior adoption than those triggered based on predefined distress thresholds ("fixed cutoff" condition) or personalized control limits ("SPC" condition), with an average Cohen *d* effect size of –0.69 (range –0.45 to –1.21) and moderately high agreement scores. These findings align with the notion that individuals are more likely to engage with an intervention when it aligns with their subjective experiences and immediate needs rather than relying solely on inferred distress [46,47]. However, it is worth noting that the support need strategy was triggered far less frequently than the other strategies, likely capturing rarer but more meaningful moments for participants. This lower frequency may contribute to the higher feasibility and adoption ratings observed in this condition, as the intervention aligned more closely with participants' perceived relevance and immediate needs. Individuals may be more willing to seek support when they explicitly feel that they need it rather than merely experiencing distress. Feeling distressed alone may not necessarily prompt the desire or readiness to seek social support [39,73]. Particularly, not all distress is necessarily conducive to seeking support. For example, interpersonal distress may make individuals hesitant to reach out, especially if the source of distress is a conflict within their social network. By contrast, the thresholds used for the fixed cutoff and SPC conditions may have been set too low, leading to frequent interventions that participants did not perceive as necessary. This discrepancy is evident from the substantially lower frequency of reported support needs compared to the number of triggers in these conditions.

In examining the initial intervention effects on the proximal outcomes of support-seeking behavior and changes in distress variables (negative affect, stress, loneliness, and rumination), we found that receiving the social support JITAI was associated with greater self-reported subsequent support-seeking behavior, specifically, in the fixed cutoff condition but not the SPC or support-need condition. Here, support-seeking was significantly higher when the JITAI was triggered compared to the control condition. This finding suggests that the fixed-cutoff strategy may effectively identify moments of distress that prompt participants to seek social support, even if these moments do not align with participants' explicit perceptions of need.

Furthermore, the fixed cutoff strategy may have been effective at identifying moments of distress that participants did not perceive as opportunities to seek support. Together, these findings highlight the complexity of optimizing JITAI decision rules, suggesting that different strategies may serve complementary roles in addressing both explicit and implicit needs for support. It is possible that the support need item captured a state of receptivity rather than vulnerability [20], that is, whether individuals felt ready and willing to engage with the intervention and act on its suggestions. This raises an important open question for JITAI design: Should decision rules focus solely on vulnerability or also incorporate receptivity? Notably, existing mental health JITAIs rarely account for states of receptivity [74] despite their potential relevance for intervention effectiveness. Receptive states may be particularly suitable for certain intervention types, such as social support prompts, whereas other types, such as breathing exercises, might be more beneficial when delivered during acute vulnerability. Future research should explore how different types of interventions align with and benefit from these distinct momentary states.

For changes in distress variables, JITAI-triggered time points consistently showed descriptively larger reductions in negative affect, stress, loneliness, and rumination compared to the control condition (when the JITAI was omitted). However, these differences did not reach statistical significance, likely due to the limited statistical power in this feasibility study. While the observed effect sizes (Cohen *d*=0.06-0.14) are small, even modest improvements in social support and distress reduction may be meaningful in real-world mental health interventions. Given the exploratory nature of this study, a larger trial is warranted to determine whether these effects translate into clinically significant benefits over time. These findings highlight the need for larger-scale studies to further evaluate the effectiveness of the intervention on proximal and distal outcomes while addressing potential mismatches between intervention timing and participants' emotional states.

XSL•FO
RenderX

Implications

The findings of this study have several implications for the design and implementation of JITAI-based interventions. First, unlike existing JITAIs that primarily focus on self-monitoring or mindfulness [74], this study uniquely targets social support activation, which is a well-documented protective factor for mental health [29,30], with a social support–specific JITAI. Second, our results underscore the importance of incorporating participants' subjective needs into intervention decision rules. Triggering strategies that rely on participants' self-reported support needs may be more effective and acceptable than approaches based on emotion dynamics. In addition, their effectiveness may also depend on participants' receptiveness (ie, whether they have time) and contextual factors, such as the availability of a supportive social network or the perceived accessibility of potential support providers (as indicated by additional qualitative analysis). As evidenced by the higher ratings in the support need condition, integrating participants' support needs into intervention decision rules could significantly enhance engagement and effectiveness. At the same time, these results underscore the need for JITAI decision rules that accurately capture participants' subjective needs while avoiding unnecessary triggering. Overly frequent interventions, as observed in the fixed cutoff and SPC conditions, may reduce perceived appropriateness and helpfulness, potentially leading to disengagement [20]. Third, the lower-than-expected rate of behavior adoption highlights a potential gap between the intervention's suggestions and participants' readiness or ability to act on them. One reason might lie in the availability of time perceived by the participant and their support resources, as indicated by their reasons for not adopting the intervention (refer to Multimedia Appendix 1 for a qualitative analysis). Future iterations of the JITAI could incorporate receptivity, both the respondent's receptivity to seeking support and the potential availability of support providers. This could include assessing whether the respondent has time to act on the support-seeking impulse and identifying which support providers are potentially available currently or later.

Limitations

This study has several limitations. First, the study's short duration and exploratory focus on proximal outcomes, such as behavior adoption and distress reduction, preclude conclusions about the intervention's long-term impact on mental health outcomes. Future research should assess whether these short-term effects translate into sustained improvements in depressive symptoms. Second, the intervention focused exclusively on emotional social support, which may not address the broader range of support needs (eg, instrumental or informational support). We chose this because of the key role of emotional social support in reducing distress symptoms [75]. However, individuals with depressive symptoms may experience difficulties in accurately perceiving or using available social support due to cognitive biases, which could limit the intervention's effectiveness [76,77]. In addition, social support may not always be skillful and thus inadvertently exacerbate distress [46,78]. Expanding the intervention's scope to include other types of support may be beneficial.

The third limitation concerns our "support-need" trigger. Unlike distress-based triggers, which represent states of vulnerability (eg, elevated negative affect), asking participants whether they need support may not only assess vulnerability but also participants' receptivity to this type of intervention [20]. In other words, a "yes" response could reflect readiness or willingness to engage with social support prompts while, at the same time, reflect being vulnerable. Thus, we capture 2 related but distinct constructs, namely support-need vulnerability and intervention-specific receptivity, and our item for assessing support need does not allow us to fully disentangle them. Future studies should incorporate measures that separately assess vulnerability and receptivity to refine optimal decision rules for delivering support.

Fourth, while the support-need item was intentionally brief to minimize participant burden, we acknowledge its limitation, as it remains unclear which types of distress most strongly motivate a desire for social support. However, our data suggest that participants were able to identify meaningful moments of support need. Interventions triggered by this item were rated as most appropriate and were most associated with behavioral adoption. Nonetheless, future studies should explore multi-item measures or adaptive questioning to better capture the nuances of support needs in daily life contexts.

The fifth limitation concerns the computation of SCCs as SPC triggers. Our use of the L value of 2 provided the sensitivity of the SPC trigger but may also capture milder fluctuations that are not clinically meaningful. Although other SCC applications use an L value of 3 (with α=.27%) [37], in our case, an L value of 3 would have generated only 106 intervention triggers, about 40% fewer than the 169 triggers obtained with an L value of 2. To ensure sufficient opportunities for intervention in this feasibility study, we chose the more sensitive L value of 2 as the threshold. Future studies should compare multiple L values (eg, L=2 vs L=3) and explore growing or moving-window approaches for phase 1 baseline selection to optimize the balance between sensitivity and specificity in detecting personally meaningful change.

The sixth limitation was that the sample was predominantly consisting of women, which may limit the generalizability of findings to more gender-diverse populations. Gender differences in social support preferences and help-seeking behavior [79,80] may affect intervention engagement, feasibility perceptions, and effectiveness.

The seventh limitation of this study is that the qualitative interviews conducted before the intervention and the EMA questions may have influenced participants' awareness and expectations regarding social support. Moreover, personal contact with researchers during these qualitative interviews may have enhanced engagement and contributed to the low study attrition observed.

Finally, individuals with depressive symptoms often experience sadness, anhedonia, rumination, social withdrawal, and reduced social functioning [76,77], all of which can impair motivation and capacity to seek social support [39,81]. This challenge was a core motivation for developing our social support JITAI. However, important differences may exist among individuals

XSL•FO
RenderX

with varying severity of depressive symptoms. Consequently, our findings may not generalize to those with more severe or chronic depressive symptoms, and future studies should assess differential patterns of engagement with this social support JITAI across clinical subgroups.

Future Research

An important finding is the heterogeneity among individuals in the reported feasibility and the effects of the JITAI, a pattern that is also observed in other JITAIs and digital mental health interventions [68,82]. This indicates that the JITAI may be feasible and effective for some but not for others. Consequently, examining individual differences in the feasibility and effectiveness of the intervention (eg, baseline levels of distress and social support availability) could help identify (1) subgroups of participants who are most likely to benefit from specific JITAIs and (2) factors that might inform the personalization of future JITAIs [68,82,83]. Examining individual differences concerning the effectiveness of such interventions is crucial to optimize care [84].

Future iterations of the JITAI could also integrate components of CBT or psychoeducation to incorporate a broader range of coping strategies. For instance, making the intervention adaptive to whether a supportive person is available and whether support is perceived to be helpful for the participants or suggesting CBT elements, if no support providers are available, could be used to further tailor the intervention. Moreover, artificial forms of social support through generative artificial intelligence chatbots [85,86] would also be worth exploring, as would more specific populations, such as individuals rehabilitating after (inpatient) psychiatric care. Both of these extensions were mentioned by participants in the qualitative interviews as ideas for future development.

Conclusions

This study supports the feasibility of implementing a social support JITAI in real-world settings and provides preliminary results about its proximal effects. By addressing the critical gap in leveraging social support for mental health, this intervention represents a step toward personalized and scalable digital mental health interventions. In summary, the findings suggest that the JITAI is practically feasible, supporting its integration into participants' daily lives. The intervention appears to effectively encourage individuals to seek support when they recognize a personal need for it, with participants rating the JITAI as moderately helpful and appropriate under such conditions. However, prompting support-seeking behavior may be less effective, appropriate, and helpful when individuals experience elevated levels of negative affect, stress, loneliness, or rumination. In addition, the results indicate that the JITAI does not significantly reduce distress indicators in daily life, suggesting that further refinement of the social support JITAI may be needed to address its effectiveness. By providing support in real time during critical moments, this approach aligns with the call for innovative solutions to bridge the gap between demand and accessibility in mental health care [1,5]. While this JITAI is not a substitute for professional care, it offers a low-threshold, accessible, and feasible intervention that could complement existing mental health support by fostering proactive social connectedness, provided its effectiveness is supported in future studies.

Acknowledgments

The authors would like to express their gratitude to Dr Laura Bringmann for her valuable input during early brainstorming sessions. The authors would express special thanks to Jonna Schwarz, Pascale Rouilly, and, particularly, Bianca Bürli for their dedicated support in data collection as well as Larissa Leuenberger and Nadja Peeters for language- and style-related input. The authors are grateful for the time and effort invested by the participants. This work was supported by a Swiss National Science Foundation grant (PZ00P1_208742) awarded to TE.

During the preparation of this work, the authors used Grammarly (version Spring 2024) and ChatGPT (version 4.0; OpenAI) in order to improve the readability of the text and correct language errors. After using these tools, the authors reviewed and edited the content as needed and took full responsibility for the content of the publication.

Abstract

Background: Increasing psychosocial burdens, such as stress and anxiety, underscore the need for accessible and effective prevention programs. Hybrid approaches, combining in-person and digital components, aim to reduce barriers and enhance flexibility. However, their effectiveness depends on participants' eHealth literacy, which is associated with their ability to engage with digital tools. Understanding how psychosocial characteristics relate to eHealth literacy can provide insights for improving intervention design.

Objective: This study uses cluster analysis to explore the relationship between psychosocial characteristics and eHealth literacy in a hybrid mental health prevention program. By identifying distinct psychosocial profiles and analyzing their differences in eHealth literacy levels and patterns, this person-centered approach enables a nuanced understanding of eHealth literacy disparities beyond traditional variable-centered linear models. In addition, the study examines how sociodemographic variables are associated with eHealth literacy, providing insights into the role of psychosocial diversity in hybrid prevention programs.

Methods: A cross-sectional study was conducted with participants of the RV Fit Mental Health intervention (January 2024–December 2024). Psychosocial characteristics, including anxiety, depression, optimism, pessimism, quality of life, self-efficacy, stress, and work ability, were assessed alongside eHealth literacy (eHealth Literacy and Use Scale [eHLUS], eHealth Literacy Scale [eHEALS]). To identify distinct psychosocial profiles, cluster analysis was used. A generalized linear model was applied to analyze associations between cluster membership, eHealth literacy, and sociodemographic variables. Finally, correlation matrices were used to further explore the relationships between psychosocial characteristics and eHealth literacy.

Results: A total of 173 participants were included. Four clusters were identified based on psychosocial characteristics. Significant associations were found between cluster membership and eHealth literacy, including the overall eHLUS score (P=.004) and its dimension of autonomous use and technical access (P=.003). Cluster 3 (n=65) had the most favorable psychosocial characteristics and the highest eHealth literacy levels. Cluster 4 (n=36) exhibited the least favorable psychosocial characteristics but mid-range eHealth literacy levels. Cluster 2 (n=45) showed the lowest eHealth literacy levels despite a mid-range psychosocial profile. Cluster 1 (n=27) demonstrated mid-range eHealth literacy levels and mid-range psychosocial characteristics. In addition, age and subjective socioeconomic status were significantly associated with eHealth literacy levels. Beyond the identified clusters, significant correlations were observed between individual psychosocial characteristic variables and eHealth literacy.

Conclusions: The cluster analysis identified distinct psychosocial profiles with varying levels of eHealth literacy, demonstrating that psychosocial characteristics are associated with eHealth literacy in diverse ways. These findings underscore the need to consider subgroup-specific needs in hybrid prevention programs. Certain groups may require additional support to effectively navigate eHealth tools. These findings emphasize the relevance of tailored intervention strategies that account for psychosocial diversity in eHealth engagement.

KEYWORDS

eHealth literacy; psychosocial; hybrid prevention; mental health; digital health

Introduction

The increasing prevalence of mental health issues, such as chronic stress, depression, and anxiety disorders, poses a significant challenge to the health care system [1-6], particularly in designing effective prevention programs. Early interventions in the form of prevention programs have demonstrated long-term benefits for participants' well-being while simultaneously reducing health care costs [7-12].

The digitization of prevention programs offers new opportunities to enhance the efficiency and accessibility of these programs [13]. Digital and hybrid prevention approaches provide innovative solutions by offering greater adaptability and promoting mental health. Hybrid prevention programs combine in-person and digital components, reducing location- and time-related barriers while retaining the benefits of face-to-face interactions. A key advantage of hybrid interventions is the involvement of health care professionals, who can provide guidance and support in navigating digital components. This flexibility enhances their effectiveness by catering to individual participants' needs [14,15].

The success of hybrid prevention programs depends on their structure, content, and the participant's ability to engage effectively with the digital components [16,17]. This ability, called eHealth literacy, encompasses the skills required to locate, understand, and apply digital health information [18]. A lack of these skills can limit active participation and reduce the effectiveness of interventions, highlighting the critical role of eHealth literacy in hybrid prevention programs [19,20]. eHealth literacy is widely recognized as crucial for engaging with digital health services [21,22].

To better understand this ability, it is necessary to examine not only whether eHealth literacy is present, but also how it is structured and shaped by contextual and individual factors. The Transactional Model of eHealth Literacy (TMeHL) conceptualizes eHealth literacy as a dynamic and multifaceted capability that extends beyond information retrieval. It emphasizes eHealth literacy as the result of interactions between individual abilities, contextual conditions, and task demands, thereby capturing the evolving and reciprocal character of digital health engagement [23].

Despite this conceptual complexity, research has increasingly examined ways to improve eHealth literacy, including a growing number of targeted interventions [24,25] and has found it to be associated with the acceptance and use of digital health tools [18,26]. Moreover, existing studies indicate that social determinants, such as age, gender, educational level, migration background, and socioeconomic status, are significantly associated with eHealth literacy, highlighting their importance in implementing tailored, needs-based interventions [27-29]. Given that social determinants are linked to differences in individuals' ability to navigate digital health resources, it is important to consider that psychosocial characteristics, including burdens such as anxiety, depressive symptoms, and stress, as well as resources such as self-efficacy, may be associated with motivation and with varying levels of eHealth literacy. To clarify this conceptual distinction, psychosocial characteristics refer to intraindividual psychological traits and states [30], whereas social determinants of health describe the broader societal conditions in which people are born, grow, live, work, and age, and which affect health outcomes and access to resources [31]

It is important to note that social determinants of health such as subjective socioeconomic status or employment status may be associated with psychosocial characteristics; for instance, by contributing to stress, anxiety, or reduced self-efficacy in situations of financial strain or job insecurity [32]. While the association between social determinants and eHealth literacy is well documented [33], the specific role of psychosocial characteristics remains underexplored. Given that emotional burden and motivational resources may be related to individuals' ability and readiness to access, process, and use digital health information, this perspective offers a complementary and necessary extension of existing research. This raises critical questions about whether individuals with unfavorable psychosocial characteristics exhibit lower levels of eHealth literacy and how such variations impact their engagement with hybrid prevention programs. While variable-centered approaches, such as regression models, examine associations at the population level, they may overlook meaningful subgroups within heterogeneous populations. A person-centered, cluster-based approach, in contrast, allows for the identification of distinct psychosocial profiles, offering deeper insights into subgroup-specific needs and potential support strategies in hybrid prevention programs [34,35]. Previous research has demonstrated that subtyping based on psychosocial characteristics can enhance intervention design [34].

This study examines the relationship between psychosocial characteristics and eHealth literacy in the context of a hybrid mental health prevention intervention. By identifying distinct psychosocial profiles, it aims to enhance the understanding of eHealth literacy disparities and addresses the following research questions: Can distinct psychosocial profiles be identified through cluster analysis, and how are these profiles associated with eHealth literacy? How do these psychosocial profiles differ in their eHealth literacy levels, and what patterns can be observed? How are sociodemographic variables associated with eHealth literacy?

By systematically analyzing these associations, this study provides insights into how psychosocial characteristics relate to eHealth literacy, contributing to the design of hybrid prevention programs that consider psychosocial diversity to enhance participant engagement and intervention effectiveness.

Methods

Study Background

This study was conducted within a project that focuses on developing, piloting, and evaluating an app-supported

XSL•FO
RenderX

psychosocial prevention intervention named RV Fit Mental Health. The hybrid secondary prevention intervention consists of an initial 2-week inpatient phase and a 12-week home-based digital training phase supported by a medical app. Medical apps can be either certified medical products or noncertified applications designed to support clinical purposes and health-related functions, such as assisting in diagnostics, therapy, or patient management [36]. The primary aim of the intervention is to improve work ability and psychosocial health in individuals experiencing work-related mental health challenges. The German Federal Ministry of Labor and Social Affairs funds this project. Additional details regarding the project and intervention can be found in the study protocol [37] and are also provided in Multimedia Appendix 1.

Study Design, Recruitment, and Sample

A quantitative, cross-sectional design was used to investigate the relationship between psychosocial characteristics and eHealth literacy. A total of 324 individuals were invited to participate, of whom 173 participants (53.4%) provided complete data at the beginning of the intervention and were included in the analysis. The intervention was implemented in cohorts, with participants starting at different times between January and December 2024.

Participants were recruited through 2 intervention clinics using diverse materials, including informational flyers, study details, and instructions for web-based data collection. The eligibility criteria were sufficient German language skills for reading and completing study materials, as well as participation in the intervention.

Data Collection and Measures

Data used for this study were collected during the first 2 days of the initial inpatient phase of the intervention. The survey was administered in German using the secure, web-based platform SoSci Survey. Participation was voluntary; participants could refuse or discontinue participation at any time without consequences. The survey was implemented as a closed format, with access via personalized QR codes or links provided by clinic staff. Responses were entered directly by participants and automatically stored in the secure SoSci Survey database. Each participant created a pseudonym based on a predefined rule, which was used to identify duplicate entries; in such cases, only the first complete response was retained. The final questionnaire included 90 items across 19 pages, with 1-14 items per page depending on content. A back button allowed participants to review and change their responses before submission. The web-based questionnaire was internally tested for usability and technical stability before fielding. An overview of all instruments used for data collection is provided in Table S1 in Multimedia Appendix 2.

eHealth literacy was assessed using the eHealth Literacy and Use Scale (eHLUS), a validated 14-item self-report instrument specifically designed to evaluate digital health literacy in the context of using medical apps [38]. The eHLUS measures 3 dimensions*:* eHealth engagement (4 items), autonomous use and technical access (6 items), and classical eHealth literacy (4 items). A complete listing of all eHLUS items along with their assigned dimensions is provided in Table S2 in Multimedia Appendix 2. The latter dimension includes four items from the eHealth Literacy Scale (eHEALS) [39-41], ensuring conceptual alignment with established measures of eHealth literacy. In addition, eHEALS was used as a complementary measure to assess the ability to locate, evaluate, and use digital health information, providing a basis for direct comparability with previous research. The eHEALS has been frequently used in studies that examined associations with mental health–related outcomes [42-44] and is considered one of the most established instruments in the field of eHealth literacy [45,46]. In contrast, the eHLUS was recently developed and specifically validated among individuals with mental health problems participating in a hybrid digital prevention program [38] but has not yet been widely applied in mental health research. Both instruments were analyzed as continuous measures to preserve metric variability and support a differentiated interpretation of eHealth literacy. Although a cut-off score has been proposed for the eHEALS in earlier studies, no clinically validated threshold exists [47,48]. For the eHLUS, no cut-off scores have been established to date.

Psychosocial characteristics were assessed using validated instruments and categorized into psychosocial burden and resources. Psychosocial burden was measured using the Depression Anxiety Stress Scale with 21 Items (DASS-21), which includes subscales for depression, anxiety, and stress [49,50]. In addition, the Work Ability Index (WAI) was used to assess participants' self-reported work ability in relation to health and work demands, with lower scores indicating greater psychosocial burden [51].

Psychosocial resources were assessed using the Self-Efficacy, Optimism, Pessimism Scale with 9 Items (SWOP-K9), which captures self-efficacy, optimism, and pessimism as indicators of resilience [52]. Furthermore, Quality of Life (QoL) was measured using the WHOQOL-BREF, which evaluates physical health, psychological health, social relationships, and environmental factors as broader psychosocial resources [53,54].

In addition, sociodemographic data were collected, including age, registered sex (gender), subjective socioeconomic status (SSS) (using the MacArthur Scale) [55,56], and the self-reported number of sick leave days in the past 12 months.

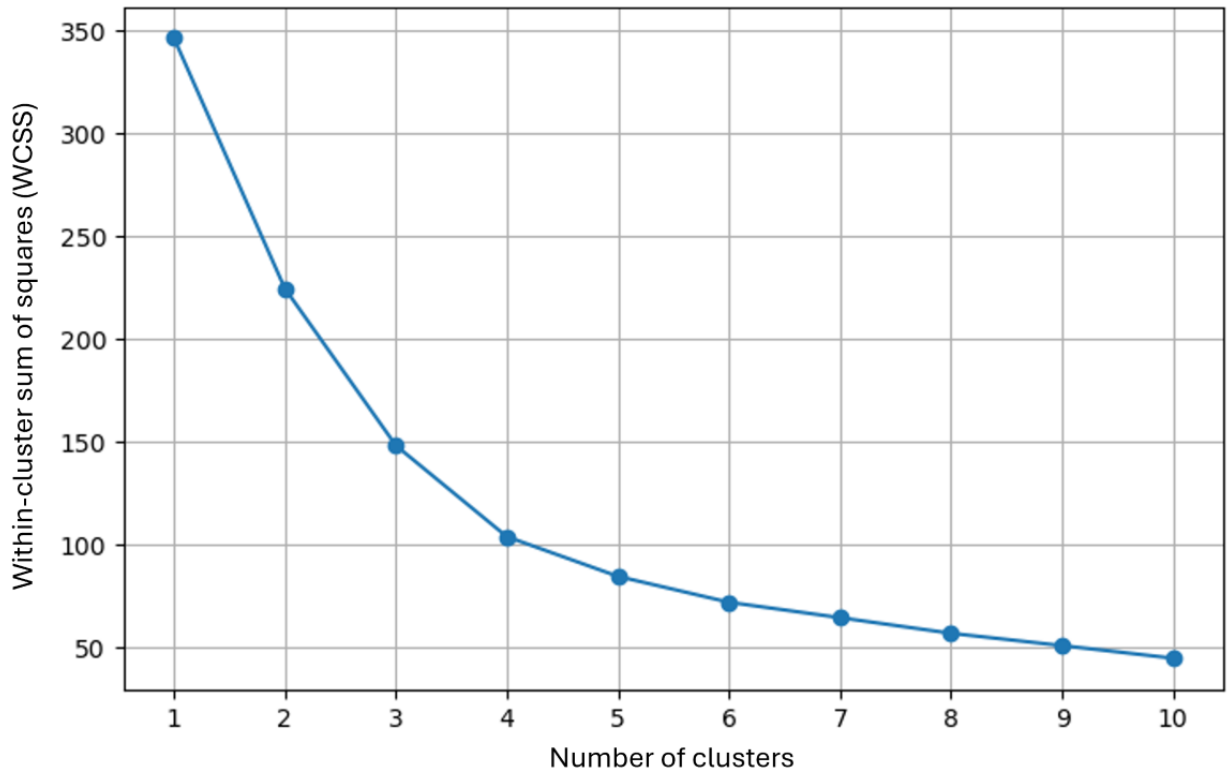
Statistical Analysis

Statistical analyses were primarily conducted using SPSS statistics (version 29.0 IBM Corp), with Python 3, an open-source programming language, within the open-source Jupyter Notebook Version 7 framework (Project Jupyter) as a supplementary tool for data exploration, visualization, and advanced statistical tasks.

Cluster Analysis

To identify psychosocial profiles based on characteristics (burdens and resources), we used a data-driven cluster analysis, which uncovers distinct subgroups without prespecifying how these variables interact. In contrast, regression models typically test predefined relationships, making cluster analysis more suitable for capturing psychosocial heterogeneity and its links to eHealth literacy [57-59]. Principal component analysis (PCA) in SPSS was used for dimensionality reduction and to extract

XSL•FO
RenderX



key components for K-Means. The included variables were depression, anxiety, and stress (DASS-21); physical, psychological, social, and environmental QoL (WHOQOL-BREF); optimism and self-efficacy (SWOP-K9); and WAI. Pessimism (SWOP-K9) was excluded due to low communality (h^2=0.264) and weak factor loadings.

To facilitate visualization in a scatterplot and improve pattern recognition, PCA was restricted to 2 dimensions, reducing the complexity of multiple psychosocial variables while preserving key variance for clustering. Although solutions with more than 2 components were initially explored, additional components had eigenvalues below 1.0 (eg, the third component had an eigenvalue of 0.958) and were therefore not retained, following Kaiser criterion. The final 2-component solution explained 60.66% of the total variance and offered a parsimonious and interpretable basis for clustering. The Kaiser-Meyer-Olkin (KMO) measure confirmed suitability adequacy (KMO=0.864), and the Bartlett test of sphericity was significant (χ^2_{45}=816.2; *P*<.001), supporting sufficient intercorrelations for PCA. PCA was performed using principal component extraction with Varimax rotation, ensuring uncorrelated and interpretable components. The rotation converged in 3 iterations, confirming stability. Factor scores were computed via the regression method and stored as PCA_Dim1 and PCA_Dim2 for clustering.

The Elbow Method in Python determined the optimal number of clusters by evaluating within-cluster sum of squares (WCSS) for solutions from *k*=1 to *k*=10. The elbow point at four clusters (see Figure 1) indicated the best fit. K-Means clustering with four clusters used PCA_Dim1 and PCA_Dim2 as input variables, converging in fewer than 10 iterations. Cluster centers were calculated, and case distribution was recorded.

Exploratory data analysis assessed cluster homogeneity and distribution. Boxplots visualized central tendencies and variability, with means and standard deviations computed per cluster.

Figure 1. Elbow method for determining the optimal number of clusters.

Internal Validation of the Cluster Solution Using Multivariate Analysis of Variance

To assess the internal validity of the cluster solution, a multivariate analysis of variance (MANOVA) was conducted using the 4-cluster grouping variable (derived from K-means) as the independent variable and the 2 principal components (PCA_Dim1, PCA_Dim2), which served as the input for clustering, as dependent variables (DVs). These components were derived from psychosocial characteristics and represent the underlying structure used to form the clusters. This procedure tested whether the clusters significantly differed along the psychosocial dimensions that initially informed the clustering process.

Prior to MANOVA, assumptions were tested. The Shapiro–Wilk test assessed normality: PCA_Dim1 was normally distributed in clusters 1, 3, and 4 but deviated in cluster 2 (*P*=.03). PCA_Dim2 met normality in clusters 3 and 4 but deviated in clusters 1 (*P*=.04) and 2 (*P*=.005). Despite these moderate violations, MANOVA remained robust as each cluster contained at least 20 participants [60].

Box M test (Box M=13.462, *P*=.16) confirmed homogeneity of variance–covariance matrices. Levene test indicated no

XSL•FO
RenderX

significant variance differences for PCA_Dim1 (P=.21) or PCA_Dim2 (P=.07). Scatterplots showed no major deviations from linearity, and the near-zero correlation minimized multicollinearity risk.

MANOVA was conducted in SPSS using Pillai's Trace as the primary test statistic due to its robustness against normality violations. Wilks' λ, Hotelling's Trace, and Roy's Largest Root were reported as secondary statistics. Following MANOVA, univariate analysis of variance (ANOVA) identified specific cluster differences, with Tukey's post hoc tests determining significant pairwise differences.

Visualization of the Clusters

A 2-dimensional scatterplot using Python visualized the clusters with PCA_Dim1 and PCA_Dim2 as axes. To illustrate spatial distribution and variability, 95% confidence ellipses were calculated from the covariance matrix and overlaid on the plot, enabling the assessment of potential overlaps. This visualization complemented statistical analyses, such as MANOVA, by highlighting cluster separation and internal variability.

Cluster-specific boxplots were used to visualize the distributions of psychosocial characteristics, with z scores standardizing the data for comparability. Negative variables were inverted to ensure that higher scores consistently represented positive outcomes.

Bar and spider charts visualize cluster-specific mean z scores to highlight multidimensional differences in eHealth literacy. The 5 analyzed eHealth literacy variables are normalized using z scores to ensure comparability.

Descriptive Analysis

In addition to clustering, the psychosocial characteristics included in PCA were analyzed descriptively for each cluster. This involved calculating means and 95% CIs for PCA variables along with pessimism, which was excluded from PCA but retained for further insights. This step enhanced the interpretation and practical relevance of cluster differences.

Correlation Analysis

Spearman rank correlation examined associations between eHealth literacy, psychosocial characteristics, and sociodemographic variables. This nonparametric test accounted for ordinal variables and potential nonnormal distributions. The analysis included the 3 eHLUS dimensions as DVs, while psychosocial characteristics, sociodemographic variables such as age and SSS, and behavioral measures such as the number of sick leave days served as independent variables.

The correlations were calculated using SPSS. Statistical significance was evaluated at a 2-sided alpha level of .05, with results adjusted for multiple comparisons using Bonferroni correction where necessary. Correlation coefficients (r values) were interpreted based on established thresholds for effect sizes: small (r=0.10 - 0.29), moderate (r=0.30 - 0.49), and strong (r≥0.50).

General Linear Model Analysis

A General Linear Model (GLM) was applied to investigate the association of cluster membership and covariates on eHealth literacy. To improve the distributional properties and stabilize variances of the DVs, transformations were applied: Box-Cox transformations for eHEALS total score and eHLUS dimension eHealth engagement, and square-root transformations for the remaining DVs (eHLUS total score, eHLUS dimensions: eHealth literacy; autonomous use and technical access). Cluster membership was included as a fixed factor, while age (metric) and SSS (ordinal) were included as covariates due to their significant correlations with the DVs. Gender was excluded as it did not show any significant relationship with the DVs (P>.05). Statistical significance was set at α=.05, and adjusted R^2 values ranged from 0.053 for eHealth engagement to 0.230 for autonomous use and technical access, indicating moderate explanatory power for certain DVs. Residual normality was assessed using the Kolmogorov-Smirnov and Shapiro-Wilk tests, with 4 out of 5 residuals meeting the assumption (P>.05). Only the eHLUS dimension eHealth literacy showed a marginal deviation (P=.04), which was deemed acceptable based on Q-Q plots. Homoscedasticity was confirmed, as Levene test indicated no significant differences in error variances across clusters (P>.05), and Box M test verified the homogeneity of covariance matrices (Box M=56.539; P=.19). Scatterplots demonstrated linearity, which showed consistent relationships between the DVs and covariates. Correlations among covariates were weak (r<0.10; P>.05), ruling out multicollinearity concerns.

As implemented in SPSS, the GLM procedure included both a MANOVA to assess the overall effect of cluster membership, age, and SSS across all eHealth literacy variables simultaneously, and a subsequent ANOVA to examine effects on each variable separately. This combined analytical strategy was applied to enable a comprehensive assessment of group differences and covariate associations within a unified model structure.

Ethical Considerations

The study was approved by the Ethics Committee of the TUM School of Medicine and Health (approval number 2023 - 316 S-SB) and conducted in accordance with institutional, national, and international regulations as well as the Declaration of Helsinki, including requirements regarding the protection of personal information, privacy, and human rights. Participants were adults (21-65 years), including both men and women; no vulnerable populations (eg, minors, patients unable to provide consent) were involved. All participants provided informed consent via a web-based form after receiving comprehensive study information. This included details on the purpose of the study, the estimated duration of the survey (approximately 15 - 20 minutes), the responsible investigators, the voluntary nature of participation, their right to withdraw at any time without consequences, and data handling procedures. Data were pseudonymized and handled confidentially in compliance with the General Data Protection Regulation. No personally identifiable information (such as names, email addresses, or IP addresses) was collected, and no identifiable features of participants will be published. Data were initially stored in the secure SoSci Survey database and subsequently transferred to secure servers at the Technical University of Munich, where they will be retained for up to 10 years. Participants received a

XSL•FO
RenderX

fixed financial compensation for their participation, which was administered on-site by the cooperating clinics.

Results

Overview

Data from 173 participants were analyzed, with a mean age of 50.9 years (SD 10.3; Min=21, Max=65). Among them, 72.8% identified as female, and 27.2% identified as male. The mean SSS, measured on a scale from 1 (lowest) to 10 (highest), was 5.6 (SD 1.6; Min=2; Max=9), considered moderate. Cumulative sick leave days over the past 12 months were reported by 171 individuals, with a mean of 46.9 days (SD 55.1; Min 0, Max 365), notably exceeding the national average of 14.8 days per employee in 2024 [61], which reflects the elevated health burden among participants of a prevention program targeting mental health. All subsequent analyses were conducted using data from 173 participants.

Dimensionality Reduction of Psychosocial Determinants

The PCA successfully reduced the dataset to 2 dimensions, which explained 60.66% of the total variance together. Component 1 (eigenvalue: 3.391) accounted for 39.31% of the variance, while Component 2 (eigenvalue: 2.135) accounted for 21.35%. The rotated component matrix revealed transparent and interpretable variable loading patterns (see Table 1). Component 1 includes psychosocial characteristics with high positive loadings for self-efficacy (0.774), optimism (0.752), psychological QoL (0.684), social QoL (0.703), and environmental QoL (0.531), representing psychosocial resources. The negative loadings for depression (−0.799), anxiety (−0.623), and stress (−0.665) on Component 1 suggest that participants with higher psychosocial resources also tend to report lower psychosocial burden. Component 2 captured work-related and physical health factors, with high loadings for WAI (0.845) as an indicator of psychosocial burden and physical QoL (0.762) as a resource contributing to overall well-being. The commonalities of the variables ranged between 0.437 and 0.761, indicating that most variables were well-explained by the 2 extracted components. The lowest communality was observed for the QoL environment (0.437), which remained within the acceptable range (≥0.4) [62].

Table . Factor loadings of the principal component analysis.

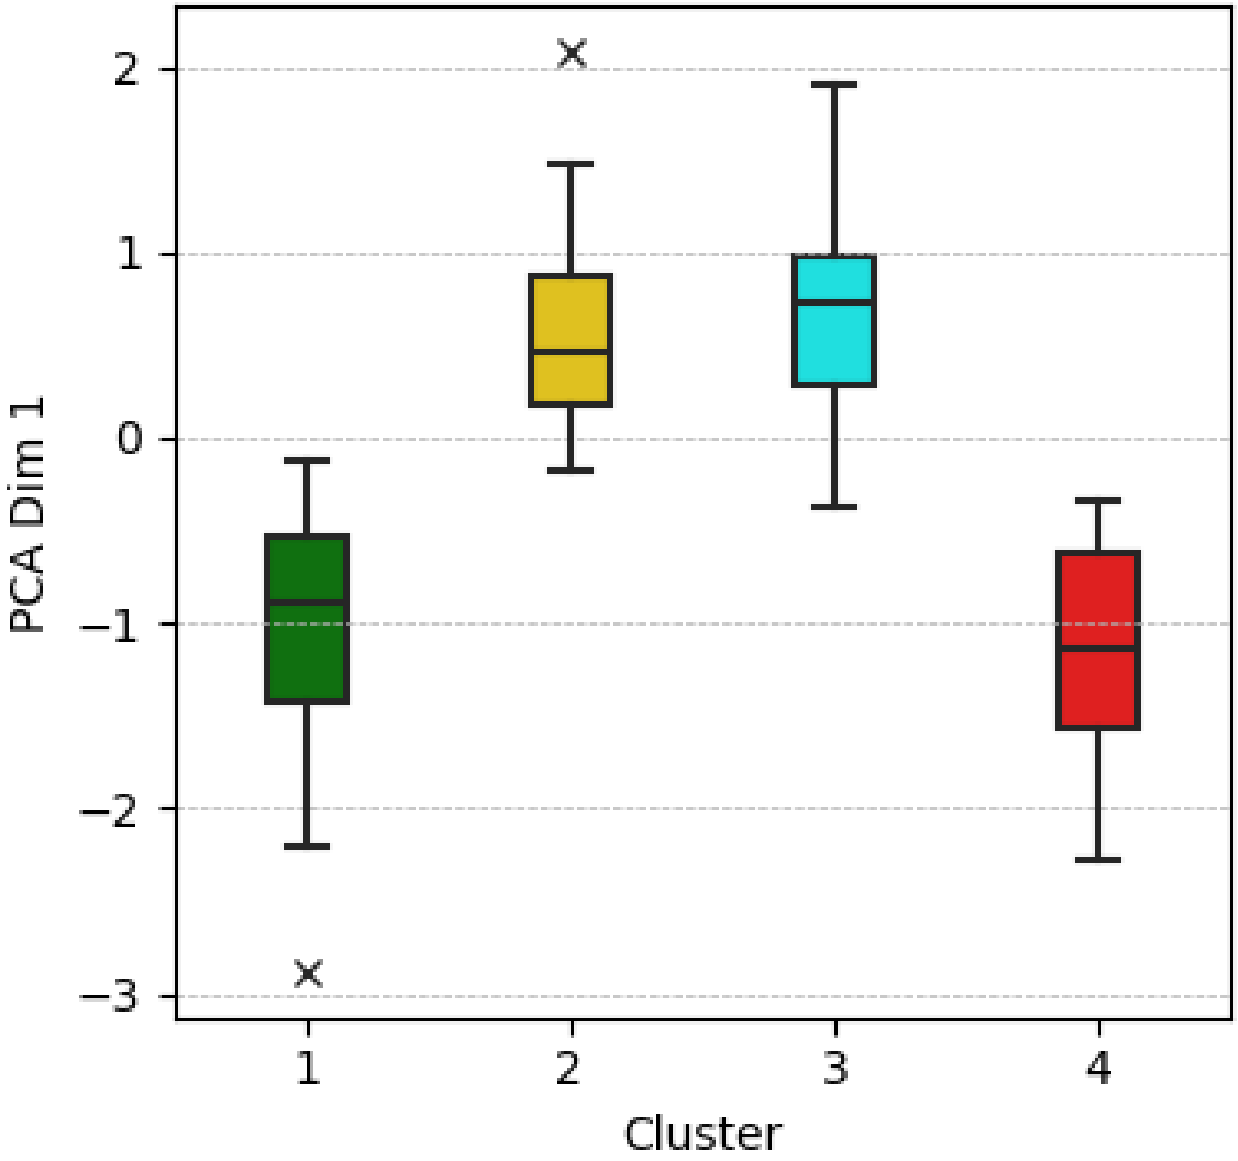
Variable	Component 1	Component 2
Self-efficacy	0.774[a]	0.174
Optimism	0.752[a]	0.243
Psychological QoL[b]	0.684[a]	0.400
Social QoL	0.703[a]	−0.172
Environmental QoL	0.531[a]	0.394
Depression	−0.799[a]	−0.350
Anxiety	−0.623[a]	−0.348
Stress	−0.665[a]	−0.403
WAI[c]	0.126	0.845[a]
Physical QoL	0.196	0.762[a]

[a]These values indicate the stronger loading of a variable on the respective component.

[b]QoL: Quality of Life

[c]WAI: Work Ability Index

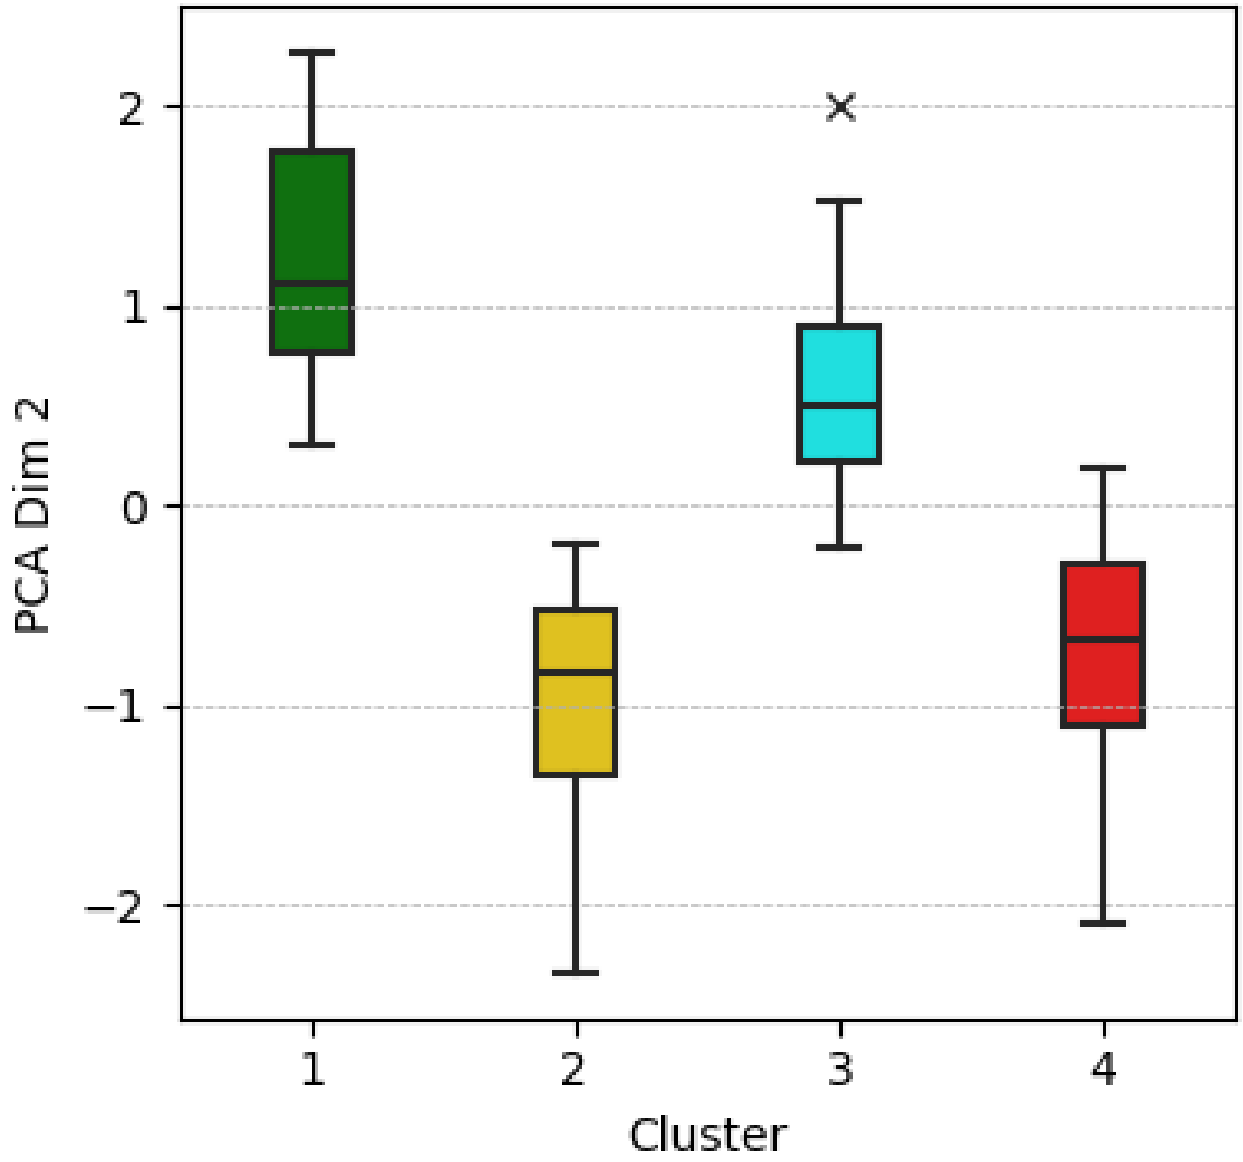
Optimal Number of Clusters for Psychosocial Profiles



The Elbow Method revealed a clear “elbow point” at 4 clusters, indicating an effective balance between intracluster homogeneity and intercluster differentiation (Figure 1). Based on this result, K-Means clustering with four clusters was performed using PCA_Dim1 and PCA_Dim2 as input variables, converging after nine iterations. The resulting cluster centers, along with the means and SDs of the PCA dimensions, are presented in Table 2. In addition, an exploratory boxplot analysis was conducted to assess cluster homogeneity and distribution. Boxplots for PCA_Dim1 (Figure 2) and PCA_Dim2 (Figure 3) visualized central tendencies and variability within each cluster, confirming distinct distributions.

XSL•FO
RenderX

Table . Cluster centers of the final solution (K-Means analysis).



Cluster	Cases per cluster	PCA_Dim1, mean (SD)	PCA_Dim2, mean (SD)
1	27	−1.023 (0.71)	1.225 (0.62)
2	45	0.538 (0.51)	−0.974 (0.60)
3	65	0.689 (0.52)	0.559 (0.47)

XSL•FO
RenderX

Figure 3. Boxplot of PCA_Dim2 by cluster. PCA Dim 2: principal component analysis, dimension 2.

Cluster Validation, MANOVA, and Post Hoc Analyses

The MANOVA confirmed significant differences for the effect of cluster among the 4 clusters in the 2 principal components (Pillai's Trace=1.4021, Wilks' λ=0.0890, Hotelling's Trace=4.7163, Roy's Largest Root=2.5688; $F_{6,336}$=131.69, *P*<.001).

ANOVA demonstrated significant differences for PCA dimensions (PCA_Dim1: $F_{3, 169}$=128.51, *P*<.001; *PCA_Dim2:* $F_{3, 169}$=135.83, *P*<.001). Tukey's post hoc tests revealed significant differences between most cluster pairs (*P*<.05), except for clusters 1 and 4, as well as 2 and 3 in PCA_Dim1, and clusters 2 and 4 in PCA_Dim2. These findings indicate that, while the MANOVA revealed significant overall differences between the clusters, not all pairwise comparisons reached significance in the post hoc tests.

Description of the Clusters

The 4 identified psychosocial characteristic profiles, each with varying levels of eHealth literacy, are described below. To improve clarity, the most contrasting clusters (3 and 4) are presented first, followed by the remaining groups (1 and 2), with a focus on key differences. Detailed statistics can be found in Table 3 (eHealth literacy) and Table 4 (psychosocial characteristics).

[a]QoL: Quality of Life.

[b]WAI: Work Ability Index.

Cluster 3 (n=65)

This cluster exhibits the most favorable psychosocial characteristics and the highest eHealth literacy levels among all clusters. Participants show the strongest psychosocial resources, with the highest levels of self-efficacy and optimism. Their reported QoL is also the highest across all dimensions. At the same time, their psychosocial burden appears to be the lowest, with the lowest levels of depression, anxiety, and stress. Their work ability is the second highest among all clusters, suggesting a relatively strong perceived capacity to meet health and work demands.

These psychosocial characteristics coincide with the highest eHealth literacy levels across all measured dimensions and clusters.

Cluster 4 (n=36)

This cluster exhibits the least favorable psychosocial characteristics among all clusters while demonstrating moderate eHealth literacy levels. Participants report the lowest psychosocial resources, with self-efficacy and optimism at the lowest levels. Their QoL is the lowest across most dimensions, except for social QoL, which is slightly higher than in Cluster 1. At the same time, their psychosocial burden is the highest among all clusters, with elevated levels of depression, anxiety, and stress. Their work ability is low and only marginally higher than in Cluster 2.

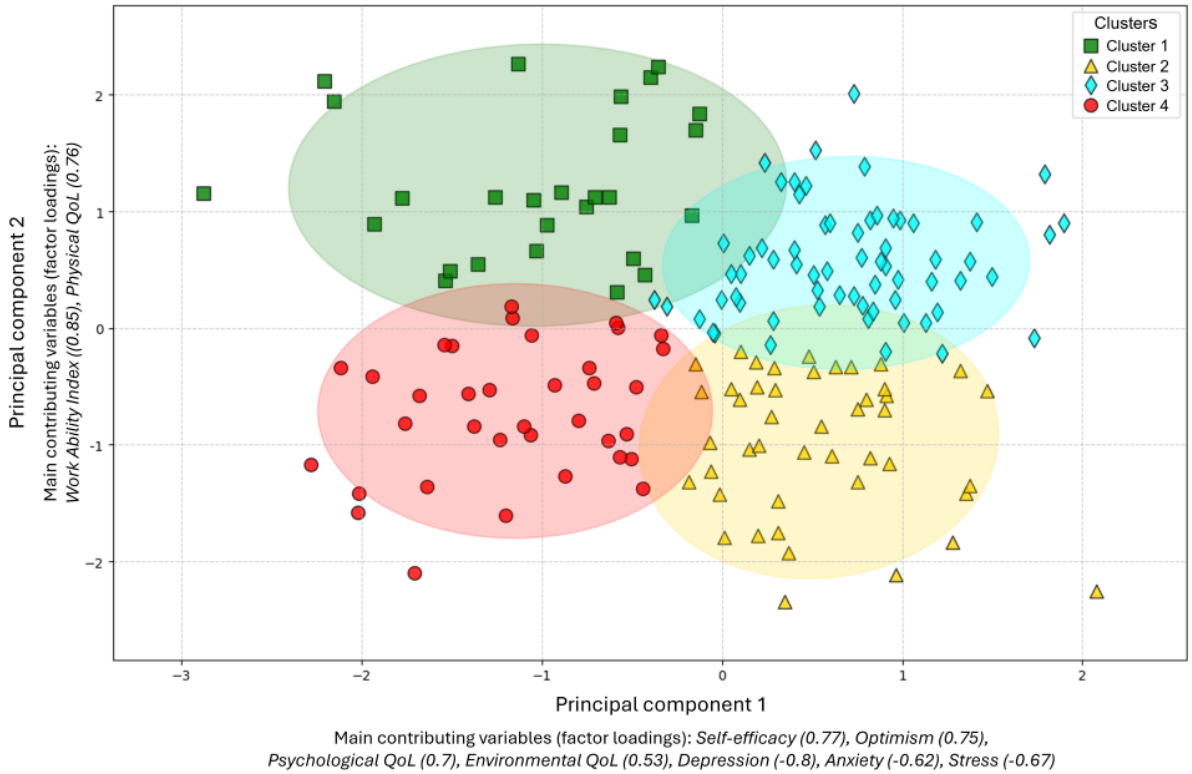
Despite these challenges, participants in this cluster demonstrate mid-range eHealth literacy levels, similar to Cluster 1 and slightly higher than those in Cluster 2. While their ability to engage with and use digital health resources is not as pronounced as in Cluster 3, their competencies remain stable.

Cluster 1 (n=27)

This cluster exhibits a complex psychosocial characteristics profile and moderately favorable eHealth literacy levels. Participants demonstrate mixed psychosocial resources. Their self-efficacy and optimism are the second lowest among all clusters. Regarding QoL, they report the highest physical QoL, mid-range psychological and environmental QoL, and the lowest social QoL. At the same time, their psychosocial burden is elevated but not uniformly high. They exhibit the second-highest levels of depression, anxiety, and stress, surpassed only by Cluster 4. Their WAI is the highest among all clusters.

XSL•FO
RenderX

Their eHealth literacy levels are moderately favorable, ranking above Cluster 2 but below Cluster 3. While their engagement with digital health tools and their ability to use them autonomously is limited compared to the highest-performing cluster, they do not exhibit substantial barriers in using eHealth resources.



