
Results

Overview

We contacted 143 physicians to participate in an interview. Forty-two physicians accepted and enrolled in the study (21 practicing in psychiatry and 21 in family medicine). Our total participation rate was 29.37% (42/143 physicians invited). Major themes from their perspectives on benefits and risks of AI in psychiatric medicine along with their overall assessments are described in the following sections. While physicians often responded in the context of the presented cases, they also speculated on other potential AI tools and how they might affect their clinical practice.

Benefits

Physicians identified multiple potential benefits to the adoption of AI tools in psychiatric medicine. These were interpreted as benefits related to clinical support, administrative burden, patient needs, and health access.

Physicians Believed AI Could Provide Valuable Clinical Support

Participants noted that AI may be helpful in supporting clinical decision-making. Physicians explained the potential for AI to aid diagnoses and treatment and discussed how it could add another layer of clinical assessment. In the context of psychiatric diagnoses, physicians suggested that AI may support them where their insights be limited. "AI can help classify people's major depression, but maybe there's subcategories of major depression that I'm not smart enough to discern [...]" (Interview 24, Psychiatry). Participants also described the potential for AI to mitigate errors such as missed symptoms or provide a set of default actions or recommendations that may be able to identify issues that could go undetected.

> *I think it [AI diagnosis tool] would be brilliantly helpful in reminding us that, for instance, [...] cannabis use looks like ADD, so with the racing thoughts and these sorts of things. I think to remind us all the time, like, in a casual conversation I didn't ask her that.* [Interview 32, Family Medicine]

Physicians felt that AI could be potentially helpful in synthesizing information on patients to guide treatment. Participants also discussed personal limitations to their clinical knowledge and noted that AI could offer diagnostic and treatment insights based on data that exceed their range of clinical experiences. "That [AI diagnostic tool] might help to guide what treatments I recommend, drugs or psychotherapy or behavioral activation or other factors" (Interview 17, Psychiatry). Participants noted that AI could offer opportunities for guidance in situations where physicians are uncertain about treatment plans.

> *It [AI diagnosis tool] could augment the clinical assessment because our attention, our working memory, our problem-solving capacity is limited by the built-in, beautiful things and inefficiencies of the*

XSL•FO
RenderX

> *human mind [...] It helps us add another layer of empirically validated reasoning that will help us overcome the shortsightedness that we inherently have.* [Interview 37, Psychiatry]

Physicians Believed AI Could Alleviate Administrative Burden

Participants described how AI could reduce their administrative burden by offloading tasks such as clinical documentation and information synthesis. Many physicians expressed hope that using AI would decrease their overall administrative workload and allow them to spend more time on direct patient care.

> *If there's a way for AI to help with documentation and administrative burden, and do some of that for you 'cause I think that's where a lot of burnout in practice is. It's not having to see a bunch of patients. It's having to do all the paperwork that goes with it.* [Interview 02, Family Medicine]

Physicians voiced the potential for AI to support their clinical workflows such as improving the efficiency of data access. AI tools were also thought to be useful for information gathering and helping to retrieve more quality data that could be used for clinical decisions.

> *I think that [AI diagnosis tool] would be useful as well, simply, because a lot of those different conditions that you had mentioned have very specific DSM criteria to meet that diagnosis. It's hard for any one person to have all of that in their head at one time [...].* [Interview 02, Family Medicine]

Some physicians highlighted that there would be considerable use of such tools in particularly complex clinical situations.

> *I'm going to look through the system [AI diagnosis tool] and say, hey, what does the system say about this? If I encounter a case that it's so tough for me that I can't figure anything out, then maybe I'll wanna do that because then that's a more efficient use of my time.* [Interview 19, Psychiatry]

Some participants even suggested that aspects of their practice could be automated by allowing AI to handle certain tasks.