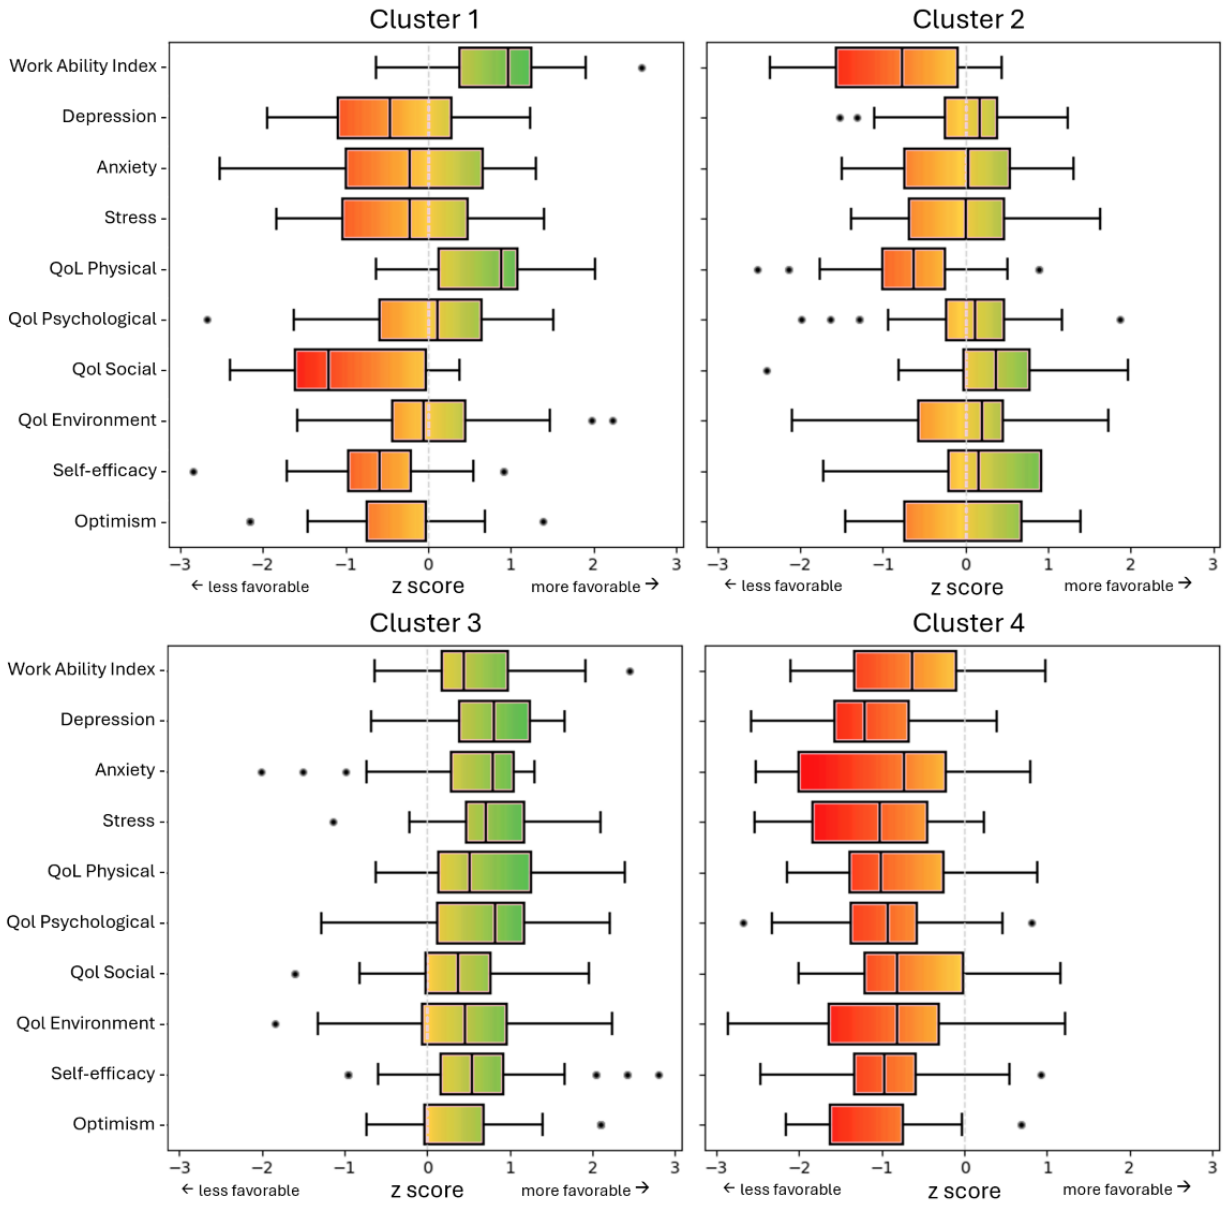
Cluster 2 (n=45)

This cluster exhibits a mixed psychosocial characteristics profile and the lowest eHealth literacy levels among all clusters. Participants demonstrate relatively strong psychosocial resources, with self-efficacy and optimism ranking second-highest among all clusters. Their social QoL is the highest, indicating strong interpersonal connections. In contrast, physical QoL is low, while psychological and environmental QoL fall within the mid-range, reflecting a more nuanced profile of well-being. At the same time, their psychosocial burden is moderate. Their work ability is the second lowest, reflecting a perceived strain in balancing health and work demands. Depression, anxiety, and stress levels fall within the mid-range, indicating a moderate psychosocial burden. Their eHealth literacy is the lowest among all clusters, with the lowest levels of eHealth engagement, autonomous use, and technical access.

Cluster Visualization: Psychosocial Characteristics

The scatterplot (Figure 4) illustrates the distribution of the four clusters across the PCA dimensions, accompanied by 95% confidence ellipses. These ellipses indicate slight overlaps between adjacent clusters along both the x- and y-axis. Cluster 1 (green squares) overlaps moderately with Clusters 3 (cyan diamonds) and 4 (red circles), while Cluster 2 (yellow triangles) shows similar overlap with Clusters 3 and 4. Likewise, Cluster 3 overlaps with Clusters 1 and 2, and Cluster 4 overlaps with Clusters 1 and 2. These overlaps suggest shared characteristics between neighboring clusters while maintaining distinct separations. The variability within the clusters is reflected in the sizes of the ellipses. Cluster 1 has the largest ellipse, indicating greater variability within this group, followed by Cluster 4. Clusters 2 and 3 have smaller ellipses, suggesting more compact groupings.

Figure 4. Scatterplot of the clusters on PCA dimensions.

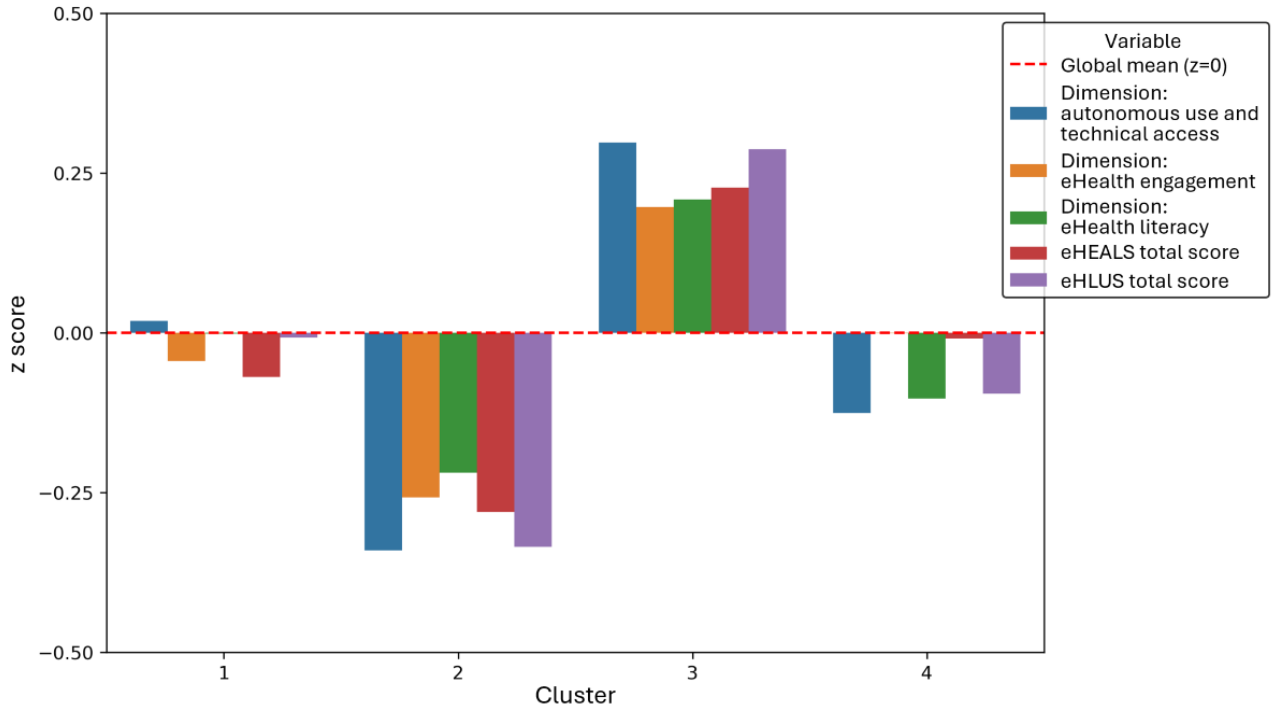


The color-coded boxplots (Figure 5) illustrate the psychosocial characteristic profiles across clusters, using a gradient from red (less favorable outcomes) to green (more favorable outcomes). These colors represent relative differences between clusters rather than absolute measures of health or illness.

Cluster 3 consistently exhibits the most favorable psychosocial characteristics (green hues), whereas Cluster 4 shows the least favorable characteristics (orange and red shades). Clusters 1 and 2 display mixed profiles: Cluster 1 combines moderate WAI (green) with limitations in social QoL and self-efficacy (orange), while Cluster 2 contrasts strong social QoL (green) with lower physical QoL and WAI (orange to red).

XSL•FO
RenderX

Figure 5. Color-coded z score profiles across clusters: relative differences in psychosocial characteristics.



Cluster Visualization: eHealth Literacy

Figure 6 displays bar charts of average *z* scores for five eHealth literacy variables per cluster. Cluster 3 consistently shows above-average scores, reflecting high eHealth literacy, while Cluster 2 demonstrates negative z scores, indicating lower competencies. Clusters 1 and 4 lie in between, with moderate scores that vary across variables. To complement this visualization, Figure 7 presents a spider chart, offering a multidimensional perspective on these patterns. The results were robust, even without the removal of outliers, confirming their minimal impact.

Correlation Analysis of eHealth Literacy Dimensions

The correlation analysis (see Table 5) revealed significant associations between eHealth literacy dimensions (eHealth engagement, autonomous use and technical access, and eHealth literacy), psychosocial characteristics, as well as age, sick leave days, and SSS.

XSL•FO
RenderX

Table . Correlation coefficients between eHealth literacy dimensions and psychosocial variables.

Variable	eHealth engagement		Autonomous use and technical access		eHealth literacy	
	r[a]	*P value*	*r*	*P* value	*r*	*P* value
Depression	−0.061	.43	−0.142	.06	−0.121	.11
Anxiety	−0.001	.99	−0.133	.08	−0.065	.39
Stress	0.014	.85	−0.025	.75	−0.002	.98
QoL[b] Physical	0.111	.15	0.102	.18	0.094	.22
QoL Psychological	−0.021	.78	0.101	.18	0.099	.20
QoL Social	0.071	.35	0.091	.23	0.135	.08
QoL Environment	0.209	.006	0.382	<.001	0.386	<.001
Self-efficacy	0.103	.18	0.382	<.001	0.386	<.001
Optimism	0.138	.07	0.141	.06	0.198	.009

SSS[d]	0.143	.06	0.222	.003	0.240	.001

[a]*r*: Pearson correlation coefficient.

[b]QoL: Quality of Life.

[c]WAI: Work Ability Index.

[d]SSS: subjective socioeconomic status.

For the eHLUS dimension eHealth engagement, significant positive correlations were observed with environmental QoL (r=0.209; P=.006), indicating that individuals with higher engagement in eHealth literacy tend to report greater satisfaction with their physical and social surroundings. In addition, a weak negative correlation with age (r=−0.190; P=.01) suggests that younger individuals are more engaged with eHealth tools. However, no significant correlations were found between eHealth engagement and other variables.

eHLUS dimension autonomous use and technical access demonstrated moderate positive correlations with self-efficacy (r=0.382; P<.001) and environmental QoL (r=0.382; P<.001), suggesting that individuals with greater confidence in their abilities and satisfaction with their environment are more likely to use eHealth tools autonomously. This dimension also exhibited small correlations with SSS (r=0.222; P=.003) and WAI (r=0.191; P=.01). Negative correlations were found with sick leave days due to illness (r=−0.338; P<.001) and pessimism (r=−0.153; P=.05), indicating that individuals with fewer psychosocial challenges and health disruptions are more likely to use eHealth tools independently.

eHLUS dimension eHealth literacy showed a similar pattern of associations, with significant positive correlations with self-efficacy (r=0.386; P<.001), optimism (r=0.198; P=.009), environmental QoL (r=0.386; P<.001), SSS (r=0.240; P=.001), and WAI (r=0.169; P=.03). Negative correlations were observed with sick leave days (r=−0.278 P<.001), indicating that individuals with fewer health-related disruptions exhibit higher levels of eHealth literacy.

GLM Results: Associations Between Clusters, Covariates, and eHealth Literacy

The GLM examined the associations between eHealth literacy dimensions and cluster membership, age, and SSS (see Table S1 in Multimedia Appendix 3). Significant associations were found for several predictors across the DVs, although some did not reach statistical significance.

Age was significantly associated with all eHealth literacy dimensions (P values ranging from <.001 to .01), with younger individuals consistently reporting higher eHealth literacy levels. SSS was significantly associated with the eHEALS total score (P=.03), the eHLUS total score (P=.004), and the eHLUS dimensions autonomous use and technical access (P=.01) and eHealth literacy (P=.001). Participants with a higher SSS level tended to report higher eHealth literacy in these dimensions.

Cluster membership was significantly associated with the eHLUS total score (P=.01) and the eHLUS dimension autonomous use and technical access (P=.004). Post hoc analyses using the Tukey test identified significant differences between clusters, specifically between Cluster 3 and Cluster 2, with Cluster 3 showing significantly higher values than Cluster 2 for both the eHLUS total score and the eHLUS dimension autonomous use and technical access (P=.004, P=.003).

The model explained the highest variance for the eHLUS dimension autonomous use and technical access (adjusted R^2=0.230) and the eHLUS total score (adjusted R^2=0.202). A lower proportion of variance was explained for the eHLUS dimension eHealth engagement (adjusted R^2=0.053), indicating

XSL•FO
RenderX

a weaker model fit for this variable. Multivariate tests confirmed the robustness of the findings; detailed results are provided in Table S2 in Multimedia Appendix 3.

Discussion

Principal Findings

The findings of this study highlight the complex interplay between psychosocial characteristics and eHealth literacy within a hybrid secondary prevention program for mental health. Cluster analysis enabled a nuanced examination of how psychosocial burdens and resources relate to eHealth literacy.

Four distinct psychosocial profiles were identified, indicating that psychosocial characteristics are associated with eHealth literacy, though patterns of association vary across dimensions. Significant differences based on cluster membership emerged in the overall eHLUS score and the eHLUS dimension of autonomous use and technical access. No significant associations were found for the overall eHEALS score and the eHLUS dimensions eHealth engagement and eHealth literacy.

To further interpret these findings, the psychosocial characteristics of the clusters were examined in relation to their eHealth literacy levels. Cluster 3, which exhibited the most favorable psychosocial profile, combining high psychosocial resources and low burden, also demonstrated the highest eHealth literacy across all dimensions. This pattern may reflect a resilient subgroup with minimal barriers to digital engagement. In contrast, Cluster 4, despite having the least favorable psychosocial characteristics overall, showed mid-range eHealth literacy levels, challenging the assumption that less favorable psychosocial characteristics necessarily correspond to the lowest eHealth literacy. This nonlinear pattern is also evident in Cluster 2, which displayed the lowest eHealth literacy levels despite an overall moderate psychosocial profile. While participants in this cluster reported relatively poor work ability and physical QoL, they also had one of the highest social QoL scores. In fact, when considering mean scores across all psychosocial characteristics, Cluster 2 appeared more balanced than Cluster 1, which exhibited both psychosocial characteristics and eHealth literacy at moderate levels. The results emphasize that eHealth literacy is not uniformly distributed across psychosocial profiles. Rather than following a straightforward gradient, our findings indicate a complex relationship between specific psychosocial characteristics and eHealth literacy. While traditional models suggest a linear relationship where higher psychological burden corresponds to lower eHealth literacy, our approach reveals a more nuanced and heterogeneous pattern. Even when examined in isolation, no single psychosocial characteristic variable visually indicates a clear linear trend with eHealth literacy, reinforcing the need for a more nuanced understanding of this relationship.

In the correlation analysis of isolated psychosocial and sociodemographic variables, QoL environment was the only variable to show a significant correlation across all three eHLUS dimensions. Self-efficacy and work ability were significantly correlated with the eHLUS dimensions autonomous use and technical access as well as eHealth literacy. In addition, optimism and pessimism each correlated with only one of the eHLUS dimensions. Overall, these findings suggest that eHealth literacy may be more closely linked to psychosocial resources, particularly resilience factors, than to psychosocial burdens.

Regarding sociodemographic variables, correlation analyses showed that fewer sick leave days were associated with higher scores in both autonomous use and technical access and eHealth literacy. Further, the GLM revealed that age was significantly associated with all eHealth literacy dimensions, with younger individuals consistently demonstrating higher eHealth literacy levels. SSS also had a significant effect on the overall eHEALS and eHLUS scores, as well as on the eHLUS dimensions autonomous use, technical access, and eHealth literacy, indicating that participants with higher SSS tended to report higher eHealth literacy. Notably, gender did not show a significant relationship with eHealth literacy in our analysis.

The inclusion of age and SSS as covariates reflects the relevance of social determinants for variation in eHealth literacy. These factors represent broader structural conditions that may also relate to psychosocial characteristics. For instance, financial strain or job insecurity as reflected in lower SSS, may coincide with increased stress or reduced self-efficacy. Although not explicitly examined, such interdependencies may help contextualize subgroup differences in digital health engagement. These findings emphasize the importance of considering both psychosocial and social determinants of health when designing hybrid secondary prevention programs.

Examining these psychosocial subgroups is critical for tailoring hybrid interventions, as varying psychosocial burdens may lead to distinct challenges in behavioral adaptation and sustained app use. These challenges likely differ across participant subgroups, requiring targeted strategies at different intervention stages (in-person or digital) that account for differences in digital engagement and self-management skills. Health care professionals play a crucial role in this process by providing tailored support that meets the specific needs of each subgroup. Their involvement ensures that participants receive optimal guidance to navigate both the digital and in-person components of hybrid interventions effectively, addressing subgroup-specific barriers.

Implementing such individualized support in routine health care settings presents several challenges. Health care professionals vary in their eHealth literacy and often lack adequate support, training opportunities, and resources to provide individualized digital guidance during regular consultations [63,64]. To address these barriers, the integration of digital health navigators or trained support personnel could offer valuable assistance, particularly for participants with lower eHealth literacy [65]. These roles can facilitate meaningful engagement through structured onboarding, low-threshold support, and continuous accompaniment. Rather than excluding individuals with limited digital competencies from online treatment options, tailored support can promote their participation and ensure equitable access [65].

In this context, stratifying digital health interventions based on the combination of psychosocial profiles and eHealth literacy levels identified through clustering offers a practical framework

XSL•FO
RenderX

for adapting support intensity, interface complexity, and onboarding formats to individual needs. These tailored implementation strategies acknowledge the heterogeneity of user prerequisites and lay the foundation for more equitable and responsive hybrid prevention programs. By integrating these insights into intervention design, hybrid prevention programs can be adapted to overcome subgroup-specific barriers, enhance eHealth engagement, and improve accessibility. In addition, these findings help health care professionals better understand the challenges different subgroups face in adopting eHealth solutions, enabling them to provide more targeted support.

Comparison With Prior Work

Prior studies have shown that higher eHealth literacy is linked to lower psychosocial burden. Yang et al [66] found significant negative correlations between eHealth literacy and depression, insomnia, and post-traumatic stress disorder, while Akingbade et al [67] reported a reduced likelihood of anxiety and depression among individuals with high eHealth literacy. Our findings partially align with this, as we observed that psychosocial resources (eg, self-efficacy and optimism) were positively associated with eHealth literacy. However, unlike some prior studies, we did not find a direct association between psychosocial burden (eg, depression and stress) and eHealth literacy, suggesting that digital engagement may be more closely related to resilience factors than distress.

Sociodemographic disparities in eHealth literacy are widely documented, particularly regarding age and education. Consistent with prior research, we found that younger individuals and those with higher SSS exhibited significantly higher eHealth literacy. These results align with broader findings that eHealth literacy declines with age and is positively associated with education and income [68,69]. While gender differences in eHealth literacy have been inconsistently reported in the literature, our analysis found no significant gender effect, which supports findings from previous large-scale studies that suggest gender is not a primary determinant once socioeconomic factors are controlled [68].

Much of the existing research on eHealth literacy has relied on variable-centered methods (eg, correlations and regressions), linking eHealth literacy to factors like depression, age, and education [67,69]. In contrast, our study applied cluster analysis to identify distinct subgroups, capturing heterogeneity in eHealth literacy, psychosocial burden, and resources. This approach aligns with prior work demonstrating that clustering can reveal meaningful subpopulations. For example, Petrič et al [46] identified eHealth literacy-based user segments in online health communities, distinguishing highly engaged help-seekers from low-engagement users. Similarly, Andersen et al [70] profiled hospital patients, isolating a vulnerable subgroup with low eHealth literacy, older age, and lower education. These findings underscore how person-centered approaches offer deeper insights into eHealth literacy disparities, informing targeted interventions.

Limitations

This study has several limitations that warrant consideration. The cross-sectional design restricts the ability to draw causal inferences between psychosocial characteristics and eHealth literacy. While this limits our understanding of temporal or directional effects, the cross-sectional nature is sufficient to identify associations and patterns that provide a strong foundation for future longitudinal studies. The homogeneity of the sample, which included participants with adequate German language proficiency and involvement in the RV Fit Mental Health intervention, may constrain the generalizability of the findings to other populations. However, this focus on a specific, well-defined group ensures internal validity and allows targeted insights into individuals' psychosocial and eHealth needs in hybrid secondary prevention programs. The recruitment process and eligibility criteria introduce the possibility of selection bias, as only participants who were actively engaged in the intervention and met language proficiency requirements were included. This could mean the sample reflects a more motivated and health-conscious group than the general population. Nonetheless, this targeted recruitment aligns with the study's aim to understand eHealth literacy within the context of a specific intervention, making the sample highly relevant to the research objectives. In addition, both the eHEALS and eHLUS are self-report instruments that reflect participants' perceived abilities and motivational orientation toward digital health use, rather than objectively tested eHealth competencies. While both instruments provide valuable continuous scores, the resulting scores lack validated cutoffs and therefore cannot be translated into clinically actionable categories. Furthermore, potential interrelations between psychosocial characteristics and social determinants of health were not explicitly modeled, as the primary aim was to identify psychosocial subgroups. Including additional structural variables may have compromised model parsimony, given the sample size and the exploratory focus of this study. These considerations underline the importance of interpreting the results within their methodological context while affirming the study's strengths in exploring the interplay between psychosocial characteristics and eHealth literacy.

Conclusions

This study highlights the importance of a person-centered approach in understanding the interplay between psychosocial characteristics and eHealth literacy within a hybrid secondary prevention program. By using cluster analysis, we identified distinct psychosocial subgroups with varying levels of eHealth literacy, which would not have been fully captured through traditional variable-centered methods. This analytical approach allowed us to uncover nuanced relationships, demonstrating that psychosocial resources, rather than psychosocial burden alone, are closely linked to eHealth literacy. Our findings emphasize that eHealth literacy is not uniformly distributed and that subgroup-specific differences must be considered when designing and implementing eHealth interventions.

The implications of these findings for hybrid prevention programs are substantial. Health care professionals play a critical role in supporting participants by tailoring interventions to match individual needs. By addressing both eHealth literacy deficits and psychosocial challenges, personalized support strategies can enhance the effective adoption and sustained use of eHealth tools. This targeted approach may improve user engagement,

XSL•FO
RenderX

reduce barriers to the use of eHealth applications, and ultimately strengthen the impact of hybrid prevention models.

However, further research is needed to fully understand the relationships between eHealth literacy, psychosocial characteristics, and the actual use of medical apps. Moreover, future studies should investigate the interplay between psychosocial characteristics and social determinants of health to inform integrated intervention strategies. To strengthen the interpretability and practical relevance of eHealth literacy measures, future research should also examine how self-reported eHealth literacy relates to actual digital competencies and behavioral outcomes and work toward the validation of clinically meaningful categories to support actionable use in health care settings. In this context, Ecological Momentary Assessment methods could be applied to capture real-time patterns of digital engagement in naturalistic settings, thereby complementing self-report data and enhancing ecological validity. Longitudinal designs will be essential to determine causal pathways and to assess how tailored interventions can improve both eHealth literacy and overall health outcomes. Moreover, expanding research to diverse populations will be essential to ensure that eHealth interventions are accessible to all. By continuing to refine our understanding of these dynamics, we can move toward more effective, inclusive, and person-centered prevention strategies.

Acknowledgments

This study is part of the PE³PP project, led by the German Pension Insurance Central Germany and funded by the Federal Ministry of Labour and Social Affairs, Germany (662S0033X1).

The authors wish to sincerely thank the PE³PP study group (Olaf Ballaschke, Florian Finke, Frank Gabel, Claudia Gruhner, Kathleen Kaminski, and Andreas Seemann – listed in alphabetical order) for their dedicated support and invaluable contributions to this project. Furthermore, we are profoundly grateful to all study participants, whose engagement and input were indispensable to the success of this research.

Abstract

Background: Mental health problems and adverse health behaviors are enriched in individuals with obesity and need to be considered in weight loss interventions. Regarding weight loss, hybrid interventions combining digital and in-person elements have proven superior to eHealth-only interventions. However, it remains unclear whether minimal group or individual enhancement could bring additional benefits to the mental health and health behavior domains in individuals with obesity.

Objective: This study aimed to explore whether minimal group or individual enhancements could offer additional benefits to an eHealth intervention in relation to mental health, perceived work ability, and health behavior in a sample of occupational health patients with obesity. In addition, the study sought to examine the overall effects of the health behavior–focused intervention across these domains.

Methods: This study was a randomized controlled trial with a 12-month intervention (March 2021-2022), with selected variables followed for another 12 months without additional support. Recruited from occupational health care, 111 working-age adults with BMI 30 - 40 kg/m^2 were randomized to one of the 3 treatment arms, such as eHealth, eHealth+Group, or eHealth+Individual. All treatment arms received a web-administered, coach-assisted eHealth program based on acceptance and commitment therapy, and, in addition, the eHealth+Group and eHealth+Individual arms received 3 remotely facilitated group or individual meetings. The overall intervention effects were evaluated quasi-experimentally by combining the 3 treatment arms into a single eHealth arm. Participants were assessed for depression (the Beck Depression Index 21 [BDI-21]), burnout (Bergen Burnout Inventory 18 [BBI-15]), perceived work ability, eating behavior (ecSatter 2.0, Three Factor Eating Questionnaire [TFEQ], and Binge Eating Scale [BES]), and physical activity (Baecke Habitual Physical Activity Questionnaire, BHPAQ).

Results: We observed inconsistent fluctuations between the treatment arms in depression and burnout scores, indicating a lack of meaningful intervention effects despite statistical significance. Therefore, none of the treatment arms showed superiority over another. Across all participants, depression showed an estimated mean decrease of 2.5 BDI-21 points, with older participants experiencing a greater reduction in depressive symptoms. Furthermore, binge eating tendency decreased by 4.9 BES points during the 12-month intervention. We also observed increases in eating competence, controlled restraint, and physical activity. However, the 24-month measurements showed an adverse effect on eating competence, especially on attitudes toward eating and food, during the follow-up period without further support.

Conclusions: Minimal enhancement through either group or individual video-conference meetings did not provide additional benefits in the mental health or eating habit domains compared with the eHealth intervention alone. Nevertheless, our results indicate that eHealth interventions for weight loss have the potential to reduce depression symptoms and binge-eating tendencies, while also improving eating competence and physical activity across the study population. Continued support may be necessary to sustain positive changes.

Introduction

Obesity and mental health problems are intricately connected, with evidence suggesting a bidirectional relationship between the two [1,2]. Depression, one of the most extensively studied mental health issues, increases the risk of obesity by 58%, while obesity elevates the risk of depression by 55% [3]. Furthermore, both obesity and depression are significant risk factors for reduced work ability [4,5], and occupational burnout has been linked to these conditions [6-8]. Several mechanisms, including weight-related stigma [9], hypothalamic-pituitary-adrenal axis dysregulation [10], and adverse health behaviors [11], have been proposed to explain these associations, with these factors likely interacting in complex ways [12].

Originally developed for mental health treatment, transdiagnostic treatment approaches target common underlying factors across multiple disorders [13] and are also applied in obesity treatment to support weight management [14]. Among these, cognitive behavior therapy is often considered the first-line treatment option. However, research suggests that cognitive behavior therapy may not consistently produce desired weight loss outcomes, and its emphasis on thought suppression could even contribute to binge eating and weight gain [15,16]. As a result, mindfulness-based methods have gained popularity as alternatives in psychological obesity treatment, with acceptance and commitment therapy (ACT) showing the most consistent results in reducing BMI in adults with overweight and obesity [17].

ACT aims to enhance psychological flexibility, a trait linked to improved psychological well-being [18,19], and has demonstrated efficacy not only in weight management but also in the treatment of various mental and somatic health conditions [20]. This is particularly relevant in obesity treatment, as individuals with obesity face an elevated risk of mental health issues and eating disorders, which can be exacerbated by weight-normative interventions that emphasize weight loss [21,22]. In their review, Iturbe et al [21] found that while ACT supports psychological well-being even in weight loss contexts, more favorable outcomes were observed in interventions that prioritized health promotion over weight reduction. Consequently, ACT-based interventions that focus on sustainable health behaviors rather than weight loss alone may be more effective in promoting long-term well-being.

Furthermore, ACT is applicable in a variety of formats [23], including digital and hybrid interventions [24,25]. These modes of delivery are underscored by the widespread prevalence of obesity and mental health issues, as they have shown great potential for cost-effectiveness, scalability, and accessibility [26,27]. Hybrid interventions, which integrate digital and in-person elements, have shown superior outcomes in somatic metrics compared with fully digital approaches [28,29]. Nevertheless, the introduction of in-person elements reduces the scalability of the intervention, emphasizing the need for minimal face-to-face input.

To date, it remains unclear whether group or individual contact could bring additional benefits to mental health and health behavior domains following a weight-management intervention, and if these benefits are notable following minimal face-to-face enhancement. To take a step forward in evaluating the optimal mode and frequency of contact for digital support [30], we aimed to explore whether a 3-time group or individual enhancement could offer additional benefits to a coach-assisted eHealth intervention in relation to mental health, perceived work ability, and health behavior. In addition, we examined the overall effects of the health behavior–focused intervention that combined ACT and behavioral components across these domains. We hypothesized that the hybrid treatment arms would be more effective than the eHealth-only arm. Given the mixed findings of previous research, we could not predict whether the group or individual format would differ in overall effectiveness.

Methods

Study Design

This study was a randomized controlled trial (RCT) aiming to improve participants' health behavior and thus, weight loss [31]. Participants were assigned to one of the 3 treatment arms: eHealth, eHealth+Group, or eHealth+Individual. Each treatment arm used an eHealth program, Healthy Weight Coaching (HWC), extensively detailed by Suojanen et al [32]. In addition, the hybrid treatment arms received 3 remotely facilitated group or individual sessions. In all 3 treatment arms, the intervention lasted 12 months (March 2021-2022), followed by a 12-month unsupported follow-up period.

The HWC integrates behavioral weight management themes (eg, eating habits, physical activity, sleep, and stress management) with the core processes of ACT (values, committed action, contact with the present moment, acceptance, defusion, and self as context) with information and exercises covering these themes (refer to Table S1 in Multimedia Appendix 1 for a more detailed description of the intervention). The aim of the HWC is to teach weight-management skills and improve psychological flexibility, resulting in long-term weight loss. Participants were asked to complete 1 "session" per week, covering information and exercises. They received tailored one-on-one written feedback every 2 weeks for the initial 3 months and every 3 weeks for the remaining year, totaling 19 interactions. The same coach was responsible for the HWC program support and any supplementary contacts. All 3 coaches had master's degrees in nutrition and further education in

XSL•FO
RenderX

psychology and were randomly allocated to one-third of the participants in each treatment arm.

Helsinki city employees with a BMI of 30-40 kg/m^2 were recruited for the study from February to March 2021 via advertisements on city employees' platforms and the nursing staff of Occupational Health Care Helsinki. Besides BMI, inclusion criteria included the capacity to engage in potential group or individual sessions and access to a computer with internet connectivity. Exclusion criteria included participation in other weight loss programs, recent pregnancy or lactation, weight fluctuations of more than 5 kg in the past 3 months, major medical conditions impacting safety or readiness for weight loss, and the use of weight loss medication.

After passing the initial screening by a research assistant, eligible candidates underwent phone-based health screening conducted by a medical doctor to assess their health status and medications. Suitable participants then proceeded with laboratory assessments and body composition measurements. When written consent was provided, the statistician (JM) used stratified random allocation for SPSS (IBMCorp) to randomize the participants into 3 treatment arms stratified by sex, age, and BMI. The sample size was determined with a priori power analysis by a statistician (JM) and was based on the expected weight change.

Treatment Arms

eHealth

Participants received the HWC eHealth program, which included a 20-minute kickoff call 3 weeks into the program to monitor their progress. They also received written feedback every 2 weeks for the first 3 months and then every 3 weeks for the rest of the year, totaling 19 contacts.

eHealth+Group

Participants received the HWC eHealth program (as detailed in item 1) and participated in 3 remotely facilitated group meetings via video (each lasting 2 h). Due to the COVID-19 pandemic, these meetings were held remotely and included brief introductions to topics, such as goal setting, stress management, and self-compassion, followed by small-group discussions (Table S2 in Multimedia Appendix 1). Group meetings were held at 1, 6, and 10 months during the 12-month treatment period.

eHealth+Individual

Participants received the HWC eHealth program (as described in item 1) and engaged in 3 remotely facilitated individual meetings via video (each lasting 45 min). These sessions were tailored to each participant's current needs, recognizing their achievements and addressing challenges. Individual meetings were held at 1, 6, and 10 months within the 12-month treatment period.

Outcome Measures

Depression Symptoms

Depression symptoms were measured using the Beck Depression Index 21 (BDI-21) [33]. BDI-21 is one of the most used depression indicators measuring both cognitive and somatic symptoms of depression [34,35]. Question 19 was modified to ask if the participant had lost or gained weight. Since all participants were involved in a weight-management intervention, weight loss was considered intentional and was scored as zero. Each question is scored on a scale of 0 - 3. The total score of the questionnaire ranges from 0 to 63, with higher scores indicating more severe symptoms. A score of 0 - 12 indicates a normal condition, 13 - 18 indicates mild depression, 19 - 29 indicates moderate depression, and 30 or above indicates severe depression.

Burnout Symptoms

Burnout symptoms were measured using the Finnish version of the Bergen Burnout Inventory (BBI-15) [36]. The BBI-15 assesses exhaustion, cynicism, and reduced professional efficacy, which are the 3 key symptoms of burnout according to the most widely accepted definition [37]. Each question is scored on a scale of 1 - 6, with a total score range of 15 - 90. Higher scores indicate more severe symptoms. The total score of the questionnaire is calculated as the sum of these subcategories.

Perceived Work Ability

Perceived work ability was measured using a subjective single-question assessment ("What score would you give your current work ability on a scale of 0 - 10?"), with 8 - 10 indicating good, 6 - 7 reduced, and 0 - 5 poor work ability. This question is part of the work ability index and has a good predictive value for work ability risk [38,39].

Eating Behavior

Eating behavior was measured with 3 different questionnaires covering different aspects of eating behaviors and attitudes. Eating competence was measured with the Finnish version of the ecSatter Inventory 2.0 (ecSI2.0) questionnaire [40,41], including 4 subcategories: eating attitudes (has positive attitude toward food), food acceptance (is comfortable with familiar foods and skilled at trying unfamiliar foods), internal regulation skills (recognizing and trusting hunger and satiety signals in choosing food amounts), and contextual skills (prioritizing meals and having the skills and resources for food handling). All questions are scored on a scale of 0 - 3, with a total score range of 0 - 48. Higher scores indicate better eating competence, with a cutoff score of 32 used to indicate good eating competence. Cognitive restraint, uncontrolled eating, and emotional eating were measured with an 18-item Finnish version of the Three Factor Eating Questionnaire (TFEQ-R18) [42,43], reporting the relative proportion (0% - 100%) of the maximum possible raw score for each subscale (the higher the value, the greater the level). Binge eating was measured by the Binge Eating Scale (BES) [44,45]. The BES has 16 items scored 0 - 2 or 0 - 3, with the total score range of 0 - 46. A score below 20 is considered normal, whereas scoring 20 - 29 indicates moderate binge eating tendency, and 30 or above indicates a severe binge eating tendency.

Physical Activity

Physical activity was measured with the Baecke Habitual Physical Activity Questionnaire (BHPAQ), covering work,

XSL•FO
RenderX

sports, and leisure [46]. The questionnaire has 16 items, each scored 1 - 5. For each subcategory (work, sports, and leisure), a mean score is calculated, and the overall score is the total sum of the subcategory scores. A higher score indicates greater physical activity.

Participant assessments were conducted at baseline, midintervention (6 mo), postintervention (12 mo), and follow-up (24 mo). Baseline, midintervention, and postintervention questionnaires were answered as a part of the eHealth program, and follow-up questionnaires were mailed to all participants regardless of their activity in the program. Hence, most questionnaires cover data up to 12 months, while a selection of questionnaires also cover 24-month follow-up data.

Of the questionnaires, BDI-21, BBI-15, perceived work ability, TFEQ-R18, and BHPAQ were added to the HWC program at a specific time point (0, 6, and 12 mo), while the ecSI2.0 and the BES were integrated into the program structure. Since participants filled the ecSI2.0 and the BES while progressing through the program, not everyone reaching the recommended pace of 1 session per week, we pooled the answers to the 0-, 6-, and 12-month time points from the nearest actual answering time (baseline questionnaire answered during intervention months ranged 0 - 3, 6-month questionnaire during months ranged 4 - 8, and 12-month questionnaire during months ranged 9 - 12). We report the subscales only for variables where the total score showed significance, except for the TFEQ, for which only subscale results are provided. Age, sex, and profession were retrieved from the electronic health record system, and BMI was calculated from height and weight measured by trained research assistants [31].

Statistical Methods

Data analysis was conducted using IBM SPSS Statistics (version 28.0.0.0). Baseline differences were analyzed by Fisher exact test for categorical variables, ANOVA for the parametric continuous variables, and Kruskal-Wallis nonparametric continuous variables.

EcSI2.0 was normally distributed. Perceived work ability, ecSI's subcategories Eating attitude and Internal regulation skills, BHPAQ, and its subcategory Leisure had negatively skewed distribution, and thus, inverted variables were used in the analysis with gamma distribution and log link function. All other variables had positively skewed distribution, and thus, gamma distribution with log link function was used in the analysis.

We used the Generalized Estimating Equations method [47] to analyze the differences between the treatment arms and overall change over time. The Generalized Estimating Equations method includes all available data points and uses estimated means in the analysis, applying the intention-to-treat principle to decrease attrition bias. Following the unadjusted primary analysis, we added sex, age, and weight change (0-6 mo and 0-12 mo) to the model as covariates to explore their impact on the results. For mental health variables, we also included psychotropic medication use or changes in the medication (0-12 mo and 12-24 mo) as covariates (Table S3 in Multimedia Appendix 1). Considering the model size, each covariate was initially tested individually in a preliminary covariate model, reported in Multimedia Appendix 1. Statistically significant covariates were then combined into a single model, and the results of the full covariate model were reported in the text. To avoid multicollinearity, the 2 time points of weight change and medication change variables were tested separately in different models.

Little's missing completely at random (MCAR) analysis was used to determine whether the data were MCAR. With variables whose data were not MCAR, we used Full Information Maximum Likelihood estimation with Mplus computer software version 8.11 to correct for the potential bias. Crosstabs with Fisher exact test were used to analyze change in depression and burnout incidence between the measurement points. Incidence was separately calculated for completers and for the entire baseline sample with last observation carried forward. The Spearman correlation coefficient was used for correlation analysis, and the Dancey and Reidy definition was applied to determine correlation strength [48].

Cohen *d* effect size was calculated for the differences between different arms, using the square root of the average variance of measures and correcting for baseline differences. In the analyses for the entire group, the pooled SD between measurement times was used to calculate the effect size [49]. Effect size of 0.2 was considered small, 0.5 medium, and 0.8 large [50]. Figures were drawn with GraphPad Prism.

Ethical Considerations

The study protocol was approved by the Ethics Committee of the Helsinki and Uusimaa Hospital District (29.4.2020, HUS/922/2020). Informed consent was obtained from all individuals participating in the study. To protect privacy and confidentiality, the data were pseudonymized and securely processed to prevent identification of individual participants. Participants received access to the intervention and their personal health data but did not receive any additional compensation. Detailed reporting of the study is provided in the CONSORT-EHEALTH checklist (Checklist 1) .

Results

Baseline Characteristics

After the screening, 111 participants fulfilling the inclusion criteria were randomized into the 3 treatment arms with a 1:1:1 ratio (Figure 1). The mean age was 50 (SD 8.9) years and mean BMI was 34.2 (SD 2.9) kg/m^2 (Table S4 in Multimedia Appendix 1). Of the 111 participants, 90 (83%) were female and 97 (87%) were "white collar" workers (manager, specialized expert, expert, or office and customer service worker).

XSL•FO
RenderX

Figure 1. Flowchart of participant progress through the three study groups (eHealth, eHealth+Group, and eHealth+Individual) in the randomized controlled trial, with a total sample size of N=111.

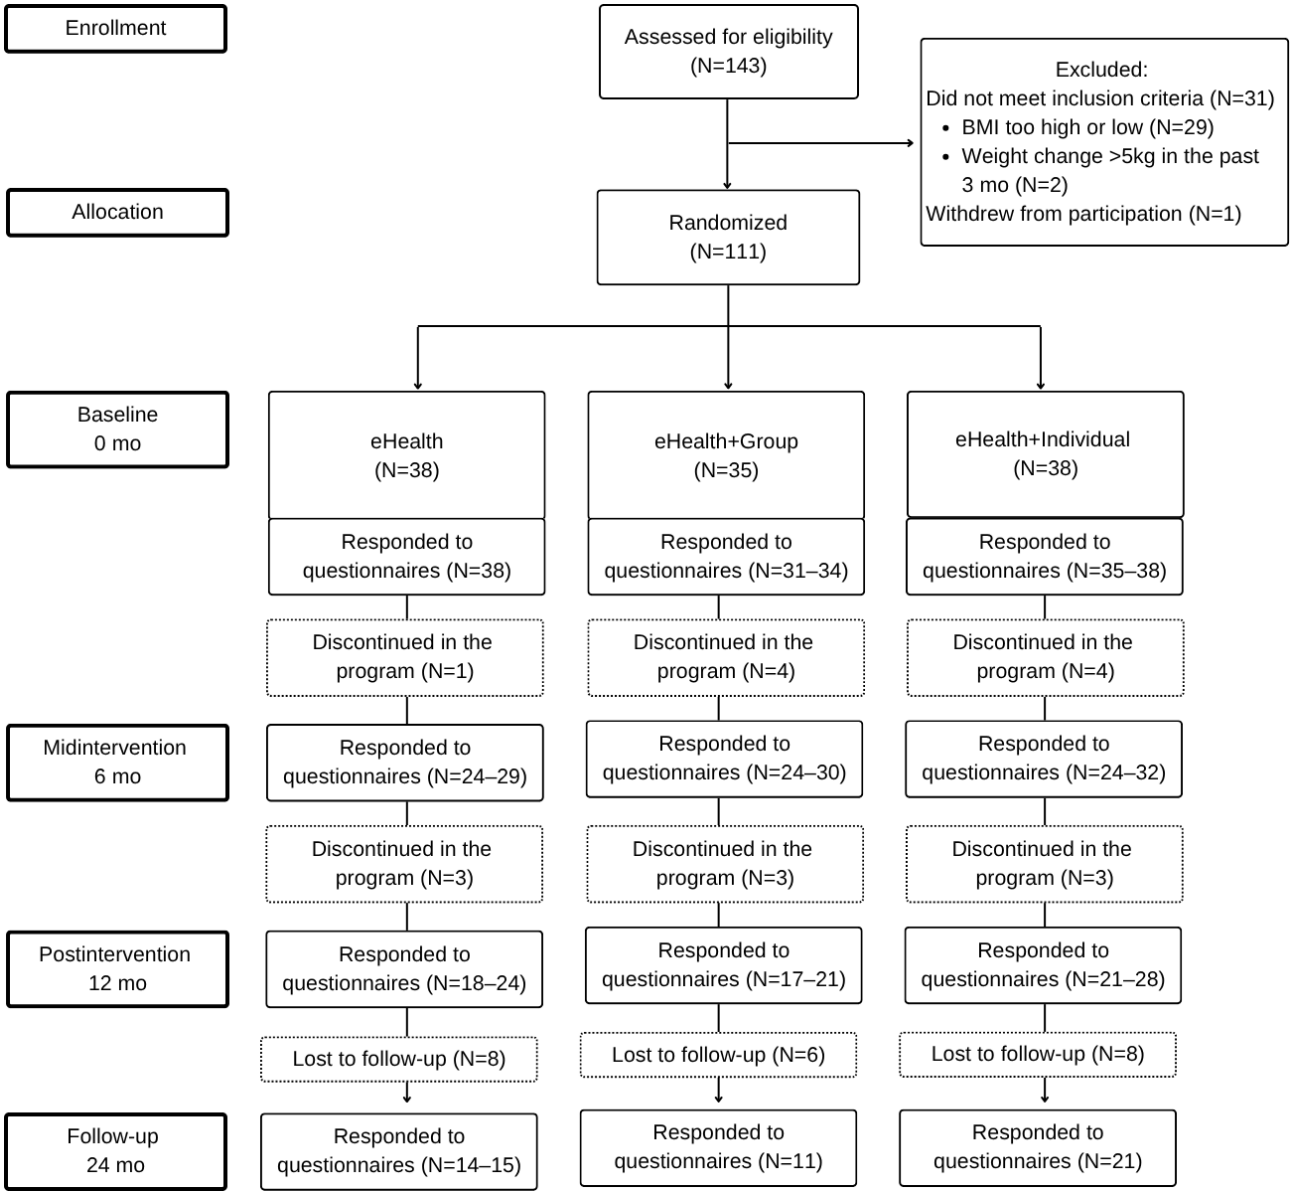

Figure 1 illustrates group allocation and participant retention over the 24-month follow-up, showing variation in the number of respondents across questionnaire time points. As 1 participant did not reply to the baseline questionnaires, the total data pool analyzed for the mental health and health variables included 110 participants (Table S4 in Multimedia Appendix 1). Baseline characteristics did not differ between the treatment arms except for 1 subscale (leisure) of the physical activity questionnaire, where the eHealth+Group treatment showed lower baseline values than the other 2 arms. Regarding mental health and work ability, 36/110 (33%) participants indicated at least mild depression, 32/100 (29%) participants at least mild burnout, 36/100 (33%) participants reduced or poor perceived work ability, and 15/100 (14%) participants reported using psychotropic medication (Table S3 in Multimedia Appendix 1). Considering eating behavior, 16/110 (15%) participants indicated at least moderate binge eating tendency, and 91 (88%) participants had “poor” eating competence. No between-groups differences were observed in these categories.

The correlation between depression and burnout scores was moderate at baseline (r=0.563, P<.001), indicating that depression and burnout symptoms occurred largely in the same participants. Furthermore, the participants whose BDI score indicated clinical depression at baseline had a higher baseline burnout score (P<.001), lower perceived work ability (P<.001), higher emotional eating score (P=.02), and higher binge eating tendency score (P<.001) than nondepressed participants (Table S5 in Multimedia Appendix 1). The participants whose BDI score indicated clinical burnout at baseline had a higher depression score (P<.001), lower perceived work ability (P<.001), and lower eating competence (P=.03) at baseline compared with those without burnout. The participants using psychotropic medication had higher baseline depression (P<.01), lower perceived work ability (P<.001), and higher binge eating tendency (P<.001) than nonmedication users.

Comparison of the Treatment Arms

To compare the impact of the 3 treatment arms concerning mental health, perceived work ability, and health behavior

XSL•FO

[a]Not applicable

In Table 1, the results for all participants are presented in the title row, while between-group results are reported in the "eHealth" rows. Concerning depression, we observed an overall time–group interaction (χ^2_4=17.99; *P*<.01), indicating that the treatment arms responded differently to the intervention (Table 1 and Figure 2). The significant differences between the groups were pinpointed between 0 and 6 months (χ^2_1=11.17; *P*<.01), and 6 and 12-month time points (χ^2_1=9.12; *P*=.01). Post hoc analysis comparing the 3 groups revealed that the eHealth+Individual yielded greater declines in the depression score compared with the eHealth (χ^2_1=6.73; *P*<.01; *d*=0.42) between 0- and 6-month time points. Between 6- and 12-month time points, the eHealth condition showed significantly greater decline in the depression score than the eHealth+ Individual condition (χ^2_1=8.87; *P*=<.01, *d*=0.14). The statistically significant time–group interaction was not observed between 0- and 12-month time points (χ^2_1=3.27; *P*=.20), suggesting an absence of a relevant intervention effect. The covariate model showed that the between-group interaction was attributed to 12-month weight change (χ^2_6=20.43; *P*<.01), baseline use of psychotropic medication (χ^2_6=70.04; *P*<.001) and 0 - 12 month changes in psychotropic medication use (χ^2=73.93; *P*<.001). In the full covariate model, the time-group interaction did not remain significant (χ^2_4=7.37; *P*=.12), suggesting that the observed changes were not attributable to differences between the intervention arms.

RenderX

Figure 2. Changes in depression symptoms between the eHealth, eHealth + Group and eHealth + Individual treatment arms during the 12-month intervention.

We also observed a statistically significant time–group interaction in burnout (χ^2_2=12.910; *P*=.04), pinpointed between the 0- and 6-month (χ^2_2=8.065; *P*=.02), and 6- and 12-month time points (χ^2_2=8.299; *P*=.02) (Table 1 and Figure 3). Between the 0- and 6-month time points, we observed no difference between the eHealth and the intervention arms. Between the 6- and 12-month time points, however, the eHealth+ Group treatment showed a greater decrease in burnout compared with the eHealth treatment (χ^2_1=4.611; *P*=.03*; d*=0.29). These differences were not statistically significant between 0- and 12-month (χ^2_2=0.73; *P*=.70*)* or 0- and 24-month time points (χ^2_2=3.60; *P*=.17*)*, indicating a lack of a meaningful intervention effect. Furthermore, the covariate model showed that the between-group interaction was driven by sex (χ^2_8=30.05; *P*<.001), baseline use of psychotropic medication (χ^2_8=80.35; *P*<.001) and 0 - 12 month changes in psychotropic medication use (χ^2_6=70.38; *P*<.001). The time-group interaction did not remain significant (χ^2_6=9.75; *P*=.14) when using the full covariate model, indicating that none of the observed changes were attributable to differences between the intervention arms.

Figure 3. Changes in burnout symptoms between the eHealth, eHealth+ Group and eHealth+ Individual treatment arms during the 12-month intervention and further 12-month follow-up without additional support.

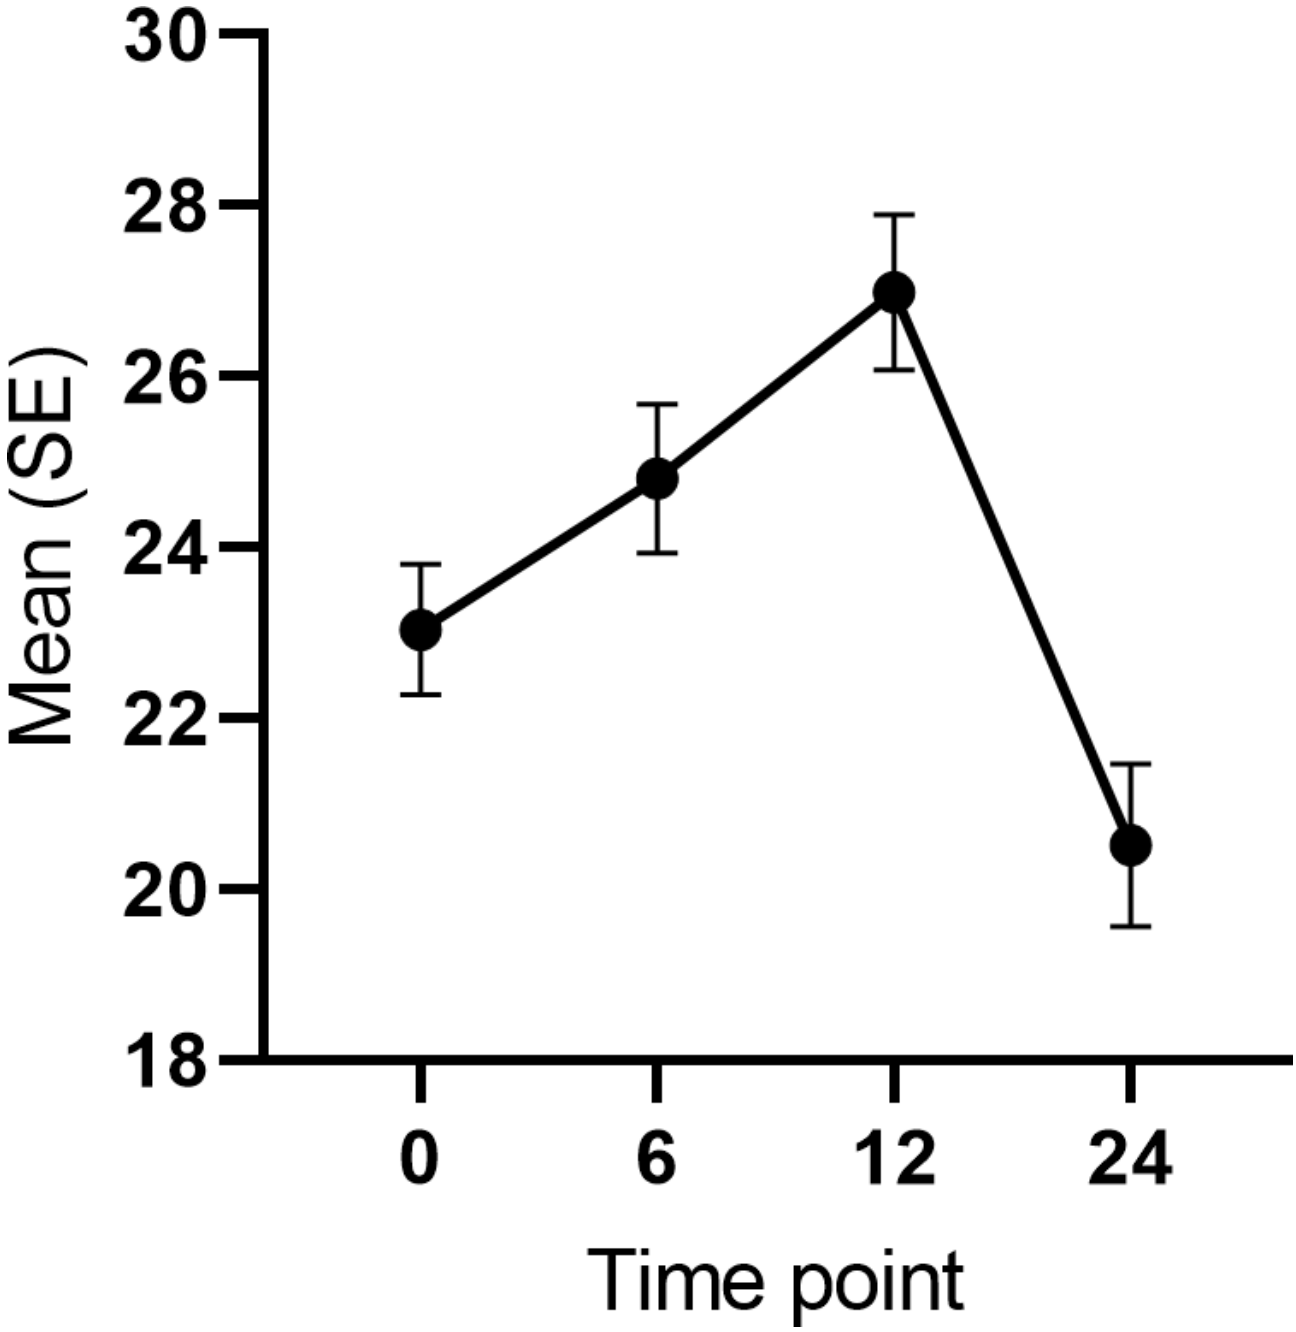
We did not observe significant time–group interactions in perceived work ability, eating behavior, or physical activity, indicating that the changes between the treatment arms did not differ over time (Table 1).

Overall Effects

To study the overall impact of the intervention, we combined the 3 treatment arms into a single eHealth arm for further analysis. Across all participants and time points, we observed an estimated mean decrease of 2.5 BDI points in depression

XSL•FO
RenderX

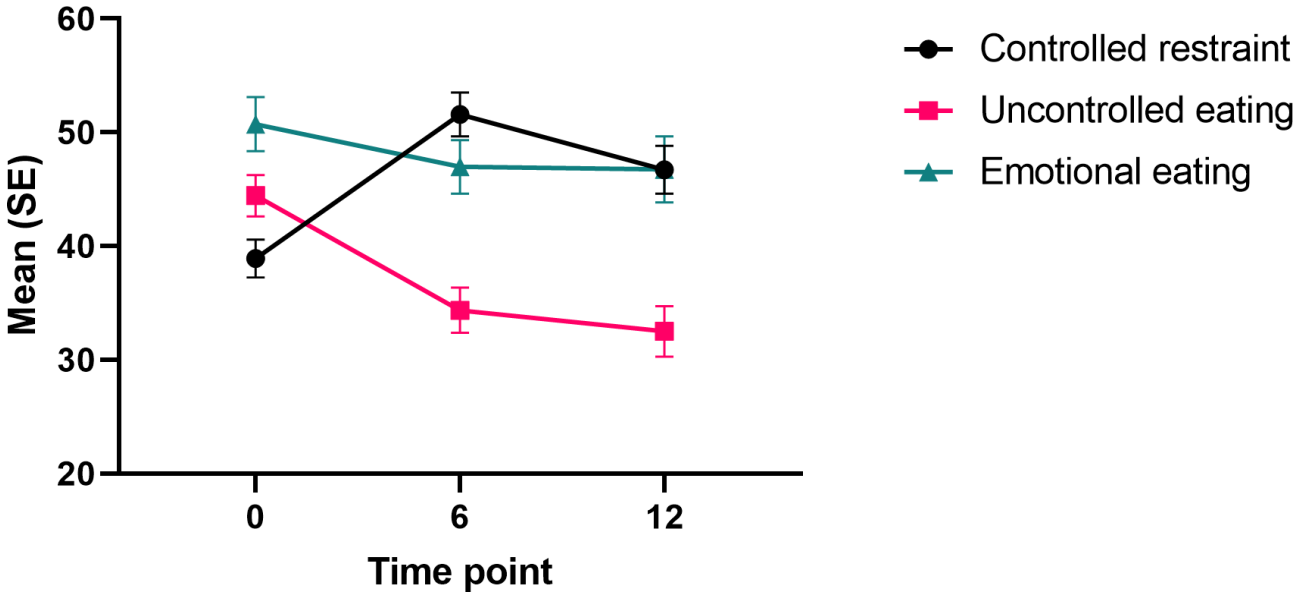
(χ^2_1=12.41; *P*<.01; *d*=0.38) (Table 1 and Figure 2). Covariate analysis revealed that older participants experienced a greater reduction in depressive symptoms (χ^2_2=8.74; *P*=.03). Notably, the main effect of time remained statistically significant in the full covariate model, controlling for age, and this significance was maintained when applying Full Information Maximum Likelihood estimation to correct for potential bias, both in the full model (*P*=.007) and age-controlled model (*P*=.02). Furthermore, we observed a statistically significant decrease in clinical depression incidence in the completer (*P*=.02) but not in the intention-to-treat analysis (*P*=.23; Tables S8a and S8b in Multimedia Appendix 1).



We found an increase in burnout symptoms between 0- and 6-month time points (χ^2_1=9.56; *P*<.01; *d*=−0.25), and a decrease between 6- and 12-month time points (χ^2_1=5.65; *P*=.02; Table 1). The results were attributed to changes in psychotropic medication at 0 - 12 months (χ^2_3=20.08; *P*<.001), as the main effect did not remain significant (χ^2_3=5.55; *P*=.14) in the covariate model. The increase in the burnout score was not reflected on the clinical burnout incidence between the 0- and 6-month time points (Tables S9a and S9b in Multimedia Appendix 1). Perceived work ability did not change over time (Table 1).

Furthermore, we observed an increase in eating competence (χ^2_3=72.788; *P*<.001), controlled restraint (χ^2_1=45.65; *P*<.001), and physical activity (χ^2_1=13.501; *P*=.001, and a decrease in uncontrolled eating (χ^2_1=50.34; *P*=.001) and binge eating tendency (χ^2_1=43.22; *P*<.001; Table 1) during the 12-month intervention. However, the 24-month follow-up measurements showed an adverse effect in eating competence, especially in attitudes toward eating and food, in the absence of continued support.

Specifically, eating competence increased between 0- and 6-month (χ^2_1=5.34; *P*=.02; *d*=0.23) and 0- and 12-month time points (χ^2_1=22.86; *P*<.001; *d*=0.53), and decreased between 0- and 24-month time points (χ^2_1=7.27; *P*<.01; *d*=−0.36; Figure 4). The subscale analysis revealed increases in Contextual skills at 0 - 6 months (χ^2_{11}=25.35; *P*<.001; *d*=0.52) and 0 - 12 months (χ^2_1=37.09; *P*<.001; *d*=0.69) and Food acceptance in 0 - 12 months (χ^2_1=37.61; *P*<.001; *d*=0.92), and a decrease in the Eating attitudes subscale at 0 - 24 months (χ^2_1= ; *P*<.001; *d*=−0.68; Figure 5). The change in eating competence was not explained by any of the controlled variables when using the full covariate model.

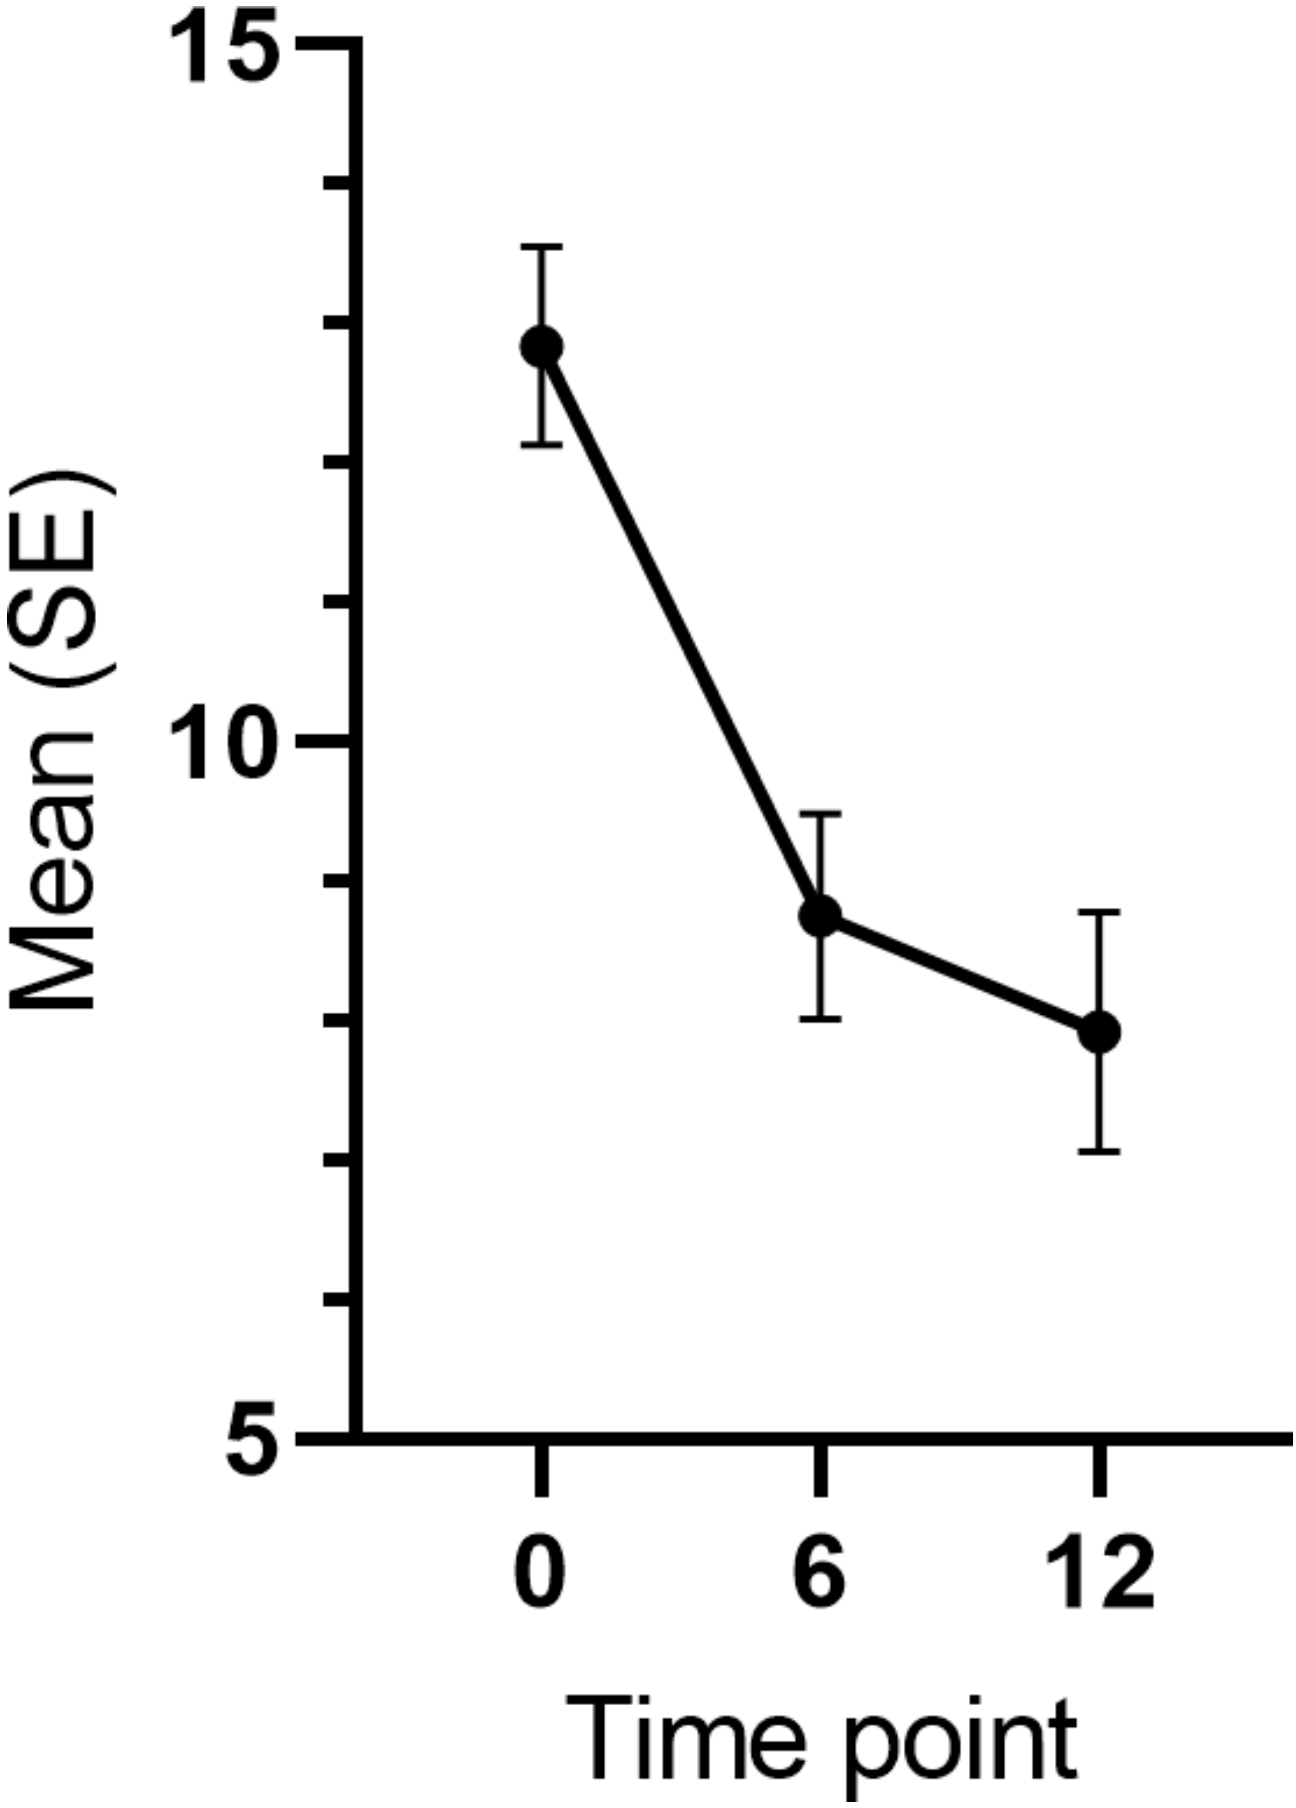


XSL•FO
RenderX

Figure 4. Changes in eating competence in all participants during the 12-month intervention and further 12-month follow-up without additional support.

XSL•FO
RenderX

Figure 5. Changes in controlled restraint, uncontrolled eating, and emotional eating in all participants during the 12-month intervention.



Uncontrolled eating decreased between the 0 - 6-month (χ^2_1=43.29; *P*<.001; *d*=0.54) and 0 - 12–month time points (χ^2_1=25.90; *P*<.001; *d*=0.67). The decrease in uncontrolled eating was explained by age (χ^2_2=7.97; *P*=.02) and 6-month weight change (χ^2_2=8.44; *P*=.02), with older participants and those who lost more weight showing greater reduction in uncontrolled eating (Table S7 in Multimedia Appendix 1). The main effect of time on uncontrolled eating did not remain significant (χ^2_2=2.69; *P*=.26) after controlling for age and weight change, indicating that the observed changes were attributed to these confounders.

Conversely, controlled restraint increased from baseline to 6 months (χ^2_1=44.87; *P*<.001; *d*=0.74) and to 12-months (χ^2_1=14.20; *P*<.001; *d*=0.40; Figure 5). Covariate analysis (Table S7 in Multimedia Appendix 1) revealed that the increase in controlled restraint was greater in the participants who lost more weight from baseline to 6 months (χ^2_2=15.92; *P*<.001) and to 12 months (χ^2_2=27.90; *P*<.001). The main effect of time on controlled restraint remained significant (χ^2_2=30.46; *P*<.001 and χ^2_2=30.64; *P*<.001, respectively) after controlling for changes in weight.

Binge eating tendency showed a steady decline, decreasing 4.9 BES-points during the intervention (0 - 6 month χ^2_1=31.51; *P*<.001; *d*=0.58 and 0 - 12 month χ^2_1=22.97; *P*<.001; *d*=0.67 Figure 6). The covariate analysis revealed that the participants who lost more weight from baseline to 6 months exhibited greater improvement in the binge eating tendency (χ^2_2=4.88; *P*=.03). The main effect of time remained significant in the full covariate model (χ^2_2=42.14; *P*<.001).

XSL•FO
RenderX

Figure 6. Changes in binge eating tendency during the 12-month intervention in all participants.

XSL•FO
RenderX

Physical activity (χ^2_1=13.51; *P*<.001; *d*=0.38), and the sports subscale (χ^2_1=18.54; *P*<.001; *d*=0.44) increased between 0- and 12-month time points. The change in physical activity was not explained by any of the controlled variables.

Discussion

Principal Findings

This study examined whether minimal group or individual enhancement would offer additional benefits to a 12-month eHealth weight maintenance intervention on mental health, perceived work ability, and health behavior. We observed the 3 intervention arms to change differently over time in terms of the depression and burnout scores. Nevertheless, post hoc analysis revealed that these changes were not consistent over the 12- and 24-month follow-up periods, indicating fluctuations rather than meaningful intervention effects. Furthermore, the different trajectories of the treatment arms were explained by baseline use and changes in psychotropic medication for both depression and burnout. In addition, 12-month weight change and sex contributed to the differences in depression and burnout, respectively. These results further indicated that the observed group-level differences were explained by factors other than the intervention.

In addition, we sought to explore the overall effects of an ACT-based weight management intervention on these domains. Across the entire study population, we observed statistically significant reductions in depressive symptoms and binge eating tendencies, along with improvements in eating competence and physical activity. Although the overall findings were quasi-experimental and must be interpreted cautiously, they collectively suggest that the standard HWC protocol may provide mental health and health behavioral benefits.

Comparison With Previous Work

While hybrid weight management interventions have shown superiority over digital interventions in somatic health, no relevant studies have reported their differences in mental health domains. In mental health interventions, personal guidance has been shown to enhance efficacy compared with unguided approaches [51]. Regarding health behavior, early findings suggest that personalized coaching leads to greater reductions in emotional eating than fully digital weight maintenance programs [52]. To our knowledge, no previous research has directly compared coach-assisted eHealth interventions with those supplemented by face-to-face contact. Given the low engagement levels of stand-alone digital applications, theoretical considerations suggest incorporating face-to-face elements to improve the efficacy and acceptability of interventions [30,53,54].

In our study design, each participant was supported by the same coach through written communication in the eHealth program, and during all face-to-face sessions in the enhanced arm. Therefore, we hypothesized that group or individual meetings would strengthen the therapeutic alliance [55] with the coach, leading to greater engagement with the program, increased exposure to therapeutic content, and, ultimately, improved outcomes.

Several factors may explain the absence of meaningful intergroup differences. One possibility is that the 3 sessions in the hybrid conditions were insufficient to create a meaningful distinction from the standard HWC intervention in relation to mental health variables, mirroring the findings of our previous paper on somatic health [31]. Increasing the number of sessions in the hybrid intervention might have led to more noticeable differences between the treatment arms. Alternatively, written coach assistance alone may provide sufficient support to participants, rendering face-to-face sessions unnecessary.

To our knowledge, no previous studies have examined the effects of an ACT-based eHealth weight loss intervention on depression. While our results with the overall sample are preliminary due to the quasi-experimental design, the small-to-medium effect size reduction in depressive symptoms across the entire sample is consistent with previous research demonstrating the effectiveness of ACT interventions for depression [56,57], including in the context of eHealth [58] and weight loss interventions [21]. Although our study included a general population that on average did not score within the range of clinical depression, the result might be meaningful from a population health perspective. Notably, among the completers, a reduction in the number of participants with clinical depression was observed. This effect was not evident in the intention-to-treat analysis, which may indicate the importance of retention in meaningful mental health improvements. Furthermore, while eHealth interventions targeting weight loss have been shown to effectively reduce depression symptoms in participants with obesity [59], our results show that the reduction in depressive symptoms was not explained by the amount of weight loss. This is supported by a meta-analysis by Fabricatore et al [60], which showed that nondiet interventions can significantly reduce depression symptoms in the absence of weight loss.

Contrary to expectations, we did not observe changes in burnout symptoms or perceived work ability between the baseline and postintervention assessments. Interestingly, burnout symptoms increased between the baseline and the 6-month time point, which contradicts previous research showing that ACT-based interventions can alleviate severe burnout [57,61]. Given the strong influence of workplace psychosocial factors on work ability [5], these findings suggest that interventions focused solely on individual change may be insufficient to impact occupational well-being. Future efforts might benefit from incorporating workplace-focused interventions along with individual treatments to enhance work ability more effectively.

Our results show positive changes in eating behavior, with medium-to-large effect sizes, and physical activity, with small to medium effect sizes. These results align with previous studies reporting positive effects of ACT-based interventions on eating behavior [62-65] and physical activity [65,66].

Overall eating competence improved during the intervention, particularly in the food acceptance and eating context subdomains, suggesting a more versatile, mindful, and planned approach to eating. Despite these improvements, eating

XSL•FO
RenderX

competence was not sustained at the follow-up, as indicated by a significant decline in the eating attitude subscore, which reflects positive emotions related to eating. This suggests that, following the end of the intervention, the participants became less relaxed and comfortable about eating. The weight-neutral approach may have initially promoted a more balanced attitude toward eating, but once the intervention ended, participants may have struggled to maintain this mindset independently. Considering that longer treatment durations are associated with more substantial improvements in dysregulated eating behaviors [64], providing continued support during the follow-up phase could help preserve any positive changes achieved during the intervention.

The binge eating tendency decreased with medium-to-large effect sizes, consistent with previous ACT research [64,65,67]. Unlike behavioral interventions that emphasize daily self-weighing, an approach that has not been shown to impact binge eating [68], our intervention integrated ACT and behavioral strategies without imposing external constraints, such as calorie restrictions or mandatory physical activity plans. This suggests that a more intuitive treatment approach might be more effective in reducing binge eating than focusing on weight loss. Furthermore, we observed an increase in controlled restraint, indicating that the participants' conscious efforts to restrict their food intake increased during the intervention. This finding contrasts with previous ACT-based weight loss interventions, which did not report significant increases in controlled restraint [65,67]. This result appears to contradict the "restraint theory," which suggests that higher controlled restraint may lead to higher levels of overeating and binge eating [69]. Nevertheless, this effect may differ in populations with obesity, where increased controlled restraint has been linked to a decreased binge eating tendency [70]. This discrepancy could also be attributed to the method used in this study. The 18-item version of the TFEQ used here does not distinguish between rigid and flexible cognitive restraint, with the latter being associated with successful weight management [71].

Strengths and Limitations

The strengths of this study include the use of an RCT setting to explore the differences between treatment arms. Furthermore, we used validated questionnaires with robust psychometric properties and a lengthy follow-up period of up to 24 months for some measures, providing a comprehensive view of the long-term effects.

Despite these strengths, there are several limitations to consider. First, the requirement for internet access and the predominantly female, middle-aged, and "white-collar" sample limits generalizability to other populations. Although we controlled for sex and age using them in stratification and including them as covariates in our analyses, these characteristics are still likely to influence the outcomes. Second, the analysis could have been underpowered, as we used prospective weight change rather than mental health outcomes to calculate the statistical power, which may have led to biases in the observed effect sizes. Third, the substantial amount of missing data due to attrition and inactivity may have affected the reliability of the questionnaires used in this study. To mitigate potential bias from missing data, we used a statistical method with an intention-to-treat approach and applied the necessary statistical corrections. Fourth, although the between-group analysis was conducted in an RCT setting, the overall analysis relied on a quasi-experimental design. We were therefore unable to fully evaluate the individual intervention effect without a control group for comparison, making the overall results sensitive to bias.

Finally, the timing of the intervention during the COVID-19 pandemic may have substantially affected the results. The pandemic's social restrictions, along with the increase in remote work, could have exacerbated the symptoms of burnout and disordered eating, as well as reduced physical activity levels. These factors may have confounded the observed effects of the intervention. In addition, the need to adapt the intervention to a remote format, which had originally been planned for in-person support groups, may have further affected the effectiveness of the support provided.

Conclusions

Minimal enhancement through either group or individual video-conference meetings did not provide additional benefits in the mental health or eating habit domains compared with the eHealth intervention alone. Across the entire study population, we observed positive changes in depressive symptoms, binge eating tendencies, eating competence, and physical activity during the intervention. Future research should continue to explore the differences between hybrid and digital interventions on mental health domains, distinguishing for delivery mode and contact frequency, as well as the impact of continued support for the maintenance of positive outcomes.

Acknowledgments

The authors sincerely thank all involved parties at HealthyWeightHub and Occupational Health Helsinki for their significant contributions to the intervention and related research. We are especially grateful to the parties funding the study: Finnish Work Environment Fund and Helsinki City (grant 200379); Juho Vainio Foundation (grant 202400066); Academy of Finland (grants 335443, 314383, and 266286); the Academy of Finland, Centre of Excellence in Research on Mitochondria, Metabolism and Disease (FinMIT; grant 272376); Finnish Medical Foundation; Gyllenberg Foundation; Novo Nordisk Foundation (grants NNF20OC0060547, NNF17OC0027232, and NNF10OC1013354); Finnish Diabetes Research Foundation; Paulo Foundation; Occupational Health Helsinki, City of Helsinki, University of Helsinki and Helsinki University Hospital; and government research funds. Abstract

Background: Line managers play a key role in preventing poor mental health but often lack necessary skills and knowledge. Existing interventions typically focus on mental health awareness rather than practical skills. The evidence-based Managing Minds at Work (MMW) web-based training program was developed to address this gap by enhancing line managers' confidence and competence in prevention.

Objective: This study piloted the MMW intervention to assess its feasibility. Objectives included evaluating (1) uptake potential across small, medium, and large companies; (2) perceived suitability and effectiveness of the intervention; and (3) feasibility of outcome data collection methods.

Methods: We conducted a 2-arm pilot cluster randomized controlled trial of a self-guided, web-based training intervention for line managers. Twenty-four organizations were randomly assigned to the MMW intervention or a 3-month waitlist. A total of 224 line managers completed baseline measures (intervention: n=141, 62.9%; control: n=83, 37.1%), along with 112 of their direct reports (intervention: n=74, 66.1%; control: n=38, 33.9%). Follow-up data were collected at 3 and 6 months. Semistructured interviews with line managers and stakeholders (n=20) explored experiences with the study and intervention, and qualitative data were analyzed thematically. Line managers also completed feedback forms after each of the 5 MMW modules.

Results: The recruitment of organizations and line managers exceeded targets, and retention rates of line managers were good at 3 months (161/224, 71.9%) but not at the 6-month follow-up (55/224, 24.6%). Feedback on the intervention was very positive, indicating that line managers and organizational stakeholders found the intervention acceptable, usable, and useful. We observed significant improvements with moderate to large effect sizes for all trial outcomes for line managers in the intervention arm from baseline to the 3-month follow-up. Line managers completed a variety of questionnaires, which showed increased scores for

XSL•FO
RenderX

confidence in creating a mentally healthy workplace (intervention group: mean change 3.8, SD 3.2; control group: mean change 0.6, SD 3.2), mental health knowledge (intervention group: mean change 1.9, SD 3.0; control group: mean change 0.2, SD 2.9), psychological well-being (intervention group: mean change 3.6, SD 8.3; control group: mean change −0.7, SD 7.7), and mental health literacy at work (intervention group: mean change 11.8, SD 8.9; control group: mean change 0.8, SD 6.2). Collecting data from direct reports in both study arms was challenging, with results inconclusive regarding observed changes in trial outcomes. Time constraints and workload were commonly cited barriers to completion of the intervention.

Conclusions: This pilot feasibility trial provides strong evidence for the usability and acceptability of the MMW digital training and the research design. MMW shows potential to improve line managers' confidence and competencies in promoting mental health. The study also identified key considerations for future large-scale implementation and evaluation.

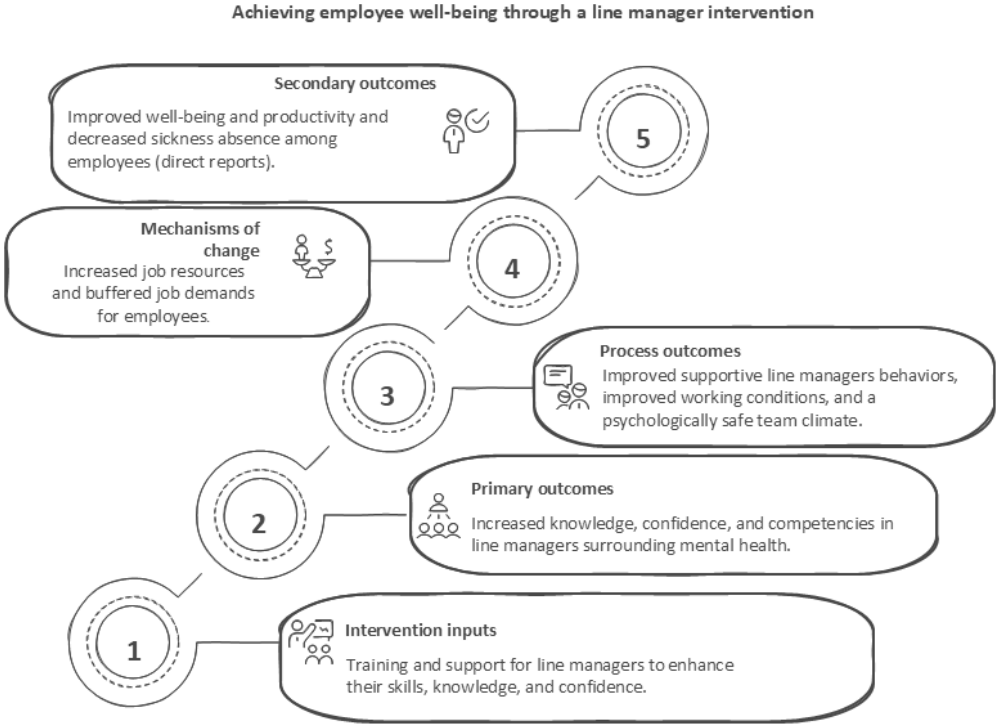
Introduction

Background

It is estimated that 15% of the global working-age population have a mental health condition [1]. This has been exacerbated by the COVID-19 pandemic, which led to a rise in mental ill-health among working-age adults [2,3]. In the United Kingdom, approximately 7.9% of sickness absence was due to mental health conditions [4], and more than half of all working days (approximately 17 million) were lost due to depression, anxiety, and work-related stress in 2021 to 2022 [3]. The human and economic costs of poor mental health at work are profound, impacting both employers and society at large [5,6]. It is estimated that poor mental health across the UK workforce is costing employers £51 billion (US $68.4 billion) per annum [7]. Despite these costs, many employers lack awareness of their responsibility to support the mental health of their employees [2], with many lacking provisions or policies to promote employee psychological well-being [8].



Workplace mental health interventions are typically categorized as primary (taking action to eliminate the sources of stress or poor mental health in the workplace), secondary (detection and management of experienced stress and poor mental health by increasing awareness, knowledge, skills, and coping resources), or tertiary (minimizing the effects of poor mental health at work once they have occurred through treatment of symptoms). Best practice advocates for a holistic approach integrating all 3 levels of intervention, targeting both workplace- and worker-directed strategies [9,10]. In particular, primary prevention is crucial to maximize employee health and productivity [8,10] and is clearly emphasized in national (eg, from Canada [11], Australia [12], and the United Kingdom [13]) and international (eg, International Organization for Standardization standard 45003 [14], the International Labour Organization [15], and the World Health Organization [1]) standards on promoting mental health at work and preventing work-related stress. The need for and use of prevention-oriented approaches is strongly emphasized across these national and international standards, with reference to the central and ongoing role played by line managers throughout this process.

The role that line managers play in preventing work-related stress and promoting better mental health at work includes designing and managing work tasks, communicating with employees respectfully and clearly, fostering psychologically safe and supportive team environments, and encouraging open dialogue about mental well-being [16-21]. These responsibilities are central to a primary prevention approach, which targets work-related stressors before they result in harm. Drawing on the job demands–resources (JD-R) model [22], job demands refer to aspects of a job that require sustained physical or psychological effort (such as workload, time pressure, and emotional demands), whereas job resources refer to elements that help achieve work goals, reduce demands, or stimulate growth and development (such as role clarity, supervisory support, and autonomy).

The intervention program theory, developed during the earlier Medical Research Council guided intervention development phase [23], outlines how the Managing Minds at Work (MMW) training is expected to enhance these job resources by improving line manager knowledge, confidence, and behavioral competencies (*primary outcomes*). These improvements are theorized to lead to more supportive, clear, and psychologically safe management practices (*process outcomes*), which in turn help buffer the impact of job demands and create more favorable psychosocial work environments. Ultimately, these mechanisms are hypothesized to improve employee well-being, perceptions of managerial competency, and productivity and reduce sickness absence behaviors (*secondary outcomes*). These pathways are visually represented in the conceptual model in Figure 1, which maps the theorized links between intervention components and outcomes at the individual and organizational levels.

XSL•FO
RenderX

Figure 1. Conceptual framework linking the line manager (LM) intervention to mental health and well-being outcomes.

Before the COVID-19 pandemic, approximately half of line managers had not been offered the necessary training to support them in these managerial duties and responsibilities [24,25]. However, recent figures indicate an upward trend of enterprises now offering mental health training for line managers as part of their well-being practices [26], with growing evidence of their impact on managers' behaviors and well-being [27] and organizational outcomes [26,28-30]. This underscores the need for evidence-based line manager training interventions focused on developing their knowledge, confidence, and behavioral competencies to prevent work-related stress and promote mental health at work.

Recent evidence and systematic reviews have highlighted a lack of robust evaluations of managerial or leadership training to improve employee well-being [10,31-33]. There is a limited number of line manager–targeted intervention studies using trial methodology in the literature [32,34-40]. There are 2 notable gaps in this existing evidence base. First, only 4 of the line manager–targeted intervention studies include a broad prevention-oriented approach [32,36,39,40], only 3 of which are cluster randomized controlled trials (RCTs) [32,36,40]. Therefore, there is a need to develop and rigorously test a line manager training intervention underpinned by primary prevention. Second, most existing training interventions are delivered face-to-face rather than using a digital or hybrid (face-to-face and digital) delivery method except for those reported in 4 studies [32,36,39,40]. Digital interventions are increasingly being used within applied contexts (eg, workplaces [41]) due to their time- and resource-efficient nature [42-44]. However, little is known about their usability and acceptability to line manager recipients or indirect impact on those they manage (their direct reports), in particular for those digital interventions targeting knowledge and behavior change. The MMW digital training intervention seeks to address this evidence gap.

This study addresses key gaps in the existing literature by developing and testing a digital line manager training intervention explicitly grounded in primary prevention and informed theoretically by the JD-R model [22]. It contributes to the limited number of rigorously designed trials evaluating line manager training for mental health by using a cluster randomized controlled design, following the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) guidelines [45], and ensuring transparency through trial preregistration (December 8, 2021) and protocol publication [46]. In doing so, this study strengthens methodological rigor in this area; supports standardization of intervention approaches; and generates insights into the feasibility, acceptability, and potential impact of digitally delivered line manager training. The findings will inform the design of a future definitive trial and help guide evidence-based workplace mental health strategies.

Objectives

This study aimed to pilot and test the feasibility of a future definitive cluster RCT of the MMW digital training intervention [46].

The overarching objectives were to assess (1) the potential for uptake within small, medium, and large companies; (2) the perceived suitability and effectiveness of the line manager training; and (3) the feasibility of the data collection methods for primary and secondary outcome measures.

Table 1 provides an overview of the pilot feasibility trial objectives and the data sources used to investigate them.

XSL•FO
RenderX

Table 1. Overview of trial objectives and mapped data sources used to explore them.

Feasibility trial objectives	Data source and data collection method	Criterion
The potential for uptake within small, medium, and large companies by identifying and monitoring several aspects (objective 1)		
Willingness of employers to register interest in participating in the trial and allow LMs[a] to take part in the trial (objective 1.1)	End-of-study records used to examine the percentage of organizations converted from expressed interest to recruitment to the study	Minimum of 8 organizations (4 in each arm)
Recruitment and retention rates of LMs in the trial (objective 1.2)	End-of-study records of percentage of eligible LMs who consented and percentage of consenting LMs who completed the 3- and 6-mo follow-ups	70% retention rate from baseline to follow-up assessments
Recruitment and retention of LMs' DRs[b] (objective 1.3)	Study records of percentage of consenting DRs who completed the 3- and 6-mo follow-ups	50% retention rate from baseline to follow-up assessments
The perceived suitability and effectiveness of the LM training by determining several aspects (objective 2)		
Acceptability, usability, and utility of the training among LMs and stakeholders within the participating organizations (objective 2.1)	Qualitative data from stakeholder postintervention interviews and qualitative feedback provided by LMs after each training module	—[c]
Potential for improving LMs' confidence (primary outcome) and knowledge, managerial behavioral competencies, and psychological well-being (secondary outcomes) to inform the planning of a larger trial (objective 2.2)	Web-based survey at baseline, completion of the intervention (intervention arm only), and 3 and 6 mo after baseline using psychometrically validated measures (see the Primary and Secondary Outcomes section)	Change in mean score over time in the intervention group as compared to the waitlist control arm
Potential for improving employee outcomes (DRs' well-being, absence, and productivity) and their perceptions of their LMs' managerial competencies by assessing changes to inform the planning of a larger trial (objective 2.3)	Web-based survey at baseline, completion of the intervention (intervention arm only), and 3 and 6 months after baseline on DRs' well-being, productivity, and perceptions of their LMs' managerial behavioral competencies using psychometrically validated measures; sick absence information was collected through organizational records	Change in mean score over time in the DRs managed by LMs in the intervention group as compared to that among the DRs in the waitlist control arm
Barriers to and facilitators of intervention implementation and effectiveness to inform the delivery of the intervention for the full trial (objective 2.4)	Qualitative postintervention data from interviews with stakeholders and qualitative feedback completed by LMs after each training module	—
The data collection methods for primary and secondary outcome measures to inform key parameters for a larger trial related to sample size and clustering (objective 3)	End-of-study qualitative data and researcher reflections to examine the willingness to allow access to organizational-level data on sickness absence	—

[a]LM: line manager.

[b]DR: direct report.

[c]No criterion specified, as thresholds were only set for quantitative outcomes to assess feasibility metrics such as recruitment and retention. For qualitative objectives, the focus was on generating rich, contextual insights into acceptability, usability, and implementation (objective 2), where predefined thresholds are not appropriate or meaningful.

Methods

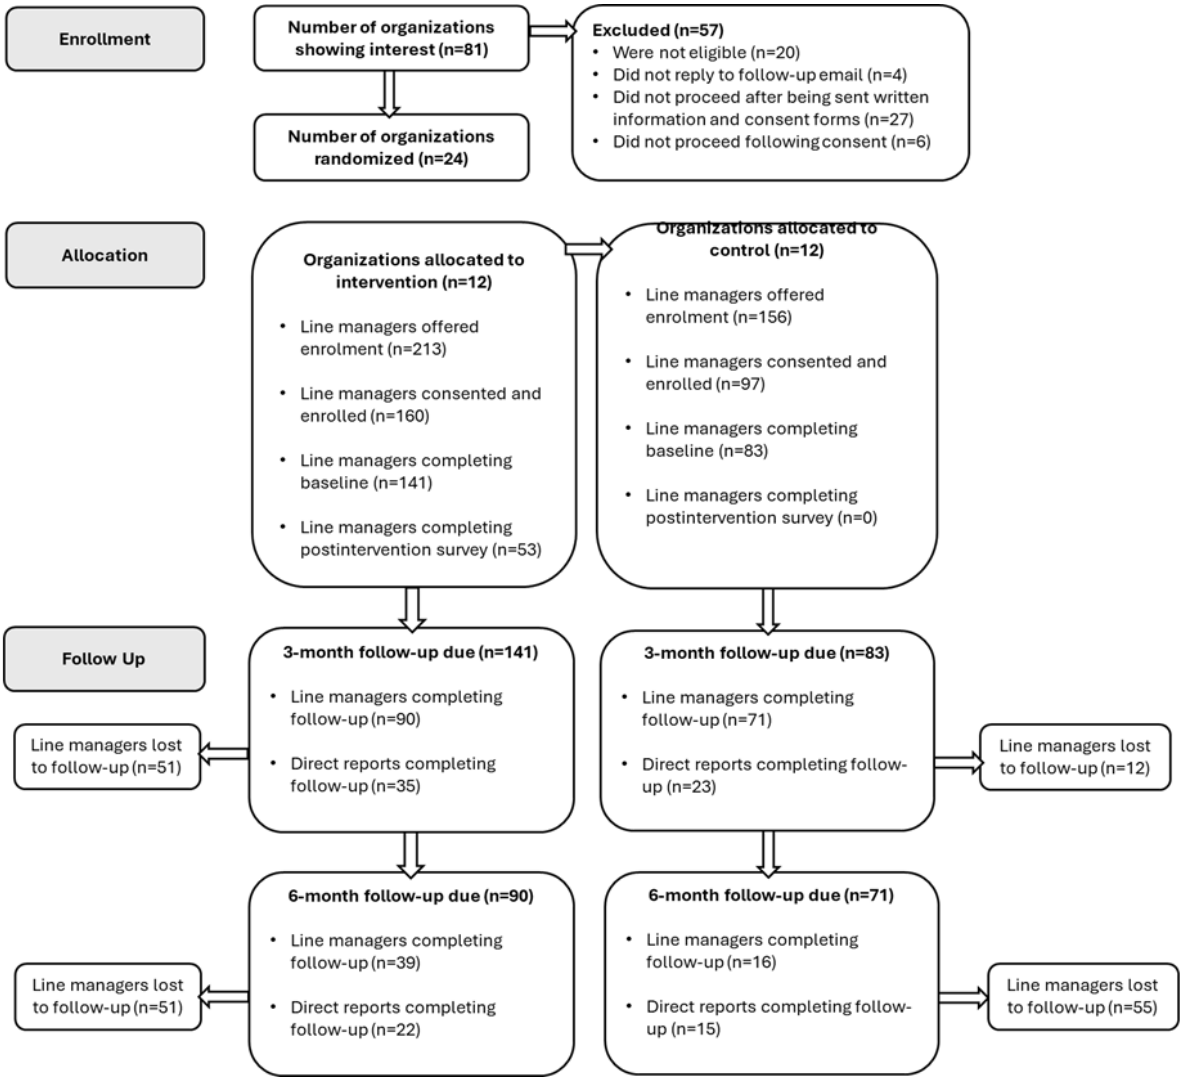
This study adhered to the CONSORT-EHEALTH guidelines [45] for pilot and feasibility trials and a focus on both implementation and outcome feasibility (Multimedia Appendix 1).

Ethical Considerations

Ethics approval was granted by the University of Nottingham's Faculty of Medicine and Health Sciences ethics committee (reference 299-0621, with an amendment approved on June 6, 2022). Written informed consent was obtained from all individual participants before participation, and organizational consent was secured from all participating companies before onboarding. Participant data were handled in accordance with data protection guidelines. All responses were anonymized, securely stored on encrypted drives common accessible only to the research team. No financial or material compensation was provided to participants or organizations for their involvement in the study.

Design

MMW was evaluated using a multisite, 2-armed pilot and feasibility cluster RCT with an embedded qualitative study in organizations of different sizes and sectors in England [46]. The organizations (the clusters) were the specified units of randomization, and the line managers were the participants. Follow-up assessments from baseline were completed 3 and 6 months later. While pilot feasibility studies typically use shorter follow-up periods [23], we included both 3- and 6-month follow-up assessments to explore longer-term outcomes and acceptability. This extended follow-up was made possible due to additional project funding and was formally documented as a change in the trial registration and published study protocol [46].



XSL•FO
RenderX

Initially, a postintervention follow-up for the intervention arm was planned to be completed at the end of the intervention and estimated to be approximately 6 weeks after baseline. However, due to variation in the length of time taken to complete the intervention, for many participants, the 6-week postintervention follow-up was very close to the 3-month follow-up. Although we did not formally track completion of each module through the platform hosting MMW, optional end-of-module feedback forms allowed for an informal mechanism to monitor progress. These forms indicated some variation in the length of time taken to complete the intervention. To prevent participant burden and maintain a standardized 3-month follow-up across both arms, the 6-week postintervention follow-up was removed from the schedule. Those in the waitlist condition completed the 3-month follow-up assessment before gaining access to the intervention. Similarly, employees that the line managers managed (their direct reports) were assessed at baseline and 3 and 6 months later. Blinding was not applied in this study for pragmatic reasons (eg, the need to send reminder emails for intervention completion by the research team). Both the participants and organizations were aware of the condition to which they were assigned. The trial ended when the last participant had completed follow-up data collection.

Recruitment

Organizations were recruited into the study via study websites, newsletters, and social media posts, and formal consent from organizational representatives was obtained. Line managers within each of the consenting organizations were contacted directly by the research team to invite them to participate in the study. Inclusion criteria for line managers were that they must be aged ≥18 years, have responsibility as a manager or supervisor, and have access to a work computer or mobile phone and an email address. Exclusion criteria for line managers were being due to retire or be made redundant in the following 6 months or having completed training on mental health at work in the previous 6 months. As this was a pilot feasibility trial, we aimed to recruit a minimum of 8 clusters (randomized into 2 groups of 4) and 30 line managers per arm to inform the parameters for a possible future trial. We exceeded these targets, recruiting 24 organizations and enrolling 141 line managers in the intervention arm and 83 in the control arm. A detailed overview of participant flow is provided in Figure 2.

Figure 2. Participant flow diagram.

XSL•FO
RenderX

Intervention

The intervention is reported in line with the Template for Intervention Description and Replication checklist [47] (Multimedia Appendix 2) and the published protocol [46]. MMW was developed using a collaborative participatory design process over a period of 6 months from February 2021 to July 2021 [48]. It is a self-guided, stand-alone, web-based training intervention that asks recipients to work through 5 training modules. Table 2 provides a summary of MMW module content and empirical grounding. The study by Blake et al [48] provides further details on the module development process, content, and empirical grounding.

Table 2. Overview of the Managing Minds at Work training modules and theoretical foundations.

Module number and title	Summary description	Theoretical basis or empirical grounding
Introduction	Introduces the concept of mental well-being at work, the business case for focusing on mental health, and the legal responsibilities of line managers	Legal and organizational frameworks and introductory grounding for subsequent modules
Module 1: "Looking After Your Own Mental Health"	Focuses on self-care strategies for line managers, such as movement, flexible working, gratitude, and self-compassion	Self-care theory, reflective practice, and stress management literature
Module 2: "Designing and Managing Work to Promote Mental Well-being"	Covers the HSE's[a] Management Standards (demands, control, support, relationships, role, and change) on how to address and manage these work stressors through job design and management practices	HSE [49] Management Standards for work-related stress, primary prevention, and job design theory
Module 3: "Management Competencies that Prevent Work-related Stress"	Focuses on 4 key managerial competencies: respectful and responsible behavior, communication and workload management, handling difficult situations, and managing individuals	Management competencies for preventing work-related stress [50-52] and leadership and stress prevention literature
Module 4: "Developing a Psychologically Safe Working Environment"	Explores psychological safety, trust, inclusion, positive team relations, and peer support using interactive activities	Psychological safety theory [53] and team climate and inclusion literature
Module 5: "Having Conversations About Mental Health at Work"	Teaches communication skills to initiate, maintain, and respond in conversations about mental health with staff	Supportive communication models, mental health conversation frameworks, supporting openness about mental health, and behavior change theory

[a]HSE: Health and Safety Executive.

The web application used to host the MMW digital training (Xerte software; The Xerte Project [54]) was fully automated and did not provide the user with any contact with a therapist or coach. The training was hosted using the Xerte Online Toolkits platform (version 3.10; Apereo Foundation; accessed February 2022), a free, open-source tool designed for interactive content creation. Each module included written content but also interactive (eg, quizzes to test their knowledge) and reflective (eg, case studies) exercises to support learning. We did not include film and audio recordings as part of the training package due to budgetary restrictions. Module content was shaped by stakeholder feedback [48] and was designed to take 20 to 30 minutes to complete. Users were encouraged to complete 1 module per week (estimated intervention completion time: 5 to 6 weeks) and in the specified chronological order. The participating organizations agreed to allow line managers to complete this training during their working hours.

Once the baseline survey was completed, line managers in the intervention arm were provided with a username and log-in details for the training materials by a member of the research team. Line managers were asked to complete an end-of-module feedback form. These forms provided a proxy record of module completion by users as the software used did not allow for this functionality, and their completion was voluntary. These forms included closed (*yes* or *no* and Likert scales) items, as well open-ended questions to explore participants' views on the module's relevance, utility, acceptability, and content clarity.

During the intervention completion stage, the research team sent email reminders to encourage and remind line managers to work through the modules. A reminder email was sent once every 2 weeks. A maximum of 2 reminder emails were sent to participants.

Randomization

The onboarded organizations were randomly assigned to either the intervention (the MMW digital training) or 3-month waitlist condition using an online random number generator [55]. This allocation was stratified to ensure a spread of different organization sizes within the intervention and control arms. Each organization was allocated a number, and 50% of the numbers generated were assigned to the intervention group, with the remaining 50% assigned to the waitlist control group.

Procedure for Data Collection

Participants provided electronic informed consent by actively selecting a checkbox on the web-based survey platform before proceeding to the baseline assessment. Follow-up meetings were conducted with key organizational contacts to address any questions and confirm participation. In all cases, formal consent was obtained from senior management, indicating organizational-level support for the study. As part of this onboarding procedure, organizations agreed to provide time and support for the line managers in completing the training but were not informed of which line managers chose to participate in the study.

XSL•FO
RenderX

Once consent was obtained by the employing organizations, they were asked to provide a list of line managers with contact details. Once this list was received, a member of the research team contacted the line managers directly to invite them to participate in the study. The onboarded line managers received a link to the line manager baseline survey, the participant information sheet, and the consent form via their preferred email address.

To maximize engagement with the MMW digital training intervention, line managers were given flexibility as to when they completed the baseline survey and started the training intervention. Therefore, opening and closing dates varied across organizations (opening date: October 13, 2021; closing date: March 31, 2022). Onboarded line managers supported the study's recruitment of direct reports by sending them an email with information about the study and a link to the baseline survey. These communications were drafted by the research team. However, to ensure confidentiality, the line managers were not informed of which direct reports opted into the study. No incentives were offered to direct reports due to budgetary constraints. Nevertheless, line managers and participating organizations agreed to support the study by allowing both direct reports and line managers time during their working day to complete the study materials if they wished. All feedback mechanisms provided direct report findings aggregated across the study, not by organization.

Both line managers and their direct reports across experimental conditions were sent a follow-up survey 3 months (closed on June 22, 2022) and 6 months (closed on October 7, 2022) following the completion of their baseline measure using their preferred email address as indicated on their completed consent form. In the control arm, line managers were asked to complete the 3-month measurement before they were given access to the intervention. The completed surveys were linked using the participants' assigned username (eg, managingminds1, managingminds2, and so on) for the web application. All log-in details for users were unique and were not connected to their name or work site but, rather, to their preferred email address as provided on the consent form. Most participants chose their work-connected email addresses. The study participants were informed about the security of the web-based application and how their provided data would be securely stored and managed. Information provided as part of the interactive exercises on the platform was not held or stored.

Following the completion of the 6-month survey, a member of the research team contacted the participating organizations to see whether they were willing to share their sickness absence data for direct reports associated with the line managers in the trial. Line managers in the intervention arm and organizational stakeholders in both arms were invited to take part in semistructured interviews to gather qualitative data on their experience of the intervention and its acceptability, usability, and utility. The interviews were conducted using Teams (Microsoft), recorded, and transcribed verbatim.

Feasibility Outcomes

Table 1 shows the data sources and methods used to address each of the feasibility objectives (objectives 1.1, 1.2, 1.3, 2.1, and 2.4). In summary, end-of-study records were used to assess recruitment of organizations into the trial (objective 1.1), recruitment and retention rates for line managers (objective 1.2), and recruitment and retention rates for direct reports (objective 1.3). The acceptability, usability, and utility of the MMW web-based training intervention among line managers and stakeholders (objective 2.1) and barriers to and facilitators of implementation of the intervention (objective 2.4) were assessed through qualitative interviews and web-based feedback forms completed at the end of each of the 5 MMW modules.

Primary and Secondary Outcomes

To assess objectives 2.2 and 2.3 (Table 1), we measured a series of outcomes for both line managers and direct reports to examine the potential effectiveness of MMW to inform the design of a full trial. Improvement in line manager outcomes (objective 2.2) was assessed by measuring their confidence to foster a healthy workplace, mental health knowledge and literacy at work, psychological well-being, and self-rated management competencies to prevent work-related stress. Improvement in direct report outcomes (objective 2.3) was assessed by measuring their psychological well-being, self-rated productivity, perceptions of their line managers' management practices and behaviors, and sickness absence. Table 3 provides an overview of the study measures.

[a]WEMWBS: Warwick-Edinburgh Mental Well-Being Scale.

Confidence in managing mental health issues and promoting a mentally healthy workplace was measured using a previously published supervisor scale [60] later modified by Gayed et al [56]. This is a 6-item measure describing various workplace scenarios such as "creating a work environment that prevents and reduces stress within my team." Line managers were asked to rate their confidence in dealing with each of these scenarios on a 5-point Likert scale ranging from *not at all* to *extremely confident*. This measure has a minimum score of 6 and a maximum score of 30, with higher scores indicating increased confidence in creating a mentally healthy workplace. This measure has demonstrated good psychometric properties previously and been validated against manager behavior [61]. The Cronbach α was 0.84 at baseline.

Mental health knowledge was measured using the Mental Health Knowledge Schedule [57], a 6-item questionnaire rated on a Likert scale from 1 to 6 (1=*strongly disagree*; 5=*strongly agree*; 6=*I don't know*). In line with scale guidance, responses of *I don't know* (6) were recoded to *neutral* (3). The sixth item was reverse coded before creating a composite score. Higher composite scores were suggestive of better mental health knowledge (scale range 6-36) The 6 key areas explored by the scale include help seeking, recognition, support, employment, treatment, and recovery. The reliability of this scale was weak in our line manager sample at baseline (Cronbach α=0.40).