> *I think it [AI] can, hopefully, cut out doctors when they're not needed but also bring to light important pieces of information to doctors when it would be helpful. It can also help guide treatment and get people the right care at the right time [...] rather than just fatiguing doctors with all the alarms and warnings all the time that I just quickly click through to get them out of my face, it might be helpful to just automate a lot of these things.* [Interview 06, Family Medicine]

Physicians Believed AI Could Support Patient Needs

Physicians noted the potential for AI to provide accurate and early diagnosis of psychiatric conditions and shape initial treatment recommendations. "I think that [AI pharmacogenomics tool] would be an excellent way to be able to help people choose what, hopefully, is the most successful medication right off the bat" (Interview 11, Family Medicine). Beyond the individual use cases we discussed, physicians also extrapolated broader benefits of other AI technologies being applied in psychiatric medicine.

> *I know thinking of psychiatric care and depression care, if there was an AI tool that helped pick more accurately the most successful antidepressant or something like that, that is a challenge that we deal with every day, and something that could have immediate results.* [Interview 04, Family Medicine]

Participants commented on the potential for AI tools to support shared decision-making conversations with patients. This was often explained by noting that the additional evidence provided by AI could be empowering for clinical recommendations as both patients and clinicians will have another data point to evaluate when considering a decision.

> *Sometimes it helps me to show patients, too. I can say, "Hey, look right here. The computer says it's worried about you having this more serious problem. We need to do some more testing." It can help persuade some of those people that it's not just me telling them that I have this idea and "I just wanna order more tests," or "I think we should be on a different medicine." If I have sometimes some of that information on the computer, it's useful.* [Interview 11, Family Medicine]

Participants highlighted how AI might reduce common patient barriers to seeking treatment for psychiatric concerns, particularly in cases where behavioral therapy would be appropriate. They noted that patients might consider AI preferable to conventional human-directed therapy due to additional barriers such as stigma, cost, or inconvenience.

> *Going to therapy or even seeing a psychiatrist for many people is super scary. It makes people feel vulnerable and metaphorically stripped naked, and if they could interface with an app [...] it might be a way to get someone care earlier and more effectively than not having an interaction at all because of fear of coming in, or having to take time off of work, or any number of reasons that are barriers to people seeking mental healthcare.* [Interview 17, Psychiatry]

Physicians Believed AI Could Expand Health System Access

Physicians discussed factors such as declining availability of specialty providers, increasing demand from patients, and lingering effects of the COVID-19 pandemic as limitations to current behavioral health systems.

> *There's a lot of backlog and waiting, especially with the pandemic, to have that [psychiatric] care, so it's a big barrier. Access is a big barrier. I think, in this specific instance, using AI [chatbot tool] that comes from a provider might be helpful to, again, get people care.* [Interview 35, Family Medicine]

Participants noted opportunities for AI to expand access to psychiatric support by providing another way for patients to

XSL•FO
RenderX

access services that they would otherwise be unable reach through conventional means. "The ability to do it [therapy] on your phone on your own time at home with something like a chatbot does seem super-convenient [...] especially in rural communities where there's not great access" (Interview 04, Family Medicine). In addition to supporting areas where resources might be limited, participants noted that AI tools might aid patients who are unable to connect with a clinician in the near-term.

> *We talked a minute ago about how unavailable therapists are. I hear that all the time that even in a town as provider-rich as [City] is, people can't get in. If there is an electronic application [chatbot tool] that's proven to help, probably it's a good thing.* [Interview 10, Family Medicine]

Participants voiced the potential for AI to extend the capabilities of general practice physicians, who are increasingly involved in providing psychiatric care but who may have limited formal training in psychiatric medicine. Physicians also reflected on the potential impact AI could have on health systems, noting that AI support for general practitioners could aid their capacity to assist patients with complex psychiatric needs.

> *Yeah, because they're [primary care physicians are] dealing with a lotta psychiatry. They are very under trained. [...] They're like, "What? I have no idea. I had one month of training in med school. What am I supposed to do with this?" If there is a way to attack that with AI, that would be really helpful.* [Interview 28, Psychiatry]

In addition to supporting general practice physicians, participants also commented on how AI tools might allow psychiatric specialists to handle more complex care needs.