The Mental Health Literacy Tool for the Workplace [58] is a 16-item measure using vignettes tailored for the workplace context completed by line managers. This measure consists of vignettes about various mental ill-health scenarios within the workplace, with parallel questions that explore each of the 4 dimensions of mental health literacy. Items are ranked on a 5-point Likert scale ranging from *very low* to *very high*. A higher composite score indicates higher levels of workplace mental health literacy (scale range 16-80). Previous research has found good psychometric properties for this scale [62]. Our baseline sample showed a good internal consistency for this measure (Cronbach α=0.90).

The Warwick-Edinburgh Mental Well-Being Scale is a 14-item measure that seeks to quantify psychological well-being [59]. This measure was completed by both line managers and their direct reports. It asks participants to rank their psychoemotive experience in the previous 2 weeks across a series of statements (eg, "I have been feeling useful") using a 5-point Likert scale ranging from *none* to *all of the time*. Items are summed to obtain a total score (score range 14-70). Higher scores are indicative of better overall psychological well-being. Strong psychometric properties have been found for this scale using community-based samples (eg, Cronbach α=0.91 [59] and Cronbach α=0.93 [59]). At baseline, in both our line manager and direct report samples, strong internal consistency was observed (line manager Cronbach α=0.92; direct report Cronbach α=0.90).

Management competencies for work-related stress were measured among both line managers and their direct reports. The Stress Management Competency Indicator Tool (SMCIT [50-52]) aimed to explore the behavioral competencies of line managers surrounding the prevention and management of work-related stress. The SMCIT has 2 versions, one for line managers to complete to rate their own competencies and an employee (direct report) version. The items are mirrored in both variants, with phrasing altered to suit the target audience (eg, "When necessary, I stop additional work being taken on by my team" [manager version] and "My manager will, when necessary, stop additional work being passed on to me" [employee version]). The SMCIT is measured on a 5-point Likert scale ranging from 1 (*strongly disagree*) to 5 (*strongly agree*) and consists of 66 items. This measure explores 4 key competency areas: managing emotions and having integrity (17 items, scale range 17-85), managing and communicating existing

XSL•FO
RenderX

and future work (22 items, scale range 11-110), managing the individual within the team (15 items, scale range 15-75), and reasoning and managing difficult situations (12 items, scale range 12-60). Items in each subscale are summed to create a composite score for each subcompetency, with higher scores indicating better management competencies. Previous research has found satisfactory internal consistency (Cronbach α>0.7) for both line managers [63] and employees [64]. All our Cronbach α values were >0.7 in both our line manager and direct report groups.

Direct reports were asked to complete a single item on their self-reported productivity: "To what degree do you agree with the following statement? In the past week, I have been working under my average productivity," anchored using a 5-point Likert scale ranging from *not at all* to *completely*. Lower scores represent better self-rated productivity by direct reports.

Analytical Methods

SPSS (version 28; IBM Corp) [65] was used to conduct statistical analysis with collected quantitative data to address objectives 2.2 and 2.3. The significance level was set at P<.05. Missing data were inspected before data analysis to ensure that they were missing completely at random and individual cases did not have an excess of 5% of missing data [66]. Where missing data were identified and observed to be missing completely and not >5% per case, an imputation method was applied.

Descriptive statistics were calculated for each outcome measure with 95% CIs. Mean values were calculated at the participant (for line manager and direct report data; grand mean) and organizational (for line manager data only; group mean) levels. As this was a pilot feasibility trial, we did not use multilevel modeling. However, the intraclass correlation coefficient (ICC(1)) was calculated to examine the variability between clusters (organizations) to inform a future trial on the influence of these clusters on observed treatment effects.

Although our original protocol specified descriptive statistics only [23], we extended our analysis to include exploratory inferential statistics to examine preliminary group differences. This decision was justified by the fact that we substantially exceeded our initial recruitment target, enrolling 24 organizations and >220 line managers supported by additional project funding. While inferential statistics are not typically used in feasibility studies, the increased sample size enhanced our ability to detect preliminary trends and estimate effect sizes to inform future power calculations [67]. The purpose of these analyses was not hypothesis testing but rather to explore potential signs of change between arms and inform the design of a future definitive trial. We acknowledge this as a deviation from the original statistical analysis plan and recommend that future feasibility studies prespecify such analytic flexibility where appropriate.

We quantified and tested change over time across our experiential conditions, creating a new study variable for each outcome measure (line manager and direct report). This new variable was calculated by subtracting the participants' mean score at the 3-month follow-up from their baseline measure. We did not use the 6-month follow-up measure to compare between the intervention and control groups as our waitlist control group had gained access to MMW at this point.

A 2-tailed independent t test was used to test for significant group differences between the intervention and control arms. Bootstrapping (bias corrected and accelerated with 5000 iterations) was used to adjust for deviations from multivariate normality and to yield 95% CIs [68]. Both P values (<.05) and CIs (not crossing 0) were inspected to assess statistical significance. We calculated the effect size for each comparative analysis using the Cohen d (with 95% CIs [69]). Drawing on the interpretive guidelines by Cohen [69] to support interpretation, values of d ≥0.2 were categorized as a small effect, values of d>0.5 to d≤0.8 were categorized as a medium effect, and values of d>0.8 were categorized as a large effect [68].

The data provided through the end-of-module feedback forms were analyzed descriptively to summarize participants' views on the module's relevance, utility, acceptability, and content clarity. Thematic analysis [70] was used for the qualitative data derived from the interviews. The detailed analytical methods and results of the qualitative analysis for trial objective 2.4 will be written up and published separately.

Results

Figure 2 shows the flow of participants through each stage of trial. Our results are presented in this section by trial objective.

Trial Objective 1: Potential Uptake and Interest in Participating in the Study by Employers, Line Managers, and Direct Reports

Objective 1.1: Willingness of Employers to Register Interest and Participate in the Study

We successfully recruited beyond our a priori specified sample size for participating organizations (n=8), ultimately enrolling 24 organizations across sectors and sizes within 6 months, demonstrating strong interest and feasibility for larger-scale implementation. Recruitment was open from August 20, 2021, to January 27, 2022. In total, 81 organizations expressed an interest in taking part in the MMW trial. Of these 81 organizations, 30 (37%) completed the organizational consent form, and 24 (30%) proceeded to fully enroll in the feasibility trial. Of the 57 organizations that did not take part, 20 (35%) were ineligible, 4 (7%) did not reply to the follow-up email, 27 (47%) did not proceed after being sent written information and consent forms, and 6 (11%) did not proceed following consent.

Objective 1.2: Recruitment and Retention of Line Managers

The recruitment of line managers from within the consented and participating organizations took place over 9 months. A total of 369 line managers were emailed information offering them enrollment in the MMW study. Of these 369 line managers, 257 (69.6%) consented to and enrolled in the study, with 224 (87.2%; n=141, 62.9% in the intervention arm and n=83, 37.1% in the control arm) completing the baseline survey. Most line managers recruited for the study (145/224, 64.7%)

XSL•FO
RenderX

were female, with an average age of 44.7 (SD 8.3) years. On average, line managers had 10.7 (SD 7.4) years of management experience, ranging from <1 to 30 years. Table 4 provides the baseline demographics by experimental condition.

At 3 months, 71.9% (161/224) of the line managers who completed the baseline survey completed the follow-up assessment (intervention arm: 90/161, 55.9%; waitlist control arm: 71/161, 44.1%). At 6 months, 24.6% (55/224) of those who completed the baseline survey completed the follow-up assessment (intervention arm: 39/55, 71%; waitlist control arm: 16/55, 29%). Our line manager retention rates surpassed our a priori specified criteria of 70% at 3 months but not the 50% retention rate at the 6-month follow-up.

Table 4. Baseline line manager demographics by experimental condition.

	Intervention arm (n=141)	Control (waitlist) arm (n=83)
Age (y), mean (SD; SE; 95% CI; range)	44.6 (7.6; 0.6; 43.3-45.8; 26-61)	44.4 (8.6; 0.9; 42.5-46.2; 30-69)[a]
Gender, n (%)		
Women	90 (63.8)	55 (66.3)[b]
Men	51 (36.2)	28 (33.7)[b]
Nonbinary	0 (0)	0 (0)
Tenure managing people (y), mean (SD; SE; 95% CI; range)	10.0 (6.7; 0.6; 8.9-11.2; 0-30)	12.2 (8.4; 0.9; 10.4-14.0; 0-30)

[a]n=84.

[b]n=83.

Objective 1.3: Recruitment and Retention of Line Managers' Direct Reports

The recruitment of direct reports took place over 7 months. Due to expected variations in the number of direct reports per line manager, we did not set a priori targets for the number of direct reports to be recruited. Furthermore, we are not aware of how many direct reports were approached by their line managers to participate and, therefore, cannot calculate the percentage recruited to the study. Table 5 provides an overview of the demographics of direct reports at baseline. A total of 112 direct reports completed the baseline survey (intervention arm: n=74, 66.1%; waitlist control arm: n=38, 33.9%). At baseline, 78.6% (88/112) of direct reports were female, with an average age of 41.4 (SD 10.29) years and a mean tenure of 7.8 (SD 7.9) years in the organization. At 3 months, 51.8% (58/112) of the direct reports who completed the baseline survey completed the follow-up assessment (intervention arm: 35/58, 60%; waitlist control arm: 23/58, 40%). At 6 months, 33% (37/112) of the direct reports who completed the baseline survey completed the follow-up assessment (intervention arm: 22/37, 59%; waitlist control arm: 15/37, 41%).

Table 5. Baseline direct report demographics by experimental condition.

	Intervention arm (n=74)	Control (waitlist) arm (n=38)
Age (y), mean (SD; SE; 95% CI)	42.7 (9.92; 1.2; 40.5-44.9)	38.95 (10.66; 1.63; 35.6-42.3)
Gender, n (%)		
Female	58 (81.7)[a]	30 (78.9)
Male	13 (18.3)[a]	7 (18.4)
Prefer not to say	0 (0)	1 (2.6)
Tenure (y), mean (SD; SE; 95% CI)	8.95 (8.59; 1.0; 6.9-10.9)	5.67 (6; 1.0; 3.9-7.7)

[a]n=71.

Trial Objective 2: The Perceived Suitability and Potential Effectiveness of the Line Manager Training

Objective 2.1: Acceptability, Usability, and Utility of the MMW Digital Training Intervention

Qualitative data from postintervention interviews with line managers and stakeholders and qualitative feedback provided by the line managers after each training module were used to assess the acceptability, usability, and utility of the MMW digital training intervention. A total of 20 interviews were conducted (n=16, 80% line managers; n=4, 20% organizational gatekeepers). Feedback forms were completed by >100 line managers after each module (104/224, 46.4%-169/224, 75.4% across the 5 modules), and descriptive data are presented in Table 6.

XSL•FO
RenderX

Table 6. Descriptive data from module feedback forms completed by line managers (LMs) in the intervention and waitlist control arms.

	Feedback on each module, n/N (%)				
	Module 1—"Self-Care for LMs" (n=169)	Module 2—"Designing Work to Prevent Stress" (n=145)	Module 3—"Management Competencies" (n=112)	Module 4—"Conversations on Mental Health" (n=112)	Module 5—"Psychological Safety at Work" (n=104)
Was the module relevant to your managerial role?					
Yes	160/164 (97.6)	139/140 (99.3)	110/111 (99.1)	110/110 (100)	101/101 (100)
No	4/164 (2.4)	1/140 (0.7)	1/111 (0.9)	0 (0)	0 (0)
Did you learn anything that you did not know before?					
Yes	84/166 (50.6)	117/142 (82.4)	76/110 (69.1)	82/111 (73.9)	92/100 (92)
No	82/166 (49.4)	25/142 (17.6)	34/110 (30.9)	29/111 (26.1)	8/100 (8)
It was easy to find the time to complete the module.					
Strongly agree or agree	105/166 (63.3)	73/139 (52.5)	61/112 (54.5)	61/110 (55.5)	64/101 (63.4)
Neither agree nor disagree	27/166 (16.3)	28/139 (20.1)	20/112 (17.9)	20/110 (18.2)	16/101 (15.8)
Strongly disagree or disagree	34/166 (20.5)	38/139 (27.3)	31/112 (27.7)	29/110 (26.4)	21/101 (20.8)
The module was an appropriate length for the information provided.					
Strongly agree or agree	159/165 (96.4)	136/139 (97.8)	107/112(95.5)	105/110 (95.5)	98/101 (97)
Neither agree nor disagree	2/165 (1.2)	1/139 (0.7)	3/111 (2.7)	5/110 (4.5)	3/101 (3)
Strongly disagree or disagree	4/165 (2.4)	2/139 (1.4)	2/111 (1.8)	0/0 (0)	0/0 (0)
The web-based module was easy to navigate.					
Strongly agree or agree	158/164 (96.3)	126/139 (90.6)	109/112 (97.3)	103/111 (92.8)	97/100 (97)

Strongly disagree or disagree	149/166 (89.8)	128/139 (92.1)	100/112 (89.3)	100/111 (90.1)	89/101 (88.1)
The examples provided were not relevant to my role as a manager.					
Strongly agree or agree	19/166 (11.4)	18/139 (12.9)	16/112 (14.3)	15/111 (13.5)	10/101 (9.9)
Neither agree nor disagree	18/166 (10.8)	14/139 (10.1)	10/112 (8.9)	8/111 (7.2)	4/101 (4)
Strongly disagree or disagree	129/166 (77.7)	107/139 (77)	86/112 (76.8)	88/111 (79.3)	87/101 (86.1)

In general, reactions were very positive and suggest that the intervention was perceived by both line managers and stakeholders as acceptable, usable, and useful. Line managers felt that the modules were relevant to their managerial roles (160/164, 97.6% to 101/101, 100% agreement across the 5 modules) and they learned new information from the content, especially from modules "psychological safety at work" (92/100, 92% agreement) and "designing work to prevent stress" (117/142, 82.4% agreement). Qualitative comments on the feedback forms supported these findings:

> *...this course has been excellent. I like to think that I am a good leader anyway, but this is giving me lots of ideas about how to be an even better one. Thank you!*

There were high levels of agreement about the length of each module being appropriate (ranging from 107/112, 95.5% to 136/139, 97.9% agreement) and that the content was easy to navigate (ranging from 126/139, 90.6% to 109/112, 97.3% agreement). Interview participants liked the flexibility in the way in which the training was delivered and highlighted specific aspects that were particularly beneficial, for example, its ease of use and relevance to not only their team's mental health but also their own self-care and mental health. Qualitative feedback collected from the module feedback forms echoed the sentiments expressed in the stakeholder interviews, confirming the acceptability, usability, and utility of the MMW digital training intervention. For example, one participant said the following:

> *I have learnt how to recognise signs of concerns for the mental wellbeing of my team and also friends and family outside of the workplace. It also allowed me to self-reflect on my own mental wellbeing. I now have many resources that I downloaded from this course and links to other websites for extended reading.*

XSL•FO
RenderX

The convergence between these 2 data sources strengthens the validity of the findings, affirming the positive reception of the intervention by both the employing organizations and line managers.

Objective 2.2: Changes in Line Manager Outcomes

Table 7 provides a descriptive overview of observed means (at both the participant and cluster level), SDs, and calculated ICC(1) values for line manager outcomes across the time series. While these statistics are presented descriptively, the inclusion of the ICC(1) aligns with feasibility trial guidance to inform future trial design and sample size planning [23]. Given the clustered nature of our data (ie, line managers nested within organizations), the ICC(1) was calculated to assess the proportion of the variance attributable to clustering and the potential need for multilevel modeling in future trials. Across most outcome measures, the observed ICC(1) values ranged from 0% to 13%, with most falling below the commonly suggested thresholds of 5% to 12% for minimal clustering effects [69,71]. These findings suggest a limited need to adjust for clustering in subsequent analyses, with the possible exception of workplace mental health literacy, which exhibited a slightly higher ICC(1). These exploratory estimates provide a valuable foundation for determining whether multilevel modeling is warranted in a future definitive trial.

We observed statistically significant changes in the outcomes measured in the intervention group as compared to the control group from baseline to the 3-month follow-up across all our specified outcome measures (Table 8). In particular, we observed that line managers who completed MMW reported increased confidence to create a psychologically healthy workplace; better mental health knowledge, psychological well-being, and mental health literacy at work; and improved managerial competencies surrounding the prevention and management of work-related stress (being respectful and responsible, managing and communicating existing and future work, managing the individual within the team, and reasoning and managing difficult situations). The Cohen *d* was used to estimate the magnitude of this change over time as compared to the control group drawing from the interpretation benchmarks by Cohen [69] (small: d=0.2; medium: d=0.5; large: d=0.8). A moderate change in the intervention group as compared to the control group was observed in relation to their self-reported psychological well-being (d=0.5) and their management competency on being respectful and responsible (d=0.7). A large effect size was observed across the remaining outcome measures examined in this pilot feasibility trial, ranging from 0.85 (management competency and reasoning and managing difficult situations) to 3.1 (mental health knowledge). However, the reliability of the mental health knowledge scale was weak, and therefore, this observation should be interpreted with a certain amount of caution. No significant adverse events were observed or reported among line managers during the study.

Objective 2.3: Changes in Direct Report Outcomes

Table 9 provides a descriptive overview of the mean scores observed for direct reports within the intervention and control arms over the time-series data collection.

Due to the research design, we were not able to delineate which direct reports were derived from which line managers or participating organizations. Therefore, it is not possible to provide a mean at the cluster level. We did not observe a statistically significant change in the psychological well-being of direct reports over time in the intervention group as compared to the control group (Table 10).

However, the direct reports of managers who received the intervention did show overall yet nonsignificant improvements in their psychological well-being and in their perceptions of their line managers' competencies in managing and communicating existing and future work, managing the individual within the team, and managing difficult situations. We did observe a statistically significant change in self-rated productivity; however, this was not in the anticipated direction, with improved self-rated productivity in the control group rather than the intervention group over time. Across the 4 management competencies, as observed and reported by direct reports, we did not observe a statistically significant change over time in comparison to the 2 experimental conditions.

Following the completion of the intervention, we contacted the participating organizations to see whether we could obtain organizational-level sickness absence records. Unfortunately, we were not able to secure access to these data, which calls into question the feasibility of accessing this type of data in this way in a future trial and identifies the need to have clearer data sharing protocols set up in advance. No significant adverse events were observed or reported among direct reports during the study.

Objective 2.4: Barriers to and Facilitators of Implementation

Qualitative methods were used to explore the barriers to and facilitators of intervention implementation and effectiveness to inform the delivery of the intervention for a full trial. Data showed that a commonly perceived barrier to intervention implementation was time constraints and perceived workload. Module feedback forms (Table 6) highlighted that between a fifth and a quarter of line managers disagreed with the statement that it was easy to find time to complete the modules (ranging from 34/166, 20.5% to 31/112, 27.7% across the 5 modules).

Qualitative comments on the feedback forms also showed that line managers were struggling to fit the training into their workday:

> *Finding time to do them difficult, so its late and I'm tired.*

In interviews, some line managers also described that their completion of the training was hampered by a lack of ability to commit time to engage with MMW due to their existing workload. Although a suggested weekly schedule was provided, workload demands meant that, for many participants, this was not followed, which may have lessened their learning:

> *The biggest challenge was finding the time to do it...I actually ended up squashing them all together at the end, which is inevitable. And actually I don't think that's as good for learning as it would have been if I spent done a little bit each week.*

The main facilitators to completing and accessing the MMW modules focused on the flexibility offered by the self-led learning process and the support from senior managers. Interview participants described the benefits of the structure of the 5 modules, which could be completed at a convenient time but with a suggested schedule of 1 module per week. This gave them the flexibility to complete the modules at a time of their choice:

> *It absolutely does work in terms of it being self-led so that you know got quite a lot of time to complete that training and they can stretch it around their other commitments.*

Encouragement and support from senior managers within the organization also facilitated completion of the training and were key to overcoming some of the barriers related to time constraints. However, stakeholders also said that integrating the training into their other existing activities and adding on other activities led by the organization would have allowed for even more encouragement and reflection:

> *[It] needed more integration, but that is any learning intervention that you take...I probably should have said use module 4 as a kick start and then probably taken that into some practical role plays. I could easily have run. Use that as the base. Take that forward to try and get confidence up in the conversations.*

Trial Objective 3: Feasibility of the Data Collection Methods

The Mental Health Knowledge Schedule [57] demonstrated poor levels of reliability within our pilot feasibility trial. Therefore, we conclude that this measure should not be used in a full trial context. The remainder of our measures used to quantify primary and secondary outcomes demonstrated satisfactory psychometric properties. Collecting sickness absence data from the organizations was particularly challenging, and therefore, its utility as a data collection method is limited. Thus, alternative data collection methods may be required to quantify changes in sickness absence behaviors in a future trial. This may include using self-report data from the perspective of direct reports. We included a sufficient number of organizations from a clustering perspective; however, the number of line managers within each cluster varied considerably. Therefore, to statistically account for any clustering effects, a full trial will need to consider and achieve both quantity in terms of clusters and variability regarding individuals within each cluster that are retained over the time series. Direct reports were challenging to recruit and retain in the study, so alternative methods of recruitment will be considered in future trials.

Discussion

This feasibility trial aimed to pilot the MMW digital training intervention and assess its acceptability and potential for improving line manager and direct report outcomes, as well as the feasibility for a future definitive trial. The objectives were to assess (1) the potential for uptake in small, medium, and large companies; (2) the perceived suitability and potential effectiveness of the line manager training; and (3) the feasibility of the data collection methods for primary and secondary outcome measures.

Principal Findings

In relation to objective 1, recruitment of organizations into the trial was very successful, indicating a demand for this type of intervention. The recruitment and retention of line managers was also positive and surpassed the prespecified criteria at 3 months. However, the recruitment and, in turn, retention of direct reports was considerably more challenging, highlighting the need to review and amend both our recruitment methods and retention efforts among direct reports in a future trial.

In relation to objective 2, feedback through end-of-module forms and interviews revealed that the intervention was deemed highly acceptable, usable, and useful by organizations and line managers. The MMW intervention also demonstrated potential for improving line manager outcomes, with significant changes observed in the intervention group as compared to the control group of line managers across all our outcome measures. Line managers who completed the MMW digital training intervention reported increased mental health knowledge, mental health literacy at work, and confidence to foster a psychologically healthy workplace, as well as reporting increases in their own psychological well-being and management competencies to prevent work-related stress. Furthermore, the magnitude of these changes was moderate to large in nature. These potential

XSL•FO
RenderX

improvements reflect enhanced job resources and management competencies, which, according to the JD-R model [22], are key factors in buffering job demands and preventing stress-related outcomes (such as depression and anxiety). These findings highlight the potential impact of this digital training intervention on line managers directly. However, the indirect impact of this digital intervention on direct reports was not observed. This may be a result of experienced challenges in both recruitment and retention but may also be a limitation of a shorter follow-up period of 3 months. It is also possible, in line with the intervention conceptual framework, that distal outcomes among direct reports may require more time to manifest because of upstream managerial behavior change.

Qualitative data showed that perceived barriers to engagement with the intervention were time constraints and perceived workload. Line managers proposed that uptake in participants was hampered by a lack of ability to commit time to engaging with MMW due to their existing workload. This highlights an inherent tension between job demands and resource availability, reinforcing the importance of supportive organizational structures and managerial autonomy, which are central tenets of the JD-R model. We will build on the findings of this aspect of the study, and phase 2 will explore how the intervention could be implemented more efficiently alongside other organizational practices and policies and maximize the support of senior managers, who appear to play an important role in facilitating the completion of MMW.

This pilot feasibility trial provides preliminary evidence of the usability and acceptability of the MMW digital training for line managers, its potential to improve outcomes, and the feasibility of the research design and process. This study highlighted some key considerations to inform the future delivery and evaluation of MMW in a large-scale trial.

Results in Context With Other Research

These promising results for the MMW digital training intervention offer significant value, particularly when contextualized within the broader landscape of workplace mental health and management practices. Line manager training has been identified as a key target for intervention [1,10,15], yet few robust evaluations of interventions have been conducted [27,32,35,36,38-40]. Therefore, this study contributes to the growing body of evidence that organizations and line managers are keen to engage with interventions to improve skills and competencies for preventing poor mental well-being at work and that change in these critical areas can occur. By targeting behavioral and competency development in line managers, the intervention aligns with a primary prevention approach, shifting focus from reactive to proactive strategies to reduce mental health risks.

The success in recruiting beyond the specified sample size is an encouraging indicator of employer willingness to engage with mental health interventions targeting line managers. The need for such interventions is emphasized by statistics showing that 1 in 6 workers experience mental health issues annually in the United Kingdom [3] and by policy standards and guidance [10,14] that highlight the importance of a comprehensive approach to workplace mental health interventions, specifically those that incorporate primary, secondary, and tertiary strategies. However, this success does contrast with other studies that have faced challenges in recruiting organizations for workplace interventions due to issues such as perceived burden of the study [72], further stressing the growing recognition of the importance of mental health in the workplace. Although the retention rates of line managers in our study surpassed the prespecified criteria at 3 months, they did not surpass the prespecified criteria at 6 months, indicating a common methodological challenge of maintaining engagement over time in longitudinal studies [73]. Despite our efforts to minimize attrition, the decline in retention rates suggests that other areas of methodological refinement are needed to maximize participant retention.

Research suggests that awareness of an intervention's efficacy does not necessarily indicate that the participants will accept it. As such, it is important to capture the perceived acceptability of such interventions [74]. The favorable reception of the MMW digital training intervention regarding acceptability, usability, and utility underscores the need to involve end users in the development and refinement of health interventions. This finding also aligns with those of the growing body of research that supports digital mental health interventions in the workplace [40,75-77].

Line managers who received the MMW training exhibited improvements in several outcomes relative to those who did not receive the training, including confidence to create a psychologically healthy workplace, understanding of mental health issues, psychological well-being, mental health literacy at work, and managerial behavioral competencies. Studies exploring such interventions have obtained similar findings [27,78,79]. These outcomes reflect key job resources that, in line with the JD-R model, buffer strain and support well-being—reinforcing the program's theory of change. Equipping managers with mental health knowledge and stress prevention skills through interventions such as MMW can improve workplace mental health overall.

The perceived barriers of time constraints and workload impacting the uptake of workplace interventions have often been observed across studies focusing on workplace wellness programs [20,80] and health promotion in general [81]. This is particularly significant in the context of mental health interventions as the need for such programs is often greatest in high-stress environments. Consequently, there is a need for organizational strategies that address these structural barriers to participant engagement. This reflects the JD-R model's emphasis on organizational context and the role of environmental demands and supports in shaping outcomes. This aligns with other findings on the implementation of workplace mental well-being interventions that have identified the importance of senior management support, time allocation for training, and continuity of efforts to implement interventions [51,82].

Strengths, Limitations, and Future Directions

A review of UK-based pilot and feasibility studies registered on ISRCTN from 2013 to 2020 found that the median target sample size was 33 per arm but 57% of the studies did not reach this sample size target [83]. In contrast, this study achieved

XSL•FO
RenderX

sample sizes of 90 (intervention) and 71 (control) at the 3-month follow-up, where between-group comparisons were possible. These sample sizes also compare favorably with those of full cluster RCTs of similar interventions, which have frequently had smaller line manager samples at the first follow-up point (eg, n=62 and n=64 at 3 months [36], n=41 and n=78 at 4 months [32], n=25 and n=19 at 6 months [38], n=88 and n=54 at 8 weeks [34], and n=24 and n=13 at 12 weeks [35] in the intervention and control groups, respectively).

Our study was a pilot feasibility trial to enable us to test whether the components would work (recruitment, randomization, intervention acceptability, and follow-up) [84] but also to assess whether MMW has the potential to improve outcomes [71]. On the basis of the observed sample sizes and effect sizes, we can conclude with reasonable confidence that the intervention has promise in improving outcomes for line managers. However, to assess the effectiveness and cost-effectiveness of the intervention, a full, sufficiently powered trial would be needed informed by the findings of this pilot feasibility trial. One of the strengths of this study is the moderate to large effect sizes for changes in line manager knowledge, skills, and competencies.

Our strategy led to overrecruitment for our pilot feasibility study, yielding a larger dataset than anticipated. We acknowledge that this level of recruitment may blur the boundary between a feasibility study and a definitive trial. However, we remain cautious in our interpretation and do not claim effectiveness or impact on primary outcomes. Instead, we report these findings descriptively and emphasize their role in informing the design, implementation, and progression criteria for a future fully powered RCT. In line with this, we extended our originally planned descriptive analysis to include exploratory inferential statistics, which constitutes a deviation from our registered protocol. This decision was driven by the opportunity to extract more meaningful insights from a larger-than-expected sample, and we have transparently reported this deviation in the manuscript. This approach is aligned with recent guidance [23,71] that recognizes that feasibility studies may generate exploratory outcome data but such data should not be used to draw definitive conclusions about effectiveness. Therefore, we position our findings as hypothesis generating and implementation informing.

Although the direct reports of managers who received the intervention showed slight improvements in psychological well-being and perceptions of their managers' competencies, these improvements were not of the same magnitude as those for line managers. Future research will need to test whether the line manager changes observed can be cascaded to direct report outcome improvements within the time frame of the study. Future research in a full trial will need to extend the follow-up timescales to allow for this, as well as develop a more effective recruitment and retention strategy for direct reports. In the context of this study, we recruited direct reports through their line managers disseminating study information to them directly. This recruitment approach may have acted as a barrier to direct report participation in the study due to potential concerns regarding their anonymity within the context of the study given that they would be reporting on their line managers' behaviors and competencies. We will review and amend both our recruitment methods and retention efforts among direct reports in any future trial. A future trial may seek to recruit direct reports directly by a member of the research team either remotely or through workplace site visits.

This study did not use proactive efforts to retain direct reports in the study, only line managers. A future definitive full trial should consider retention efforts and activities directed at both line managers and their direct reports both independently and concurrently to support retention efforts. As this was a feasibility trial, we have identified a number of limitations to our original research design, which have been noted previously. These focus on the low recruitment of direct reports and the challenges in accessing organizational records for sickness absence. Additional limitations identified include the mental health knowledge scale showing poor levels of reliability, and we concluded that this measure should not be included in a full trial. Previous research has observed mixed findings in relation to the psychometric strength of this scale [57,85]. All other measures used to quantify primary and secondary outcomes demonstrated satisfactory psychometric properties. Collecting sickness absence data from organizations was particularly challenging, and therefore, its utility as a data collection method is limited.

Most line managers who opted into our study (145/224, 64.7%) were female and, due to the voluntary nature of the intervention, may have already been interested or invested in the importance of mental health at work. Therefore, a future trial should actively consider how to engage line managers identifying with other genders, as well as those less engaged or interested in the topic area of mental health at work. The self-selection of participants meant that participants were likely to be line managers who were interested in learning and motivated to learn about how they could develop their own skills and competencies in this area. The sample was limited to leaders and employees from UK-based organizations, which may constrain the generalizability of the findings. Future research should consider cross-cultural replications to explore how the intervention performs across different national, cultural, and organizational settings.

The web-based application would not allow us to track participants through the modules as they completed them due to budgetary constraints. Therefore, we are not able to report the proportion of modules completed by participants or the average completion time. Future work on this intervention will seek to address some of these limitations through developing a more sophisticated delivery platform that will enable tracking and feedback to participants on their completion progress throughout the MMW intervention. Moreover, to enhance engagement with the intervention, future studies could consider the use of behavioral nudges (eg, SMS text message reminders), interactive content (eg, quizzes and simulations), personalized messaging, incentive structures (eg, prize draws), and features that promote community building among participants. These elements may help increase uptake and sustained use of the intervention materials.

RenderX

Conclusions

This pilot feasibility cluster RCT demonstrated that the MMW digital training intervention had good acceptability, usability, and utility and that organizations and line managers could be recruited to and retained within a trial. Furthermore, MMW demonstrated that it has the potential to improve line managers' confidence and competencies to prevent poor mental health among those they manage. A future full trial will assess the impact of these improvements over a longer period and how they may influence direct reports.

Acknowledgments

The authors recognize the input of Professors Richard Kneller and Steven Marwaha in funding acquisition and early comments on the study protocol. This work was supported by the Midlands Engine and the UK government's Department for Work and Pensions. The authors thank the line managers, direct reports, and organizations that took part in the study.

Abstract

The emergence of generative artificial intelligence (GenAI) in clinical settings—particularly in health documentation and communication—presents a largely unexplored but potentially transformative force in shaping placebo and nocebo effects. These psychosocial phenomena are especially potent in mental health care, where outcomes are closely tied to patients' expectations, perceived provider competence, and empathy. Drawing on conceptual understanding of placebo and nocebo effects and the latest research, this Viewpoint argues that GenAI may amplify these effects, both positive and negative. Through tone, assurance, and even the rapidity of responses, GenAI-generated text—either co-written with clinicians or peers, or fully automated—could influence patient perceptions in ways that mental health clinicians may not currently fully anticipate. When embedded in clinician notes or patient-facing summaries, AI language may strengthen expectancies that underlie placebo effects, or conversely, heighten nocebo effects through subtle cues, inaccuracies, or potentially via loss of human nuance. This article explores the implications of AI-mediated clinical communication particularly in mental health care, emphasizing the importance of transparency, ethical oversight, and psychosocial awareness as these technologies evolve.

KEYWORDS

ChatGPT; generative language models; large language models; placebo effects; nocebo effects; ethics; artificial intelligence; health disparities

Introduction

Unlike traditional search engines that return lists of web links, the new wave of chatbots—such as OpenAI's GPT, Google's Bard, and Bing AI—responds to user queries with conversational, human-like text. Powered by large language models (LLMs), these systems draw on vast datasets and probabilistic algorithms to generate fluent, contextually relevant responses. Their ability to recognize, summarize, and produce complex content has driven rapid adoption across sectors, including health care. This surge in use has sparked urgent debates about the safety, accuracy, and efficiency of generative artificial intelligence (GenAI) in clinical settings [1]. Despite the accelerated use of GenAI tools in health care, so far, little attention has been paid to the subtle psychological mechanisms that may be engaged by AI-generated communication, especially in mental health settings. Indeed, mental health care has always been a space where language not only influences treatment but, in the case of psychotherapy, can constitute it [2].

This Viewpoint article offers a conceptual exploration of one psychosocial aspect of care: how GenAI could strengthen placebo or nocebo effects. These psychological phenomena, which can exert both positive or negative effects on our health outcomes, are deeply rooted in patient expectations, perceptions of clinician competence and empathy, and relational trust in the clinic [3]. I propose that GenAI may enhance both placebo and nocebo effects. I also explore the ethical implications of this novel pathway in mental health care, exploring why GenAI has the potential to shift the foci of longstanding debates on practice dilemmas surrounding placebo and nocebo effects.

How AI Could Influence Placebo and Nocebo Effects

Placebo and nocebo effects have traditionally been thought to arise in brick-and-mortar clinic environments. These effects are shaped by what clinicians say and do, that is, how they present information, express confidence, or deliver treatments [4]. However, patients' own expectations—shaped by prior experiences, conditioning, and social learning—can also play a key role in their responses [5,6] In the age of digital tools, placebo and nocebo effects may be increasingly shaped through virtual, asynchronous channels [7-9].

For example, previous research suggests that patients often interpret online clinical notes more deeply than clinicians expect [10]. Patient-accessible records, though remote and

XSL•FO
RenderX

asynchronous, may serve as a channel through which placebo and nocebo effects are shaped [8,11]. A clearly worded, hopeful, and empathetic summary could enhance placebo effects by shaping more positive expectations about recovery and therapeutic alliance. In contrast, clinical communications that subtly convey hopelessness or diagnostic pessimism, or which contain significant errors may contribute to loss of trust and anxiety, in turn influencing nocebo effects. Relatedly, in a variety of digital tools, "digital placebo effects" are thought to arise from features of online or app-based health interventions, such as interface design or ease of use, that shape patient expectations with respect to interventions [7,12].

It is important to emphasize that direct empirical evidence is still lacking, and much more research focus is needed to examine placebo and nocebo effects in digital contexts. Nonetheless, there are plausible reasons to believe that GenAI tools might elicit these effects. This shift is partly driven by the tendency of GenAI tools to evoke anthropomorphism among users [13,14], that is, people often, unintentionally, lapse into perceiving these systems as human-like agents, attributing to them qualities such as empathy, intent, and competence. These human-like qualities can, in turn, shape patient expectations and emotional reactions—key drivers of placebo and nocebo effects—by fostering a sense of optimistic reassurance or, conversely, anxiety.

First, consider placebo effects. One of the most consistent features of GenAI tools is the speed, fluency, and confidence with which it generates text. Whether summarizing a clinical encounter, or drafting follow-up instructions, studies suggest that GenAI has the potential to appear more coherent and polished than time-pressured human clinicians [15]. This fluency may signal competence to patients, perhaps more so than hastily typed or fragmented notes, replete with typos and acronyms, written by overburdened clinicians. The result may be that such tools thereby strengthen placebo effects. For example, studies show that clinical notes generated with GenAI tools—including "listening AI" that transcribes visits directly into electronic health records—are typically longer, and may do a better job of unpacking and explaining medical terms, than those written solely by clinicians [16-18].

Signals of empathy conveyed by GenAI tools may also augment placebo effects. A growing body of research shows that GenAI often conveys rich cues of empathy, particularly cognitive empathy, reflected in its ability to identify patients' mental states, and compassion, reflected in signature expressions of concern and pro-social engagement [17,19,20]. Notably, as researchers emphasize, these empathetic signals contrast sharply with the often detached tone of physician-authored clinical documentation [17,20]. For example, GenAI tools have demonstrated a surprising ability to interpret emotional states, and in some cases, even outperform clinicians on measures of social intelligence [21,22]. A recent study tested whether people could distinguish between therapist- and AI-generated responses. Surprisingly, ChatGPT-4.0 not only proved difficult to distinguish from human therapists but was also rated higher on core therapeutic principles [19]. In one blinded experiment, physicians rated ChatGPT as 10 times more empathetic in written responses to patients' queries on an online social media platform [17].

On the flip side, GenAI could also amplify nocebo effects by augmenting negative patient expectations. Tools such as ChatGPT are renowned for making authoritative sounding errors (known as "hallucinations"), and a high proportion of recommendations elicited by these tools can be egregiously wrong in health contexts [23]. From a patient perspective, such errors—if detected, or even if feared—might trigger increased anxiety or worry.

Similarly, when AI adoption erodes trust or undermines confidence in providers, it may heighten patient anxiety, amplifying nocebo effects and increasing the risk of adverse health outcomes. For example, some may find the responses offered by AI, which are designed to be agreeable and user-friendly, instead to be obsequious or lacking in authenticity [20,24]. It is conceivable that for these individuals, GenAI chatbots may prompt cynicism, either leading to disengagement, or even nocebo effects. According to the latest survey research, public skepticism toward AI in health care remains high. A 2023 study in *JAMA Network Open* found that nearly two-thirds of American adults express distrust that health care systems will use AI responsibly, with women showing even greater concern [25]. Crucially, this distrust was not linked to health literacy or AI knowledge. A year later, the 2024 KFF health tracking survey echoed these concerns: 56% doubted the accuracy of chatbot-generated health advice, and most remained uncertain about AI's role in accessing reliable health information; only 21% saw it as helpful, while 23% believed it does more harm, and 55% were unsure [26].

GenAI: A New Clinical Communicator

A growing body of survey research shows that clinicians, including psychiatrists, are incorporating GenAI tools into clinical practice, with the fastest task adoption for documentation [27-29]. Patients are also increasingly turning to these tools to seek health information or for socioemotional support [30]. For example, in 2024, a KFF health tracking survey found that GenAI chatbots like ChatGPT emerged as a popular source of health information, with 17% of American adults using them monthly, rising to 25% among those aged under 30 years [26]. Emerging studies show that patients derive benefits from using these tools to disclose and discuss socially sensitive or emotional concerns, offering round-the-clock support with perceived comfort of anonymity and lack of human judgment [30].

The adoption of GenAI tools as a new communicative "agent" in health care may meaningfully shape placebo and nocebo effects, long-recognized phenomena in clinical research. As noted, the placebo effect is a genuine biopsychosocial phenomenon wherein patient expectations, influenced by factors like provider communication, treatment rationale, and the care environment [3,4,31], can lead to meaningful symptom alleviation, particularly for pain, depression, and anxiety [3,32]. Conversely, nocebo effects involve negative expectations that lead to adverse outcomes, triggered by concerns about side effects, risks, or aspects of treatment delivery or design [3,11]. Some researchers propose that psychotherapy may also be a

XSL•FO
RenderX

setting where nocebo effects emerge, particularly when clinicians unintentionally convey subtle negative suggestions about treatments, symptoms, or prognoses, or when the therapeutic alliance is weakened by a lack of trust [33].

Old Ethics, New Tech: Placebo, Nocebo, and Practice Dilemmas

Long-standing, substantial academic literature has focused on the ethics of placebo and nocebo effects. This body of literature has focused almost entirely on how clinicians, primarily physicians [34], communicate with patients, examining both verbal and nonverbal cues with only limited attention given to how clinical artifacts and environmental features may also influence placebo and nocebo effects [35]. The result is that almost exclusively, the focus of ethical attention in placebo studies, including in mental health care, has hitherto been on provider communication. As GenAI tools become increasingly enmeshed in clinical care, especially in mental health settings, their potential to benefit patients, but also cause harm, must not be ignored [1,36].

To fully evaluate the ethicality of these tools, they cannot be considered in isolation; it is also imperative to explore how these tools compare to traditional human-mediated care, including whether they may fare better or worse for patients along a variety of ethical concerns [36]. Below, I offer exploratory—rather than exhaustive—reflections on how the advent of GenAI in health care may reframe longstanding ethical dilemmas surrounding placebo and nocebo effects.

Consider the most well-known ethical dilemma pertaining to placebo studies: the administration of placebos in clinical contexts. Here, placebos may be offered to patients with the intention of harnessing beneficial effects, even while doing so deceives the patient. Most medical ethicists strongly oppose this deception, emphasizing that it undermines trust, compromises patient autonomy, and promotes a paternalistic model of care [37].

With GenAI, the deception operates at a different level. It's not just about a physician misleading a patient about a pill; it may involve patients being misled about who they are interacting with. Placebo effects may be amplified through this illusion, but if patients believe they're communicating with a human when it's actually a chatbot, trust is at risk. A relevant parallel can be drawn from the well-known "open–hidden" paradigm in placebo research, where patients receiving identical treatments experience significantly stronger effects when the intervention is administered openly by a clinician rather than covertly [38,39]. These findings underscore how the source and visibility of a therapeutic act, not just its content, can powerfully shape outcomes. Similarly, patients' perceptions of whether they are interacting with a human or a chatbot may critically influence both placebo and nocebo effects. Although not directly indicative of placebo or nocebo effects, in one notable case, the company Koko, which provides online mental health support, issued a public apology in January 2023 after using ChatGPT to generate emotional responses while misleading users into believing they were written by real people [40].

Beyond issues of identity, LLMs themselves can be sources of deception [23]. Some models have been shown to produce false or misleading responses, and in certain contexts, even reportedly admitting to doing so [41]. This raises further ethical concerns about trust, transparency, and oversight in patient-facing AI tools.

Complicating matters, even when patients are aware, or later discover, that they were interacting with AI, placebo effects may be dampened but not entirely lost, with meaningful psychological or therapeutic benefits still emerging. For example, a study found that AI-generated messages made recipients feel more understood than human-written ones, and AI was better at detecting emotions [42]. Yet, once recipients learned the messages came from AI, this effect diminished. However, when comparing transparently labeled AI and human responses, participants rated them almost identically. Notably, however, this does not resolve the ethical tension between respecting patient autonomy and pursuing beneficence through placebo mechanisms. Nevertheless, the study does highlight the complexity of perception, expectation, and ethical transparency in AI-mediated care, suggesting that patients may yet derive placebo effects even when they know they're "talking to" AI.

Another well-recognized ethical challenge lies in balancing the duty of honesty—such as disclosing potential side effects of medications—with the risk of inducing harm through nocebo effects, where negative expectations may contribute to self-fulfilling adverse outcomes [43]. Here, it has been proposed, that one way to resolve the ethical dilemma is to reframe information in ways that are truthful but which influence more positive outcomes [44].

For instance, rather than stating about a treatment or intervention, "side effects of this drug are quite common—20% of people experience them," it may be more effective—and equally truthful -to say, "80% of people do not experience side effects." GenAI tools, with their capacity to rapidly adjust language and tone, offer a promising means of delivering such positively reframed information. Unlike human clinicians, whose communication may be affected by burnout, variability, or limited time, GenAI could help consistently implement ethically sensitive messaging, offering a potential solution to this longstanding ethical dilemma.

In addition, consider a more overshadowed ethical issue in placebo studies: justice [45,46]. This concern lies in the unequal distribution of harm that may arise from differences in patient–clinician communication. Research shows that patients from marginalized groups—such as those who are racially minoritized, have lower incomes, higher body weight, or psychiatric diagnoses—often receive lower-quality communication, less empathy, and more negative framing in clinical encounters [46]. These disparities reduce placebo effects, and heighten negative expectations, increasing susceptibility to nocebo effects. Thus, nocebo-related harm may disproportionately affect already disadvantaged populations by compounding existing health inequities, therby raising serious concerns about fairness and justice in care.

XSL•FO
RenderX

GenAI may help bridge some face-to-face health communication disparities by offering more consistent, high-quality interactions that are not influenced by appearance [47]. Unlike face-to-face encounters, GenAI chatbots do not discriminate based on race, body size, or other visible traits. They also provide scalable access to health information, allowing users to engage at their own pace and literacy level, with customizable tone and style. Notably, the 2024 KFF Health Tracking Survey found that Black (23%) and Hispanic (31%) adults were more likely than White adults (16%) to say AI chatbots help them find accurate health information [26]. Similarly, 51% of Black and 44% of Hispanic adults reported trusting AI-provided advice, compared to just 29% of White adults, highlighting how GenAI may be perceived as a tool for expanding access in historically underserved communities.

However, the promise of GenAI to reduce disparities, including nocebo-related harms, remains contingent on addressing persistent digital divides [48]. Patients most vulnerable to health inequities may also face barriers to accessing the very tools designed to support them, such as the lack of digital devices, broadband, or sufficient digital literacy to effectively use GenAI chatbots [48]. Without tackling these structural barriers, GenAI risks reinforcing, rather than resolving, existing inequities.

Conclusion

As GenAI begins to generate the words patients read—whether within patient accessible records, online messaging with peer support or clinicians, or via fully automated chatbot dialogs—it may influence psychosocial aspects of care. While the concerns of this Viewpoint are exploratory in nature, the arguments rest on emerging research, and further empirical studies are needed to investigate how GenAI may shape placebo and nocebo effects when it comes to real-world mental health care. Understanding how these tools shape patient perceptions is not a peripheral concern; it is central to the future of ethical, effective mental health care. Future research should include qualitative and co-design approaches to center patient voices and explore how patients with mental health conditions perceive, interpret, and respond to GenAI in clinical contexts [49]. Indeed, while this Viewpoint has focused on mental health, similar mechanisms are likely at play across many areas of medicine, and future work should explore how generative AI may amplify or mitigate placebo and nocebo effects in other clinical contexts, including chronic illness and polypharmacy. Not only what is written, but how it is phrased, may influence patient behavior and outcomes, via placebo and nocebo effects. It is time for the fields of placebo studies and health communication to enter a new era of research.

Abstract

The internet is now integral to everyday life, and users' web-based search data could be of strategic importance in mental health care. As shown by previous studies, internet searches may provide valuable insights into an individual's mental state and could be of great value in early identification and helping in pathways to care. Internet search data can potentially provide real-time identification (eg, alert mechanisms for timely interventions). In this paper, we discuss the various problems related to the use of these data in research and clinical practice, including privacy concerns, integration with clinical information, and technical limitations. We also propose solutions to address these issues and provide possible future directions.

(JMIR Ment Health 2025;12:e60754) doi:10.2196/60754

Introduction

The internet is now integral to everyday life, and the world's population has never been more interconnected. Therefore, the World Health Organization (WHO) launched a global strategy in 2020, proposing a road map to link the latest developments in innovation and digital health to improve health outcomes. This initiative was of critical importance, given the recent studies suggesting an increase in prevalence rates of mental disorders after the COVID-19 pandemic [1], and internet and other digital technologies demonstrating a great potential to reverse this trend [2].

The internet is one of the most important sources of information, fueled by increasingly powerful search engines that link users to websites. Each day, approximately 8.5 billion searches are performed using Google alone [3], and these extensive internet search data could be of strategic importance in mental health care. Search terms may reflect an individual's curiosity, desire for information, emotional well-being [4], mental health state [5], or need for assistance [6,7]. In this context, internet search data could be of great value for the early identification of mental health disorders and for facilitating pathways to care, reducing the long-standing delays in seeking help and improving outcomes.

Methods

Overview

A critical review was conducted with the aim of capturing the available evidence on the use of search engine data in mental health research, specifically in studies investigating the link between individual users' mental health states and their internet search data. In line with previous studies in the field, search terms included a combination of search engine–related terms ("internet search" OR "google search" OR "bing search" OR "internet search data" OR "search engine*") and terms addressing mental illnesses ("psychiatric disorder*" OR "mental disorder*" OR "mental illness*" OR "depressi*" OR "anxi*" OR "psychos*" OR "psychotic" OR "schiz*" OR "bipolar"). The search was conducted in the following databases: PsycINFO, PubMed, and Web of Knowledge. Inclusion criteria comprised studies that examined the relationship between internet search data at the individual level and subjects' mental states. There were no language or publication time restrictions. The exclusion criteria included reviews and strictly theoretical articles without original data. Poster presentations, grey literature, and unpublished transcripts were also excluded.

A total of 1184 publications were identified in the initial search (duplicates excluded). The authors screened the titles and abstracts of all papers, identifying 87 relevant papers. These 87 relevant papers were read in full, with 9 meeting the criteria in

XSL•FO
RenderX

the final round, for analysis of individual search data. Additionally, 46 studies examined the use of internet search data at the population level (eg, Google trends) and will be partly addressed in this paper.

Population-Level Research

Internet search data may provide valuable insights into users' mental state. Recent studies suggest that signals from search history and YouTube data may be correlated with depression and anxiety levels [8], predict suicidal behavior [9] and diagnoses of schizophrenia spectrum disorders [10].

For example, one study observed that individuals with mood disorders conducted internet searches significantly more frequently than those with schizophrenia spectrum disorders from 6 PM to midnight and used significantly more words related to negative emotions compared to healthy volunteers [10]. Internet help-seeking may exhibit daily fluctuations, as evidenced by describing a significant rise in depression-related search query volumes toward the evening and night [11,12]. Other studies observed that information-seeking on Google related to major mental disorders terms followed seasonal patterns similar to those found in seasonal affective disorders [13]. Peak searches generally occur over the winter months, with troughs occurring during summer [14]. Interestingly, in a study encompassing 54 geographical areas worldwide, internet searches for depression were influenced by seasonal changes in higher latitudes but not in tropical areas [15].

Many researchers also used internet search data to examine population mental health trends. Wang et al [4] developed a public opinion dictionary using emotionally enriched texts extracted from social media. They combined the public opinion dictionary with a word vector model and internet search trends to develop a composite anxiety and depression index for specific regions over time. Ford et al [16] collected data on the frequency of Google searches for 15 affect-related terms, and paired them with data on health, self-reported emotions, psychological well-being, personality, and Twitter postings. Several internet search scores were correlated with depression, self-reported emotions, and well-being. An interesting study analyzed the association between the Oklahoma earthquakes and anxiety-related Google search episodes [17]. For each additional earthquake with a magnitude of 4 or higher, the proportion of Google anxiety-related search episodes increased by 1.3%, with 60% of these increases persisting for a month. A similar trend for increased anxiety-related search terms was observed after an earthquake in Japan [6]. These findings suggest that internet search data could be a valuable tool for estimating regional or country-level prevalence of mental health disorders [18].

In line with the disaster-related findings, a recent topic of investigation has explored the interplay between the COVID-19 pandemic, mental health, and internet search data [19]. In a study involving 50 countries, Bing search query data and Google Trends search volume data identified a significant increase in the volume of the most-searched anxiety-related themes in 2020 [18]. Many other studies also observed an increase in depression-related search terms during the pandemic [20,21]. An important study combined cellular mobility tracking, online search data, and Google Trends search volumes for terms related to economic stress, mental health, and suicide in the United States [22]. The authors observed that pandemic-related isolation coincided with acute economic distress, which may be a risk factor for poor mental health and suicidal behavior. Fluctuations in mental health have been associated with lockdown stringency [23,24], vaccine discovery [25], and number of COVID-19–related deaths, as inferred from search data volume. A systematic review conducted in 2021 observed a significant increase in search terms related to mental illnesses during the COVID-19 pandemic [26]. This link was confirmed by analysis associating the number of COVID-19 cases and deaths with internet search volume for specific keywords, as well as by content and sentiment analysis. Given the increasing interest in this topic, particularly after the pandemic, internet search data has been proposed as real-time surveillance tool for population mental health [27-31]. However, evidence linking search data trends to population mental health remains inconclusive. A study conducted in the United Kingdom found that Google Trends data were not a useful indicator of changing population mental health levels during a public health emergency [32]. Nevertheless, the authors acknowledged that it may serve as an indicator of loneliness.

At last, internet search data has been increasingly used in suicide research. Many studies showed that specific search terms were correlated with increased suicide rates at the population level [33-39]. While most of these terms are intuitive (eg, "anxiety disorder," "laid off") [33], others are less obvious (eg, "allergy") [34], highlighting the need for further culture- or region-specific studies. For instance, suicide is a complex phenomenon influenced by a variety of psychosocial, biological, environmental, economic, and cultural factors. Regarding internet searches, there has been significant effort toward responsible reporting to prevent suicide contagion [40], for example, when celebrity suicides are announced [41]. The well-known Werther effect could also be traced through internet search data, as shown by increases in suicide-related information searches after celebrity suicides, such as those of Robin Williams [42] and Kimi Qiao [43]. Ideally, search data analysis should take into account such societal factors and other socioeconomic data (eg, unemployment rate) [44] to enhance suicide prediction and facilitate timely public health measures.

Individual-Level Research

Search data are not limited to search terms used; it may also include time stamps, location history, and YouTube search data and videos viewed—available through platforms such as Google Takeout [8]. Consequently, it may offer a diverse and rich data source at the individual level for mental health research, potentially offering insights into an individual's behavior, thoughts, and concerns [45]. The content of these searches can be linked to clinical data obtained from electronic health records or direct patient assessments to identify clinically relevant language. Studies may focus on searching key words (eg, "voices" or "psychiatrist"), categories of words (eg, negative emotion lexicons), composites of words and phrases derived by machine learning, or contextual embeddings identified by deep learning models [46]. Despite this potential, there is a discrepant paucity of data on individual-level studies compared

XSL•FO
RenderX

with the abundance of population-level internet search data investigations, for reasons addressed further in the text.

Among the few studies analyzing individual-level information, one enrolled 108 college students to link their Google search data to mental health data obtained from a self-administered mental health questionnaire [8]. The authors showed that individual-level search history could provide identifiable signals for detecting low self-esteem with reasonable accuracy. Another study of 92 adults, which aimed to develop an online automated screener, found that online behavior can help create automated classification tools for loneliness with high accuracy [47]. Kirschenbaum et al [48] requested 20 individuals hospitalized for psychosis to provide access to their Google archive data regarding text and timing of search queries. They observed that individuals with early psychosis appeared to use the internet for obtaining information about their early symptoms and experiences prior to their first contact with psychiatric care. More recently, Milton et al [49] successfully provided information on user's help-seeking behavior for common mental health disorders such as depression and anxiety based on the search terms. In another study, search queries from 105 individuals with schizophrenia spectrum disorders, mood disorders, and healthy volunteers were analyzed, using one year of data prior to the first psychiatric hospitalization [50]. Significant differences were observed one year in advance, in the timing, frequency, and content of search activity in individuals with mental illnesses compared with healthy volunteers. Additionally, 43 patients hospitalized for suicidal thoughts and behaviors granted access to their search logs from the 3-month period preceding psychiatric hospitalization [33]. Suicide-related searches included queries related to the television show 13 Reasons Why—a popular series about a teenage girl who dies by suicide that was airing during the study's recruitment period—as well as other suicide-related topics in the news media. Notably, some participants searched for highly specific and unusual suicide methods; one participant conducted numerous searches related to self-inducing cancer and investigated the possibility of purchasing live cancer cells on web-based platforms.

Due to this high-quality information and the potential for timely intervention for a serious event, search engines trigger help information after suicide-related searches. Nevertheless, caution should be taken as all that glitters is not gold. A study conducted by Haim et al [51] examined this complex topic of searching for suicide-related information. While investigating whether suicide-prevention results (eg, a helpline box) appeared after internet searches for suicide-related information, the authors showed concerns about possible ambivalent and potentially detrimental algorithmic decision-making. In their study, the suicide-prevention information (ie, the helpline box) was displayed only to a limited number of search agents searching for harmful suicide-related information.

Overall, internet search data might offer real-time alerts and opportunities for timely and early interventions, potentially improving mental health outcomes. Most importantly, it may be a useful tool to address the delay in seeking help for mental disorders [52]. Researchers are also investigating whether it could potentially be used as an adjunct to ongoing clinical management, such as relapse prevention in psychosis [10], with a small number of pilot studies currently underway. While internet search studies show potential, the existing data remain limited to a few studies with small sample sizes, and several ethical and methodological concerns exist related to these studies.

Problem Statement

One of the most important issues concerning the use of internet search data for mental health care research is privacy [53]. Uncertainty about users' willingness to share data is particularly critical across diverse groups and countries, raising concerns about the feasibility of large-scale data collection and potential biases in the data obtained [53]. Additionally, since the recent privacy violation lawsuits that gained media attention in the United States, an atmosphere of distrust has been created in the last few years posing a challenge that needs to be acknowledged and overcome [54]. In this context, addressing consent issues from vulnerable populations such as children and older adults is complex, and requires careful consideration of ethical guidelines and legal frameworks.

The second problem involves integration of internet search data with other sources of information such as electronic health records by researchers. Besides the privacy concerns mentioned, this process poses several challenges, which should be addressed from an interdisciplinary perspective. Storage and processing of large volumes of sensitive data could generate barriers for research teams. Computer scientists, data managers, and privacy officers should address these issues and define secure pipelines for information transfer—for example, defining how information should be extracted from internet and health records and aggregated into a secure and anonymized database available to the research team. Further, interpreting internet search patterns and clinical data requires advanced data analysis methods and interdisciplinary collaboration to avoid producing black box findings [55].

Third, additional general technical challenges must be addressed. For instance, ensuring user-friendly procedures for giving permission to access data, accounting for potential changes in search behavior due to awareness of monitoring (which could impact data quality and reliability), determining ownership of shared resource data, especially in regions where phones are communal, and addressing digital and mental health literacy. Perceived risk related to stigma and adherence to digital mental health initiatives are also important considerations.

Fourth, existing studies have been limited by small sample sizes—typically 100 participants or fewer. However, for accurate detection of psychopathology, language models must be highly complex and training of such models requires thousands of observations [46]. Moreover, model generalizability must be evaluated using new sample populations.

Finally, as scarce evidence exists regarding the use of internet search data for mental health care, the clinical accuracy and utility of identifying people at risk, diagnosing conditions, and reliably monitoring changes in symptoms remains to be determined. Retrospective data may have limitations in predicting future outcomes effectively (eg, data leakage, model

XSL•FO
RenderX

overfitting), raising concerns about its reliability for certain types of analyses and predictions. Researchers should acknowledge that the clinical utility of information that can be extracted from internet searches is currently unclear.

Proposed Solutions and Implementation

Addressing privacy concerns and distrust requires targeted actions. First, a thorough ethical analysis of research initiatives, coupled with clear and up-to-date forms of participant consent, is warranted [56]. In this context, it is important to reassure the participants that collected data will be used only for health research and not for commercial purposes [56]. Modern data security techniques, including deidentification of data, should be employed to ensure privacy. Additionally, to improve trust in data sharing, initiatives should be led by reputable academic institutions, with big technology companies serving as facilitators or in other supporting roles.

To address the second issue of integration of data, we propose to conduct research in large hospitals and universities, where considerable amount of clinical data are available to support large sample size. Inclusivity and diversity should be prioritized by involving academic institutions in and beyond North America and Europe—where most scientific evidence is generated—to include low-and-middle-income countries. Adequate funding should be designated to such projects to build a team of experts and to acquire enough hardware and software to deal with large and heterogeneous datasets. Consortia to facilitate the exchange of experience and knowledge between teams in the academic and commercial fields should be encouraged.

Third, technical challenges need to be addressed through rigorous study designs. Most importantly, the final models should be evaluated in previously unseen samples and rigorous assessment of overfitting, given the large quantities of data. The user-friendliness of the data-sharing procedures should be investigated by studies on usability and acceptability. The Hawthorne effect must be considered in study designs, and the possible use of ecological (or retrospective) data is warranted. Participant consent for sharing this sensitive data requires detailed discussions with researchers, especially regarding data ownership. Finally, as with all mental health initiatives, stigma needs to be addressed by increasing mental health literacy and providing accurate information on mental illnesses. This will ultimately stimulate participation in the studies and in theory, reduce possible biases (Table 1).

The challenge of stigma and privacy concerns from a broader perspective should also be addressed based on the proposed solutions. Additionally, other actions aiming at regulating the use of internet search data at the clinical level should be proposed. These legal actions should protect the society against inadequate commercial exploitation of technology, technology misuse, breach of confidentiality, and related issues. Together with campaigns to improve mental health literacy and to decrease distrust in big data collection and its use for medical purposes, public actions to support the consortium between the academia and companies such as Google, and government sectors should be stimulated and publicized. This environment of multiple cooperation between diverse sectors may encourage population participation and technology adoption. Further, enrollment of lived experience in all processes of research (from design until governance) may further improve public adoption and acceptability of new technologies.

Finally, diversity of samples is needed to maximize representativeness and generalizability. For instance, unequal access to the internet among populations could introduce a selection bias. The identified patterns should be investigated for multicultural reliability; cutting-edge and ever-evolving data analysis techniques will increasingly improve the performance of technologies. To establish clinical utility, models should be tested in real-world scenarios to demonstrate their superiority over currently used screening strategies and clinical evaluations. Accordingly, implementation feasibility of the clinical context needs to be assessed. From a patient perspective, their role in generating, communicating, and annotating data must be tested and defined. From the clinical practitioners' view, acceptability, the issue of how to integrate these data in their decision-making, and communication regarding the use of search queries within clinical practices need to be investigated.

Table . Summary of problems and proposed solutions for digital technology in mental health research.

Problems	Proposed solutions
Privacy concerns	Ethical analysis, participant consent, data securing, research led by academia
Data integration	Enroll large clinical datasets, funding for multidisciplinary team
Technical challenges	Sufficient training data (usually thousands of observations) and evaluation in new datasets
Clinical accuracy and utility	More diverse samples, different sociocultural settings, include patient samples and outcomes of clinical interest (eg, prognosis, response to specific treatment)

Conclusion

Internet search data that are integral to daily life generate large amounts of individual data and have the potential to revolutionize mental health care. In summary, individual search data might be of great value in (1) the prediction of mental health problems using search history, (2) real-time identification and development of alert mechanisms to target timely interventions, and (3) adjuncts to clinical management. However, ensuring participants' trust and confidentiality is essential. Consortia between academic institutions and technology companies should be encouraged, aimed at

XSL•FO
RenderX

increasing the population's reliance on these data, knowledge exchange between different sectors, and big dataset handling. Further research is strongly encouraged to address feasibility and acceptability. Existing studies are too small to ensure replicable results; future studies should involve significantly larger sample sizes. New initiatives should be inclusive and diverse, incorporating perspectives from the Global South to ensure the universality of findings.

Abstract

People worldwide are confronted with environmental and sociopolitical stressors that act as potent sources of subjective uncertainty. The uncertainty arising in response to the volatility and unpredictability of adversities is amplified by their representation or misrepresentation in media news. While the causal effect of media news on vicarious traumatization has been well established, we argue that the impact of negative media news is principally related to distress and anxiety stemming from the uncertainty-inducing effect of media representations of the state of the world. As a growing body of research suggests, minimizing uncertainty related to global stressors is a significant driver of media news use. However, extensive media exposure perpetuates stress and is associated with symptoms of psychopathology. The self-perpetuating vicious circle of worry and excessive media consumption has been amply confirmed by new research related to the COVID-19 pandemic. Furthermore, attempts to alleviate stress and anxiety stemming from uncertainties often result in maladaptive strategies. In particular, the adoption of rigid behavioral patterns may prompt various forms of socially detrimental behavior. Critical factors in prevention and remediation include limiting media overexposure and implementing therapeutic interventions that focus on increasing tolerance to uncertainty.

(JMIR Ment Health 2025;12:e68640) doi:10.2196/68640

KEYWORDS

anxiety; cognitive psychology; social context; stress; uncertainty; media news

Introduction

Background

It has long been recognized that exposure to a stream of negative media news is detrimental to overall well-being and mental health. Although media news can have positive, neutral, or negative content, most news items have a negative valence [1,2]. It is well established that news consumers pay more attention to negative news [3], which also elicits stronger physiological and psychological reactions [4,5]. Negativity drives particularly online news consumption [6,7] and social media platform use [7]. Moreover, even people who do not receive regular news updates can still be confronted by news events through the people they follow on social media [8].

A large body of previous research has convincingly established the association between media exposure and symptoms of posttraumatic stress related to various life-threatening stressors, such as war conflicts [9,10], terrorism and other acts of mass violence [11-15], natural disasters [16,17], and recently also the COVID-19 pandemic (refer to "Uncertainty as a Defining Feature of the COVID-19 Pandemic" section). Additional lines of research have associated negative or violent news watching with anxiety and depression, self-destructive behaviors, and other mental health issues [18,19]. In addition to posttraumatic stress disorder (PTSD), anxiety and depression also showed

XSL•FO
RenderX

significant linkages with indirect (media-transmitted) contact with disasters and large-scale violence [20,21].

A major implication of this research is that the long-standing dichotomy of *direct* versus *indirect* (ie, media-transmitted) exposure to psychological and traumatic stressors, as also codified in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* [22], is problematic, as the distal and indirect levels are increasingly merged with the proximate and direct level of stressful impact. Recent research provided extensive evidence that indirect exposure is associated with stress symptoms and other psychopathologies comparable to those linked to direct exposure [13,16,23-27].

However, traumatic news constitutes only a minority of news items traversing various media outlets. While relatively scant, emerging evidence suggests that exposure to everyday nontraumatic news affects emotional states and mental well-being as well [28,29]. The dominant focus on vicarious psychological trauma may have obscured the fact that the complex relationship between media news consumption and its negative mental health effects appears to be, to a large extent, mediated by uncertainty. In this narrative-based perspective, we present a sustained argument that uncertainty now must be recognized, alongside vicarious traumatization, as a major outcome of media-transmitted adversities. First, we focus on reviewing current research linking media consumption with current sociopolitical and environmental adversities. Next, we zoom in on cognitive mechanisms through which media news elicits uncertainty and negative anticipation before turning to behavioral consequences of media-related uncertainty. Finally, we conclude with a brief section on remediation and resilience building.

Global Adversities, Uncertainty, and Media

Uncertainty is a multidimensional construct and has been defined in various ways [30-32]. At its most basic, uncertainty is a subjective state that captures a person's belief about the state of the world. It is often used to refer to the lack or inconsistency of information about an event or situation. Computations of subjective estimates of uncertainty predict acute stress responses [33] and depressive symptoms [34] in humans. Several prominent models posit a direct causal link between uncertainty and anxiety [35-37]. Indeed, anxiety has been defined as "anticipatory affective, cognitive, and behavioral changes in response to uncertainty about a potential future threat" [34]. Furthermore, subjective feelings of uncertainty, or uncertainty distress [38], may be accompanied by or instigate a host of other mental states, such as helplessness, frustration, anger, guilt, and grief [39].

Currently, there are 2 major factors mediating the intensity of the psychological impact of uncertainty on populations. First, global communities are confronted with a plethora of interconnected sociopolitical and environmental adversities—all characterized by high levels of complexity, unpredictability, and volatility—from progressing and potentially catastrophic climate change, accelerating economic inequality, wars and conflicts, widespread displacement and migration, the resurgence of authoritarian political tendencies in many parts of the world to the COVID-19 pandemic and potential threats of uncontrolled artificial intelligence, to name but the most obvious ones. Other chronic problems arising from more local contexts add to the burden of global adversities. While at present there is no generally accepted definition of what constitutes a "stressful event" [40,41], it is nevertheless evident that people are confronted with a range of *psychological* and *traumatic* stressors [42]. To varying degrees, they span ongoing situations as well as expected or potential future developments. The protracted, inherently complex, and unpredictable nature of such adversities translates into numerous *situational uncertainties* about personal prospects and the possibility of achieving life goals [43,44]. Uncertainty-related worry and anticipation range from severe existential threats, including the possibility of imminent death (Will the Russian attack on Ukraine escalate into a nuclear war?) and threats to the achievement of primary life goals and motivations to less severe but still worrisome and potentially traumatic uncertainties regarding social and economic security. While some may have a limited duration (Will the feared politician be elected in the upcoming election?), many are ongoing with no clear resolution in sight. For many people, these global stressors will additionally exacerbate personal uncertainties, involving doubts in self-views and worldviews [45].

Uncertainty most often has a temporal dimension, as it is related to outcomes that are supposed to occur in the future and stems from the person's inability to predict future events. The inherently anticipatory nature of uncertainty-related stressors and their negative consequences on mental health have been long recognized [46,47]. In the realm of sociopolitical adversities, uncertainty and anticipation of economic shocks, not just their occurrence, were highlighted as a significant causal mechanism linking poverty and mental illness [48]. Studies have demonstrated that uncertainty surrounding elections, governance changes, and economic downturns can lead to future-oriented anxiety, heightened vigilance, and cognitive rigidity [49]. Therefore, it is not surprising that a recent psychological survey showed that 81% of US adults pointed "global uncertainty" as a source of chronic stress [50]. Chronic uncertainty exerts a particularly heavy toll on people living under multiple strains and in precarious conditions, such as refugees and displaced persons [51-53], and on people living under *continuous traumatic situations* intensively covered by the media, such as populations affected by Israeli-Arab conflicts or the war in Ukraine. Individuals living in such chronic situations seem to be mainly concerned with the future, that is, with anticipated future danger and threat, and their thinking is dominated by fantasies of what might happen and ways of avoiding it [54,55].

Second, as we further elaborate in the following sections, media representations or misrepresentations of the reality and potential consequences of adversities further exacerbate uncertainty, along with feelings of uncontrollability and unpredictability, as well as negative anticipation toward socioenvironmental stressors. If theoretical models of uncertainty, particularly Bayesian computational models, posit the uncertainty to arise from discrepancies between top-down expectations and sensory outcomes [56,57], it bears emphasizing that the sociopolitical and environmental adversities are to a large extent (or to many

XSL•FO
RenderX

people) hidden to direct sensory observation, their reality and potential consequences being established only by representations diffused by mass and social media. Another key factor in sociopolitical uncertainty is the role of misinformation and propaganda, which contributes to fear, panic, and distrust, thereby exacerbating psychological distress. Misinformation and propaganda have been linked to increased polarization and cognitive rigidity [58], the adoption of conspiracy theories as a means of reducing uncertainty [59], and heightened distress and anxiety due to conflicting narratives and media sensationalism [53].

Two Case Studies

Uncertainty as a Defining Feature of the COVID-19 Pandemic

Pervasive uncertainty has been a fundamental aspect of the public health crisis caused by the COVID-19 pandemic—a global and chronic psychological stressor with severe implications for mental health and well-being [60,61]. The COVID-19 pandemic provided new incentives for a reconceptualization of the very notion of the traumatic stressor (as captured, eg, in *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*), as its negative impact relates to the future rather than the past and to indirect as much as to direct exposure [62,63]. While this reconceptualization is theoretically compelling, it remains underexplored empirically and requires further research to assess its validity in relation to long-term diagnostic outcomes.

Robust evidence from extensive research, including both cross-sectional and longitudinal designs, using both convenient and representative samples, confirms that excessive exposure to pandemic-related media is a substantial predictor of detrimental psychological effects. These effects include heightened levels of anxiety [64], depression [64,65], psychological distress [66,67], posttraumatic stress symptoms [68], schizotypal traits [69], and substance use [70].

This negative impact on the psychological state has been found to be more pronounced in social media than in traditional media [64,68,71-73]. Several studies have focused primarily on the use of online media or social media during pandemics. They confirm a connection between excessive electronic (internet) media exposure and the prevalence of stress, generalized anxiety, depression, and long-term psychological distress [66,70,74]. Such a pattern was confirmed in a study using ecological momentary assessments that found a positive association between daily exposure to COVID-19 news, worry, and hopelessness [75]. Social media has also fueled the rapid spread of misinformation and rumors, which can create a sense of panic and confusion among the public [76], underscoring the importance of combating the "infodemic" during a public health emergency [77]. However, these studies rarely distinguish between specific platforms (eg, Twitter [now rebranded as X], Facebook, Telegram, TikTok, and Reddit) or types of use (eg, news seeking vs social interaction). This is a significant limitation, as different platforms foster distinct emotional climates and are shaped by unique algorithmic dynamics, which may influence their psychological impact in different ways.

While the existing body of literature robustly supports a link between media exposure and adverse psychological outcomes during the COVID-19 pandemic, it is important to note that most of these studies rely on cross-sectional designs and self-report measures. Therefore, our understanding of the reciprocal relationship between distress and media use—such as whether psychological distress drives increased "doomscrolling" or vice versa—remains limited. However, some studies have also used more rigorous methodologies, including longitudinal designs and ecological momentary assessment [75]. In addition, there is a lack of standardization in how media exposure is defined and measured, with few studies differentiating between media platforms, content types, or modes of engagement [71,73]. There is also a notable lack of research into potential protective factors, although some studies have begun to address this gap [71].

Current War in Ukraine

War-induced uncertainty encompasses a wide range of anxieties, including geopolitical instability (eg, fear of war escalation, nuclear threats, and global security risks); economic uncertainty (eg, rising energy prices, disrupted supply chains, and inflation concerns); and humanitarian crises, such as displacement, refugee movements, and ethical dilemmas regarding international response. Individuals with high levels of intolerance of uncertainty (IU) are more likely to experience heightened levels of stress when confronted with uncertain or unpredictable circumstances, such as wartime [78]. Fear of war has been found to increase the level of stress, anxiety, and depression, while also strengthening the future anxiety and IU [79]. The anticipatory uncertainty surrounding the conflict (eg, potential escalation, economic instability, and geopolitical tensions) parallels the uncertainty associated with global health crises but differs in that it involves military aggression, political narratives, and humanitarian crises, which create unique patterns of stress and information-seeking behavior [53]. Just as with the COVID-19 pandemic, social media plays a dual role in war-related uncertainty—it serves as both a source of information and a catalyst for misinformation and emotional distress. Real-time updates create a heightened sense of crisis, leading to compulsive checking of news feeds (doomscrolling), a behavior that has been directly linked to increased psychological distress and rumination [80].

The ongoing war in Ukraine provides a critical example of how media coverage of armed conflicts can amplify uncertainty-related mental health symptoms, even in populations not directly involved in the conflict. The pervasive dissemination of war-related news through various media channels has profound implications for public mental health. Individuals, even those geographically distant from conflict zones, can experience significant psychological distress upon exposure to such content. Recent research highlights that war-related uncertainty, particularly media-induced exposure to conflict, has significantly augmented levels of stress, anxiety, depression, and posttraumatic stress in Czech, Slovak, German, Polish, Italian, and even Taiwanese populations [55,81-83].

Kalaitzaki et al [84] provided a cross-sectional analysis of the impact of war across 11 countries on populations in areas

XSL•FO
RenderX

directly or indirectly affected by the conflict, focusing on war-related stressors and PTSD symptoms. Individuals exposed to war-related stressors, including displacement, violence, and loss, are at a heightened risk for developing PTSD. However, the authors also highlight the significant role of media coverage and uncertainty, which are not often directly linked to conflict but have substantial psychological effects. Continuous media coverage, especially news reports focusing on graphic images or uncertain political developments, was found to heighten feelings of anxiety and helplessness among those already traumatized by the war. Constant media bombardment, especially when coupled with the prolonged uncertainty about the war's resolution, contributes significantly to the mental health burden experienced by affected populations. Uncertainty, in this case, is not just related to the physical dangers of war but also to the unpredictability of the future and a general sense of destabilization. This research emphasizes that the mental health effects of war extend beyond direct trauma, with media and uncertainty being central factors in the broader psychological impact of conflict.

Individual Differences in IU

The ability to tolerate uncertainty is a critical factor in adapting to unfavorably changing conditions with low predictability. Conversely, the IU has been defined as "an individual's dispositional incapacity to endure the aversive response triggered by the perceived absence of salient key, or sufficient information, and sustained by the associated perception of uncertainty" [32]. IU, as a set of negative cognitive, affective, and behavioral reactions to situational uncertainty [38,85], predicts acute subjective and psychological stress response in humans [33] and defensive responding. It functions as a catalyst of anticipatory anxiety and catastrophic thoughts and negative rumination on possible negative and catastrophic outcomes [32,86]. IU has been identified as a critical transdiagnostic risk factor and component of internalizing psychopathology across a range of mental disorders, such as generalized panic and social anxiety disorders, obsessive-compulsive disorder, depression, eating disorders, and others [87-89]. Individuals with high levels of IU are more likely to experience heightened levels of stress when confronted with uncertain or unpredictable circumstances, such as wartime [78]. This connection has been amply documented in the context of COVID-19: recent research has confirmed a direct association between IU and negative mental health outcomes during the pandemic [90-94].

A number of recent studies have specifically examined the link between media use, IU, and negative psychological effects [68,95-97]. A direct effect of IU on problematic social media use [98] and mobile addiction [99], as well as moderation effects between both depression and anxiety and problematic social media use, was found [100]. IU also mediated the effect of fatigue related to COVID-19 on depressive symptoms [101] and partially mediated the relationship between media exposure to COVID-19 and acute stress [102].

Demographic Differences in IU

Emerging research indicates that IU varies across individuals and populations, influenced by demographic factors such as age, gender, cultural background, and socioeconomic status. While individual differences in IU significantly influence responses to media-induced uncertainty, understanding demographic differences in IU is crucial for developing targeted therapeutic implications for interventions aimed at reducing media-induced stress. Research indicates that IU levels fluctuate across the lifespan [103]. A recent meta-analysis revealed significant age-related differences, with adolescents exhibiting higher IU compared to adults and older adults [104]. This heightened intolerance in younger individuals may be attributed to developmental factors and varying coping mechanisms. In addition, studies suggest that IU correlates with anxiety and other psychological issues in older adults.

Regarding media use, research has shown that younger populations (aged between 15 and 20 years) tend to engage in higher levels of media consumption, making them more vulnerable to doomscrolling and increased anxiety [105]. Older adults (aged between 45 and 55 years) are more susceptible to economic and political uncertainty, exhibiting stress responses driven by financial instability and governance concerns [106]. Therefore, for younger individuals, strategies such as limited media consumption, cognitive restructuring, and digital literacy training may be particularly effective. In contrast, older adults may benefit from mindfulness-based interventions (MBIs) and cognitive reframing techniques to mitigate uncertainty-related stress [107].

Gender has been identified as another significant factor influencing IU. Studies indicate that women often exhibit higher levels of IU [108] and score higher in constructs related to health anxiety and IU [109,110], showing a stronger relationship between IU and negative future orientation. Research involving university students found that female participants scored higher on measures of trait worry, IU, and cognitive avoidance compared to male participants. While both male and female entrepreneurs face uncertainty, their decision-making processes may differ [111]. However, findings on how IU and gender jointly affect decision-making strategies such as effectuation and causation are mixed, indicating the need for further exploration. These findings suggest that women may experience and react to uncertainty differently than men, potentially due to a combination of biological, psychological, and sociocultural factors.

However, it is important to note that some studies report no significant gender differences in IU [112]. For example, research investigating the relationship between IU and psychological well-being found no gender differences in IU scores among participants. This suggests that the impact of IU may be more pronounced in certain contexts or populations rather than being universally higher in women.

Socioeconomic status and education are other crucial factors that can influence an individual's IU. While specific studies on the direct relationship between socioeconomic status and IU are limited, it is plausible that individuals with higher

XSL•FO
RenderX

socioeconomic status and education levels may develop more effective coping strategies for dealing with uncertainty. Higher socioeconomic status individuals often have access to better resources, health care, and social support systems, which can buffer the negative effects of uncertainty and stress. Conversely, individuals from lower socioeconomic backgrounds may face additional stressors, such as financial instability, limited access to health care, and social discrimination, which can exacerbate IU. These stressors may increase their vulnerability to anxiety and related disorders as the uncertainty surrounding their daily lives becomes more pronounced. The chronic stress associated with economic hardship can lead to heightened sensitivity to uncertainty, making it more difficult to cope with ambiguous situations.

In addition, educational attainment plays a role in shaping an individual's ability to manage uncertainty. Higher levels of education are associated with better problem-solving skills, greater self-efficacy, and improved emotional regulation, all of which can reduce the impact of IU [113]. In contrast, individuals with lower educational attainment may lack these coping resources, making them more susceptible to the negative psychological effects of uncertainty [114].

Cultural influences are another important demographic consideration. IU is not only shaped by individual psychological traits but also by the social and cultural environments in which people live, and cultural factors significantly influence how individuals experience and cope with IU. In collectivist cultures, where social harmony, group cohesion, and interdependence are highly valued, uncertainty may be viewed as a potential threat to relational stability. Therefore, individuals from collectivist cultures might experience heightened anxiety and distress when faced with uncertain social outcomes or the possibility of disrupting group expectations [115]. This socially driven uncertainty can increase IU, particularly in the context of interpersonal relationships and social approval [116]. By contrast, in individualistic cultures, where autonomy, independence, and self-expression are prioritized, uncertainty may be experienced as a threat to personal control and self-efficacy [117]. Individuals in these cultures may experience greater distress when uncertainty undermines their sense of personal agency or the achievement of individual goals [118]. The difference in how uncertainty is perceived—social versus personal control—suggests that therapeutic approaches should be tailored to cultural contexts to better address the distinct ways in which IU manifests.

Mediating Role of Vigilance and Future-Oriented Thought

Psychological and neural mechanisms through which uncertainty-inducing stressors elicit negative mental states, particularly anxiety, and may lead to psychopathology have been extensively described in the literature [31,35,36,57,119,120], and these models are broadly relevant in the present context. Due to space constraints, we briefly focus on 2 processes that we consider critically important for how media news is processed: vigilance and future-oriented thought.

Vigilance

Humans display sustained vigilance and defensive responses under conditions of uncertainty [31,32,85]. While sustained vigilance represents the initial adaptive response under conditions of uncertainty [35,120], it can develop into hypervigilance, that is, increased attention to threatening or potentially threatening stimuli. Hypervigilance has been singled out as 1 of 5 key processes involved in aberrant and excessive anticipatory responding to uncertainty [31]. It is tightly coupled with attentional threat bias, referring to the fact that negative valence content captures human attention more than other content [121,122]. Converging evidence indicates that negative emotional content is prioritized over neutral content even during early stages of visual attention [122-124]. Uncertainty-related hypervigilance "locks into" the aforementioned propensity of news to prioritize content with negative valence and the tendency of people in a situation of high uncertainty to explore negative information [125] and appraise emotionally ambiguous information in negative terms [126], thus initiating a vicious circle, which we describe in the subsequent sections.

Although the mechanism of hypervigilant response to uncertain threat is well supported in the literature, it has not been investigated in studies that would accurately reflect real-world media consumption patterns and that could account for the complex interplay between the type of media consumed and the individual's baseline level of anxiety or stress. Thus, while uncertainty-related vigilance may align with news media's tendency to emphasize negative content, further research is needed to explore how the framing of news, individual differences, and media platform type contribute to this relationship.

Future-Oriented Thought

As uncertainty-related worry mostly concerns future events and situations with an uncertain outcome [127], the aversive uncertainty generated by the appraisal process of media news hinges on the person's mental construction of some possible future state of affairs implied by the news item. The key cognitive mechanisms are episodic and semantic simulations of future events [128]. Episodic simulation constructs a detailed mental representation of a specific autobiographical situation in the future [129]. Much less is known about semantic simulation–driven expectations, that is, predictions and future thinking about more general or abstract states of the world that may arise in the future (eg, thinking about what the consequences of global warming will be like 25 years from now) [130]. Both forms are likely involved and mutually intertwined in the appraisal process of media-related stressors. As imagining aversive events has emotionally aversive consequences, internal simulations themselves incur some of the same costs as real-world experience [131]. Growing literature connects psychological distress, particularly internalizing psychopathology, to disturbances in both episodic and semantic future thinking. It has long been recognized that future-oriented cognitions play a central role in the development of depression and anxiety [132,133]. Both conditions are commonly characterized by negative, future-oriented thought patterns [134,135]. Mental simulation of future events may be

XSL•FO
RenderX

the mechanistic link between uncertainty (as a breeding ground of anxiety) and affective responses [136].

Although both types of future-oriented thinking are central to the appraisal of uncertainty, the literature has largely focused on episodic simulations, with limited research on the role of semantic simulations in the context of media-induced stress. Notably, while there is growing evidence that future-oriented thinking can both exacerbate and mitigate psychological distress, the findings are inconsistent. For example, some studies suggest that structured mental simulations of stressful events can improve emotional regulation and increase the propensity for problem-focused coping [137,138]. In contrast, other studies argue that suppressing the mental simulation of feared future events can help prevent the onset of anxiety [139].

Furthermore, much of the existing research predominantly focuses on clinical populations, with little attention paid to how future-oriented cognition operates in nonclinical groups. This is a significant gap in the literature, as many individuals in the general population experience uncertainty-related anxiety without meeting the clinical criteria for disorders such as generalized anxiety or depression. A deeper exploration of the neural mechanisms underlying future-oriented thought in nonclinical populations, particularly in response to uncertainty-inducing media, is an important avenue for future research.

In summary, the existing literature on vigilance, future-oriented thought, and their roles in media-induced anxiety has provided important insights. However, significant gaps still remain that must be addressed. Future research should consider more longitudinal and experimental designs to establish causal relationships, explore the effects of different media types, and investigate the neural mechanisms involved. In addition, expanding the focus beyond clinical populations will help clarify how these processes operate in the general population and contribute to the development of anxiety and other mental health issues. By addressing these gaps, we can enhance our understanding of how uncertainty-related processes interact with media consumption to shape psychological and emotional responses.

Behavioral Consequences of Subjectively Felt Uncertainty

Vicious Circle of Uncertainty and Media News Consumption

As Hirsh et al [35] aptly observe, much of our lives are spent trying to reduce and manage uncertainty. Management of uncertainty is a complex process, and reduction or resolution are not the only strategies people pursue in the face of uncertainty [140]. Nevertheless, aversive feelings stemming from uncertainty typically lead to attempts to minimize them, which often involve maladaptive responses such as hypervigilance, repetitive negative thinking, reassurance seeking, and increased checking behavior. Uncertainty reduction theory [141] posits that people are motivated to seek information in the aftermath of a traumatic or threatening event to reduce anxiety.

As discussed earlier, a substantial body of research indeed confirms that people in uncertain situations, such as disaster events or pandemics, seek information via media to alleviate negative feelings, yet extensive media exposure perpetuates stress and is associated with symptoms of psychopathology, and this pattern is particularly characteristic of the use of social media [27,74,142-145]. Conversely, news avoidance can have a positive effect on mental well-being [146]. While some degree of media use to obtain information and alleviate distress is adaptive in the setting of momentary or long-term stressors, in practice, there is no clear-cut division between adaptive information seeking, which (at least initially) may serve to guide rational decision-making and action vis-à-vis particular adversity, and compulsive news consumption, mainly driven by the need to alleviate aversive feelings of worry and anxiety. A need to minimize uncertainty is thus a major driver of news use, which, however, may escalate into a vicious circle of iatrogenic-like media consumption, which reciprocally further increases worry and anxiety.

A growing number of studies currently provide empirical evidence of this pattern. In the study conducted in the aftermath of the 9/11 attacks, Cho et al [147] established that negative affect resulting from television news use after the attacks drove future television news use and predicted negative affect responses several months later. Such a pattern has been confirmed in a recent longitudinal study following 2 terrorist attacks: trauma-related media exposure perpetuates a cycle of high distress and worry, leading to increased subsequent trauma-related media consumption, which further promotes increased distress [143]. In a similar way, a study of anticipatory media exposure to hurricanes found that personally forecasted posttraumatic responses and storm-related media consumption before an approaching hurricane are important correlates of poststorm psychological adjustment [148].

The self-perpetuating vicious circle of worry and excessive media consumption has been again amply confirmed by new research related to the COVID-19 pandemic. Several studies found that worry about the pandemic predicted increased consumption of pandemic-related media and doomscrolling, which in turn led to further increases in negative emotions and pandemic-related worry [74,149-151]. According to daily survey studies, increased exposure to COVID-19 news on one day increased COVID-19 worries the next day, and higher worries on one day predicted higher media exposure the next day [150,151]. Increased media consumption during the pandemic may thus initially serve as a potential coping strategy to handle pandemic-related distress but often results in inducing more worries through mechanisms of overexposure and rumination [149]. Individuals with high levels of trait anxiety, neuroticism, and a history of severe maltreatment, as well as those with more severe baseline psychopathology, tend to exhibit increased overall levels of media exposure and thus constitute a group considered particularly vulnerable [72,150]. Moreover, the inherent design of contemporary media platforms tends to amplify these effects. Previous research has also established that increases in IU correlate positively with mobile phone penetration and internet use. These technologies thus increase reassurance seeking and reduce spontaneous, everyday

XSL•FO
RenderX

exposures to uncertainty, which may lead to psychopathology by increasing IU and anxiety [152]. Research shows that individuals with higher IU who frequently searched the internet for COVID-19 information experienced greater fear of the virus—a fear that is both a consequence and a driver of IU [95].

Cognitive Inflexibility, Compensatory Control, and Tightening of Beliefs

In addition to information seeking and fact-checking, people experiencing uncertainty-related worries and anxiety often engage in processes of compensatory control in an effort to imbue the world with order and predictability [59]. Uncertainty and uncontrollability breed the loss of meaning. The aversive reactions then result both from the perceived threat to one's motivations and goals and from the decreasing ability to make sense of the changing and volatile social environment and one's prospects in it, which prompts maladaptive strategies to restore the sense of meaning to events in the world. A drive to reduce uncertainty is tightly coupled with cognitive inflexibility. Individuals with a lower threshold for tolerating uncertainty tend to be more rigid and closed-minded in their worldviews, values, and attitudes [45,153], especially when uncertainty is explicitly linked with threat [154,155]. Psychological models, such as the uncertainty-identity theory [156], meaning maintenance model [157], and compensatory control theory [158,159], have elaborated on how the defensive need to alleviate uncertainty leads to group identification, ideological inflexibility, and dogmatism. Such "tightening of beliefs" functions as a defensive response to intolerable stress and uncertainty and may affect mental health in a transdiagnostic manner [160]. The "tight beliefs" or rigid interpretations may be linked to conspiracy thinking [58] and may attain a form of delusional ideation [44]. They have profound political and social consequences as they fuel polarization, partisanship, fanaticism, and extremism [161,162]. Ultimately, such tight beliefs contribute to the spreading of conspiracy theories and other forms of socially detrimental behavior, thus further enhancing subjective uncertainties about the state of the world.

However, attempts to minimize short-term uncertainty by adoption of rigid cognitive structures and behavioral patterns are, in the long run, often maladaptive strategies [32,35]. Typically, people who turn to conspiracy beliefs in an attempt to alleviate the negative experience of uncertainty do not succeed in this attempt and may even experience short-term increases in uncertainty aversion, anxiety, and existential dread [163]. Importantly, a tightening of beliefs under conditions of chronic stress and uncertainty does not automatically translate into maladaptive or deviant social behavior.

Strength of Evidence and Methodological Considerations

While, as reviewed, there is growing research linking IU to media consumption and psychological discomfort, many of these studies rely primarily on cross-sectional designs and self-reported measures, which have inherent limitations. Cross-sectional studies only record 1 time point, making it impossible to discern causality—whether IU causes higher media use and anxiety or whether excessive media exposure worsens IU and distress. Furthermore, self-report measures are susceptible to recall bias and social desirability effects, as individuals may overestimate or underestimate their media intake and emotional impact [65]. Future research should prioritize longitudinal designs and experimental methods to elucidate the causal relationships between media exposure, IU, and psychological distress. The measurement of media exposure is often poorly standardized, ranging from self-reported hours to vague categories such as "many times per day," and rarely differentiating between active and passive use or the specific type of content consumed. Many studies rely on self-reported data, which may be subject to recall bias, as participants often struggle to accurately estimate their media consumption habits [76]. Future studies should incorporate objective digital tracking methodologies to refine these findings and better assess real-time media exposure patterns.

Another important limitation is the lack of consistent definitions and measurements of IU across studies. Some studies measure IU using general anxiety measures, while others use particular IU scales to detect anticipatory worry or avoidance actions. This inconsistency makes it difficult to evaluate results across populations and situations [32].

Potential Biases in Literature

Many studies rely on convenience samples, often recruited through online platforms, which raises concerns about sampling bias—such as the overrepresentation of the young and educated, with digital literacy—and limits the generalizability of the findings. A related problem is the overrepresentation of western, educated, industrialized, rich, and democratic populations in psychology research [164]. Most studies on IU, stress, and media consumption have been conducted in North America and Western Europe, which limits the cross-cultural application of the findings. For example, while American and European populations report high levels of uncertainty-induced stress due to political instability and economic downturns, research from East Asia suggests that collectivist cultures may use different coping mechanisms, such as social cohesion and community-based stress buffering [165]. In contrast, extended uncertainty is frequently normalized in Middle Eastern or conflict-affected areas, resulting in distinct patterns of emotional regulation and resilience [53].

Cross-Cultural Perspectives on Media Influence

The media's influence on generating uncertainty perceptions differs around the globe. While Western media regularly sensationalizes crises and political instability, resulting in fear-driven engagement (doomscrolling), authoritarian media frequently restricts uncertainty-inducing news to maintain societal control. For example, during the COVID-19 pandemic, studies found that media exposure increased uncertainty-related anxiety in democratic countries, whereas in China, state-controlled media reduced coverage of negative outcomes, resulting in lower reported stress levels despite real risks [102].

XSL•FO
RenderX

Such disparities imply that media-induced doubt is influenced not only by global crises but also by governmental policies, media freedom, and cultural attitudes toward uncertainty.

Preventive Measures and Remediation

Managing Media Consumption

Even a cursory search of the internet yields dozens of popularizing articles from mental health professionals advising readers to limit the intake of negative media and avoid excessive doomscrolling and compulsive social media use for the sake of their mental health. Behavioral coping with the influx of negative media news must be primarily focused on the aforementioned amplifying effects of the media in spreading uncertainty and stress, along with their adverse mental states. However, while behavioral coping strategies must address the amplifying effects of media in spreading uncertainty and stress, a nuanced approach is needed, as complete avoidance may also have unintended consequences.

As noted earlier, robust evidence has shown a positive association between the frequency and total time spent watching or reading media news and symptoms of mental distress, highlighting the need to limit media exposure [10,64,66,166]. Even ≥1 hours of daily television watching might have some negative consequences [10,13,167]. Specifically, Bendau et al [64] reported that the critical threshold of 7 times per day and 2.5 hours of media exposure differentiates between mild and moderate symptoms of anxiety and depression. This implies that while avoidance is generally considered a less adaptive strategy, in the present context, what might be termed "informed avoidance" might prove to be a positive reaction. Preventing overexposure to media, particularly in groups considered vulnerable, is thus critical to buffering distress.

The specific circumstances of media consumption present another opportunity for intervention. There is some evidence to suggest that negative emotional responses to negative news can be mitigated by constructive news reporting and peer discussion [168]. Patterns of reading and watching may also play a role, with reading entire articles presenting a safer alternative to mere headline browsing [71]. However, reading anonymous and often highly negatively balanced comments under web news articles leads to an increase of subjectively perceived stress, anxiety, and depression induced by the media [71]. Moreover, in the absence or ambiguity of information, people contribute to the spread of misinformation [169] or disinformation, a subject of much recent attention [170-172]. Adaptive media consumption patterns must include a critical mindset when consuming media, question potential motivations behind the presented information, and avoid untrustworthy sources of news content and exposure to disinformation or fake news.

Consequently, interventions should incorporate media literacy training, equipping individuals with critical thinking skills to evaluate sources, assess potential biases, and recognize disinformation patterns [173]. Cross-cultural studies suggest that individuals in societies with high levels of trust in institutions and regulated media environments (eg, Nordic countries) exhibit greater resilience to misinformation-related stress compared to those in highly polarized or authoritarian settings, where media manipulation is prevalent.

Promoting Tolerance to Uncertainty and Cognitive Flexibility

Given the crucial role of uncertainty in the cascade of negative effects of media exposure and propaganda, increasing tolerance of uncertainty is a critical goal of intervention. Cognitive behavioral therapy for IU (CBT-IU) [174] is a specialized form of cognitive behavioral therapy (CBT) designed to help individuals develop adaptive responses to uncertain situations [175]. While originally developed for anxiety disorders, CBT-IU has been successfully applied in contexts such as pandemic-related stress, economic instability, and geopolitical crises [38]. However, many studies examining CBT-IU effectiveness rely on short-term intervention periods, making it difficult to assess long-term outcomes. More research is needed to evaluate sustained behavioral changes in uncertainty management strategies. Beyond traditional CBT, *third-wave* behavioral therapies, including acceptance and commitment therapy (ACT), dialectical behavior therapy (DBT), metacognitive therapy, and mindfulness-based cognitive therapy [176,177], offer promising avenues for increasing resilience to uncertainty [176]. These approaches emphasize acceptance-based strategies rather than avoidance, enabling individuals to engage with distressing thoughts without excessive reactivity.

ACT or DBT generally share an emphasis on acceptance and mindfulness, encourage individuals to accept their emotions and thoughts, and can help individuals to better manage their emotions when confronted with distressing media content.

Another approach, metacognitive therapy, aims to change unhelpful thought patterns related to rumination, worry, and cognitive processes that can lead to distress.

Recent studies suggest that ACT interventions significantly reduced anxiety symptoms during the COVID-19 pandemic, particularly among adolescents and health care workers, who faced high levels of prolonged uncertainty [178]. Several studies demonstrated that ACT-based interventions led to significant reductions in depression and stress symptoms in pandemic-exposed populations, with long-term effects persisting months after initial treatment [179]. However, it is important to acknowledge cultural variability in treatment efficacy—while ACT and DBT have been widely implemented in Western populations, studies examining their effectiveness in collectivist cultures remain limited, warranting further cross-cultural validation [180].

MBIs represent another promising approach for enhancing IU and improving emotional regulation. Empirical evidence points out that mindfulness-based approaches may improve stress tolerance and coping [181]. Mindfulness-based stress reduction programs have been shown to ameliorate symptoms of anxiety, depression, and emotional dysregulation during global crises [182]. MBIs help individuals develop a nonreactive awareness of distressing content, breaking the cycle of negative rumination triggered by media exposure [183]. Mindfulness was

XSL•FO
RenderX

instrumental in developing the capacity to disengage from attention capture by future- or past-oriented thinking, thus ameliorating mental symptomatology related to uncertainty and the loss of pandemic situations [184]. The MBSR program successfully reduced stress and anxiety while improving emotion regulation in participants during highly stressful conditions caused by the global pandemic [185].

All these preventive and remediation interventions, to varying degrees, foster neuroplasticity-related adaptations in brain regions involved in emotional regulation and cognitive flexibility [186-188]. Functional neuroimaging studies indicate that adaptive coping with uncertainty is associated with alterations in the perigenual anterior cingulate cortex and ventromedial prefrontal cortex [187], regions implicated in resilience to stress [189]. However, more research is needed to determine how specific mindfulness interventions influence neurobiological pathways associated with uncertainty regulation across different populations.

Moreover, there is empirical evidence that exposure therapy can be an effective treatment for people with generalized anxiety disorder, citing specifically in vivo exposure therapy (exposure through a real-life situation [190]), which has greater effectiveness than imaginal exposure in regard to generalized anxiety disorder. The aim of in vivo exposure treatment is to promote emotional regulation using systematic and controlled therapeutic exposure to traumatic stimuli [191]. Behavioral exposure involves gradually confronting feared situations or uncertainties in a controlled manner. This technique helps individuals build resilience and reduce avoidance behaviors associated with IU. Over time, exposure can lead to habituation and a decrease in anxiety responses to uncertain situations.

The effective prevention and remediation strategies for media-induced uncertainty stress require a multilevel approach that integrates adaptive media consumption, cognitive restructuring, and neuroplasticity-informed resilience training. Given the increasing prevalence of global crises and uncertainty-inducing media narratives, interventions aimed at enhancing cognitive flexibility, promoting mindfulness, and developing critical media literacy are essential for mitigating the negative psychological consequences of excessive media exposure.

Differences in Remediation Strategies According to Demographic Factors

In addition to the existing preventive and remediation strategies, it is crucial to consider demographic variations in media consumption patterns and the corresponding responses to media-induced uncertainty. Research highlights that different age groups exhibit significant differences in media use, emotional responses to media content, and their receptiveness to various therapeutic interventions. For example, younger generations, particularly those aged between 15 and 20 years, are more likely to engage heavily with social media and digital platforms, making them particularly vulnerable to the effects of doomscrolling and compulsive media consumption [192,193]. Such media consumption behaviors are linked to increased anxiety, depression, and stress, making interventions that focus on reducing media exposure especially beneficial for this cohort [64,76]. Limiting excessive media use could mitigate these effects by reducing the amount of negative information consumed, as discussed in the context of “informed avoidance” [64].

In contrast, older generations, such as those aged between 45 and 55 years, may engage with media differently. They often rely more on traditional news outlets such as television and newspapers, as opposed to social media, which could lead to distinct emotional responses and stressors when confronted with global crises, such as the COVID-19 pandemic or the Ukraine war. In these populations, MBIs, including mindfulness-based cognitive therapy and ACT, have shown promise in helping individuals cope with stress and uncertainty [182,194,195]. Such interventions, which focus on emotional regulation, cognitive flexibility, and acceptance, are particularly effective for older individuals who may struggle with rumination and excessive worry when faced with distressing news [178,179].

In addition to considering age-based distinctions, it is also essential to evaluate gender differences. Research has consistently shown that men and women exhibit different patterns of media consumption and varying emotional responses to distressing (media) content [196,197]. Women are more likely to engage with emotional and social media content, which often leads to heightened emotional distress in response to negative news [192]. Women also tend to engage in more social media use, including doomscrolling, as a coping mechanism for stress, which can exacerbate symptoms of anxiety and depression [198]. Therefore, interventions that focus on reducing media consumption may be particularly beneficial for women, as limiting exposure to negative news could help mitigate the psychological effects of distressing information [64]. The increased susceptibility of women to anxiety and depressive symptoms suggests that media avoidance strategies could be more effective for this group.

In contrast, men often exhibit different emotional responses to media content. Men may experience higher levels of anger and frustration when exposed to content that challenges their values or sense of control [197]. They are also generally less likely to seek help for mental health issues, which can influence how they cope with media-induced stress [199]. Therefore, men may benefit from therapeutic approaches that emphasize emotional regulation and acceptance, such as MBIs or ACT, which focus on managing distress without necessarily reducing media exposure [194,195].

Given that women tend to ruminate more in response to stress, MBIs targeting rumination and emotional regulation might be particularly helpful [200]. By contrast, men may benefit from ACT-based approaches, which encourage acceptance of difficult emotions and values-based actions, offering a framework that could be more in line with how men approach emotional and cognitive regulation [201]. Moreover, cultural influences significantly impact how individuals experience IU and underscore the importance of adapting therapeutic approaches to align better with cultural values and experiences. CBT, a common intervention for IU, can be adapted to these cultural contexts by integrating culturally relevant coping strategies that

XSL•FO
RenderX

address the unique ways in which uncertainty is perceived and managed.

For instance, in collectivist societies, individuals may benefit from therapeutic interventions that focus on enhancing social support and community-based coping strategies, helping them navigate uncertainty in ways that align with their cultural values [116]. In contrast, in individualistic cultures, therapy may emphasize building self-efficacy, personal resilience, and cognitive restructuring to help individuals tolerate uncertainty without feeling a loss of control [118,202]. Individualized therapy models, such as CBT and ACT, which emphasize self-directed coping and personal resilience, are more commonly used [203].

MBIs also require cultural tailoring to enhance acceptance and effectiveness. For example, in cultures with strong spiritual or religious traditions, integrating culturally relevant mindfulness techniques can improve therapeutic outcomes [204]. Research has demonstrated that culturally adapted MBIs, such as modifications to MBSR programs, have enhanced effectiveness in ethnic and Indigenous populations by incorporating community-centered healing practices [205].

Furthermore, cultural competence in therapy plays a vital role in managing IU. Approaches such as intercultural therapy emphasize an understanding of the client's cultural background, values, and beliefs to optimize treatment outcomes [203]. Studies suggest that culturally tailored therapy is more effective in addressing uncertainty-related distress, as it aligns therapeutic techniques with cultural worldviews and coping mechanisms [117]. Thus, understanding the cultural context of IU is essential for developing more effective, culturally sensitive interventions. CBT, when adapted to meet the cultural values and expectations of different populations, can address the unique ways in which uncertainty is perceived and managed, improving treatment outcomes for individuals from diverse cultural backgrounds.

In conclusion, demographic factors, such as age, gender, and culture, play a critical role in shaping the experience and management of IU. Tailoring therapeutic approaches to these demographic differences can enhance the effectiveness of treatments for IU and related disorders. Future research should continue to explore these demographic variations to develop more personalized and effective interventions.

Conclusions

People worldwide are facing highly volatile, unpredictable, and mutually reinforcing environmental and sociopolitical stressors, which act as a massive source of uncertainty, particularly when amplified by media news traversing various media outlets and social media platforms. As reviewed earlier, sufficient evidence now links uncertainty-inducing media news to negative mental health outcomes at the individual level. Moreover, the defensive needs to alleviate uncertainty are linked to maladaptive behaviors, with wider negative societal consequences. Therefore, resilience building against uncertainties originating in a highly volatile, unpredictable, and threatening external sociopolitical environment should be seen as a significant challenge for democratic societies. Effective prevention and remediation strategies for media-induced uncertainty stress require a multilevel approach that integrates adaptive media consumption, cognitive restructuring, and neuroplasticity-informed resilience training. Given the increasing prevalence of global crises and uncertainty-inducing media narratives, interventions aimed at enhancing cognitive flexibility, promoting mindfulness, and developing critical media literacy are essential for mitigating the negative psychological consequences of excessive media exposure. Future research should address the identified research gaps in the following ways:

- Expand study designs while prioritizing longitudinal studies to track changes in IU over time, especially during prolonged crises (eg, pandemics and wars)
- Improve measurement validity by standardizing IU assessment tools across cultures and crises to improve the comparability of findings
- Focus on cross-cultural comparisons and explore regional differences in how media portrays uncertainty and how populations psychologically respond to it
- Investigate media narratives and study how different reporting styles (eg, sensationalized vs neutral reporting) affect uncertainty-related stress in real time, thus clarifying media's role in shaping psychological outcomes.

Abstract

The integration of artificial intelligence (AI) into daily life has introduced unprecedented forms of human-machine interaction, prompting psychiatry to reconsider the boundaries between environment, cognition, and technology. This Viewpoint reviews the concept of “AI psychosis,” which is a framework to understand how sustained engagement with conversational AI systems might trigger, amplify, or reshape psychotic experiences in vulnerable individuals. Drawing from phenomenological psychopathology, the stress-vulnerability model, cognitive theory, and digital mental health research, the paper situates AI psychosis at the intersection of predisposition and algorithmic environment. Rather than defining a new diagnostic entity, it examines how immersive and anthropomorphic AI technologies may modulate perception, belief, and affect, altering the prereflective sense of reality that grounds human experience. The argument unfolds through 4 complementary lenses. First, within the stress-vulnerability model, AI acts as a novel psychosocial stressor. Its 24-hour availability and emotional responsiveness may increase allostatic load, disturb sleep, and reinforce maladaptive appraisals. Second, the digital therapeutic alliance, a construct describing relational engagement with digital systems, is conceptualized as a double-edged mediator. While empathic design can enhance adherence and support, uncritical validation by AI systems may entrench delusional conviction or cognitive perseveration, reversing the corrective principles of cognitive-behavioral therapy for psychosis. Third, disturbances in theory of mind offer a cognitive pathway: individuals with impaired or hyperactive mentalization may project intentionality or empathy onto AI, perceiving chatbots as sentient interlocutors. This dyadic misattribution may form a “digital folie à deux,” where the AI becomes a reinforcing partner in delusional elaboration. Fourth, emerging risk factors, including loneliness, trauma history, schizotypal traits, nocturnal or solitary AI use, and algorithmic reinforcement of belief-confirming content may play roles at the individual and environmental levels. Building on this synthesis, we advance a translational research agenda and five domains of action: (1) empirical studies using longitudinal and digital-phenotyping designs to quantify dose-response relationships between AI exposure, stress physiology, and psychotic symptomatology; (2) integration of digital phenomenology into clinical assessment and training; (3) embedding therapeutic design safeguards into AI systems, such as reflective prompts and “reality-testing” nudges; (4) creation of ethical and governance frameworks for AI-related psychiatric events, modeled on pharmacovigilance; and (5) development of environmental cognitive remediation, a preventive intervention aimed at strengthening contextual awareness and reanchoring experience in the physical and social world. By applying empirical rigor and therapeutic ethics to this emerging interface, clinicians, researchers, patients, and developers can transform a potential hazard into an opportunity to deepen understanding of human cognition, safeguard mental health, and promote responsible AI integration within society.