> *Really, anything that extends the ability of psychiatry to take care of the more complex patients and not deal with the day-to-day routine stuff would be wonderful. I mean, we're looking at a massive die-off of psychiatrists in the near future, and there's not gonna be enough of us around [...].* [Interview 25, Psychiatry]

Risks

Physicians also identified discrete risks with the adoption of AI tools. These perceived risks related to how AI tools might be unreliable, could increase burden, result in patient harm, or create medicolegal issues.

Physicians Were Concerned AI Could Be Unreliable

Physicians expressed some apprehension toward AI due to concerns that these systems might produce unreliable recommendations. They discussed the importance of having strong underlying research and data to support AI that informs clinical decision-making and noted that improperly developed tools or skewed data could lead physicians to make poorly informed decisions.

> *If we don't have a really robust analysis of the things that determine health for that patient informing the decision making, then I think we would run risk of making inappropriate decisions or having that data be harmful perhaps.* [Interview 16, Family Medicine]

Participants mentioned concerns over the capabilities of AI compared with human practitioners, often considering whether these technologies would be acceptable for guiding patient care. Chatbots, for instance, were sometimes viewed as being incapable of capturing aspects of therapeutic relationships.

> *With psychotherapy, in particular, a big part of the concept is having an experience with another person who's helping you that can then generalize to other relationships that you have. While I think some concepts can come out of dialogue, so to speak, with a chatbot, I am not convinced that being able to trust a human being can be accomplished by being able to trust an app [...].* [Interview 17, Psychiatry]

Some physicians were skeptical that AI could produce rigorous decisional support that would be comparable with advice generated by a physician.

> *My reservations, I guess, have to do with uncertainty about the flexibility and the reliability of those algorithms and whether a system would recognize as well as a human practitioner when that algorithm may not be serving the patient best, and that some other approach may be necessary.* [Interview 24, Psychiatry]

Participants also noted problems that could arise from physicians being overly reliant on AI in the future. They explained the potential for physicians, particularly those with less experience, to become dependent on AI and fail to properly develop their clinical skills.

> *[...] if you roll this [AI diagnosis tool] out in a residency clinic and the clinicians at that time get used to using an AI system and then going out to a rural practice where maybe that AI system is not available [...] maybe they don't know exactly how to come up with that diagnosis or everything because they're relying on artificial intelligence versus rote memory.* [Interview 41, Family Medicine]

They noted that this dependence could cause additional problems if AI systems turn out to be faulty. Furthermore, participants expressed concerns about physicians consistently deferring to AI recommendations without considering additional patient factors beyond what is required by a model.

> *I think risks would be if you utilize—you relied on it heavily, black and white, and you didn't consider the other aspects of the patient that aren't going into the algorithms.* [Interview 05, Family Medicine]

Physicians Were Concerned AI Could Increase Burden

Physicians expressed concerns that AI could be a source for additional administrative burden by adding to their clinical workflows. Some participants noted that AI could potentially overwhelm physicians with data, making it difficult to interpret recommendations. In addition, physicians were also concerned about additional data collection and entry requirements in

XSL•FO
RenderX

support of AI tools noting that these requirements could be disruptive to their clinical encounters.

> *If I need to click 60 click-boxes as far as symptomatology to get the AI tool to tell me this sounds more like anxiety than bipolar or depression, that's just a clerical burden that's hard to overcome in primary care, where time is short in most visits.* [Interview 04, Family Medicine]

Participants also discussed how AI could ultimately lead to an increase in their clinical workload. Physicians noted that additional training might be necessary to leverage AI systems, and that general practitioners might require additional psychiatric training to provide appropriate follow-up. Some physicians discussed the likelihood of an increase in the number of referrals to specialists because of new AI-enabled screening tools.

> *The irony is that a tool that we think may be implemented to leverage service may wind up increasing our workload instead of relieving us of some workload. Patients are referred to us [...] and there's nothing really abnormal. That doesn't mean the screening tool is bad or that it shouldn't be used, but there will be some false positives, I imagine, in that process.* [Interview 24, Psychiatry]

Physicians also discussed the potential for AI tools to increase their burden by providing additional information but without accompanying resources to intervene. Participants commented that situations like these ultimately place a greater burden on physicians as they are provided insights but are unable to act and noted that AI insights alone are not enough to provide a benefit.

> *You're telling me you're [suicide risk prediction tool] gonna identify this and you're gonna give me the problem, give me the solution. Tell me what intervention's gonna help prevent this suicide. Give me the resources available. If you say, "See a counselor and do this" and I don't have a counselor, then it doesn't do me any good. We have to really have the identified intervention named, the process and the resources for it.* [Interview 15, Family Medicine]

Physicians Were Concerned AI Could Result in Patient Harm

Participants raised concerns that AI could result in clinical harms to their patients. Physicians were concerned about potential errors associated with poorly designed or unvalidated AI systems. Participants were also concerned about whether AI tools would be designed to be inclusive of their patient population.

> *[...] we assume a lot of these tools are going in blind, and there are no biases, but I would be concerned about, is my algorithm racist, for instance, or other way is it disadvantaging—putting certain groups at a disadvantage?* [Interview 22, Psychiatry]

In addition to clinical harm, physicians identified other risks including security and cost concerns. Participants considered patient data privacy, especially in circumstances where models leverage sensitive information related to psychiatric health concerns. "For example, that [chatbot] app [...] can get hacked, so those transcripts [are] basically getting breached" (Interview 09, Family Medicine). Physicians also identified the potential for cost increases to patients if AI-supported treatment recommendations included higher cost prescriptions or services than what might otherwise be assessed by a physician.

> *[...] if it's [AI] an added cost to the healthcare system, either directly or indirectly, whether it's a waste of my time, and that time is a cost. If it's a cost that's gonna be incurred somewhere down the line in a patient's billing, because we have to have this tool integrated into our system, I don't think it would probably be worth the help there.* [Interview 08, Family Medicine]

This was often raised as a concern in the pharmacogenomics case, where physicians considered varied costs based on the types of medications being recommended by the AI tool.

> *[...] let's say that the AI [pharmacogenomics] tool suggested a non-generic medication. Now, the patient is going to have a higher cost based upon that, and I guess we don't know enough from the history, although you might've said that this is the first time the patient has ever had a depression.* [Interview 17, Psychiatry]

Physicians Were Concerned AI Could Create Medicolegal Issues

Participants expressed concerns about liability in relation to AI-supported clinical recommendations. As expressed by one physician, "how do we defend that in court if something goes wrong?" (Interview 25, Psychiatry). Physicians had various perspectives on whether a flawed AI recommendation or system error would result in personal liability to them, their institution, or the AI developer.

> *I think, ultimately, it's still going to be the doctor. Because even if it's an AI system, you know, the doctor is still supposed to be overseeing it [...] if the psychiatrist sits back and says, "I'm gonna trust the machine to do this," and the patient kills themselves. It's still the psychiatrist's fault, you know.* [Interview 27, Psychiatry]

Physicians noted potential for added complexity to their clinical decision-making given that there might be times where they disagree with AI-enabled recommendations. They discussed how in the treatment of psychiatric conditions there is often a need for additional assessment to verify indications from screening tools. "I think AI guided decisions will be wrong sometime. When that happens, who's at fault?" (Interview 24, Psychiatry). Participants were wary of legal risks they would be exposed to when their clinical assessments and actions fail to align with AI recommendations.