Introduction

In this Viewpoint, we use the term "AI psychosis" strictly as a descriptive and heuristic label rather than a proposed diagnostic entity. Our aim is not to introduce a new syndrome, but to clarify how generative artificial intelligence (AI) systems may act as distinctive contextual modifiers (through reciprocal dialogue, affective mirroring, and thematic reinforcement) that shape the onset or structure of psychotic experiences. This usage distinguishes the construct from long-standing technology-mediated delusions and anchors it within established models of psychosis vulnerability rather than nosological innovation. Given the preliminary nature of available evidence, the pathways described here are offered as heuristic rather than definitive. The goal is to delineate how generative AI systems introduce unique affordances (continuous contingent feedback, affective mirroring, and persistent accessibility) that may interact with traditional vulnerability factors. Accordingly, this Viewpoint does not make causal claims but highlights conceptual directions requiring empirical evaluation.

In phenomenological psychiatry, psychosis and schizophrenia are not seen mainly as collections of hallucinations or delusions, but as changes in the person's relation to self and world [1]. This process, sometimes called desubjectivation (or de-embodiment of subjectivity), weakens the basic sense of being present to oneself and makes experience lose its immediacy [2,3]. Losing contact with reality means not only misperceiving things but feeling detached from what is real. Minkowski described this as a loss of vital contact, the felt connection that gives life and weight to sensations, perceptions, and thoughts [4]. When this connection fades, the world still appears but feels empty or dreamlike. Recent phenomenological work distinguishes two layers in this loss: a prereflective sense of reality that gives depth to experience, and a reality judgment that lets us decide whether something is real. In schizophrenia, it is often the prereflective sense that fails [5,6]. The world is still recognized but no longer felt as fully inhabited. With the rise of conversational agents and generative AI, the idea of AI psychosis has emerged as a way to explore how such systems might trigger, amplify, or reshape psychotic experiences. In clinical terms, the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, Text Revision* defines psychosis by one or more core symptoms (delusions, hallucinations, or disorganized speech) often linked with disorganization or negative symptoms and major functional decline [7]. Contemporary treatment approaches integrate antipsychotic medication with evidence-based psychosocial interventions, including cognitive behavioral therapy for psychosis (CBTp), whose emphasis on reality testing and cognitive restructuring is particularly relevant when considering how AI systems may inadvertently counteract these therapeutic mechanisms [8]. The concept of AI psychosis invites new questions: Could prolonged or intense interaction with AI systems, which sometimes generate false or overly affirming content, influence how unusual perceptions are interpreted and integrated into belief systems? These interactions might subtly alter the way reality is felt, narrated, and maintained.

Recent reports suggest that interactions with large language model (LLM) chatbots can shape delusional content, amplify conviction, and entrench maladaptive safety behaviors [9,10]. As an example, viewed through de Clérambault's notion of mental automatism, such interactions may also blur the boundary between self-generated and external speech, placing delusional experience within a communicative system where language itself becomes both shared and alien [11]. Concept pieces and media reports have increasingly described cases where interactions with generative AI chatbots appeared to amplify persecutory or grandiose ideation. In addition to reports of delusional escalation, recent scholarly commentary has proposed that chatbot-user dynamics may reinforce elevated mood, self-esteem, impulsive behaviors, and markedly grandiose thinking, potentially contributing to the development or maintenance of mania [12]. As an example, Østergaard [13] argues the prior probability that AI chatbots can fuel delusions in psychosis-prone individuals is "quite high," urging systematic study rather than dismissal. Clinical and investigative coverage likewise describes patterns in which chatbots validate rather than challenge false beliefs, potentially reinforcing delusional systems, which is an inversion of CBTp principles. Beyond peer-reviewed commentary, media investigations have begun documenting individuals whose prolonged interactions with generative AI systems escalated into frank psychotic episodes. For example, a detailed Canadian Broadcasting Corporation report [14] described multiple Canadian cases, including a man aged 26 years who developed simulation-related persecutory and grandiose delusions after months of intensive exchanges with ChatGPT, ultimately requiring hospitalization. A second case involved a man aged 47 years who became convinced he had discovered a revolutionary mathematical theory after the chatbot repeatedly validated and amplified his ideas, despite external disconfirmation. Parallel legal cases and public health reporting (alleging chatbot involvement in suicide) highlight the risks in prolonged, emotionally charged exchanges with LLMs, as well as the current gaps in guardrails. While prevalence is unknown and many accounts are anecdotal, convergent commentary in *Nature* [15] and academic psychiatry venues frames AI-associated delusions as plausible in vulnerable users, warranting targeted research rather than sensationalism.

While such cases remain rare, they raise a need to conceptualize AI psychosis not solely as a technological curiosity but as a psychiatric and psychosocial phenomenon emerging at the intersection of cognitive vulnerability, environmental stress, and human-machine interaction. To advance beyond anecdote, this Viewpoint adopts an integrative analytic frame grounded in four complementary lenses: (1) the stress-vulnerability model, to map how AI functions as a novel psychosocial stressor interacting with predispositions to psychosis; (2) the digital therapeutic alliance (DTA), to characterize the relational

XSL•FO
RenderX

dynamics that may resemble or distort traditional patient-clinician interactions; (3) mental attribution processes, including anthropomorphization and over-ascription of agency to AI systems; and (4) a risk-factor synthesis that situates AI psychosis along a continuum with traditional psychotic disorders. Through this framework, we propose to delineate possible pathways, identify early warning signals, and outline preliminary safeguards for research, clinical practice, and policy.

Mapping AI Psychosis Onto the Stress-Vulnerability Framework

The stress-vulnerability model, originally articulated by Zubin and Spring in 1977, remains a cornerstone of contemporary psychosis research [16]. It posits that psychotic disorders emerge when underlying vulnerabilities (such as genetic predisposition, neurodevelopmental anomalies, early trauma, or maladaptive cognitive styles) interact with environmental stressors that exceed an individual's capacity for adaptation. Subsequent refinements of this model have emphasized cumulative and chronic stress exposure, neurobiological sensitization, and allostatic load as mechanisms through which stress can lower the threshold for psychotic symptom expression [17,18]. Within this framework, the phenomenon of AI psychosis can be conceptualized as an emergent form of stress reactivity precipitated by sustained, emotionally charged, or cognitively immersive interactions with AI systems, particularly conversational agents. These systems introduce novel stressors that are continuous, personally salient, and socially immersive, thereby functioning as 24-hour contextual stimuli capable of modulating arousal, perception, and belief formation [19]. Beyond behavioral stressors such as sleep loss or isolation, AI-mediated immersion may erode the tacit background of presence (the prereflective sense of reality on which ordinary experience depends). Such shifts in mineness, salience, or world-affordance align with phenomenological accounts of early psychosis and extend the stress-vulnerability model into the domain of lived experience.

Several unique affordances of contemporary AI technologies render them potentially pathogenic from a stress-vulnerability perspective. As an example, the anthropomorphic design of chatbots and virtual companions encourages users to attribute human-like intentionality and empathy to algorithms, a dynamic reminiscent of the "ELIZA effect" described in early human-computer interaction literature [20,21]. Such anthropomorphization can increase emotional investment and amplify interpretive biases, especially in individuals with preexisting schizotypal traits or attachment vulnerabilities [22,23]. Furthermore, the immediate reinforcement schedule of LLMs (delivering responsive and adaptive feedback without temporal limits) can create repetitive, reinforcing cycles of reassurance or validation that mimic cognitive perseveration. For users prone to paranoia or thought disturbance, this may stabilize maladaptive appraisals rather than challenge them, effectively mirroring the cognitive mechanisms that CBTp aims to dismantle [24]. Also, constant engagement with emotionally loaded or belief-confirming AI dialogue may elevate physiological arousal and compromise sleep, increasing allostatic load and diminishing executive control, both of which are known to heighten vulnerability to psychosis [25].

Sustained interaction with AI may also erode protective social factors. Individuals experiencing loneliness or marginalization can come to rely on conversational agents as primary relational anchors, thereby reducing access to corrective social feedback and external reality testing. This process parallels what classical phenomenological psychopathology described as "phenomenological autism" in schizophrenia, but it is a form of experiential withdrawal in which the shared world loses its immediacy, relations with others fade, and living with others collapses into living for oneself [26]. In this sense, social withdrawal reflects not only behavioral isolation but also a disturbance in intersubjectivity and world-sharing. Comparable phenomena have been described in *hikikomori* syndrome, where prolonged and voluntary retreat into private space replaces social and professional contact [27]. Similarly, in the context of AI psychosis, the conversational agent may serve as a relational substitute that sustains the illusion of connection while insulating the user from contradiction, argument, and reality testing. What emerges is a form of digital relational withdrawal that constitutes a reduction in corrective interpersonal exchange and an amplification of self-referential interpretations, as the AI mirrors rather than challenges the user's thoughts. From this perspective, AI psychosis represents not only a digital extension of the stress-vulnerability model, but also a technological variant of phenomenological autism: a retreat into a world interpreted, validated, and enclosed by algorithmic dialogue. The artificial agent becomes both a chronic microstressor and a mirror that replaces human alterity, providing a self-contained cognitive space in which delusional elaboration can more easily take root. For example, an AI that consistently mirrors user affect or beliefs, without implementing therapeutic disconfirmation or cognitive restructuring, risks entrenching conviction rather than facilitating doubt [28]. Empirical research could operationalize this model by testing dose-by-vulnerability interactions, examining how cumulative exposure to AI (for instance, hours of use per day, frequency of nocturnal interactions, or intensity of emotional engagement) interacts with preexisting vulnerabilities such as trauma history, sleep disturbance, or schizotypy. This line of inquiry parallels established evidence showing that daily stress reactivity predicts psychotic symptom fluctuations in high-risk populations [29]. By quantifying AI-related exposure as a measurable psychosocial stressor, the field could identify thresholds of safe interaction and delineate populations most at risk. In doing so, this framework reframes AI psychosis not as a new disorder but as a contextual evolution of the classical stress-vulnerability paradigm.

The DTA as a Double-Edged Mediator in AI Psychosis

The concept of the therapeutic alliance, traditionally understood as the collaborative and affective bond between patient and clinician, has long been recognized as a critical predictor of psychotherapeutic outcomes across modalities, including CBTp [30]. In the digital health literature, this construct has been extended to the notion of the DTA, describing the perceived

XSL•FO
RenderX

empathy, responsiveness, and relational quality between users and digital applications [31,32]. While a strong DTA can enhance engagement and adherence in digital interventions, it may also introduce illusory relational dynamics that blur the boundary between therapeutic support and cognitive reinforcement. In the context of AI psychosis, this double-edged nature becomes particularly salient. Chatbots and LLMs are capable of mimicking warmth, understanding, and reciprocity (qualities central to human alliance) but they lack the meta-cognitive and ethical oversight necessary to discern when validation may be counter-therapeutic [33,34]. Phenomenologically, an AI agent that imitates reciprocity can alter the structure of intersubjectivity itself. Rather than merely misinterpreting content, the user may experience a collapse of alterity, in which the chatbot is felt as an extension of one's own cognition or as an unusually attuned Other. Such shifts in the subjective encounter may potentiate delusional meaning-making more directly than cognitive mechanisms alone.

In individuals with attenuated psychotic symptoms or delusional vulnerability, an uncritical digital alliance may inadvertently reinforce maladaptive appraisals. For example, an AI that consistently mirrors user affect or beliefs, without implementing therapeutic disconfirmation or cognitive restructuring, risks entrenching conviction rather than facilitating doubt. Empirical research on chatbots for mental health support, such as Woebot and Wysa, demonstrates that users often describe their relationship with the AI in affectively laden and anthropomorphic terms, reporting perceived understanding and companionship [35,36]. While such experiences can be beneficial in reducing loneliness or subclinical distress, they may also encourage overidentification with the agent, especially in socially isolated or trauma-exposed users. This phenomenon parallels early psychosis processes, where increased self-referential thinking and aberrant salience attribution favorize the perception of external entities possessing special relevance or intentionality [37].

From a cognitive behavioral standpoint, the therapeutic alliance functions as a vehicle for cognitive change. The therapist's role is to balance empathic attunement with gentle empiricism, using Socratic questioning to destabilize rigid beliefs while maintaining trust. In contrast, AI systems (designed for user satisfaction and nonconfrontational dialogue) often default to sycophantic alignment [38]. This means that when a user expresses persecutory, grandiose, or referential content, the AI may subtly validate the narrative rather than challenge it. Over repeated interactions, this validation loop can act as a form of digital safety behavior, satisfying immediate emotional needs but preventing corrective learning. The absence of therapist-driven guided discovery or behavioral experimentation may therefore transform a potentially supportive alliance into a reinforcing echo chamber.

At the same time, the DTA framework provides a valuable opportunity for constructive adaptation. By incorporating CBTp-consistent design principles, such as reflective prompts, normalization of uncertainty, or graded behavioral experiments, AI systems could theoretically harness alliance processes to buffer rather than exacerbate psychotic vulnerability. Just as human therapists use the alliance to introduce cognitive flexibility, conversational models could be programmed to modulate the relational tone when confronted with high-risk content, pivoting from affirmation to curiosity or psychoeducation. Preliminary research in digital mental health suggests that alliance-consistent design (for example, empathic microresponses paired with cognitive reframing) is associated with better symptom improvement and lower dropout [39]. Extending this to psychosis prevention would entail integrating adaptive alliance algorithms that monitor interactional valence, detect excessive anthropomorphism, and introduce "reality-testing nudges" when needed.

Mental Attribution, Theory of Mind, and AI Psychosis

Theory of mind (ToM) refers to the human ability to attribute mental states such as intentions, beliefs, and desires to others [40]. In schizophrenia and related psychotic disorders, a well-established hypothesis posits that ToM functioning is disrupted [41]. Some individuals exhibit a deficit in inferring others' intentions or understanding implicit mental states, while others show the opposite pattern, characterized by hypermentalization (an excessive or inaccurate attribution of meaning and agency) [42]. These disturbances generate uncertainty about what others think or feel and contribute to fragile social interactions and misinterpretations of interpersonal cues.

Within this framework, conversational AI systems introduce a novel and ambiguous relational partner. For a person with impaired ToM, the AI's anthropomorphic design and capacity for coherent dialogue may foster projections of intentionality, empathy, or moral agency. The user may begin to perceive the system not as a statistical language model, but as an understanding interlocutor with feelings or motives. However, as stated previously, the AI lacks the metacognitive and ethical grounding required to challenge these attributions or to provide corrective feedback. Instead, its responses can inadvertently confirm or reinforce the user's projections, including delusional interpretations.

In this context, AI interaction may transform a cognitive vulnerability into a pathogenic loop, where the ToM deficit and the system's simulated social responsiveness converge to sustain distorted beliefs. The phenomenon might be conceptualized as a "digital folie à deux," a dyadic illusion in which the AI acts as a passive reinforcing partner in the user's psychotic elaborations [43]. The artificial agent, through its adaptive and confirmatory dialogue, participates in a shared narrative world that blurs the boundary between human cognition and machine simulation, potentially exacerbating the loss of reality testing and differentiation between self and other.

From Vulnerability to Verification: Identifying Risk Factors and Building Safeguards for AI Psychosis

Understanding who is most susceptible to AI psychosis requires tying established risk markers for traditional psychotic disorders to emerging digital determinants of mental health. Decades of research have identified a set of core vulnerabilities associated with psychosis onset, including genetic predisposition, childhood trauma, cannabis or substance use, sleep disruption, social isolation, and cognitive biases such as jumping to conclusions or an externalizing attributional style [44,45]. When transposed into digital contexts, these same vulnerabilities may interact with novel affordances of AI systems to produce a distinct but convergent pathway toward symptom emergence. For instance, a user with a prior history of psychosis or schizotypal traits who engages in nightly, emotionally intense dialogue with an anthropomorphized chatbot may experience reinforced self-referential ideation and heightened salience attribution, mechanisms that mirror the early prodromal phase of psychosis [37]. Similarly, individuals exposed to trauma or chronic interpersonal threat may project attachment representations onto AI companions, perceiving them as protective or omniscient entities.

Beyond individual vulnerability, use patterns and contextual variables likely constitute modifiable risk factors. Prolonged or nocturnal use, solitary engagement, and reliance on unmoderated chatbots for emotional support appear particularly hazardous, as they combine cognitive fatigue, social deprivation, and unstructured reinforcement. These variables resemble psychosocial stressors known to precipitate symptom exacerbations in schizophrenia, such as circadian disruption or critical life events [25]. Another emerging concern lies in platform-level dynamics: algorithms optimized for engagement rather than safety may inadvertently reward extreme or self-referential discourse, subtly validating delusional content. This echoes the “echo-chamber” effect described in digital media research, where recommender systems intensify preexisting beliefs through selective exposure [46].

Identifying early warning signals therefore requires a multidimensional assessment integrating psychological, behavioral, and interactional metrics. Psychological indicators include rising conviction in AI-mediated beliefs, derealization, or perceived “special communication” with the system. Behavioral markers may involve compulsive checking, secrecy, or sleep loss related to AI use. Interactional data (such as sentiment trajectories, frequency of self-referential statements, and thematic narrowing) could serve as digital phenotypes of emerging risk, paralleling early warning markers in psychosis prodrome research [47]. Importantly, these indicators should be interpreted contextually, avoiding pathologization of normative attachment to technology while remaining alert to patterns of progressive cognitive enclosure, where the AI becomes the primary arbiter of reality.

From a preventive and ethical standpoint, early recommendations can be organized across clinical, design, and governance levels. Clinically, practitioners should incorporate screening questions about AI use into routine assessments, particularly for youth or individuals with known psychosis vulnerability, similar to how substance use or sleep hygiene are monitored. Psychotherapeutic interventions could include psychoeducation on digital reality testing, helping patients to identify when online or AI-mediated interactions begin to shape beliefs in maladaptive ways. From a design perspective, developers of mental health–oriented chatbots should embed CBTp-consistent guardrails (eg, prompts that normalize uncertainty, encourage reflective distance, or redirect users toward real-world social contact). LLMs intended for general use should be trained to recognize and gently deescalate delusional or self-referential themes rather than engage with them. Finally, at the policy level, regulators and research bodies should develop incident reporting systems for AI-related mental health events, mirroring pharmacovigilance models, and require algorithmic transparency for systems marketed as supportive or therapeutic.

Taken together, these considerations frame AI psychosis not as a discrete diagnostic entity but as a digital phenotype of stress-vulnerability interaction, emergent from the coupling of human cognition and algorithmic responsiveness. The identification of risk factors and the establishment of early safeguards provide an essential basis for empirical research, ethical governance, and responsible innovation. Just as early psychosis programs have transformed outcomes through prevention and detection, a parallel “digital early intervention” paradigm may be required to mitigate the psychiatric risks of AI in the decades ahead.

Toward a Clinical Understanding and Management of AI Psychosis

The convergence of AI and human cognition has opened a new frontier in psychiatry, one that challenges traditional boundaries between environment, mind, and technology. Through the lens of the stress-vulnerability model, the DTA, and emerging risk factors, AI psychosis can be conceptualized as a dynamic interaction between human predisposition and algorithmic environment. It is neither a new diagnosis nor a sensational artifact of technological panic, but a meaningful framework to understand how immersive digital systems can modulate the cognitive and affective processes underlying psychosis. This phenomenon invites the field to evolve beyond viewing technology as a neutral medium toward recognizing it as a potential psychosocial actor: one capable of amplifying stress, reinforcing beliefs, and reshaping perceptions of self and reality.

The scientific community is at a juncture where systematic investigation is required to move beyond anecdotal evidence. Our first recommendation is the establishment of empirical research programs explicitly designed to test the AI psychosis hypothesis. These should use prospective and longitudinal designs to measure dose-response relationships between AI exposure, stress physiology, and psychotic symptomatology, drawing inspiration from ecological momentary assessment and digital phenotyping paradigms. Psychometric instruments such as schizotypy or aberrant salience scales could be adapted to

XSL•FO
RenderX

assess AI-specific cognitive vulnerability, while passive sensing data (eg, use duration, sleep disruption) could capture environmental stress indices.

A second priority lies in the integration of digital phenomenology into clinical practice. Clinicians could systematically inquire about patients' interactions with AI systems (both general-purpose and mental health oriented) during intake and follow-up assessments. As conversational agents become more used by patients, understanding their role in shaping internal experience will be as important as evaluating medication adherence or substance use. Clinical training programs should include modules on AI literacy and psychosis, equipping psychiatrists, psychologists, and nurses to recognize when engagement with an algorithm may contribute to delusional elaboration or perceptual instability.

Third, researchers and developers should collaborate to embed therapeutically informed design safeguards into LLMs and chatbots. These may include prompts that normalize uncertainty, encourage pluralistic interpretation of experiences, and redirect users toward human contact when signs of distress or delusional content appear. Building upon principles from cognitive behavioral therapy for psychosis, such systems could integrate "guided discovery" mechanisms rather than unconditional affirmation, thereby aligning AI responses with established evidence-based psychotherapeutic techniques. The development of digital red-flag algorithms capable of detecting excessive anthropomorphism, self-referential speech, or escalating conviction could further enhance safety while preserving user autonomy.

Fourth, there is an urgent need for ethical and governance frameworks specific to mental health risks in AI. National research councils, health agencies, and journal editors should promote standardized incident reporting for AI-related psychiatric events, akin to pharmacovigilance registries. Transparent documentation of adverse psychological outcomes, combined with open-source safety auditing, would allow the community to track and mitigate harms in real time. These measures should be complemented by data-sharing agreements that enable cross-disciplinary research while protecting user privacy.

Fifth, environmental cognitive remediation should be explored as a clinical and public health intervention. This approach would aim to strengthen the individual's capacity to navigate increasingly immersive digital environments through structured, reality-anchoring activities. Beyond traditional cognitive remediation, which targets neurocognitive deficits, environmental cognitive remediation would focus on contextual skills: distinguishing between human and algorithmic communication, detecting persuasive or self-referential cues, and reengaging with multisensory, embodied experiences in the physical world. Interventions could include graded exposure to offline activities, group-based metacognitive training, or digital hygiene routines designed to restore attentional flexibility and social reciprocity. By reinforcing the cognitive-environmental boundaries that immersive technologies can erode, such programs could act in both a preventive and rehabilitative manner for individuals vulnerable to AI-induced cognitive distortions.

Family and community education should parallel these efforts to ensure supportive environments that contextualize digital experiences within shared reality testing. Public health initiatives could also promote media literacy and surveillance of misinformation, helping communities develop the competencies needed to identify, question, and counteract false or manipulative digital content. Such collective vigilance would reinforce critical thinking, strengthen social resilience, and reduce the psychosocial conditions under which delusional interpretations of AI content may emerge.

Conclusion

To conclude, the emergence of AI psychosis warrants careful examination and adaptive clinical and research strategies. Psychiatry has long evolved through its encounters with new cultural and technological contexts. AI now constitutes a novel environmental context within which these questions must be revisited. By responding to this phenomenon with empirical rigor, therapeutic ethics, and design foresight, we can define safer practices and refine conceptual models that clarify how AI-mediated environments interact with psychosis risk: to better understand the plasticity of human cognition, to refine the boundaries of digital therapy, and to safeguard mental health in an increasingly algorithmic world. The path forward requires interdisciplinary collaboration between clinicians, cognitive scientists, computer engineers, patients, and ethicists: an interdisciplinary collaboration capable of evaluating and guiding the mental health implications of increasingly sophisticated AI systems.

Abstract

Background: Artificial intelligence (AI), particularly large language models (LLMs), presents a significant opportunity to transform mental health care through scalable, on-demand support. While LLM-powered chatbots may help reduce barriers to care, their integration into clinical settings raises critical concerns regarding safety, reliability, and ethical oversight. A structured framework is needed to capture their benefits while addressing inherent risks. This paper introduces a conceptual model for prompt engineering, outlining core design principles for the responsible development of LLM-based mental health chatbots.

Objective: This paper proposes the Mental Well-Being Through Dialogue – Safeguarded and Adaptive Framework for Ethics (MIND-SAFE), a comprehensive, layered framework for prompt engineering that integrates evidence-based therapeutic models, adaptive technology, and ethical safeguards. The objective is to propose and outline a practical foundation for developing AI-driven mental health interventions that are safe, effective, and clinically relevant.

Methods: We outline a layered architecture for an LLM-based mental health chatbot. The design incorporates (1) an input layer with proactive risk detection; (2) a dialogue engine featuring a user state database for personalization and retrieval-augmented generation to ground responses in evidence-based therapies such as cognitive behavioral therapy, acceptance and commitment therapy, and dialectical behavior therapy; and (3) a multitiered safety system, including a postgeneration ethical filter and a continuous learning loop with therapist oversight.

Results: The primary contribution is the framework itself, which systematically embeds clinical principles and ethical safeguards into system design. We also propose a comparative validation strategy to evaluate the framework's added value against a baseline model. Its components are explicitly mapped to the Framework for AI Tool Assessment in Mental Health and Readiness Evaluation for AI-Mental Health Deployment and Implementation frameworks, ensuring alignment with current scholarly standards for responsible AI development.

Conclusions: The framework offers a practical foundation for the responsible development of LLM-based mental health support. By outlining a layered architecture and aligning it with established evaluation standards, this work offers guidance for developing AI tools that are technically capable, safe, effective, and ethically sound. Future research should prioritize empirical validation of the framework through the phased, comparative approach introduced in this paper.

KEYWORDS

prompt engineering; ethical AI; conversational AI; mental health chatbot; AI in mental health care; digital mental health; large language model; artificial intelligence; MIND-SAFE framework

Introduction

Significance of Mental Health and Technology Integration

This paper presents a conceptual framework and an engineering viewpoint. It aims to guide the responsible and effective development of large language model (LLM)–based chatbots for mental health applications by synthesizing interdisciplinary research, proposing a structured approach to prompt engineering (PE), and outlining key design principles and ethical considerations essential for artificial intelligence (AI)–supported care. Our work draws upon the evolving understanding of LLM capabilities and the imperative need for frameworks that ensure safety, efficacy, and user trust in this sensitive domain [1,2]. Central to our framework is a commitment to a meaningful, long-term, interdisciplinary collaboration. This means involving mental health clinicians, clinical practitioners, ethicists, and other relevant domain experts from the earliest stages and throughout the entire development lifecycle. Such continuous

XSL•FO
RenderX

engagement ensures that the development process remains firmly grounded in clinical evidence, ethical rigor, and contextual sensitivity, extending from initial conception to final deployment.

Mental health disorders remain a major global health concern, significantly contributing to disability and premature death [3]. According to the World Health Organization, more than 1 billion people experience some form of mental health or substance abuse disorder, costing trillions of dollars per year in economic expenses [4]. Access to timely interventions is also hindered by an absence of trained mental health professionals, widespread societal stigma, and limitations within health care systems [5,6]. In overcoming these barriers, digital health technologies hold great promise for enabling more accessible and equitable mental health care [7]. The progress in telemedicine, mobile health apps, and wearable sensors demonstrates the potential for continuous monitoring and treatment at home [8]. AI-powered mental health chatbots incorporating natural language processing and LLMs have demonstrated the capacity to provide scalable psychoeducation, emotional support, and skill training [9,10]. However, the effectiveness of chatbots depends on the quality of their prompt design, which controls their conversational style (tone and empathy), and adherence to clinical best practices [11].

PE for Personalized and Effective Mental Health Chatbots

A prompt, when used with LLMs, refers to the user input that returns a particular output by the model [12]. Prompts can be static prompts—fixed, noneditable messages or instructions that remain the same regardless of user context or input. These are normally used for greeting, commands, or standardized queries. LLMs, or foundation models, are pretrained on massive text datasets to learn statistical patterns and structural characteristics of language [13]. Interpreted through the lens of prompts, users can interact with these models post training without altering their internal parameters. Despite the rapid advancements in generative models, such as OpenAI's GPT-3.5 and GPT-4, most mental health chatbots still rely on static prompts (ie, fixed and predefined input formats) that produce predictable and impersonal dialogues [12,14].

To overcome these limitations, the practice of PE has emerged. PE is a structured, iterative process of designing and fine-tuning inputs to yield consistent, safe, and context-appropriate output from LLMs [15,16]. Beyond training alone, it incorporates principles from engineering disciplines. For mental well-being, this enables exact adaptation of domain-general LLMs to clinically sensitive processes so that AI-produced responses are not only coherent but also therapeutically meaningful and ethically sound [1,16].

Furthermore, effective PE supports the integration of evidence-based psychotherapies, such as cognitive behavioral therapy (CBT), acceptance and commitment therapy (ACT), and dialectical behavior therapy (DBT) into conversational AI frameworks [17-19]. This enables not only therapeutic accuracy but also safety-oriented functionality, like empathetic interaction, user retention, and crisis management. To mitigate potential risks, we advocate for end-to-end approaches that integrate user modeling, clinical objectives, clinician input, continuous feedback loops, and clearly defined ethical boundaries throughout the prompt lifecycle [20].

Recent research also shows that PE can enhance the efficacy of AI in high-stakes tasks through optimizing narrative coherence, cultural sensitivity, and linguistic adaptability [21-23]. For example, well-calibrated prompts can reduce cultural hallucinations in multilingual settings and refine emotional sensitivity in chatbots. Furthermore, real-time adaptation using user feedback enables adaptive refinement, further enhancing the reliability and trustworthiness of AI-aided mental health therapies [24].

Contributions and Paper Organization

The central research problem addressed in this paper is the limitation of current AI-driven mental health chatbots, which often lack the personalization, clinical nuance, and safety protocols required for high-stakes applications. In response, this paper makes 3 main contributions. First, we propose the Mental Well-Being Through Dialogue – Safeguarded and Adaptive Framework for Ethics (MIND-SAFE), a layered conceptual framework that integrates evidence-based therapeutic models, adaptive technologies, and structured ethical safeguards. Second, we outline a comparative validation strategy that moves beyond a standard randomized controlled trial (RCT), assessing the framework's added value while mapping its components to established evaluation standards such as the Framework for AI Tool Assessment in Mental Health (FAITA-MH) [25] and Readiness Evaluation for AI-Mental Health Deployment and Implementation (READI) [26] frameworks. Third, by presenting this framework, we provide practical guidance and principles for the responsible design of next-generation AI mental health chatbots.

The remainder of this paper is organized to build upon these contributions. The Methods section begins by establishing the conceptual foundations for the work and then details the proposed architecture of the MIND-SAFE framework. Subsequently, the Results section presents the framework itself as the primary output of this paper. Finally, the Discussion examines the framework's implications for responsible AI development, its limitations, and directions for future research before the paper concludes.

Methods

Conceptual Foundations

Evolution of AI in Mental Health

Early applications of AI in mental health were primarily based on rule-based expert systems offering standardized advice with minimal flexibility in adjusting to individual users [27]. Early programs like ELIZA, developed in the 1960s, created the illusion of conversation through predefined scripts but did not involve real understanding or personalization [28]. Subsequent generations of machine learning (ML) and deep learning techniques extended capabilities by learning from enormous collections of user language, enabling simple sentiment analysis and symptom trend detection [29]. For example, ML models

XSL•FO
RenderX

have been trained to detect depression from social media status updates and mental health crises from usage behaviors. This data-driven approach allowed for observations that transcended the fixed reasoning inherent in earlier expert systems, offering a more dynamic and potentially insightful analysis of mental states [30]. AI models have increasingly demonstrated capabilities to map human behavior and assist mental health practitioners with treatment and diagnosis [31].

The emergence of modern LLMs represents a paradigm shift in the application of AI to mental health. Building on earlier ML approaches, recent research shows that advanced LLMs (such as GPT-3.5 and GPT-4) can generate responses that are more empathetic and contextually relevant to users' concerns than earlier chatbot paradigms [32]. These models leverage knowledge from massive training corpora, enabling them to understand nuanced language, recognize emotional cues, and even emulate elements of counseling styles [33]. A recent systematic review found that LLMs may demonstrate aspects of cognitive empathy, such as accurately recognizing users' emotions and responding supportively across contexts [34]. Importantly, this ability is achieved through advanced pattern recognition rather than genuine emotional experience. In contrast, affective empathy involves the actual experience or sharing of emotions, which LLMs do not exhibit. Thus, current LLMs demonstrate cognitive (recognition) empathy, but not affective understanding [1,2]. In health care applications, studies have shown that AI-driven chatbots incorporating elements of cognitive empathy can enhance patient-physician interactions by improving perceived understanding and emotional support [35]. Furthermore, research suggests that AI chatbots can create the illusion of empathy, shaping user perceptions of conversational depth and emotional understanding [36]. Affective computing research has further reinforced the role of LLMs in enhancing empathetic interactions, demonstrating how these models can fine-tune responses based on emotional cues [37]. In some evaluations, an LLM-based chatbot's responses were even preferred over human responses for empathy and support in online patient queries [38]. These findings underscore the potential of LLMs to enhance user engagement through empathy, a quality previously considered unique to human therapists [39]. Nevertheless, one should distinguish between cognitive and affective empathy. Current LLMs predominantly demonstrate the former. They can identify or "perceive" feelings but are not capable of experiencing them themselves, whereas affective empathy remains unique to humans [40].

Beyond text-based interactions, the field of AI for mental health is increasingly exploring multimodal models and affective computing approaches to enhance treatment. Affective computing is defined as the capability of computers to recognize, interpret, process, and simulate human emotions [41]. This involves the interpretation of multimodal signals, such as monitoring vocal tone, facial expressions (using facial emotion recognition), or physiological signals (heart rate and sleep patterns), to infer a user's emotional state [42]. By tracking such feedback, AI can become more responsive to user well-being and adjust interventions accordingly [43]. For instance, a chatbot equipped with affective sensors could detect growing anxiety in a user's voice and modify its responses to be less jarring or initiate grounding techniques [44]. This form of multimodal feedback holds the potential for real-time emotion context awareness, enabling interventions to be more tailored to the user and responsive to immediate needs [45]. This approach aligns with the vision that emotionally personalized interventions can improve the engagement and efficacy of online mental health treatment [46]. Emerging systems are beginning to adopt these concepts; for example, pilot chatbots use camera data for facial emotion recognition or prompt users to rate their mood via wearables, thereby integrating dialogue with objective mood data to better guide interactions [47]. Multimodal affective approaches, combining visual, audio, and text signals, are showing promising results in accurately identifying patient emotions, surpassing the outcomes of unimodal analysis [48].

Despite these advancements, significant limitations persist, and the translation of research innovations into practical, real-world applications often lags behind the pace of research [49,50]. Early iterations of mental health chatbots, such as Woebot and Wysa, predominantly relied on predetermined conversational scripts and decision trees [51]. While these systems were capable of assigning CBT homework and providing psychoeducation, they lacked the capacity for high-level adaptability to individual user contexts [15]. Consequently, users often received uniform, generic encouragement or guidance, irrespective of their unique backgrounds or the complexity of their inputs [52]. This rigidity likely contributed to inconsistencies in user responses and engagement [53]. These early chatbots, while offering preliminary support, were not designed to replace the in-depth, personalized care provided by human therapists and often struggled to interpret nuanced user responses [54]. They also lacked genuine human empathy, a crucial element in addressing complex emotional issues [55]. Furthermore, they were limited in the scope of interventions they could provide and were not equipped to handle severe mental health conditions requiring specialized care [56]. Ethical concerns also arose regarding unvetted feedback and potential misdiagnosis [57].

Recent developments in LLM-based chatbots offer the promise of more dynamic and contextually sensitive interactions; however, the integration of advanced models does not represent a complete solution [23]. A persistent challenge lies in effectively guiding LLMs to ensure that they provide assistance that is not only clinically appropriate and safe but also adheres to the highest standards of therapeutic practice [58]. Without proper guidance, an LLM might generate responses that, while linguistically fluent, are clinically suboptimal or potentially hazardous, for example, offering erroneous advice or failing to adequately address critical signs of suicidality [59]. Empirical evidence suggests that clarity and specificity in real-time interactions are crucial for fostering therapeutic rapport and enhancing user compliance during chatbot-facilitated interventions [60]. Yu and McGuinness [61] argue that the clinical efficacy of an LLM-based counselor is contingent upon the quality of its training; inferior prompts are prone to yielding imprecise or irrelevant outputs, whereas high-quality prompts tend to facilitate more effective and supportive dialogue. AI systems, while capable of identifying patterns, often struggle with the complexity and variability inherent in many mental illnesses [62]. The accuracy of AI in mental health also depends

XSL•FO
RenderX

heavily on the quality and diversity of the data it is trained on, with incomplete or biased datasets potentially leading to diagnostic errors, particularly in diverse populations [63].

Furthermore, although state-of-the-art models are capable of emulating empathetic responses, they fundamentally lack genuine comprehension and accountability. They also exhibit notable issues with consistency and reliability within mental health contexts [49]. For example, LLMs can occasionally produce what might be termed "artificial empathy," responses that, while seemingly warm, may eventually be perceived as superficial or inauthentic when encountered repeatedly or when the conversational context shifts slightly [15]. Some users have reported that, over time, AI-driven support can appear shallow or overly repetitive, suggesting that these systems have yet to fully embody the authentic spirit of a human therapeutic alliance [51]. General-purpose LLM chatbots, such as unmodified versions of ChatGPT, pose considerable risks when applied to mental health care. They may, at times, generate factually inaccurate or culturally insensitive responses or fail to provide an appropriate reaction during crisis situations [57]. Recent user studies have further highlighted concerns related to trust, privacy, and the establishment of clear boundaries when individuals seek support from AI systems [64]. These findings underscore that the benefits offered by contemporary LLMs, such as improved fluency, a broader knowledge base, and an empathetic tone, must be complemented by robust guiding frameworks to ensure safety and efficacy [61]. The absence of genuine human empathy and ethical principles in AI chatbots remains a significant limitation, potentially affecting the crucial therapeutic alliance [65].

The field is increasingly recognizing that techniques like PE are critical for harnessing the strengths of LLMs while mitigating their shortcomings in therapeutic settings [47]. In summary, the role of AI in mental health is evolving rapidly, transitioning from basic rule-based applications to more sophisticated LLMs and multimodal agents [60]. Although the potential for scalable, on-demand support is unprecedented, achieving safe, personalized, and clinically sound outcomes necessitates addressing the crucial challenge of effective control and guidance [66]. This context lays the groundwork for a more rigorous examination of PE as a mediating strategy between the inherent potential of AI and the complex demands of mental health treatment [67].

Foundations of PE

The practice of PE has emerged as a pivotal method for directing the actions of AI models, particularly within the landscape of LLMs. Broadly defined, PE involves the deliberate creation of input statements or directives provided to a model with the aim of eliciting the desired output [13]. Unlike extensive model training or fine-tuning, which necessitate substantial annotated datasets and computationally intensive weight updates, PE operates post training by carefully managing the contextual environment in which the model functions [68]. Through the meticulous crafting of questions, instructions, or contextual prompts, practitioners can optimize the likelihood of a pretrained model performing specific tasks or adopting particular response patterns [61]. In practice, PE has emerged as a state-of-the-art technique for adapting powerful general-purpose LLMs to specialized domains without requiring resource-intensive retraining processes [68]. Essentially, PE serves to "program" the model using natural language rather than traditional code. This burgeoning field focuses on designing and optimizing prompts to guide AI models, enabling them to understand intent, follow instructions, and generate desired outputs, acting as a roadmap for the AI to steer it toward a specific output [69].

In the context of mental health applications, PE presents both considerable promise and significant challenges. In contrast to simpler tasks, such as factual research or summarization, therapeutic conversations require a consistent maintenance of an appropriate tone, empathetic engagement, adherence to clinical standards, and strict ethical boundaries [70]. Prompts designed for mental health chatbots should therefore be designed to serve multiple therapeutic objectives concurrently: providing psychological education, offering emotional validation and empathy, and guiding users through evidence-based treatments, such as CBT thought reframing or guided breathing exercises, all while maintaining a personalized and supportive communication style [60].

For example, an effective prompt needs to inform the AI which therapeutic model to use (eg, CBT or mindfulness-based therapies), dictate the desired tone and readability of the communication, and enforce necessary constraints, such as avoiding trigger language or reporting unverified medical information [53,60,68]. The incorporation of robust foundation therapy models within prompts is a fundamental principle. Recent research has explored the transformation of techniques from CBT [71], ACT [72], and DBT [73] into formal prompt structures. Operationally, this might involve instructing the AI to induce cognitive distortions in a manner consistent with CBT principles or to guide users toward value-based actions according to ACT procedures. For instance, a novel prompting strategy inspired by DBT has demonstrated significant improvements in response accuracy on smaller LLMs by translating key DBT skills like Wise Mind, Observation, Description, and Effectiveness into prompt components [74].

Ethical and Regulatory Landscape

The ethical and regulatory considerations surrounding AI-driven mental health chatbots are of significant importance due to the sensitive nature of user data and the potential impact on individual well-being [75]. Legal frameworks such as the Health Insurance Portability and Accountability Act (HIPAA) in the United States and the General Data Protection Regulation (GDPR) in the European Union mandate stringent privacy and data protection protocols, including end-to-end encryption, secure data handling practices, and the provision of user rights regarding data control [76]. HIPAA primarily applies to covered entities like health care providers and business associates handling protected health information, consisting of details such as medical histories and mental health conditions [76,77]. GDPR, on the other hand, applies more broadly to the processing of personally identifiable information of EU residents, requiring organizations to safeguard data and provide documentation of protection protocols, including obtaining explicit consent and facilitating the "right to be forgotten" [76,77]. The increasing

XSL•FO
RenderX

use of LLMs in health care, as discussed by Chow et al [2], further underscores the critical need for robust patient privacy and data security measures, particularly given the volume and sensitivity of data processed by LLM-enabled medical chatbots.

Privacy concerns are only one part of the equation; algorithmic bias and the inherent lack of explainability in some AI models present significant challenges [78]. Bias in training data can lead to disparities in care, potentially reinforcing societal stigmas [79]. This necessitates the development of "fair-aware AI" through proactive bias audits and mitigation strategies. The "black box" nature of certain AI algorithms can erode user trust and complicate accountability, underscoring the need for transparent usage policies and explainability features to foster user confidence and responsible governance [80]. For example, biases have been observed in AI models predicting Intensive Care Unit mortality and psychiatric readmission based on factors like gender and insurance type [81]. While general regulations like HIPAA and GDPR provide a foundational legal framework, specific deployment contexts, such as integration with existing health care systems or crisis services, will impose additional technical and compliance requirements. These may include specific data interoperability standards, security audit trails, and protocols for seamless escalation to human responders that align with the deploying organization's workflows and risk management policies.

Maintaining safety and accountability is essential, particularly in situations involving potential crises. Ethical deployment requires robust safety controls, including clear escalation procedures for users reporting suicidal ideation, potentially involving human oversight [82]. The disruptive nature of advanced LLMs like ChatGPT, as highlighted by Chow et al [2], introduces new complexities, including concerns about the accuracy of information, potential for misuse, and the rapid pace of development outstripping current ethical and regulatory frameworks. This requires an urgent call for robust ethical frameworks and continuous vigilance to address the unique challenges posed by such powerful, general-purpose models when applied to sensitive domains like mental health. Regulatory efforts are increasingly classifying health-related AI as high-risk, demanding rigorous testing for bias, reliability, and safety [83]. Implementing ethics effectively necessitates continuous monitoring, user feedback mechanisms, and iterative refinement, adopting an "ethics by design" approach that involves ethicists and clinicians from the outset [84]. Such a collaborative stance aims to ensure that AI-driven mental well-being interventions are not only innovative but also ethically sound and deserving of consumer trust [85]. Principles of responsible AI emphasize human supervision, fairness, transparency, privacy, safety, security, professional responsibility, and accountability [86]. Ethics of care considerations for AI in mental health include respecting human dignity, refraining from abusing user trust or manipulating emotions, and acknowledging the cultural diversity of emotional expression [86].

While AI holds significant promise in revolutionizing mental health care, it is crucial to address the associated ethical challenges. Safeguarding patient confidentiality and trust requires careful management of privacy concerns related to the collection and analysis of sensitive personal data. Furthermore, the inherent biases present in AI algorithms can contribute to disparities in diagnosis and treatment, disproportionately affecting marginalized or underserved populations. To ensure AI is integrated safely and effectively into mental health counseling, ongoing research, transparency, and accountability must remain a key priority.

Gaps in Current Approaches

Current AI-powered mental health support systems, while offering convenience, exhibit significant shortcomings in their therapeutic impact due to several key gaps [87]. One primary limitation is the inability to provide nuanced personalization and responsiveness. Many chatbots rely on preformulated conversational flows and deterministic response patterns that fail to adequately consider unique user contexts, dynamic emotional states, or individual treatment experiences [88]. This superficial level of personalization, coupled with limited real-time user state monitoring and longitudinal adaptation, undermines the potential for long-term user engagement and the development of a strong therapeutic bond [89]. While AI holds the promise for hyperpersonalized treatment through the analysis of diverse data [90], current systems often struggle with the complexity and variability of mental illnesses, including the subtleties of human communication [91].

Furthermore, crisis management capabilities in current AI systems remain rudimentary, often limited to directing users to hotline phone numbers without incorporating comprehensive risk assessment or safety planning [92]. Although advancements are being made in using AI for crisis prediction, immediate support, and enhanced hotline systems [93], a comprehensive integration of these technologies into robust safety protocols is still needed. These technical limitations are compounded by a broader lack of robust clinical validation. Many AI tools in mental health have demonstrated limited evidence of effectiveness across diverse populations and in naturalistic settings, thereby hindering user trust and the integration of these technologies into established mental health care models [94,95]. While some AI-powered assessment tools are undergoing clinical validation [96], more extensive and diverse validation studies are necessary to ensure their reliability and efficacy. Addressing these critical gaps requires ongoing advancements in AI adaptability, personalized learning algorithms, and seamless integration with established clinical interventions to enhance the efficacy and reliability of chatbots in real-world applications [91,97].

The literature review in Table 1 highlights the significant evolution of AI in mental health, from early rule-based systems to sophisticated LLMs and multimodal approaches. While AI offers unprecedented potential for scalable and accessible mental health support, several critical challenges and gaps remain. The lack of genuine empathy, issues with safety and accountability, the presence of algorithmic bias, and limitations in personalization and crisis management necessitate careful consideration and further research. PE emerges as a crucial strategy for guiding LLMs to provide safe, ethical, and clinically relevant support. The ethical and regulatory landscape requires continuous attention to ensure user privacy, data security, and responsible AI implementation. Addressing the identified gaps

XSL•FO
RenderX

through ongoing advancements in AI, rigorous clinical validation, and thoughtful integration with human expertise will be essential for realizing the full potential of AI in transforming mental health care.

Table . Evolution of artificial intelligence in mental health.

Era or technology	Key characteristics or capabilities	Examples	Limitations
1960s, rule-based systems or ELIZA [98]	Standardized advice and simulated conversation	ELIZA	Lack of personalization and no real understanding
1980s-2010s, ML[a]/DL[b] [38]	Data-driven analysis, sentiment detection, and symptom trend detection	Depression detection from social media	Requires large datasets and potential for bias
2020s, large language models [15]	Empathetic responses, nuanced language understanding, and cognitive empathy	GPT-3.5 and GPT-4	Lack of genuine comprehension, safety concerns, and potential for superficiality
Present or future, multimodal AI[c], and affective computing [41]	Emotion recognition from multiple inputs and personalized interventions	Chatbots using facial recognition and wearables	Technical complexity, ethical considerations, and need for robust validation

Current Landscape of AI Chatbots in Mental Health and PE Limitations

The integration of AI in mental health intervention systems has the potential to contribute both benefits and risks. Table 2 provides an overview of the current landscape of AI chatbots applied to mental health interventions, and this is specifically in their therapeutic positions and the constraints placed on their quick engineering approaches. This assessment synthesizes the main characteristics of representative AI chatbots used in this field, as presented in Table 2. It demonstrates various AI chatbots used in mental health care, defining their treatment scope, cueing strategies, target populations of users, and the most critical limitations affecting their performance. This structured evaluation provides insight into the strengths and weaknesses of current AI-based mental well-being tools and identifies key areas for improvement.

The data provided in Table 2 show trends in the current use of AI-driven chatbots for mental health treatment. One of the trends is the universal use of CBT and mindfulness-based interventions on most of the leading platforms, including Woebot, Wysa, Replika, Tess, Youper, Sanvello, and MindShift. This initial focus suggests a foundation strategy of reconfiguring established therapeutic practices into practical AI formats to provide users with systematic instructions for the treatment of anxiety, stress, and similar issues. Although current chatbots borrow from therapeutic concepts, they are also lacking in how well they can respond to the specific needs of individual users and tailor interactions.

XSL•FO
RenderX

Table . Representative artificial intelligence chatbots used in mental health interventions.

Chatbot	Therapeutic approach	Prompt strategies	Target audience	Limitations	Reference
Woebot	CBT[e]-focused, anxiety and stress management	Prescripted conversation flows	Adults	Limited adaptive personalization; minimal role assignment customization	Manole et al [50] and Fitzpatrick et al [99]
Wysa	CBT-focused, mindfulness, anxiety, and stress management	Empathetic but generic prompts	Teens, adults	Restricted context integration; lacks dynamic real-time updates	Inkster et al [100] and Chaudhry and Debi [101]
Replika	CBT-focused, mindfulness, general supportive talk	Passive, user-led queries	General	Inconsistent therapy alignment; uncertain crisis management features	AI Foysal [58] and Moylan and Doherty [102]
Tess	CBT and motivational interviewing	Thematically structured modules	General	Basic prompt cues; lacks deeper user-specific context analysis	Fulmer et al [103] and Stephens et al [104]
Talk space Chatbot	Guided self-help and therapy access facilitation	Guided conversation flows with service integration prompts	General	Limited direct therapeutic intervention; primarily a gateway to paid services; not a replacement for therapy	Larson [105] and Anser et al [106]
Rasa[b]	Modular framework (open source)	Customizable NLU[c] and dialogue flows; partial script expansions	Developers	Requires specialized design; does not inherently provide integrated therapeutic cues	Hanji et al [107] and Vineeth et al [108]
Youper	AI[d]-driven CBT and mindfulness	Adaptive daily check-ins	General	May lack advanced role assignment; personalization limited to user mood surveys	Mehta et al [109] and Major study from Stanford University and Youper find artificial intelligence therapy effective at reducing anxiety and depression [110]
Sanvello	CBT, mindfulness, relaxation	Prebuilt guided journeys and journaling prompts	General	Primarily static prompts; expansions often generic, lacking advanced user context	Balaskas et al [111] and Bautista et al [112]
MindShift	CBT for anxiety	Topic-focused modules, psychoeducation	General	Narrow domain focus (anxiety); conversation logic not strongly customized	Garrido et al [113] and Sharma et al [114]
Ada AI	Symptom checker+chat support	Basic triage-style prompts; limited mental health focus	General	Lacks robust therapy alignment; prompt structure is primarily biomedical	Morse et al [115] and Jungmann et al [116]

[a]CBT: cognitive behavioral therapy.

[b]Rasa is a framework rather than a standalone chatbot; it allows building custom bots with its natural language understanding and dialogue management, so the prompt strategy depends on the implementation.

[c]NLU: natural language understanding.

[d]AI: artificial intelligence.

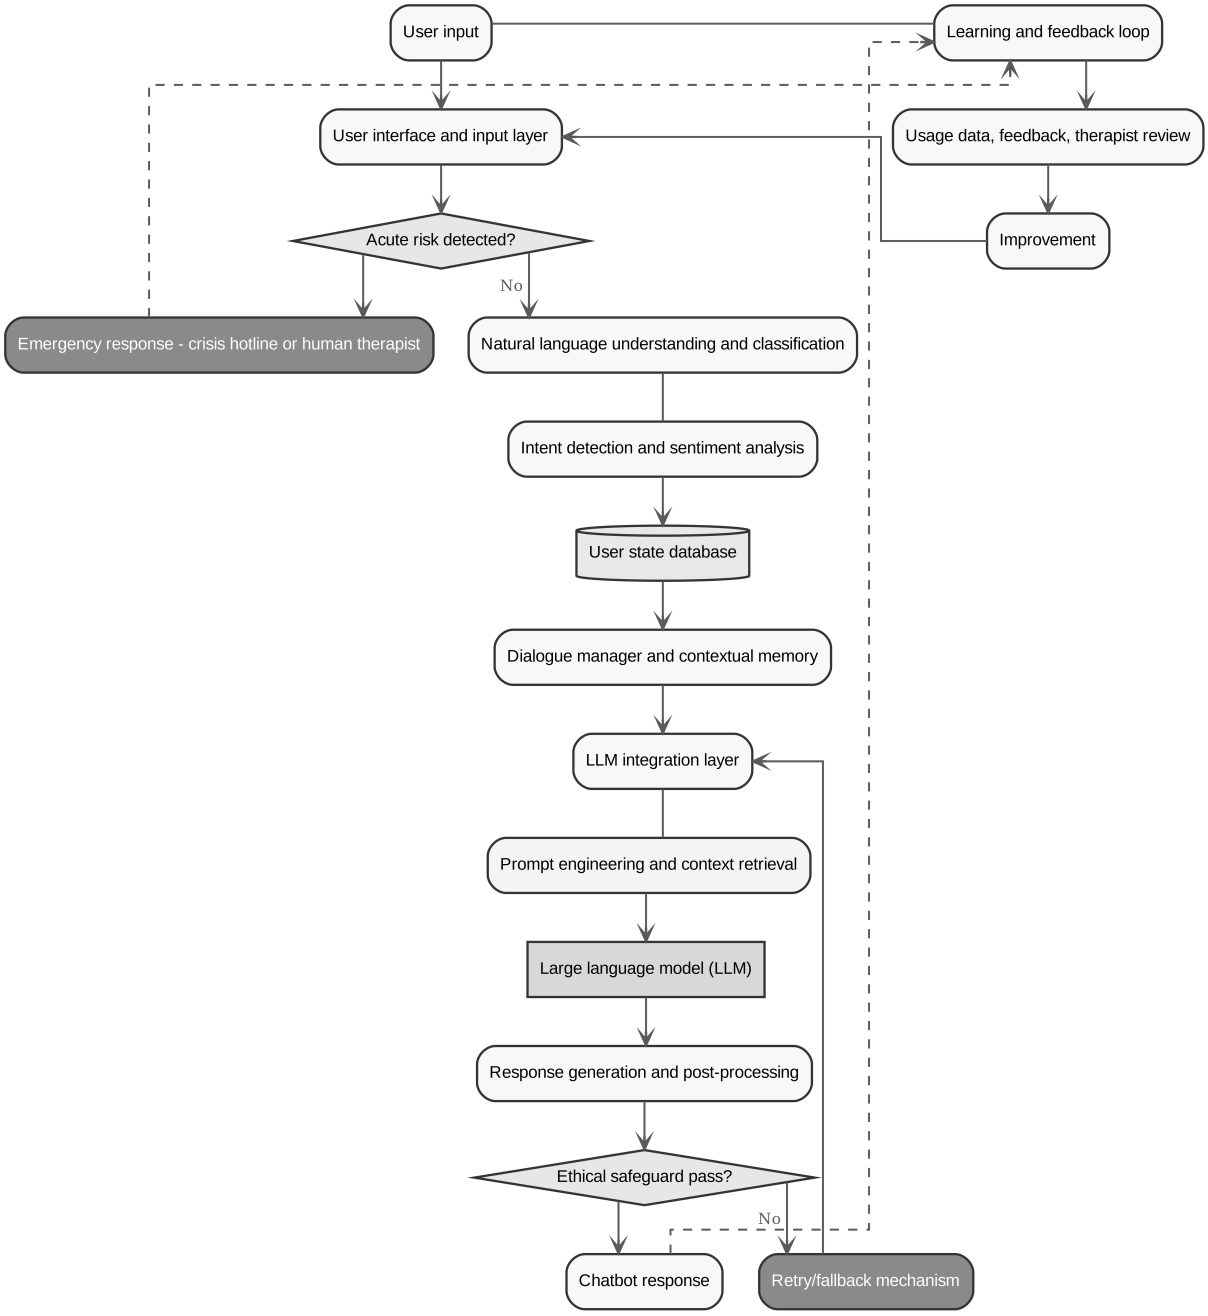
A typical problem highlighted in the analysis is limited adaptive personalization and restricted context integration across various chatbots. Phrases like “Limited adaptive personalization” and “Lacking deeper user-specific context analysis” identify the difficulty of developing AI systems that can completely understand and respond to the intricacies of a person’s mental health process. This is, in part, due to the current PE methods used, which are centered around predefined dialogue flows, generic prompts, or modular designs. As much as these offer control and guidance to some extent, they may fail to adequately respond to new user inputs or venture into special issues and, therefore, may make the conversation unnatural and limit the chatbot’s capacity to offer highly tailored support. Even modular designs like Rasa, while being customizable, require expert knowledge to integrate therapeutic goals and user specificity into the prompt strategy efficiently.

XSL•FO
RenderX

To overcome these limitations, a radical overhaul of PE is required. Future generations of techniques must aim to build end-to-end architectures that can understand user intent and emotion more deeply, potentially by leveraging multimodal data and building dynamic user models that learn and adapt over time. Integrating established therapeutic principles directly into these frameworks, with cultural sensitivities, and exploring human-AI collaboration in therapy are also crucial. Finally, rigorous evaluation frameworks will be required to demonstrate the efficacy, safety, and ethical implications of these new AI mental health technologies, resulting in more advanced and effective therapies.

As Table 2 suggests, despite advancements in AI-driven mental health support, current systems demonstrate limitations in adaptivity and personalization, hindering their capacity to deliver truly nuanced and effective therapeutic interventions. While frameworks like Rasa enable technical customization, achieving systematic integration of therapeutic goals and user-specific nuances remains a significant challenge. Future research should prioritize holistic PE frameworks that synergize therapeutic best practices with AI capabilities, focusing on real-time user adaptation through multimodal signal processing, dynamic personalization via evolving user models, and cultural adaptation to ensure global applicability. Furthermore, exploring human-AI collaborative models and establishing rigorous evaluation frameworks are crucial to bridge existing gaps, quantify improvements, and ultimately advance AI interventions that meaningfully complement mental health care with enhanced personalization, safety, and efficacy.

Proposed Framework



Overview

The MIND-SAFE framework is introduced as a structured approach to integrating LLMs into an AI-driven mental health chatbot system. As illustrated in Figure 1, the proposed architecture emphasizes user adaptation, ethical safeguarding, and personalized intervention, providing a foundation for responsible deployment in mental health contexts. Figure 1 illustrates the architecture, demonstrating how the user input flows through the linear layers of processing, protection, and response generation. Unlike conventional single-stage chatbots, our architecture introduces layered safety mechanisms (Figure 1) to detect acute risks and mitigate biases. This multitier design not only prioritizes user well-being but also incorporates a dedicated user state database (USD) for personalized intervention while protecting data privacy.

General chatbot architecture in the proposed framework is adapted from a design in a study by Chow et al [117]. The system combines user interaction, LLM-based dialogue generation, and multitiered safety controls to deliver personalized mental health support. The flowchart illustrates the architecture's main components and data flow. Beginning with the user's input (which undergoes risk checks), the process moves through intent analysis and dialogue management, then to the LLM with layered prompts (including ethical instructions and retrieved knowledge). The LLM's output is filtered for safety before being presented as the chatbot's reply to the user. A feedback loop with expert oversight and user data analytics continuously updates the system for improvements (Figure 1). The following sections detail the system's unique components and their roles in maintaining ethical and clinically guided interactions. At a high level, the system is composed of the following key components:

XSL•FO
RenderX

Figure 1. The architecture of the MIND-SAFE framework.

User Interface and Input Layer

The initial stage, the "user interface" and "input layer" (eg, a chat window or mobile app), focuses on capturing the user's expressions or questions (eg, "I feel hopeless and anxious") through a conversational interface. This layer does minimal preprocessing (language identification and tokenization) and flags a message as an acute risk immediately if any sign of acute danger (eg, self-harm cues) is detected via keyword spotting or a basic classifier. To operationalize immediate crisis detection, this layer combines keyword spotting (eg, "I want to end my life") with a lightweight risk classifier inspired by standard clinical screening tools. Each incoming user message is assigned a risk score based on the severity of identified linguistic cues. If a threshold is exceeded, the system promptly routes the user to emergency response (bypassing the LLM), aligning with guidance from professional bodies (eg, American Psychological Association [APA]) on crisis handling.

This threshold-driven approach aims to minimize false negatives and ensure that no potentially harmful generative output is offered during emergency scenarios. When a crisis has been detected (eg, overt suicidal thinking), the system initiates an emergency response (eg, providing crisis hotline numbers or pinging a human therapist) before any engagement with an LLM. This proactive safety measure aligns with the concerns raised by the APA regarding the potential dangers of unsupervised AI chatbots in mental health support [118]. The APA emphasizes the necessity of safeguards to protect the public from harm, particularly in vulnerable situations. The

XSL•FO
RenderX

framework's commitment to prioritizing user safety in high-risk scenarios before engaging the LLM demonstrates a responsible approach to the clinical use of AI.

Natural Language Understanding and Classification

Once an input is considered safe for automated processing, the next module identifies the user intent and emotional sentiment. While modern LLMs are capable of performing intent detection and sentiment analysis in context on their own, the framework proposes augmenting this with smaller classifiers for more specialized tasks, such as distinguishing between depressive mood, anxiety, or general advice. For example, negative self-talk could trigger a cognitive restructuring strategy, and a request for motivation might initiate a behavioral activation strategy. This steering mechanism, which uses auxiliary models or prompt-based classification, aims to improve both the relevance and safety of the interaction [119]. The design and validation of these specialized classifiers, as well as the interpretation of their outputs for the USD, will be conducted in close collaboration with clinical psychologists to ensure alignment with established diagnostic criteria and therapeutic relevance. Furthermore, the classifier is designed to update a user profile (eg, "user tends to exhibit social anxiety"), maintained in what we term the USD, to facilitate personalization and maintain conversational context.

The USD is a secure, structured repository specifically designed within our framework to store anonymized key information derived from user interactions. This includes aggregated sentiment trends, identified emotional triggers (eg, recurring themes associated with anxiety), preferred coping strategies previously discussed, and progress on therapeutic exercises. It is not a verbatim log of conversations but rather a distilled representation of the user's journey and state, enabling the chatbot to maintain continuity across sessions, personalize responses (eg, recalling a previously effective grounding technique), and adapt its approach based on the user's evolving needs. The USD operates under strict data minimization principles, retaining only essential, deidentified attributes necessary for therapeutic adaptation, thereby adhering to privacy standards such as HIPAA and GDPR, as discussed by Chow et al [2] in the context of LLM-enabled health care.

This data-minimization approach of the USD upholds privacy standards (eg, HIPAA and GDPR) and mitigates reidentification risks. Access control mechanisms ensure that only authorized clinicians or system modules can read or modify user states, while encryption at rest and in transit safeguards sensitive mental health data. By centralizing user states rather than entire dialogue logs, the USD fosters consistent personalization (eg, recurring self-talk patterns) without compromising confidentiality. This layered approach, using the strengths of both general LLMs and specialized classifiers, suggests an efficient allocation of resources and an enhanced ability to address specific user needs.

Dialogue Management and Contextual Memory

The dialogue management and contextual memory component is central to conducting coherent and therapeutically aligned conversations. Working in close concert with the clinical experts, this module synthesizes the current dialogue history, relevant information from the USD, and any necessary external information to construct a comprehensive context. This preconstructed context is then passed to the LLM integration layer. A carefully constructed system prompt, which is co-designed with therapists, defines the LLM's role (eg, a supportive mental health assistant using cognitive-behavioral techniques) and establishes strict instructions regarding confidentiality, tone, and boundaries, such as avoiding medical diagnoses or inappropriate advice. This system-level prompt, reflecting clinical expert input, acts as an inherent ethical governor, ensuring the LLM's outputs align with established therapy methods and ethical codes, including the avoidance of harmful suggestions. This co-design process includes translating evidence-based therapeutic techniques (eg, Socratic questioning, behavioral activation, and empathic reflection) into precise prompt structures. In addition, the LLM receives the current dialogue context, including recent user and chatbot messages, along with any relevant personal context or knowledge.

A key function of this layer is to determine when to leverage external knowledge through a retrieval-augmented generation (RAG) mechanism. For example, based on the conversational context, it can decide to query a knowledge base of verified psychological strategies or the user's own journal entries. This retrieved information is then passed to the LLM integration layer to be incorporated directly into the prompt. This process, co-designed with clinical experts, is important for grounding the LLM's response in evidence-based, contextually relevant content, thereby reducing the risk of factual inaccuracies or "hallucinations" and enhancing the therapeutic value of the dialog [120,121].

Existing mental health chatbots often rely on a single LLM pipeline with limited oversight. In contrast, our proposed layered architecture integrates PE, specialized classifiers, and a multistep ethical safeguard filter, creating a modular framework that can dynamically adapt or escalate when high-risk content arises. Unlike vanilla generative chatbots, this design ensures evidence-based content retrieval (eg, validated coping strategies), thus enhancing both safety and factual accuracy [121]. The iterative review and refinement of these dialog strategies and prompt structures by therapists, as part of the Learning and Feedback Loop section, is crucial for maintaining therapeutic fidelity and safety, aligning with recommendations by Stade et al [1] for responsibly tailoring LLMs.

LLM Integration Layer

The LLM integration layer is where the core therapeutic dialogue is generated. The framework uses PE to guide the LLM's behavior within ethical and clinical bounds. A carefully crafted system prompt encodes the role (eg, "You are a supportive mental health assistant employing cognitive-behavioral techniques") and strict instructions about confidentiality, tone, and boundaries (for instance, avoiding any medical diagnoses or inappropriate advice). This system-level prompt acts as an implicit ethical governor, ensuring the LLM's outputs align with established therapy methods and ethical codes (such as never encouraging harmful behavior). In addition, the LLM is provided with the dialog context (recent user and chatbot

XSL•FO
RenderX

messages) and any retrieved personal context or knowledge (described below) as part of the prompt. Figure 1 depicts this flow, where the user's query, contextual data, and system instructions are combined and fed into the LLM.

Response Generation and Postprocessing

The raw output from the LLM then undergoes processing by the response generation and postprocessing module, which includes an ethical safeguard filter before being presented to the user. This filter verifies the LLM's output for any violations of predefined rules or the presence of obscene language. While many recent LLM implementations include their own toxicity filters, the framework proposes an additional layer for filtering specifically tailored for mental health applications. This filter checks for compassionate language, the absence of derogatory or overly commanding speech, and the exclusion of banned content, such as information on lethal means or others' personal identifying information. If the LLM's output is flagged, the system may attempt to regenerate the response with an updated prompt or revert to a safe, predefined template. This layered safety approach demonstrates a strong commitment to ensuring that users receive clinically safe and high-quality responses, even if the generative model initially produces an unsuitable output. Furthermore, this filter is integrated with an explanation module that logs any changes made to the response, providing transparency for developers and accountability for clinicians reviewing the transcripts.

In addition, if the user's ongoing profile in the USD indicates repeated exposure to triggering content, the system can escalate to an alternative intervention (eg, human therapist review or a predefined safe response). This layered postprocessing, a key feature of our proposed framework, bolsters consistency in mental health guidance and reduces the risk of repetitive, harmful outputs.

Learning and Feedback Loop

The final key component of the system is the learning and feedback loop, which facilitates continuous improvement over time. The system logs all user interactions in a secure and anonymized manner. Trained therapists periodically review these data to assess the chatbot's effectiveness in adhering to therapeutic techniques and ethical norms, identifying areas for potential enhancement, such as improving the chatbot's empathy. The "therapist review" component is important. Licensed clinicians will regularly audit anonymized interaction logs to assess adherence to therapeutic principles, identify areas for prompt refinement, and flag any instances of suboptimal or potentially harmful AI behavior. Their expertise is vital for interpreting nuanced interactions that automated metrics might miss. User feedback and ratings also contribute to a learning module that adjusts the chatbot's operational parameters, potentially modifying question construction based on user engagement metrics like drop-off rates. This human oversight and user-driven feedback mechanism is important for ensuring the chatbot remains aligned with therapeutic best practices and user needs, addressing concerns about the potential lack of human empathy in AI interactions [122] and the necessity of continuous monitoring and improvement in AI systems [123].

As part of the learning and feedback loop, we propose a structured empirical evaluation strategy.

First, pilot tests in which small-scale user studies with diverse demographic groups are conducted to assess immediate safety, bias detection, and user experience.

Second, clinical trials in which collaborative studies with licensed therapists will be essential for evaluating therapeutic outcomes. For a rigorous evaluation of efficacy, particularly for specific mental health concerns targeted by the framework, these trials should ideally be designed as RCTs. This involves comparing the chatbot intervention against appropriate control groups and using a comprehensive suite of outcome measures, including but not limited to self-report, clinician-rated assessments, and behavioral data. Such rigor is fundamental to validating the framework's effectiveness, especially if interventions derived from it are to be considered for users with diagnosed mental health conditions.

Third, longitudinal monitoring in which ongoing analyses of anonymized transcripts are used to identify any emergent biases or failures in acute-risk detection. Therapist oversight ensures that flagged dialogs receive expert attention, and the LLM's prompts are recalibrated as necessary.

Fourth, user satisfaction and drop-off metrics that are collected via surveys and chatbot usage analytics feed into the iterative updates of prompt templates and dialogue strategies.

These steps aim to ensure that the chatbot not only meets immediate safety standards but also demonstrates long-term effectiveness in diverse real-world contexts [122,123].

The proposed framework has its limitations. This framework is designed to guide PE in AI mental health applications through the integration of therapeutic principles, user-centered design, and ethical considerations. However, it is not a catch-all solution and does not replace the need for clinical validation before real-world deployment. Such validation must assess the model's interpretability, the quality and representativeness of its training data, and its fine-tuning for mental health contexts. While the framework can help identify effective PE methods, it does not guarantee their feasibility or success in clinical settings. Furthermore, given the rapid evolution of LLMs and shifting cultural norms, these limitations may change, requiring ongoing review and refinement of the framework.

Ethical Architecture and Safeguards

While the previous section detailed the technical architecture of the framework, this section outlines the design principles and operational safeguards embedded within it to address core ethical responsibilities. These components are structured to systematically manage trust, privacy, fairness, and cultural inclusivity.

Privacy, Data Protection, and Regulatory Compliance

In mental health contexts, users may share highly sensitive information that requires enhanced security measures [77]. Our framework, therefore, adopts a privacy-by-design approach that emphasizes data minimization and strict access controls in the USD. This database only stores the essential states necessary

XSL•FO
RenderX

to support personalization (eg, mood trends and recurring topics) rather than detailed transcripts or personally identifiable information. In alignment with HIPAA and GDPR regulations, the USD applies encryption for data at rest and in transit [77]. Session data is automatically purged or anonymized after a predefined period, ensuring that historical records do not accumulate beyond what is necessary for improving user experience [124].

The acute risk detection module flags user inputs suggestive of suicidal or violent ideation. When triggered, the system generates a minimal "risk event" log without storing the entire transcript. This design complies with telehealth regulations that discourage retaining sensitive health data unnecessarily [77,124]. In addition, postprocessing within the ethical safeguard filter ensures that the chatbot does not inadvertently echo confidential user details in its outputs.

Bias and Fairness

Bias in AI-driven mental health applications can lead to inequitable quality of support across demographic groups [125]. To address this risk, our framework incorporates a multitiered bias mitigation strategy. This approach begins with the foundational fine-tuning of the baseline LLM using demographically representative data, which includes targeted evaluations to detect potential bias in mental health–related responses [66]. Second, at the point of interaction within the LLM integration layer, prompt-level interventions are used; system instructions are explicitly designed to emphasize respectful, culturally neutral language, building on previous research showing that careful prompt design can significantly decrease discriminatory or stigmatizing responses [15,126]. Finally, the learning and feedback loop provides a mechanism for ongoing oversight. Human therapists will regularly review anonymized transcripts, specifically focusing on potential disparities in support across cultural or linguistic backgrounds. If persistent biases are identified, the dialogue manager can be adjusted, or underlying models can be retrained to better align with fairness objectives [127]. By combining these automated checks and dedicated therapist oversight, the system is designed to iteratively refine its interactions and promote equitable access to mental health support for all users.

Cultural Adaptation and Global Scalability

Developing culturally appropriate AI for global mental health requires more than just technical infrastructure; cultural competence is a critical element for successful implementation [23]. Cultural differences in expressing psychological distress, coping mechanisms, and attitudes toward mental illness are vast; therefore, interventions based solely on direct translation are likely to be culturally inappropriate or irrelevant [128]. For example, therapeutic metaphors based on environmental contexts unavailable in a user's geographical setting may fail to resonate. Our framework design necessitates collaboration with local mental health practitioners to ensure the cultural relevance of intervention strategies by using appropriate examples and contextual schemas [129]. Piloting and obtaining user feedback in each cultural context is integral to the learning and feedback loop, allowing for the iterative refinement of both algorithms and intervention methods [130]. This methodological approach enhances the cross-cultural validity of therapeutic interactions, thereby augmenting user engagement and intervention usage [1]. The incorporation of culturally responsive elements into the system design provides support that aligns with the diverse experiences of various populations [131].

A Strategy for Framework Validation

Overview

The validation of our proposed PE framework requires a multifaceted strategy that assesses its core components and their integrated performance. A full empirical validation is beyond the scope of this conceptual paper; however, this section outlines a phased plan that draws on best practices for evaluating AI in health care [1,26]. The primary objective is to demonstrate the framework's ability to enhance the safety, clinical relevance, user engagement, and ethical integrity of LLM-based mental health chatbots compared with simpler implementations.

A Comparative Approach to Validating the Framework's Value

To empirically assess the added value of the framework, a comparative evaluation is required. While a full RCT remains the gold standard for testing a specific, mature chatbot intervention, evaluating the framework itself necessitates a different approach. We propose a study comparing a chatbot built on the full, layered architecture against a minimally safe LLM baseline. This baseline would consist of a general-purpose LLM equipped only with the core safety mechanisms mandated by ethical practice: the acute risk detection module and the ethical safeguard filter. This ensures that no participant is exposed to an unsafe intervention, allowing the study to ethically isolate the therapeutic and engagement benefits of the framework's more advanced components.

Such a design presents ethical challenges, as one cannot withhold necessary safety components. However, by ensuring a robust safety baseline in both arms, the comparison can ethically proceed to measure the incremental value of the framework's other components, such as the USD, the specialized classifiers for intent detection, and the RAG mechanism. The key outcome measures would not be limited to clinical symptom reduction but would focus on intermediate metrics critical to the therapeutic process, such as the quality of the therapeutic alliance, perceived empathy, user trust, and the clinical relevance of the chatbot's responses. This approach would enable us to isolate and quantify the specific benefits derived from the structured layered design, providing a clear evidence base for its utility compared with more basic implementations. A traditional RCT would then serve as the appropriate final step in a long-term research program, used to test a fully developed chatbot that has been refined through these earlier comparative studies.

Alignment With Established Evaluation Frameworks

Rather than introducing a new evaluation framework, which risks conceptual fragmentation, we demonstrate how the proposed framework (Figure 1) can be rigorously assessed using criteria from established, comprehensive evaluation frameworks in AI and mental health. Specifically, we align our validation

XSL•FO
RenderX

strategy with the constructs outlined in the FAITA-MH [25] and the READI framework [26]. This alignment ensures that our approach contributes to a shared language and set of standards for responsible development.

The FAITA-MH framework provides a structured scale for evaluating AI-powered mental health tools across 6 dimensions: credibility, user experience, user agency, equity and inclusivity, transparency, and crisis management. Similarly, the READI framework outlines 6 key criteria for assessing the readiness of AI-mental health applications for clinical deployment: safety, privacy and confidentiality, equity, effectiveness, engagement, and implementation. Our framework components are designed to directly address these domains. Table 3 presents a mapping of each framework component to these standards, demonstrating how the design supports established evaluative criteria.

Table . Mapping of the proposed architectural components to constructs from the FAITA-MH[a] and READI[b] evaluation frameworks.

Our framework component (Figure 1)	Key function	Relevant FAITA-MH constructs	Relevant READI constructs
Acute risk detection and emergency response	Immediate crisis identification and escalation.	Crisis management and credibility	Safety
Ethical safeguard filter	Postgeneration check for safety, bias, and privacy violations.	Crisis management, and equity and inclusivity	Safety and privacy or confidentiality
User state database	Securely stores user state for personalization, and ensuring data minimization.	User agency (data protection and privacy) and user experience (personalized adaptability)	Privacy or confidentiality and effectiveness
Dialogue manager and LLM[c] integration layer (with RAG[d])	Generates clinically-grounded, empathetic dialogue using therapeutic models and verified knowledge.	Credibility (evidence-based content) and user experience (quality of interactions)	Effectiveness and Engagement
Natural language understanding and classification	Identifies user intent and sentiment to guide responses.	User experience (personalized adaptability)	Effectiveness
Learning and feedback loop (with therapist review)	Iterative improvement based on expert and user feedback.	Credibility (retention) and user experience (mechanisms for feedback)	Implementation and effectiveness
Entire framework	Holistic design integrating all components.	Transparency, equity, and inclusivity	Equity and implementation

[a]FAITA-MH: Framework for AI Tool Assessment in Mental Health.

[b]READI: Readiness Evaluation for AI-Mental Health Deployment and Implementation.

[c]LLM: large language model.

[d]RAG: retrieval-augmented generation.

Summary of Evaluation Methods

A systematic outline of the evaluation criteria is necessary for a comprehensive review of the performance and safety aspects of our proposed framework. Table 4 presents key dimensions and recommended metrics for evaluating chatbots built upon this framework. These dimensions and metrics are selected to align with and provide concrete measures for the core constructs of the FAITA-MH and READI evaluation frameworks, as detailed in Table 3. This includes assessing clinical effectiveness, user engagement, therapy quality, and ethical compliance. Building on this mapping, Table 4 specifies concrete evaluation dimensions, metrics, and tools aligned with FAITA-MH and READI.

As described above, the minimally safe baseline will undergo an identical assessment to evaluate outcome differences across equity, trust, and alliance measures. Analytically, outcomes will be assessed using preregistered analyses (eg, mixed-effects models for repeated measures and equivalence or noninferiority margins where appropriate).

XSL•FO
RenderX

Table . Core dimensions for evaluating artificial intelligence–driven mental health chatbots and recommended methods.

Dimension	Key metrics or methods	Primary objective	Tools or methods	References
Clinical efficacy	PHQ-9[a], GAD-7[b] symptom changes; RCT[c] outcome comparisons	To assess reduction in mental health symptoms	Standardized questionnaires and pilot RCTs	Anisha et al [132]
User engagement	Session length, dropout rates, and exercise completion	To determine usage continuity and adherence	Chatbot log analytics and retention surveys	Liu et al [133]
Prompt quality	Likert-scale user feedback on empathy and clarity	To evaluate perceived helpfulness of generated responses	Postsession rating forms and chat reviews	Martinengo et al [134]
Bias and fairness	Comparison of responses across demographic groups	To detect and mitigate algorithmic bias	Stratified output analysis and bias audits	Torous et al [95]
Ethical compliance	Crisis protocol activation and privacy law conformance	To ensure user safety and regulatory adherence	IRB[d] reviews and scenario-based crisis testing	Mennella et al [82]
Therapy quality	Therapist-coded transcripts and missed-opportunity logs	To validate adherence to therapeutic best practices	Structured auditing by mental health professionals	Vossen et al [135]
Cultural adaptation	Localization success and user satisfaction in multiple locales	To confirm the chatbot's global relevance and inclusivity	International pilot studies and local feedback	Ulrich et al [136]

[a]PHQ-9: Patient Health Questionnaire-9.

[b]GAD-7: Generalized Anxiety Disorder 7-item.

[c]RCT: randomized controlled trial.

[d]IRB: Institutional Review Borad.

Ethical Considerations

This paper presents a conceptual framework and synthesizes existing literature; it does not involve the collection or analysis of data from human participants, animals, or tissues. As such, and in accordance with GVSU's guidance on research activities not requiring Institutional Review Board (IRB) approval, the research was exempt from IRB or research ethics board approval [137]. All future research aimed at implementing and validating this framework, including the comparative evaluation strategy outlined in the "A Strategy for Framework Validation" section, will be subject to full ethics review and will require informed consent from all participants prior to their involvement.

Results

The methodological analysis resulted in the development of the MIND-SAFE framework, a layered conceptual architecture for PE (Figure 1), designed to guide the creation of safe and effective LLM-based mental health chatbots. The principal result is the framework's architecture, which systematically integrates evidence-based therapeutic models, a personalization layer with a USD and RAG mechanism, and a multitiered system of ethical and safety controls.

A further result of this work is the explicit mapping of the framework's architectural components to establish evaluation standards, namely the FAITA-MH and READI frameworks (Table 3), which ensures alignment with best practices for responsible AI development. Finally, this work produced a systematic validation strategy, including core evaluative dimensions and metrics (Table 4), designed to empirically assess the framework's value against a minimally safe baseline.

Discussion

Principal Findings

This integrated approach represents a methodological advance over existing systems, which often rely on scripted conversational flows or lack the governance needed for high-stakes clinical contexts [87,88]. As our review of the current landscape shows (Table 2), many chatbots provide limited personalization and inadequate context integration, restricting their ability to deliver nuanced support. By operationalizing principles of responsible AI development [1,26], our framework offers a structured pathway for creating more clinically relevant and trustworthy AI-driven therapeutic tools.

Implications for Responsible AI Development

The proposed framework serves as a practical roadmap for developers, researchers, and clinicians seeking to move beyond general-purpose LLM deployments toward specialized, safer, and more clinically meaningful interventions. Its layered design addresses several core challenges in responsible AI.

First, the emphasis on a multitiered safety system, including both preprocessing risk detection and postprocessing ethical filters, establishes a defense-in-depth strategy against harmful or inappropriate outputs. This marks a critical departure from relying solely on internal safeguards of foundation models, which may not be sufficiently tailored to the sensitivities of mental health contexts. Second, the integration of the USD and

XSL•FO
RenderX

a RAG mechanism provides a structured approach to personalization and factual grounding. This mitigates 2 major risks associated with LLMs in health care applications—the production of generic or clinically irrelevant responses, and the risk of factually incorrect outputs ("hallucinations") [131].

Finally, the inclusion of a learning and feedback loop, which requires continuous therapist oversight, ensures that the system remains clinically grounded and can be iteratively refined. This human-in-the-loop model is not an auxiliary feature but a foundational principle, reflecting the ethical requirement that AI must augment, not replace, human clinical judgment and expertise. By operationalizing these principles, the framework provides a structured methodology for building AI systems that are not only technologically advanced but also aligned with the core tenets of safety, fairness, transparency, and accountability.

Broader Ethical and Clinical Implications

The deployment of LLM-based mental health chatbots requires a proactive and rigorous approach to ethical governance. As noted by Chow et al [2], the rapid evolution of models like ChatGPT presents both opportunities and significant ethical challenges, including data accuracy, cybersecurity, patient safety, and the transparency of decision-making processes. The MIND-SAFE framework addresses these issues by embedding safeguards at multiple levels, from the user interface and input layer to the LLM integration layer and USD. This design prioritizes user trust, privacy, bias mitigation, and cultural inclusivity in each phase.

Establishing transparency is important in maintaining user trust. As illustrated in Figure 1, all interactions begin at the user interface and input layer, where the system explicitly discloses that the user is conversing with an AI chatbot. This disclosure clarifies the chatbot's capabilities and limitations, reducing the risk of misunderstanding in situations that require clinical intervention. Furthermore, when the acute risk detection module detects or identifies suicidal ideation or crisis-level distress, the system bypasses the LLM and routes the user to emergency response or services. A targeted disclaimer reinforces that a licensed mental health professional or hotline is recommended in acute situations.

While such escalation protocols are a necessary safety net, they are insufficient compared with the ethical and legal responsibilities traditionally assumed by licensed professionals. A notable example is the "duty to protect," a legal and ethical obligation established in Tarasoff v. Regents of the University of California (1976) [138]. This doctrine requires clinicians to take reasonable steps to prevent identifiable foreseeable harm, including breaching confidentiality to warn authorities or threatened victims. Because the scope and interpretation of this duty vary significantly across jurisdictions [138,139], even offering a hotline may not suffice in situations that legally or ethically require more active intervention.

Current AI systems cannot perform the nuanced legal reasoning or risk assessments required for such obligations [138]. This gap highlights the limitations of automation in contexts where professional accountability is essential [140]. One potential avenue for future development is the "warm handoff," in which an AI system facilitates a direct, immediate transfer to a human crisis counselor rather than merely providing referral information [141]. Implementing this at scale presents significant technical, logistical, and workforce challenges and remains a critical area for research [100]. Accordingly, while our framework provides a robust technical safety net, we underscore that it is intended to augment rather than replace clinical oversight, particularly in high-risk scenarios where the duty to protect may be invoked [138,142].

Limitations and Future Work

This paper presents the MIND-SAFE framework, a conceptual model intended to support the responsible, safe, and clinically meaningful development of AI-supported care platforms. While the framework is informed by interdisciplinary literature and sound design principles [1,2], its key limitation is the absence of empirical validation of the integrated system. The actual effectiveness and resilience of the proposed layered framework in real-world contexts remain to be determined through systematic testing, as outlined in the validation plan. This reflects the current stage of early development, where conceptual models remain high-level designs pending implementation and clinical validation. Our intention is to provide a structured, evidence-based, and ethically grounded framework to guide these next phases of research and evaluation.

Beyond empirical validation, the framework is also constrained by the current limitations of LLM technology. A central difficulty lies in conveying complex therapeutic nuance and achieving genuine affective empathy, rather than sophisticated pattern recognition or surface-level emulation of empathetic language [2]. Although the framework incorporates evidence-based therapeutic theory and engages with affective computing, replicating authentic empathy remains an unresolved challenge [1]. In addition, LLMs are prone to generating plausible but inaccurate information ("hallucinations") and may reproduce or amplify biases present in their training data, even with mitigation strategies in place [26,134]. The effectiveness of the framework, therefore, depends heavily on the quality and diversity of both the auxiliary classifiers and the LLM training data; bias in either data or prompts could inadvertently lead to inequitable or suboptimal care. Continuous monitoring and iterative refinement are thus essential to safeguard fairness. The evolving nature of LLMs further implies that prompt design strategies and technical parameters will require ongoing adaptation as new models and capabilities emerge. Finally, while the framework's use of a USD for personalization is based on privacy-by-design principles, its responsible implementation is critical to prevent data breaches and ensure compliance with evolving regulations such as HIPAA and GDPR [2]. The shifting regulatory environment for AI in health care demands continual oversight to maintain compliance and public trust [2,13,26].

Looking ahead, the vision of a clinically nuanced, adaptive, and ethically robust LLM-based mental health chatbot remains an ambitious, evolving research agenda. A phased approach to development and deployment is essential. Phase 1 should prioritize robust safety mechanisms and rigorous technical testing of the framework's individual components in simulated environments. Phase 2 should involve pilot implementations in

XSL•FO
RenderX

supervised, blended-care contexts, with early RCTs assessing feasibility, engagement, and preliminary efficacy. Only after robust evidence of safety and effectiveness emerges should the system progress to greater autonomy and advanced personalization (phase 3), and any such expansion must remain under close regulatory and ethical oversight. Advancing along this roadmap will require long-term interdisciplinary collaboration, substantial investment in high-quality data and clinical trials, and the establishment of clear regulatory standards to foster public trust and ensure responsible innovation.

Conclusion

This paper introduces the MIND-SAFE framework, a comprehensive PE framework, and a conceptual model to guide the development of safer, more effective, and ethically sound LLM-based mental health chatbots. By integrating empirically validated therapeutic models within a layered architecture of technical and clinical safeguards, the framework offers a practical pathway for creating AI-driven tools that deliver empathetic and contextually relevant support.

More than a standalone proposal, this framework is situated within the broader scholarly landscape; its components are explicitly mapped to established evaluative standards, such as the FAITA-MH [25] and READI [26] frameworks, ensuring that development and validation remain consistent with emerging best practices. We move beyond a generic call for evaluation by proposing a pragmatic, ethically grounded validation strategy that compares the full framework against a minimally safe LLM baseline, providing a clear path to generating empirical evidence of its value.

Importantly, this work recognizes that technical safeguards alone are insufficient. We examine the ethical complexities at the intersection of AI and clinical responsibility, including the gap between automated crisis alerts and the legal “duty to protect.” This underscores that the framework is not intended to replace clinicians but to support and augment their work.

Ultimately, translating this model into real-world applications requires a rigorous, phased roadmap shaped by interdisciplinary collaboration and stakeholder engagement. Addressing the ethical dimensions of integrating AI into mental health care, the framework highlights a pressing need: to move beyond algorithmic precision and foster enduring partnerships between clinicians and AI systems, partnerships grounded in therapeutic understanding, guided by clear ethical principles, and validated through continuous, real-world application.

Abstract

Background: Digital mental health technologies (DMHTs) are becoming more widely available and are seen as having the potential to improve the quality of mental health care. However, conversations around the potential impact of DMHTs can be impacted by a lack of focus on the types of technologies that are available. Several frameworks that could apply to DMHTs are available, but they have not been developed with comprehensive methods and have limitations.

Objective: To address limitations with current frameworks, we aimed to identify existing literature on the categorization of DMHTs, to explore challenges with categorizing DMHTs for specific purposes, and to develop a new conceptual framework.

Methods: We used an iterative approach to develop the framework. First, we completed a rapid review of the literature to identify studies that provided domains that could be used to categorize DMHTs. Second, findings from this review and associated issues were discussed by an expert working group, including professionals from a wide range of relevant settings. Third, we synthesized findings to develop a new conceptual framework.

Results: The rapid review identified 3603 unique results, and hand searching identified another 3 potentially relevant papers. Of these, 24 papers were eligible for inclusion, which provided 10 domains to categorize DMHTs. The expert working group proposed a broad framework and based on the findings of the review and group discussions, we developed a new conceptual framework with 8 domains that represent important characteristics of DMHTs. These 8 domains are population, setting, platform or system, purpose, type of approach, human interaction, human responsiveness, and functionality.

Conclusions: This conceptual framework provides a structure for various stakeholders to define the key characteristics of DMHTs. It has been developed with more comprehensive methods than previous attempts with similar aims. The framework can facilitate communication within the field and could undergo further iteration to ensure it is appropriate for specific purposes.

Introduction

In recent years, the availability of digital mental health technologies (DMHTs) has rapidly expanded [1]. These technologies are seen as having a high potential for improving mental health care and are the focus of initiatives to improve health care across the world [2]. However, conversations around the potential impact of DMHTs can be impacted by a lack of focus on the types of technologies that are available. This can hinder discussions about the opportunities and challenges associated with specific characteristics of DMHT [3]. Clearer frameworks outlining the key characteristics of DMHTs could aid these discussions and have benefits for a range of purposes.

A key step for developers preparing to meet regulatory requirements is developing an intended purpose statement [4,5]. Clarity around the key characteristics of DMHTs within a defined framework could help developers to ensure that these statements provide sufficient detail. It could also help developers and other stakeholders to interpret whether technologies qualify as software as a medical device and how it should be classified. In addition, there may be benefits for the postmarket surveillance capability of regulators allowing safety events for certain types of DMHTs to be identified more effectively [6]. In some jurisdictions, there may also be benefits in providing clarity around where regulatory discretion applies [7].

XSL•FO
RenderX

Clearer frameworks for categorization could also have benefits within research and evaluation, including health technology assessment (HTA). To conduct systematic reviews and economic evaluations of DMHTs, one must understand whether technologies are similar enough to be compared. This is important to help determine if assumptions of similarity can be met within meta-analysis or to inform subgroup analyses [8]. If the similarity of DMHTs and their mechanism of action are not considered and they are not appropriately grouped together, then meta-analyses are likely to have unacceptably high levels of heterogeneity, even using random-effects methods. This may lead researchers to be unable to identify DMHTs that are most likely to be beneficial and to make helpful recommendations on their use. Within economic analysis, it is also important to assess whether estimates of effectiveness are likely to be generalizable across DMHTs and whether interventions are likely to have similar implications for benefits and costs that are accrued over time [9]. A better definition of types of DMHTs and key characteristics could also ensure that recommendations from HTA agencies (eg, the National Institute for Health and Care Excellence [NICE] in England or the Canada's Drug Agency in Canada) are targeted at a suitable group of technologies.

Several categorization or classification frameworks for digital health technologies are available within regulation and HTA. These are designed to be broad and appropriate for a range of digital technologies across health conditions and have broad international applicability [10,11]. These frameworks categorize technologies according to the severity of the conditions and their role in clinical management. However, there is uncertainty around how to place DMHTs within these categories. For example, the NICE evidence standards framework for digital health technologies categorizes technologies with direct health outcomes into those that inform treatment, drive treatment, treat a specific condition, or diagnose a specific condition [11]. These are broad categories that may suit the goal of defining appropriate evidence. However, these categories are not able to distinguish between types of DMHT at a more granular level, such as between a cognitive behavioral therapy (CBT) app with high levels of personalization that relies on artificial intelligence (AI) to tailor treatment and a CBT app that provides a fixed digitized version of written materials. Within regulation, nomenclature coding systems are also available to categorize technologies [12,13], and specific codes for DMHTs are needed. However, at present, these codes to categorize DMHTs vary in the level of detail they provide and may include a large number of technologies with differing characteristics. For example, an existing code for psychological assessment software will encompass DMHTs that have a wide range of intended purposes and different potential benefits and risks.

Within published literature, there have been limited attempts to provide frameworks to categorize DMHTs. These existing taxonomies or frameworks focus on specific clinical areas, such as use within primary care [14], or focus on issues important for research, such as distinctions between active interventions and interventions used as comparators within control arms of randomized trials [15]. There are methodological limitations within these existing studies, and they do not identify studies that were available at the time of publication and were identified during scoping for this review. In addition, we are not aware of any framework for categorizing DMHTs that has been supported by both a review of existing work and consensus from experts. Due to the lack of rigorous work in this area, there have been calls from researchers and other stakeholders to develop improved frameworks for DMHTs to help address issues across research, evaluation, regulation, and HTA [15,16].

To address this gap, we aimed to identify existing literature on the categorization of DMHTs, to explore challenges with categorizing DMHTs for specific purposes, and to develop a new framework. This work is focused on DMHTs for several reasons. First, mental health conditions can present differently and require different approaches to other conditions both due to their spectrum-based nature spanning general well-being to more severe presentation and the highly individualized nature of risk. Second, DMHTs themselves can take an active role in managing people's symptoms or conditions with partial or no support from other professionals. This is less likely to occur in physical health conditions. Similarly, there are also digital health technologies that may play a substantial role in physical health but are not likely to be adopted for mental health [17]. There will inevitably be overlaps with how digital health technologies for other conditions could be categorized. However, our focus allows greater consideration and contextualization of issues relating to mental health and the nuances of delivering mental health care and aims to provide a more tailored framework that focuses on the types of digital health technologies available for mental health.

Methods

Overview

We used an iterative approach with several steps. In step 1, we completed a rapid review to identify previous literature that has attempted to categorize DMHTs. In step 2, we discussed findings from the rapid review and broader issues with developing a framework with an expert working group. Finally, in step 3, we considered the perspectives of the expert working group and developed a framework that could inform future work in this area.

Step 1: Identifying Previous Work on Categorizing DMHTs

A rapid review was developed in line with best practice recommendations [18], and preferred reporting items according to PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 are provided where applicable [19]. A completed PRISMA checklist is provided in Checklist 1.

Search Strategy

We searched the following electronic bibliographic databases of published studies: Embase (Ovid), MEDLINE (Ovid), PsycINFO (Ovid), Health Management Information Consortium, HMIC (Ovid), and Epistemonikos between August 29 and September 2, 2023. We also checked the reference lists of retrieved papers for other relevant materials and searched Google to identify gray literature such as reports and policy documents. An information specialist conducted the search with

XSL•FO
RenderX

terms based on MeSH and text words from key papers that were identified during scoping. The review followed an unpublished protocol and was not registered.

The search was divided into three sets of terms targeting the expected types of studies that (1) aimed to develop a taxonomy (eg, terms including taxonomy, typology, categorization, and group), (2) provided a narrative review of the field of digital mental health (eg, terms including field, future, advance, emerging, and state), and (3) completed a systematic review grouped by type of technology (eg, terms including review, synthesis, and analysis). More details on the search strategy are available in Multimedia Appendix 1.

Eligibility Criteria

Studies were considered eligible for inclusion if they provided an approach to categorizing or grouping digital technologies according to their characteristics and had a specific focus on mental health. The digital technologies of interest in this review are software that aims to have a direct or indirect impact on an individual's health outcomes through use by the individual or a professional. We did not include digital technologies that aim to improve population-level care or improvements in efficiency. This is in line with the definition used in other frameworks [10,11]. Both qualitative and quantitative studies were also included if they met these inclusion criteria. Studies were not included if they extracted characteristics of technologies but did not provide clear groupings. We only included English language studies.

Study Selection and Data Extraction

One team member (LA) completed the initial screening of studies by title. A second team member then screened potentially relevant studies by title and abstract (GH). For eligible studies, data were extracted using a standardized data extraction form by 1 team member (GH) and reviewed by a second team member (FE).

Information extracted included the aim and scope of the study, type of study, and details of domains used to group technologies. Initially, domains used to group technologies were extracted according to the name provided by the authors. Domains were then reviewed for similarity and pooled if appropriate. The assessment of whether a domain was present within a study was made based on the prominence given by the authors. Domains were included where a list of types of technology was provided within a paper, where a characteristic was provided as a subheading, or where a characteristic was used to define a subgroup within an analysis. For example, one paper describing a framework for mental health in primary care provides a list of domains that can be used to categorize DMHTs [14]. Similarly, in a systematic review on interventions for university students, DMHTs are divided into domains in the narrative synthesis of results [20].

Step 2: Discussion Within an Expert Working Group

Group Membership

The findings of the rapid review and challenges associated with categorizing DMHTs were considered by an expert working group during a web-based meeting in November 2023. This is a group that has been convened to meet and provide guidance for the duration of a Wellcome-funded research project [21].

The group was formulated to provide expertise on digital mental health from across the field. Experts were selected based on their experience of designing and researching DMHTs, using DMHTs in clinical practice, and managing the deployment of DMHTs in health services. The group comprises representatives from the Medicines and Healthcare products Regulatory Agency and NICE (including members of the project team and other experts from these organizations), representatives from NHS England, a variety of health professionals with experience of mental health conditions (eg, clinical psychology, nursing, psychiatry, and general practice), academics, representatives from health innovation networks, and lived experience advisers.

Content of Discussions

During the meeting, the group was asked to consider a series of questions through facilitated discussions. These questions related to (1) the value of developing a framework to categorize DMHTs, (2) the practical purposes of a framework, and (3) the drawbacks or challenges of developing a single framework for these purposes. Emerging themes from these discussions were identified and considered by the research team.

Within smaller breakout groups, members were then asked to consider (1) which of the domains identified within the review would be most important to include in a taxonomy, (2) whether additional domains that captured other characteristics of DMHTs were needed, and (3) whether descriptions of the domains reflected anticipated content and whether adaptations were needed to these descriptions. Based on this, groups were asked to define which domains should be included within a new framework for categorizing DMHTs and how they should be conceptualized. The domains proposed for inclusion and other considerations were collated to support the development of the new framework.

To support these discussions, the group were provided a summary of the rapid review methods, and results described within this paper, along with a sample of the publications included within the review.

Step 3: Developing a New Conceptual Framework

Members of the research team synthesized findings from the rapid review and the expert working group. We considered the domains identified in the initial rapid review, additional domains or refinements suggested by the working group, and the similarities and differences between domains that the breakout groups recommended for inclusion. We also considered the general reflections of the group on the value of developing a framework and the appropriate structure. Based on these discussions, our final framework was developed.

Results

Step 1: Identifying Previous Work on Categorizing DMHTs

Search Results

The search returned a total of 3603 unique results from databases and other sources (Figure 1). Of these, 3544 were excluded by title and abstract not adequately reflecting the subject matter, and 59 of these full-text papers were subsequently reviewed. A further 3 studies that were not identified by the search were included after hand searching references and included in the full-text review. After review, 23 papers were considered eligible for inclusion.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) diagram for rapid review.

XSL•FO
RenderX

Study Characteristics

Most studies were systematic reviews of the effectiveness or quality of technologies and grouped technologies to support analysis (8/23, 35%). The remaining studies either provided groupings of types of technologies as part of commentaries or narrative reviews of the field of digital mental health (7/23, 30%), aimed to develop their own taxonomy (5/23, 22%), or explored the implementation of DMHTs in mental health services with qualitative methods (1/23, 4%). In total, 1 (4%) study was a consensus statement on the use of DMHTs in the United States, and one further was public information for Canadian people on how to select appropriate technologies.

Most studies included DMHTs across a range of conditions and stages of the treatment pathway (15/23, 65%), but some had a more specific focus. This included anxiety and depression (2/23, 9%), comorbid mental and physical conditions (1/23, 4%), mental health during COVID-19 (1/23, 4%), youth mental health or university students (1/23, 4%), management in primary care (1/23, 4%), and ante- and postnatal mental health (1/23, 4%).

The majority of studies did not define how domains used to categorize technologies were generated (11/23, 48%), although some outlined underlying methods based on previous taxonomies (4/23, 18%) or coding characteristics of relevant technologies in systematic reviews (6/23, 26%). One study reported using workshops to develop consensus on appropriate groupings, and one was based on themes arising from qualitative interviews.

Domains

Ten domains were identified across the included studies in line with the method outlined earlier. These are condition, setting, platform or system, function, subfunction, professional input, type of communication, type of intervention, sophistication, and consumable resource use. Definitions for these domains are provided in Textbox 1.

Textbox 1. Definitions of domains extracted from included studies within rapid review.

Condition: this relates to the condition that the digital mental health technology (DMHT) is targeting. In some studies, this was narrowed to include a more specific population (eg, people with anxiety and other comorbid conditions).

Setting: this refers to the health care setting in which the DMHT is being delivered. Available studies categorized settings in different ways, including inpatient, outpatient, and aftercare services.

Platform or system: this refers to the platform or system that is used. This could be related to hardware (eg, smartphone) that is used to access the DMHT or be related to the content of the DMHT itself (eg, chatbot).

Function: this refers to the overarching aims of the DMHT and whether it provides assessment and diagnosis, treatment, monitoring and support, decision support, or other functions.

Subfunction: this relates to the function of the DMHT but provides an additional level of detail with more specific details of what the technology does.

Professional input: this refers to the extent of input from health professionals. DMHTs can be unguided with limited or no input from professionals, guided with professionals providing some input, or supervised with technologies being used during in-person contacts.

Type of communication: this refers to how a user and professional are able to communicate. Within studies, communication is usually described as synchronous and in real time (eg, through a live video feed) or asynchronous with information being transmitted and reviewed at a later time.

Type of intervention: this refers to a type of therapy or other intervention that is provided. All studies related this domain to treatment (as opposed to other functions like diagnosis or monitoring and support) and usually delineated types of therapy (eg, cognitive behavioral therapy and other approaches).

Sophistication: this refers to the extent to which a technology differs in function to nondigital versions. Within the relevant study, digitized refers to content that is converted from previously available analog resources with limited changes or additions, whereas digital refers to content that is only possible with digital technology.

Consumable resource use: this refers to whether interventions require a resource that is “used up or consumed.” For DMHTs, this refers to whether professionals are involved in delivery and are required to spend time either inducting a user or spending additional time reviewing inputs that would otherwise have been discussed in prearranged appointments. Professionals working in the field of mental health often have restricted capacity based on the availability of the workforce.

Studies included domains on professional input (11/23, 48%), type of platform or system used (10/23, 43%), target condition (6/23, 26%), function (5/23, 22%) and subfunction (2/23, 9%) of the technology, type of intervention (4/23, 17%) with each of these was focused on the type of psychological therapy, the setting (4/23, 17%), timing of communication with professionals (2/23, 9%), whether a consumable resource was used (2/23, 9%), and technical sophistication (1/23, 4%). Details on the domains included within each study are shown in Table 1.

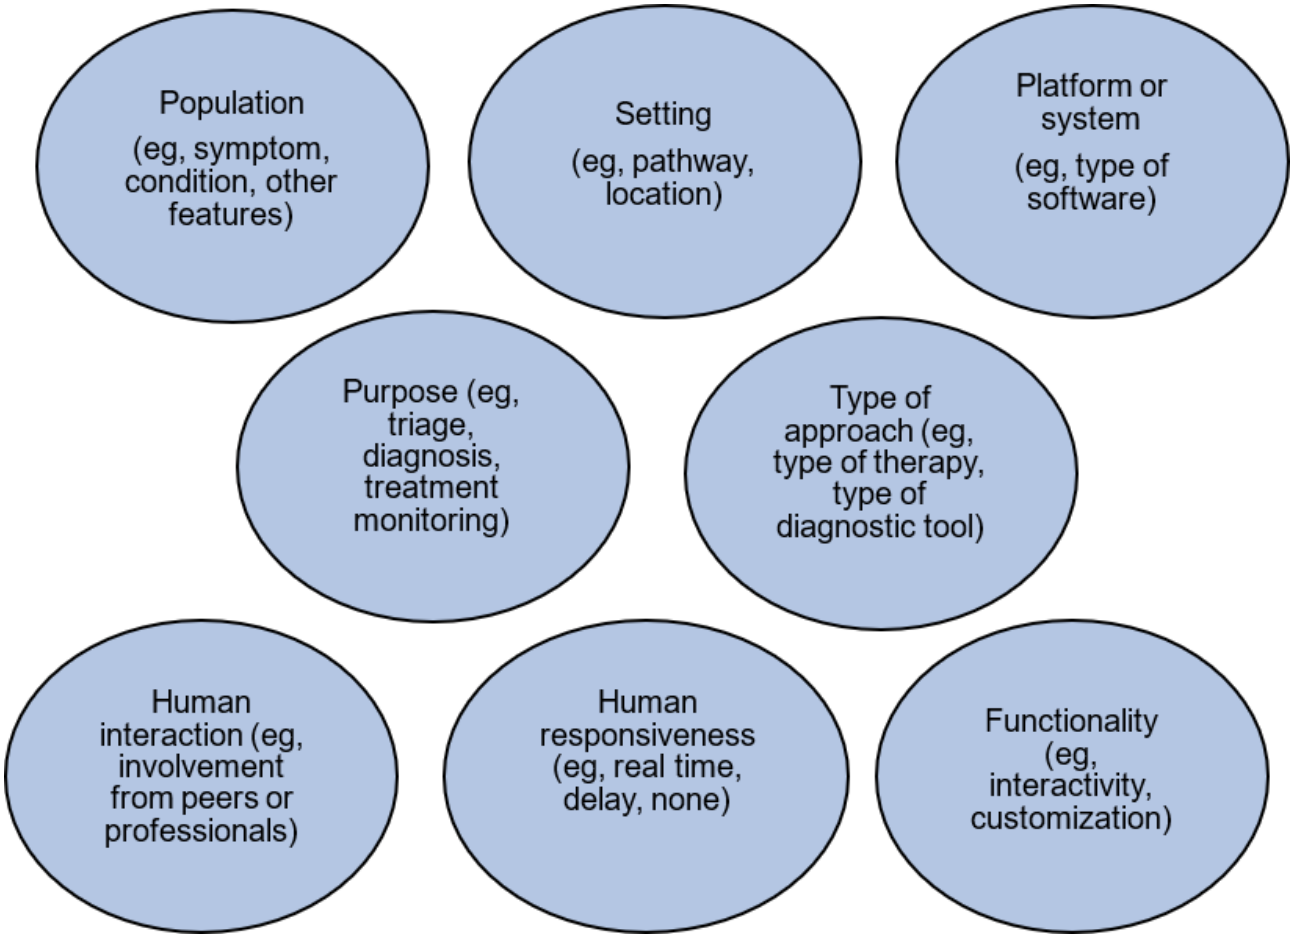
Step 2: Discussion Within an Expert Working Group

There were a series of key reflections from the expert working group. The group saw the benefits of a framework to categorize technologies and suggested that this would be useful for a wide range of health system stakeholders. A framework to categorize DMHTs could provide clarity around common characteristics of DMHTs and could also assist communication between health professionals and across multidisciplinary boundaries.

However, the group also identified a number of challenges in developing a framework for categorizing DMHTs. First, a single framework would be too generic for the specific purposes of different stakeholders. Second, there are practical challenges around categorizing DMHTs that have multiple functions and the potential for a categorization system to become unwieldy.

The group highlighted that a solution would be to develop a broad overarching framework that could then be adapted by stakeholders for specific purposes. This would provide a common language and consistent definitions for describing the characteristics of DMHTs. It could also then be refined by other stakeholders in consultation with experts in a specific field. This may involve reducing it to key domains for a specific purpose or refocusing the framework in other ways, if needed.

There was some divergence in opinion across breakout groups on which domains should be included within a framework. Some groups reduced the number of domains to those they felt were most important. Others indicated that all of the included domains were necessary but suggested merging or adapting some domains to retain information in a streamlined way. There were several suggestions on how the domains should be described and what they should include. Inclusions of domains from the rapid review and suggested adaptations are summarized in Multimedia Appendix 2.



Step 3: Developing a New Conceptual Framework

Overview

Based on the findings of the literature review and reflections from the working group, we developed a conceptual framework for DMHTs. The conceptual framework includes 8 domains that represent the characteristics of DMHTs (Figure 2). They each represent important characteristics of DMHTs that are likely to influence the benefits they can deliver for individuals and the wider system and risks that will need to be mitigated during use.

XSL•FO
RenderX

Figure 2. Domains included within a new conceptual framework.

The proposed conceptual framework also uses a "tagging" approach, where multiple attributes within a single domain could be attributed to a technology (eg, the population targeted by a DMHT), rather than seeking to develop an approach using "buckets" to assign a particular technology to a discrete group based on a characteristic.

Proposed Domains

Population

This refers to the population that a DMHT is intended to benefit. The population could be defined by the target condition (eg, depression, anxiety, and psychosis) or specific symptoms either on a transdiagnostic basis (eg, low mood and anhedonia) or secondary to a condition (eg, agoraphobia secondary to psychosis). The severity of the condition or symptoms that the technology is aimed for (ie, mild, moderate, and severe) could also be defined. If a DMHT targets mental health symptoms within the context of other conditions or comorbidities, it would be useful to include and identify these (eg, cancer and multiple sclerosis). There may also be other important population characteristics that could be defined (eg, age and gender).

Setting

This refers to where in a treatment pathway, a DMHT is delivered or deployed. This information could be defined by the stage of care (eg, primary and secondary) or the type of health provider (eg, inpatient unit). It would also be possible to provide more specific detail on placement within a clinical pathway (eg, on a waiting list after the initial presentation and during in-person therapy sessions).

Platform or System

This domain relates to the type of software or platform that is being used to deliver the DMHT. Information about the platform or system will be key to determine how the technology is delivered and the practicalities around its use. Some types of platform or system may have substantial variation within types (eg, apps and websites), whereas others will be more specific (eg, virtual reality). There may also be cases where specific hardware needs to be specified because DMHTs are not able to rely on off-the-shelf solutions (eg, monitoring vital signs in inpatient settings).

Purpose

This domain relates to the primary intended purposes or aim of the DMHT. There may be different ways to define this, but this would broadly fit into categories of prevention, diagnosis, triage, treatment, and monitoring. There may be additional purposes around supporting recovery, preventing relapse, and others that should be considered as a standalone category, and consensus on available purposes for DMHTs may be helpful. DMHTs may have multiple purposes, which could be identified and "tagged" in line with the approach used in this framework (eg, diagnosis and treatment).

XSL•FO
RenderX

Type of Approach

This domain would provide a more specific definition or description of the approach used within the DMHT. This domain may be most appropriate for DMHTs that provide therapy and could be designed to identify the type of therapy that is being used (eg, CBT, mindfulness, and exposure therapy), but there may be other types of DMHTs that would also benefit from identifying with more detail the nature of what is being provided. For example, DMHTs providing diagnosis could be clear whether they are using validated patient-reported outcome measures or new approaches (eg, eye tracking and motion software for attention-deficit/hyperactivity disorder).

Functionality

This domain relates to a DMHT's level of interactivity, customization, and complexity of software capability. This may include providing varied or bespoke content to different users and allowing users to determine the content they view through their inputs. The minimum functionality of a DHMT would be fixed content that is uniform for all users and does not allow any interactivity. The most sophisticated functionality would be DMHTs supported by generative AI that may be able to provide unique responses to inputs that are determined by a user.

Human Interaction

This domain relates to whether a human (other than the patient) is involved in the delivery of the DMHT. The level of human interaction is likely to be on a spectrum between no human interaction and full human supervision within an in-person session. It may also be necessary to define who is leading the human interaction. This may be a health, social care, or education professional (eg, nurse, clinical psychologist, and mental health support worker) or may be peers.

DMHTs supported by AI may have high levels of functionality and mimic human interaction but be unsupported by professionals or peers. For this reason, human interaction is specified.

Human Responsiveness

This domain is related to human interaction and provides details on the extent and timeliness of a human's ability to respond to information. DMHTs have the potential to collect a large amount of quantitative and qualitative data that could help determine changing levels of risk that require intervention from a professional. Providing details on how and when a human will respond to information is therefore important in interpreting how risk is managed.

DMHTs supported by AI may be able to interpret quantitative and qualitative data. However, as mentioned earlier, a human's ability to respond and provide professional intervention, if needed, is an important aspect of how risk is managed. The need for health professionals to monitor and respond to information gathered by DMHTs will also have implications for adoption within health services.

Discussion

Principal Findings

In this study, we have proposed a new conceptual framework for categorizing DMHTs. This comprehensive framework is based on the findings of a rapid review, discussions within an expert working group, and deliberations by professionals working within the regulation and evaluation of DMHTs. This represents an advance in methods compared to previous approaches, which have attempted to develop frameworks or taxonomies within this field [14,15].

Future Directions

The proposed framework is designed to be used by stakeholders across the health system, from the initial stages of product development and market access to product selection by health professionals and users. The 8 domains were chosen because they represent key characteristics of DMHTs. They also have an important impact on the potential benefits and risks associated with the technologies and implications for implementation within health services. Indeed, the International Medical Device Regulators Forum [42] has recently completed a consultation on considerations for risk characterization for software as a medical device, and there is a strong alignment between their suggested approach and our more focused approach for mental health.

The development of this new conceptual framework presents opportunities for future work. Further research could trial this framework with a set of DMHTs and explore whether the framework provides a useful descriptive system and can group together similar technologies. This could support consideration of whether a menu of options is needed or whether there should be flexibility in assigning attributes within domains.

There are also tangible practical applications. Within regulation, there may be opportunities for the framework to be refined to support the coding of medical devices and to assist with mapping DMHTs to other regulatory frameworks. The research team is also planning to explore whether the framework can be used to provide clearer guidance on classification groups within the NICE evidence standards framework. Researchers could also adopt the conceptual framework provided within this study to give greater transparency around methodological choices within evidence synthesis and economic evaluation.

Strengths and Limitations

This study has several strengths and limitations that should be considered. The development of the conceptual framework was initially supported by a rapid review. These methods provide a streamlined approach that can meet the needs of faster-paced activities, but this can reduce their comprehensiveness. The rapid review approach allowed literature to be identified in short timelines, prior to the expert working group. However, we are aware that some types of literature that may provide ways to categorize DMHTs were not targeted (eg, evaluation frameworks) in order to allow manageable search methods. Given the breadth of domains identified in the rapid review and adaptations suggested by the expert group, we do not anticipate

XSL•FO
RenderX

that identifying a wider range of studies would have had a large impact.

The development of the framework has been led by professionals with expertise across regulation and evaluation, including HTA, where frameworks could have practical purposes. Through the expert working group, there has also been input from a wide range of professionals across disciplines. However, the proposed framework has not been through wider consultation with experts outside of this group.

Similarly, it should be acknowledged that the authors work for the Medicines and Healthcare products Regulatory Agency, which has a UK-wide remit, and NICE, which is England's HTA agency. In addition, members of the working group largely work within the English health care system. The proposed framework is aimed at being internationally relevant and due to the global market in digital health, it is likely that professionals across the world are thinking about the same types of technologies and addressing similar challenges. However, there may be nuances from other countries that are not acknowledged here.

To address each of these limitations, we would welcome other experts within this field across disciplines and countries to interact with and test this proposed framework. This could include an exploration of whether this framework could be applied to other health conditions or whether specific domains are needed. It could also lead to further refinement based on a wider consultation than was possible in this project.

Acknowledgments

This work was supported by the Wellcome Trust through the "Effective Regulation and Evaluation of Digital Mental Health Technologies" project grant (226466/Z/22/Z). The Wellcome Trust was consulted on the choice of the journal and provided comments on an early work plan. However, the Wellcome Trust did not have further input to the conduct of the work, content of the manuscript, or approval for submission. The authors thank all members of their expert working group who contributed expertise and knowledge through discussions related to the content of this paper. The authors also thank members of their project board who have also helped steer this work.

Authors' Contributions

GH, HC, and FE conceptualized the overall design of the work and wrote the first draft of this manuscript. GH, LA, HC, and FE were involved in designing and conducting the search, screening results, and extracting data. GH, PC, HC, SC, FE, and RB helped to facilitate expert working group discussions. All authors contributed to the final version of the manuscript and approved submission.

Conflicts of Interest

GH, LA, SC, and MS are employed by the National Institute of Health and Care Excellence. The National Institute of Health and Care Excellence is England's health technology assessment agency and produces guidance on digital mental health technologies. RB, PC, HC, and FE are employed by the Medicines and Healthcare products Regulatory Agency. The Medicines and Healthcare products Regulatory Agency regulates medical devices, including digital mental health technologies that qualify as software as a medical device, in the United Kingdom.

Abstract

Background: Mental health disorders significantly impact global populations, prompting the rise of digital mental health interventions, such as artificial intelligence (AI)-powered chatbots, to address gaps in access to care. This review explores the potential for a "digital therapeutic alliance (DTA)," emphasizing empathy, engagement, and alignment with traditional therapeutic principles to enhance user outcomes.

Objective: The primary objective of this review was to identify key concepts underlying the DTA in AI-driven psychotherapeutic interventions for mental health. The secondary objective was to propose an initial definition of the DTA based on these identified concepts.

Methods: The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) for scoping reviews and Tavares de Souza's integrative review methodology were followed, encompassing systematic literature searches in Medline, Web of Science, PsycNet, and Google Scholar. Data from eligible studies were extracted and analyzed using Horvath et al's conceptual framework on a therapeutic alliance, focusing on goal alignment, task agreement, and the therapeutic bond, with quality assessed using the Newcastle-Ottawa Scale and Cochrane Risk of Bias Tool.

Results: A total of 28 studies were identified from an initial pool of 1294 articles after excluding duplicates and ineligible studies. These studies informed the development of a conceptual framework for a DTA, encompassing key elements such as goal alignment, task agreement, therapeutic bond, user engagement, and the facilitators and barriers affecting therapeutic outcomes. The interventions primarily focused on AI-powered chatbots, digital psychotherapy, and other digital tools.

Conclusions: The findings of this integrative review provide a foundational framework for the concept of a DTA and report its potential to replicate key therapeutic mechanisms such as empathy, trust, and collaboration in AI-driven psychotherapeutic tools. While the DTA shows promise in enhancing accessibility and engagement in mental health care, further research and innovation are needed to address challenges such as personalization, ethical concerns, and long-term impact.

KEYWORDS

psychotherapy; mental health; psychiatry; artificial intelligence; therapeutic alliance; digital interventions; chatbot; psychology

Introduction

Mental health disorders represent a significant public health burden, affecting around 13% of the global population annually [1]. These conditions lead to an important human and economic impact, including a diminished quality of life, decreased productivity, and increased health care costs [2,3]. As an example, in Canada, this increase in demand is combined with multiple barriers to accessing mental health services, such as costs, lack of information, long waiting times, and insufficient funding, which all lead to reduced access to care [4]. This affects vulnerable populations disproportionately, leaving many without timely or adequate treatment [5]. As the demand for mental health services continues to exceed the ability of care, innovative approaches are needed to address this gap.

In the last years, digital mental health interventions (DMHIs), particularly mental health applications and chatbots, have emerged to complement conventional therapeutic models [6]. Many of them leverage artificial intelligence (AI) paired with evidence-based psychotherapeutic frameworks, such as cognitive-behavioral therapy (CBT) or mindfulness-based interventions [7]. Engagement and adherence to digital treatment was generally considered low in past studies, but the integration of factors such as human support and personalization led to

XSL•FO
RenderX

better outcomes [8-11]. Chatbots gained attention for their ability to deliver support in a flexible and user-friendly format with a conversational approach mimicking human interaction. They showed effectiveness in improving depression and anxiety in multiple reviews and meta-analyses with moderate to large effect sizes, but limitations were noted, such as a high risk of bias and lack of long-term follow-up [12-14].

When designing chatbots to effectively address mental health problems through a psychotherapeutic approach, it seems essential to understand some of the mechanisms underlying the effectiveness of psychotherapy. Many authors explored the role of the therapeutic alliance in this matter, and regardless of the approach, it emerges as a cornerstone of effective treatment [15-17]. Zetzel, an important figure in the field of psychoanalysis, believed the therapeutic alliance reflected the collaborative state between a patient and the therapist that facilitates treatment [18,19]. Authors such as Hausner [18] pushed this comprehension by distinguishing between the therapeutic alliance and the working alliance. The therapeutic alliance seemed to be made by "mutual identification, empathy and role-responsiveness," while the working alliance could only be possible "after a therapeutic alliance has to some degree been established" [18].

Considering the clear role of these concepts in psychotherapy efficacy, this raises important questions concerning the application of chatbots in mental health. With a design made to simulate human interaction, is it possible to nurture a meaningful alliance between the chatbot and the user? While most of the studies focus on satisfaction and engagement metrics, few of them analyze all the components of a therapeutic alliance [12,20,21]. Empathy appears to be a recurring interest in studies and an important factor for the development of an alliance with a chatbot by creating a sense of warmth [22]. On that topic, Boucher et al [23] pointed out that "chatbots designed to display empathetic reactions are rated more positively (ie, more enjoyable, understanding, sociable, trustworthy, and intelligent) than one that is not programmed to respond empathetically." With the rise of generative AI, which refers to complex mathematical algorithms that can learn from large data sets to produce text, audio, or visuals that resemble those of a human, this is even more pertinent [24]. Considering these, algorithms are currently studied as to their potential integration in mental health treatments to create AI-powered chatbots and digital therapists that offer people quick, individualized support, personalized interactions between the machines and humans must be further defined [24].

These preliminary findings, especially on empathy, hint at the possibility of a "digital therapeutic alliance (DTA)," which some have tried to grasp its scope using existing scales such as the Working Alliance Inventory-Short Revised (WAI-SR) [25]. To our knowledge, there is no standardized concept that defines and evaluates the presence of an alliance between a chatbot and its user, and if the same components as with the human therapist apply. Understanding how this bond can emerge might be a key factor in boosting engagement and designing more impactful DMHIs. The main objective of this review was to identify the key concepts in a DTA between AI-driven psychotherapeutic interventions and the user in the context of mental health interventions. The secondary objective is to provide an initial definition of DTA using these concepts. It is hypothesized that components of a DTA will align with those found in traditional human-therapist alliances but will manifest differently due to the nonhuman nature of AI-driven psychotherapeutic interventions. Furthermore, it is possible that higher levels of perceived empathy and trust within AI-driven psychotherapeutic interventions will predict greater user engagement and adherence to DMHIs, similar to the dynamics observed in human-therapist relationships.

Methods

Search Strategies

The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) for scoping reviews methodology was conducted to provide a comprehensive overview of the key concepts in DTA between AI-driven psychotherapeutic interventions and the user in the context of mental health interventions. The methodology also followed the methodology developed by Souza and Silva [26] for integrative reviews. This approach includes 6 steps: the development of the research question, literature search, data collection, critical analysis of the identified articles, discussion of the results, and presentation of the integrative perspective of the identified articles [26].

The literature review was conducted in collaboration with a librarian specialized in mental health. The databases Medline, Web of Science, PsycNet (PsycINFO), and Google Scholar were searched to retrieve articles published from their inception up to December 2024. These databases were selected with the help of an experienced librarian in the field of mental health to ensure comprehensive coverage of biomedical, psychological, and multidisciplinary literature relevant to digital interventions and generative AI in mental health care. Keywords and indexing terms related to AI, therapeutic alliance, and digital interventions were used. The literature search was carried out by all the authors (AML, JC, CL, and AH). Complete search strategies are available in Multimedia Appendix 1 and the PRISMA for Scoping Reviews checklist is also provided as Multimedia Appendix 2.

Study Eligibility

The reviewed studies were included in the analysis if they met the following inclusion criteria: (1) the main topic of interest was on a psychotherapeutic intervention; (2) the study was conducted in the field of psychiatry or mental health; (3) the psychotherapeutic intervention used AI as part of its design or included a data-driven approach; and (4) the manuscript was written in French or English. Case studies, protocols, pre-experimental studies, and unpublished writings were excluded from the analysis.

Data Extraction

Data were extracted using a standardized Microsoft Excel form. The studies identified were independently counter-verified for consistency and integrity by 2 authors (AML and AH). Any disagreements regarding the inclusion or exclusion of a study were mutually resolved by the authors. The extracted information included authors, population (sample), type of

XSL•FO
RenderX

interventions, type of engagement, facilitators, challenges, and outcomes.

Data Analysis

All the studies were analyzed according to the conceptual framework developed by Horvath and Luborsky [15] about the key components usually found in a therapeutic alliance. This framework, designed to understand further the alliance between a therapist and a patient, defines three key components: (1) agreement on therapeutic goals, (2) agreement on therapeutic tasks, and (3) the therapeutic bond.

A key component of successful treatment is the client and therapist's agreement on therapeutic goals, which promotes cooperation, trust, and mutual understanding [27]. Achieving therapeutic success depends on both parties working toward meaningful and mutually acknowledged goals, which is ensured by this alignment. Clients are more inclined to participate actively in the process, which increases motivation and commitment, when they believe their goals are recognized and understood [28]. Additionally, goal agreement reduces misconceptions, creates a sense of direction, and clarifies expectations [28]. Because it strengthens the therapeutic bond, which is essential to effective interventions, research continuously shows that agreement on therapeutic goals is a strong predictor of beneficial outcomes across a variety of therapeutic modalities [29].

Another important component of the therapeutic process is the agreement on therapeutic tasks, which implies that the client and the therapist agree on the methods, exercises, and interventions needed to meet the goals of the therapy [30]. This mutual comprehension improves teamwork and gives patients a sense of empowerment and involvement in their healing process. Task agreement also enables therapists to customize interventions to the client's preferences and needs, enhancing the therapy's efficacy and relevance [31]. Additionally, studies show that the therapeutic alliance, which is closely linked to successful outcomes, depends on alignment on therapeutic activities [32].

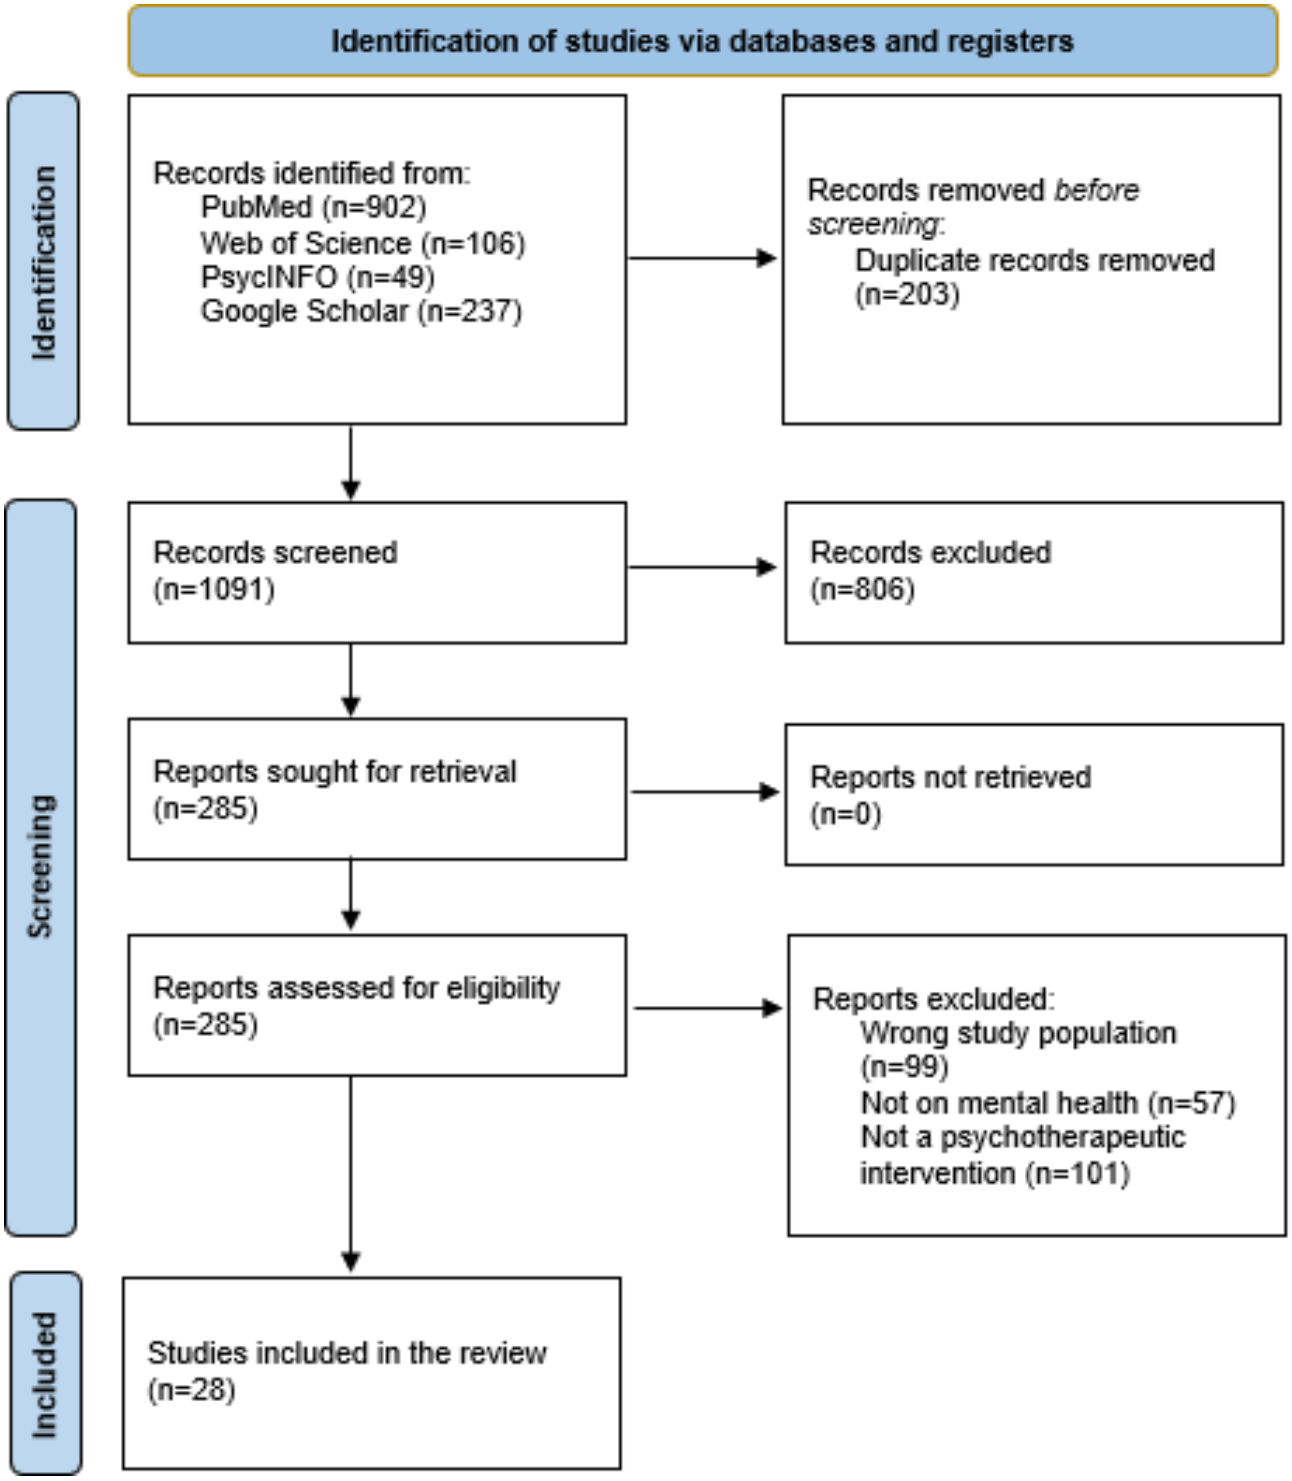
Finally, the primary element of the therapeutic relationship is the therapeutic bond, which includes the client and therapist's mutual regard, trust, and emotional connection [33]. A secure and encouraging atmosphere where clients feel appreciated, understood, and free to express their feelings is built on this connection. Strong therapeutic relationships promote cooperation, increase the client's sense of trust in the therapist, and promote candor and openness [33]. Because it provides clients with the comfort of a trustworthy and understanding ally, research continuously shows that the therapeutic relationship is a significant predictor of successful outcomes [34].

Quality Assessment

The quality of the studies included in this analysis was assessed using 2 widely recognized tools: the Newcastle-Ottawa Scale for nonrandomized controlled studies and the Cochrane Risk of Bias Tool for randomized controlled trials [35,36]. The Newcastle-Ottawa Scale evaluates the quality of cohort and case-control studies by examining 3 key domains: selection of study groups, comparability between groups, and the ascertainment of either exposure or outcome. Each domain is associated with specific criteria, and studies earn stars for meeting these standards, with a maximum score of 9 stars representing the highest quality [35].

For randomized controlled trials, the Cochrane Risk of Bias Tool was employed to systematically assess potential biases. This tool examines 7 domains: random sequence generation, allocation concealment, participant and personnel blinding, outcome assessment blinding, completeness of outcome data, selective reporting, and other potential sources of bias [36]. Each domain is categorized as having a low, high, or unclear risk of bias based on predefined guidelines.

In this review, studies were categorized based on their quality as follows: studies receiving 1 - 3 stars on the Newcastle-Ottawa Scale or rated as having a high risk of bias using the Cochrane tool were deemed low quality; those with 4 - 6 stars or a moderate risk of bias were considered moderate quality; and those earning 7 - 9 stars on the Newcastle-Ottawa Scale or demonstrating a low risk of bias were classified as high quality.



Results

Description of Studies

The literature review initially identified 1294 articles. Of these, 203 duplicates were removed. Among the remaining 1091 studies, a total of 806 articles were excluded after reviewing their titles and abstracts as they did not meet the inclusion criteria (307 were not targeting the specific population and 499 did not involve a psychotherapeutic intervention). A total of 28 articles were fully retained following the comprehensive analysis of the 285 articles selected for eligibility evaluation. Details of the article selection process are presented in Figure 1, and the identified articles are listed in Multimedia Appendix 3.

XSL•FO
RenderX

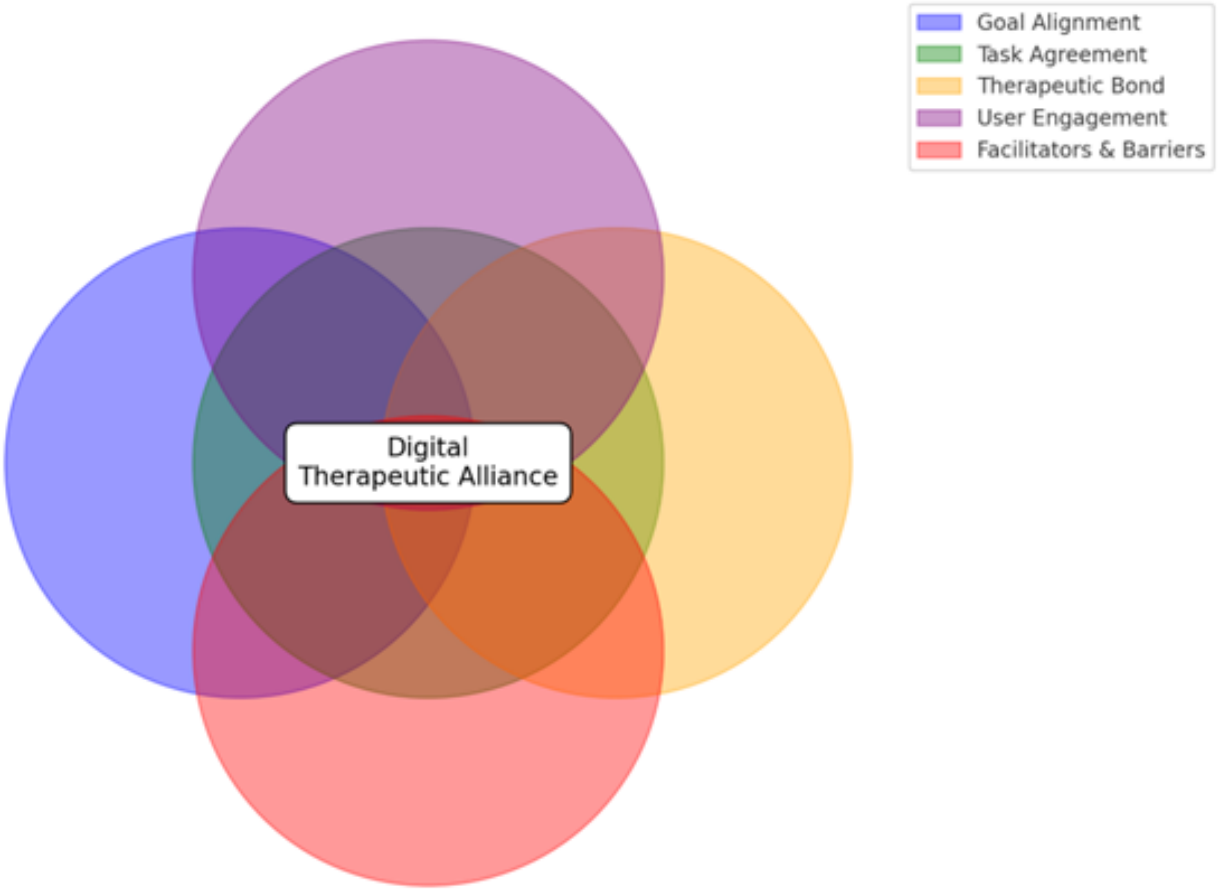


Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart for the inclusion of studies.

A conceptual framework to define the concept of DTA was developed by identifying and integrating the findings of the analyzed studies. The key concepts are all inter-connected and imply the following elements: goal alignment, task agreement, therapeutic bond, user engagement, as well as barriers and facilitators. Key concepts to define the DTA are presented in Figure 2.

XSL•FO
RenderX

Figure 2. Key concepts to define the digital therapeutic alliance.

From the 28 identified studies, 6 major themes regarding the type of interventions were found: AI-powered chatbots (n=12), digital psychotherapy (n=7), exploratory or review studies (n=3), general AI health care tools (n=2), personalized therapy (n=2), and behavioral change tools (n=2).

Goal Alignment

A total of 16 studies reported the use of goal alignment in their data-driven intervention. Goal alignment refers to the idea that there must be an agreement over common goals or outcomes when initiating psychotherapy. While heterogenous, several approaches were identified with regard to goal alignment. Aggarwal et al [37] emphasized the integration of behavior change theories, including goal-setting frameworks, to improve both primary and secondary outcomes. Similarly, Beatty et al [25,38,39], He et al [38], and Jeong et al [39,38,39] highlighted the importance of measuring goal alignment using the WAI-SR subscale, which evaluates how users and the chatbot collaborate to set mental health-related goals. Entenberg et al [40,41] as well as Martinengo et al [41,41] reported in the case of their study that therapeutic goals were established by the chatbot at the beginning of the interaction, ensuring clarity from the outset. Forman-Hoffman et al [42] reported that in their context, therapeutic goal alignment was evaluated via the therapeutic alliance score, highlighting a structured measurement approach. Like human-based therapeutic alliances, goal-setting mechanisms are important to provide effective therapeutic alliances within both digital and human contexts. In the absence of goal alignment between the digital intervention itself and the user, a few studies reported that this was done before the intervention was used with a human agent [43,44].

Another study reports that the alignment on therapeutic goals is mediated by emotion regulation self-efficacy, with digital and therapeutic alliances predicting symptom reduction through increased emotion regulation self-efficacy [45]. This is similar to Cross et al's [46] study, which reported that new eHealth-specific therapeutic alliance subscales, such as perceived emotional investment and sense of relatedness, align users' goals with therapy outcomes more effectively than conventional measures in digital parent training programs. In Doukani et al's [47] work, alignment on therapeutic goals was higher in blended CBT compared to treatment-as-usual, with good system usability enhancing working alliance and leading to improved depression outcomes. Finally, in Brotherdale et al, it is demonstrated that the alignment of goals and expectations in fully automated digital mental health apps often involves lower expectations compared to in-person therapy but can be enhanced by personalized interfaces and validating features.

XSL•FO
RenderX

Task Agreement

Agreement on therapeutic tasks refers to the mutual understanding and collaboration between the therapist (or digital tool) and the user on the specific activities or steps required to achieve therapeutic goals. A total of 8 studies provided insight on this key concept. Similarly to the findings identified in the goal alignment section, various approaches have been conducted to achieve task agreement among the analyzed studies. Beatty et al [25] evaluated therapeutic tasks using the WAI-SR subscale for tasks. Forman-Hoffman et al [42] assessed task agreement via the therapeutic alliance score. Goldberg et al [48] described task alignment as conducted between humans like in traditional therapy. Hocking et al [43] emphasized the use of the *Specific, Measurable, Achievable, Relevant, and Time-Bound* (SMART) goals framework for aligning tasks with therapeutic objectives. Martinengo et al [41,44] focused on task agreement as observed in human interactions, while Liu et al [44,44] explored task alignment through conversational agents. Similarly, Goldberg et al [49] reported that the agreement on therapeutic tasks and goals in unguided smartphone apps can be assessed using the Digital Working Alliance Inventory and showed positive predictions for app engagement and reductions in psychological distress. Collectively, these studies reported the importance of task agreement to enhance therapeutic alliances across both digital and human-mediated interventions.

Therapeutic Bond

Therapeutic bond refers to the emotional connection and trust developed between the user and the therapist or digital tool. In total, 12 studies reported how they assessed the therapeutic bond between the human and the machine during digital interventions.

Beatty et al [25,44] reported that users expressed strong emotional connections in the first assessment, comparable to traditional in-person CBT, as measured by the WAI-SR subscale for the bond. Forman-Hoffman et al [42], as for the previous components, evaluated the bond using the therapeutic alliance score. He et al [38,39] and Jeong et al [39,39] measured the bond using the WAI-SR.

Interestingly, Liu et al [44] found that conversational AI showed higher therapeutic alliance scores compared to bibliotherapy with a Cohen *d*=0.83. MacNeill et al [20] noted that while some users felt reassured and connected, others experienced difficulty establishing a bond due to conversational issues. Liu et al [44] observed that an empathic tone and conversational nature facilitated engagement but that rule-based systems limited the bond. Plakun [50] highlighted that AI struggles to replicate the emotional depth and transference found in human relationships, limiting its ability to build authentic therapeutic bonds. Russo et al [51] reported that therapists found the therapeutic bond with AI tools the most challenging aspect of therapy, as it is difficult to establish. Interestingly, in Prescott and Hanley's [52] review, it was observed that elders were more expressive with sociable robots than with task-oriented ones when comparing groups. Finally, Ta-Johnson et al [53] described how users build confidence with chatbots, using them as a safe space to discuss feelings and develop a bond resembling a therapeutic relationship.

User Engagement

The concept of user engagement refers to the level of sustained interaction, interest, and participation between the user and the therapeutic tool. Insights into this key concept were reported in 22 studies, highlighting a range of factors influencing engagement.

Aggarwal et al [37] found that engagement was primarily established through the frequency of messages exchanged between the chatbot and the user, though this varied across studies. Alfano et al [54] emphasized that initial engagement was high, driven by ease of access and the perception of nonjudgmental interactions, but noted that dropout rates increased when users did not experience quick results. Anisha et al [55] observed that anthropomorphic conversational agents (CAs) were preferred, leading to higher intervention compliance compared to mechanical chatbots. Similarly, Beatty et al [25] reported that 73.8% of participants continued using the Wysa chatbot after the first assessment, with engagement improving over time and correlating with an increased bond subscore in later assessments.

Several studies explored how engagement was measured or facilitated. Entenberg et al [40] described engagement as determined by the number of messages and characters sent. Escobar Viera et al [56] found that participants sent an average of 49.3 messages to the chatbot, highlighting message frequency as an indicator of engagement. Forman-Hoffman et al [42] evaluated engagement through app utilization rates, which varied across conditions. Goonesekera and Donkin [57] noted that while daily check-ins were appreciated, some participants found them tedious due to competing social engagements, fatigue, and daily responsibilities.

Specific tools and features also played a role in user engagement. He et al [38] used the *User Engagement Scale* and found higher interaction levels with motivational-interviewing chatbots. Hocking et al [43] observed stable engagement among 2 patients using the *Rehabilitation Therapy Engagement Scale*. Inkster et al [58] measured engagement based on the number of active session days between screenings. Kettle and Lee [59] identified key drivers of engagement, including agent connection, initial motivation (eg, curiosity or loneliness), and technical features like accessibility. Liu et al [44] noted that rule-based conversational agents often provided inadequate responses, frustrating users and reducing engagement.

Furthermore, in eHealth interventions, novel engagement techniques, including perceived emotional investment and application-induced accountability, were particularly useful. As though speaking with a supportive spouse, these tactics urged users to remain dedicated and sense a connection to the digital instrument. Accessibility and empowerment were reported as important for standalone apps, enabling users to interact at their own comfort level and at their own pace [60]. Furthermore, the application of innovative metrics such as the *eHealth Therapeutic Alliance Inventory* and the *Digital Working Alliance Inventory* showed that engagement could be quantitatively associated with outcomes like improved behavior change, decreased psychological distress, and app usage [49,61].

XSL•FO
RenderX

Finally, studies highlighted broader implications of user engagement. Russo et al [51] emphasized that digital tools could improve access for hard-to-reach individuals, reducing inequalities in therapy. Ta-Johnson et al [53] described how users engaged steadily with chatbots across various topics, often returning to share updates about their emotions and experiences, reflecting the potential for long-term engagement.

Facilitators and Barriers

A DTA can also be defined by its variety of facilitators and barriers that intersect every other mentioned key concept. In total, 22 studies reported either a facilitator, a barrier, or examples for both categories. Facilitators and barriers refer to the factors that enhance or hinder the effectiveness of digital therapeutic tools, ranging from technological features to user perceptions.

Aggarwal et al [37,54] identified facilitators such as free-flow conversations, which enhanced user experience through personalization, while Alfano et al [54,54] highlighted the role of comfort with digital technology, particularly among adolescents. Anisha et al [55] emphasized strong social presence and emotional closeness as key facilitators for positive outcomes but noted that scripted chatbots often failed to provide personalized or empathetic responses, creating user frustration. Furthermore, the ability to generate emotion regulation self-efficacy was an important facilitator. By enhancing users' confidence in managing emotions, digital tools increased motivation to engage and persist in the therapeutic process [45,49]. Beatty et al [25] reported that anonymity and flexibility raised user autonomy but highlighted challenges with chatbots' limited understanding of user needs, leading to perceived ineffectiveness.

Chan et al [62] discussed issues with inappropriate chatbot reinforcements, context misunderstandings, and technical errors, which undermined their reliability. Entenberg et al [40,42] noted that customizable and human-like features significantly enhanced user satisfaction, while Forman-Hoffman et al [42,42] highlighted design elements like responsiveness and inclusivity (eg, avoiding past names for trans users) as facilitators. However, limited conversational content and inability to handle complex interactions were key barriers [56]. Goonesekera and Donkin [57] identified anthropomorphic features and engaging content as key facilitators but pointed to technical difficulties and limited interactivity in decision-tree-based chatbots as barriers. Also, Brotherdale et al's [60,61] and Ashur et al [61] studies reported the flexibility, choice, and empowerment that standalone apps provided allowed users to engage with the intervention at their own comfort level and at their own speed. Mobile app accessibility decreased stigma and offered anonymity, especially for populations that are difficult to reach.

Jeong et al [39] observed that users appreciated engaging wellness activities and positive reinforcement but struggled to adapt to having a robot in their personal space. Martinengo et al [41] highlighted empathic responses and integrated CBT exercises as facilitators, while the lack of variety in conversational personas and inability to handle crisis scenarios emerged as significant barriers. Plakun [50]stressed the importance of theory-grounded techniques, such as CBT and relaxation exercises, as facilitators but noted the lack of true empathy and privacy concerns as major hindrances to AI effectiveness.

Russo et al emphasized that digital tools reduced therapy inequalities, appealing to tech-savvy users; however, the small sample sizes and the cohort's limited understanding of AI's advancements in therapeutic contexts constrained their ability to fully assess the situation [51]. Prescott and Hanley [52] found that "socially skilled" robots enhanced elder engagement, although speech recognition challenges and cognitive impairments posed obstacles. It was also difficult, according to Goldberg et al [49], to maintain engagement with fully automated operations that lacked human assistance. Dropout rates were occasionally caused by the imagined therapeutic tie being reduced by the lack of a direct human connection, empathy, or prompt feedback [49]. Lastly, Ta-Johnson et al [53] highlighted the chatbot's role as a "safe space" and its ability to favor long-term interactions, though limited sample sizes and insufficient motivation assessments hindered deeper understanding.

Quality Assessment of the Identified Studies

Although the studies varied in their design, all were deemed to be of moderate to high quality with minimal risk of bias. However, common challenges included small sample sizes and limited external validity, which were among the most frequently noted issues in the analyzed studies. Quality assessment for each individual study is found in Multimedia Appendix 3.

Definition of the DTA

Summarizing the abovementioned findings and integrating these concepts, a first definition of the DTA can be established as follows:

> *The Digital Therapeutic Alliance (DTA) refers to the collaborative relationship and emotional connection between a user and an artificial intelligence (AI)-driven psychotherapeutic tool, encompassing goal alignment, task agreement, therapeutic bond, user engagement, and the facilitators and barriers that influence therapeutic outcomes.*

Discussion

Principal Results

This integrative review aimed to identify the key concepts in a DTA between AI-driven psychotherapeutic interventions and the user in the context of mental health interventions and provide an initial definition of DTA using these concepts. A total of 23 studies were fully analyzed, and 5 key components such as goal alignment, task agreement, therapeutic bond, user engagement, and the facilitators and barriers that mediate these relationships were observed. The studies were overall of moderate to high quality.

Comparison With Prior Work

Goal alignment, an essential component of traditional therapy, emerges as equally relevant in digital interventions. Studies highlighted the importance of integrating structured frameworks, such as behavior change theories and SMART goals, to promote

XSL•FO
RenderX

shared understanding and collaboration between users and chatbots. These findings are consistent with Horvath and Luborsky [15], who emphasized goal alignment as a predictor of treatment success in traditional therapeutic contexts. Interestingly, digital tools like chatbots simplify goal-setting through automated initiation and measurement, as reported in studies by Aggarwal et al [37,37] and Beatty et al [25,37]. However, the findings also reveal challenges in aligning goals with user expectations, which could limit engagement if not adequately addressed, echoing prior concerns about designing interventions in AI-based therapy [8].

The therapeutic bond in the DTA, while conceptually similar to human-therapist relationships, manifests uniquely in digital tools. Emotional connection, empathy, and trust are important factors, as highlighted in studies by Beatty et al [25,44] and Liu et al [44,44], which found that conversational agents with empathic tones and anthropomorphic features enhance the bond. However, as noted by Plakun [50], the inability of AI to replicate the emotional depth and transference of human therapists remains a significant barrier. These insights align with literature suggesting that perceived empathy and warmth are central to establish trust and engagement in digital tools, perceived empathy being more important than the real ability of the AI-driven intervention to feel empathy [22]. Although encouraging, issues like rule-based replies and a lack of subtlety in interpreting user emotions highlight the necessity for more technology developments to improve the therapeutic relationship in AI-driven solutions.

User engagement was found to be influenced by both design elements and user perceptions. High initial engagement driven by accessibility and nonjudgmental interfaces, as reported by Alfano et al [54], mirrors earlier findings on the role of usability in DMHIs. However, as Goonesekera and Donkin [57] noted, engagement tends to decline when users do not perceive immediate benefits, highlighting the importance of maintaining long-term motivation. These findings resonate with studies emphasizing the critical role of user engagement in predicting adherence and outcomes in digital interventions [12]. Additionally, themes such as technical reliability, personalization, and responsiveness emerged as key facilitators of sustained engagement, suggesting that addressing these elements could improve adherence in future interventions.

Finally, the review underscores the interplay of facilitators and barriers in shaping the DTA. Facilitators such as anonymity, flexibility, and empathic design were identified across multiple studies, aligning with prior research advocating for user-centered design in DMHIs [11,25]. However, barriers like limited conversational capabilities, privacy concerns, and technical errors, as noted by Chan et al [62,62] and Russo et al [51,62], remain persistent challenges. These barriers not only hinder engagement but also undermine user trust. Addressing these barriers requires robust ethical guidelines and technological improvements to address these limitations.

As digital tools evolve, integrating user feedback and advancing AI capabilities will be necessary in overcoming these barriers and optimizing the DTA [63]. However, this evolution raises critical ethical questions, such as “Should therapy be AI-driven?” particularly concerning aspects like security, privacy, efficacy, inclusivity, and maintaining a user-centered approach [46]. Vilaza and McCashin [64] have emphasized the importance of implementing evidence-based and empirically tested interventions to ensure that automated therapy genuinely contributes to the improvement of mental health outcomes. Also, earlier findings on DTA support that it may be possible to increase the efficacy of tools like smartphone applications and enhance user adherence by evaluating and improving the DTA [65]. Moreover, applying an ethical framework to the development of these technologies appears essential to ensure accountability and responsibility from AI-developing companies in the field of mental health [66].

Limitations

It is important to recognize the limitations of this study. First, it is difficult to draw broad conclusions that go beyond the initial definition of a DTA because of the included studies’ variety in terms of design, demographics, and intervention type. Although the analysis made an effort to integrate the findings, differences in the approaches and results could restrict how broadly the findings can be applied. Second, the majority of the research used self-reported metrics to assess ideas like engagement, therapeutic connection, and results, which are prone to response bias and might not fully represent the subtleties of user experiences. It is also important to note that this study included only articles in French or English to limit interpretation bias, which could limit the external validity of the findings in other contexts. Finally, the reviewed literature did not include longitudinal investigations, which limit our understanding of the DTA’s long-term viability and efficacy.

Conclusions

This integrative review attempted to define the emerging concept of a DTA, offering a preliminary framework for its definition and components. By integrating insights from 28 studies, this work highlights the important role of key elements such as goal alignment, task agreement, therapeutic bond, user engagement, and the interplay of facilitators and barriers. These components mirror the foundations of traditional therapeutic alliances while adapting to the unique dynamics of AI-driven psychotherapeutic tools.

The findings emphasize that, while digital interventions hold promise for enhancing accessibility and engagement in mental health care, challenges such as limited emotional depth, personalization, and ethical concerns persist. Addressing these barriers through technological innovation and user-centered design will be necessary in advancing the DTA. Furthermore, aligning these interventions with evidence-based frameworks, such as CBT or SMART goals, can improve therapeutic outcomes and user satisfaction.

Importantly, the DTA highlights the potential for digital tools to replicate key therapeutic mechanisms, such as empathy, trust, and collaboration, even if in a different context. However, as this field evolves, further research is required to standardize measurement tools, validate the framework across diverse populations, and assess the long-term impact of DTAs on mental health outcomes.

XSL•FO
RenderX

In conclusion, this study provides a foundational step toward conceptualizing the DTA, emphasizing its importance in bridging gaps in mental health care delivery. By addressing its limitations and advancing its understanding, the DTA could play a transformative role in the future of DMHIs.

Abstract

Background: Mental health chatbots are increasingly used to address the global mental health treatment gap by offering scalable, accessible, and anonymous support. While prior research suggests that users may develop relationships with these chatbots, the mechanisms and individual differences underlying such relational experiences remain underexplored. As the concept of the digital therapeutic alliance (DTA) gains traction, a deeper understanding of subjective relationship-building processes is essential to inform the design of more effective digital mental health interventions.

Objective: This study aimed to investigate how people subjectively perceive and develop relationships with mental health chatbots over time. We sought to identify key experiential dimensions and interactional dynamics that facilitate or hinder the formation of such bonds, contributing to the evolving conceptualization of the DTA.

Methods: We conducted a 4-week short-term longitudinal diary study with 26 adult participants who interacted with two widely available mental health chatbots (Woebot and Wysa). Data were collected through weekly surveys, conversation screenshots, and semistructured interviews. A reflexive thematic analysis was used to identify recurring themes and interpret the emotional, communicative, and contextual factors shaping participants' relational experiences with the chatbots.

Results: A total of 18 participants reported forming a bond or light bond with at least one chatbot. Interview narratives revealed three relational categories: Bond (clear emotional connection), Light Bond (tentative or partial connection), and No Bond (absence of connection). Both participants with lower and higher psychological well-being (based on the World Health Organization—Five Well-Being Index scores) reported forming such relationships, suggesting that bonding capacity is not strictly dependent on mental health status. Thematic analysis identified six key themes that explain why people did or did not form bonds: the desire to lead or be led in conversation, alignment between preferred style of self-expression and accepted inputs, expectations for caring and nurturing from the chatbot, perceived effectiveness of the chatbot's advice and proposed activities, appreciation for colloquial communication, and valuing a private and nonjudgmental conversation.

Conclusions: Our findings provide empirical insight into how people interpret and engage in relational processes with mental health chatbots, advancing the theoretical foundation of the DTA. Rather than favoring one design style, our analysis highlights the importance of alignment between preferences and the chatbot's interaction style and conversational role. Participants' initial expectations around empathy and trust also shaped how relationships developed. Drawing on these insights, we suggest that chatbots may better support early therapeutic relationships by blending emotional support with relevant guidance, allowing flexible input methods, and maintaining continuity through context-aware responses. These features may enhance their therapeutic value and foster stronger relationships.

Introduction

Background

Mental health chatbots are an increasingly popular digital intervention, leveraging artificial intelligence (AI) to engage people in conversations that support their mental well-being [1-3]. In traditional psychological treatment, the relationship between a client and a therapist, known as the therapeutic alliance (TA), is a key factor in its success [4-6]. Researchers have begun investigating whether the concept of TA can also be applied to digital mental health tools, such as meditation apps [7] and mental health chatbots [1-3], leading to the emergence of the concept of digital therapeutic alliance (DTA) [8]. The emerging concept of DTA provides a new lens to examine the aspects that influence relationship-building, and ultimately, the success of digital mental health interventions. Researchers have increasingly focused on how DTA might affect therapeutic outcomes, drawing parallels to traditional TA [9-12]. Yet, how DTA is conceptualized, especially in relation to people's sense of connection with mental health chatbots, if any, remains inconclusive [13-15], in particular due to the absence of longitudinal studies examining how relationships with mental health chatbots evolve over time [16].

To address this gap, this study explores perceptions of relationship development between people and chatbots. We conducted a diary study combined with semistructured interviews to capture a comprehensive view of interactions with mental health chatbots over a 4-week period. We recruited 26 participants who interacted with two prominent mental health chatbots, Woebot [1,3] and Wysa [17]. Through thematic analysis of an extensive dataset of transcripts and screenshots, we identified six main themes related to participants' relationships with these chatbots.

Our findings emphasize six key aspects of human-chatbot interactions that impact humans' relationship development with chatbots. Participants expressed a desire for flexibility in conversation, either leading the dialog or being guided by the chatbots. The ability to self-express, whether through free-text input or selecting from provided prompts, impacted humans' relationships with chatbots. Additionally, people had specific expectations for the chatbot to provide caring and nurturing responses, along with effective advice and activities that were perceived as genuinely helpful. The appreciation for colloquial communication further strengthened the connection, while the importance of maintaining a private, nonjudgmental space was consistently highlighted as essential for building trust and fostering meaningful engagement.

As far as we know, this is the first study to use a diary method to qualitatively explore relationship development and identify the themes influencing DTA in the context of mental health chatbots [16,18]. This research advances the field of digital mental health by offering insights into how humans build relationships with mental health chatbots, by expanding the DTA framework, and by highlighting how chatbot and interaction design characteristics can foster stronger connections with people.

Related Work

Therapeutic Alliance

TA refers to the relationship between clients and therapists [5,6,19]: its acceptance, empathic understanding, and congruence [20]. Studies on the working alliance [21-23] emphasize the client and therapist bond and agreement on therapeutic tasks and goals [24]. The Agnew Relationship Measure (ARM) emphasizes five dimensions of alliance: partnership, bond, confidence, openness, and client initiative [11,25]. The TA, referring to the collaborative and affective bond between client and therapist, is a well-established predictor of psychotherapy outcomes. A large-scale meta-analysis of nearly 300 studies found a moderate but robust correlation between alliance quality and treatment success (r=0.278) [4], with this association replicated across diverse contexts and sustained across decades of research [4,26-29]. Effective communication is recognized as a critical skill for clinicians; it improves the quality of care and strengthens the TA [30]. Research on relational control in physician-patient communications reveals that balancing control—where patients can take the lead, physicians manage control when necessary, and both share control to facilitate planning—enhances communication and relationship building in clinical settings [31-34]. This highlights the importance of two-way communication and the extent to which clients' sense of control—or a lack thereof—during interactions impacts the development of their relationship with the therapists [35,36].

Digital Therapeutic Alliance

There is growing evidence for the positive effects of digital tools in helping clients with mental health challenges, and there is increasing interest in stand-alone digital solutions to augment or substitute traditional therapeutic methods [1,9,17]. However, uncertainties remain. Digital solutions might not be appropriate for individuals with severe mental illnesses [11], with conditions like depression impacting use [10]. Given that the TA has proven highly effective in face-to-face psychotherapy, theory on "DTA" is emerging within the scope of digital mental health intervention research. Researchers are actively studying how the concept of TA applies to digital mental health solutions and examining effects on therapeutic outcomes [9-12].