> *What if it [suicide risk prediction tool] flags and you talk to the patient and you get a sense by talking to*

XSL•FO
RenderX

them that they're not acutely suicidal, but then they go off and kill themselves, right? Now my artificial intelligence identified this as a concern and does it show some type of liability. [Interview 41, Family Medicine]

Overall Assessments

While participants shared both positive and negative perspectives on the potential impacts of AI tools, they generally saw these tools as promising in the care and treatment of patients with psychiatric conditions. Physicians were cautiously optimistic that future versions of health care AI could enhance the quality of their work and improve patient care.

I think that I embrace it [AI]. I think it's going to make us better psychiatrists. I think it's gonna give us better quality information [...] I think it's going to make us better therapists too. I hope that it's gonna get better and better and better [...]. [Interview 26, Psychiatry]

I see down the line I'm cautiously optimistic about the use of it really helping to improve the efficiency and lower costs because we're on an unsustainable growth curve of costs in health care right now. [Interview 06, Family Medicine]

Despite this general optimism, participants expressed concern about premature deployment of unproven AI tools in psychiatric medicine.

I think I'm in agreement with the idea of developing these tools, but I don't think the state of science is at the level that I would be supportive of them being used in a field of psychiatry. [Interview 14, Psychiatry]

I feel like that time has not yet come, based on my experience with AI. Even the most intelligent computer I've seen [...] doesn't feel natural [...] I feel like in the front end, I think, AI has a long way to go. [Interview 21, Family Medicine]

Discussion

Principal Findings

Our study contributes to the existing discussion of AI in health care with added nuance for applications in psychiatric medicine. Our results suggest that physicians are generally optimistic about the potential benefits of AI, but their optimism is tempered by concerns about potential risks to themselves and their patients. Some of the perceived benefits and risks identified in our study track with previous examinations of physician attitudes toward AI in health care broadly and prior survey research [40,41], suggesting that there may be a set of physician considerations, irrespective of the specialty using AI tools [42].

Our findings also support various theoretical models for technology acceptance in health care. Contributions such as the Technology Acceptance Model (and its iterations) provide a framework for examining user perspectives and intentions to adopt technologies and have been considered extensively in health care [43,44]. While the goal of this study was not to suggest a new or adapted model for AI tools, we highlight physician perspectives that may inform model constructs when applied to psychiatric medicine. For instance, our study identified that many physicians were cognizant of significant resource shortages and unmet patient needs for psychiatric care, often suggesting that AI could support these gaps. The perceived usefulness of AI tools in psychiatric medicine in the near-term might mediate these circumstances and potentially influence physician willingness to adopt such technologies. Other perceived benefits and risks identified by our study help situate the landscape of external variables that may facilitate or hinder the adoption of AI tools.

In addition to supporting theoretical models, our research advances previous work aimed at characterizing physician perspectives toward AI in psychiatric medicine. Survey research on general AI applications [40] and on generative AI [30] in psychiatry has contributed high-level considerations for physician attitudes. Our findings provide nuance and depth to some of these prior considerations. For instance, while health care access considerations have been identified in prior work, our findings detail exactly how physicians anticipate greater access will be achieved (ie, reducing stigma, enhancing convenience, and augmenting generalists). Furthermore, our results provide an understanding of potential use cases of AI tools in psychiatry from the perspective of specialists, enhancing broader understanding of how these tools might be supportive or harmful in practice. These considerations also advance previous work with psychiatrists and clinical decision support systems [41] by characterizing family medicine practitioner and psychiatrist perspectives on specific perceived risks in relation to AI tool acceptance.

One consideration for the degree of optimism toward AI tools is the backdrop of existing resource strain faced by behavioral health systems and practitioners [16]. While there may be potential for AI to shore up resource limitations in psychiatric medicine, there are still lingering questions about the fidelity of these tools and their net benefit to clinical practices [10,45]. Furthermore, there is added concern that a focus on AI to address issues in psychiatric medicine may obfuscate more systemic problems that are impacting the field. Our results show that physicians are still mindful of these systemic issues limiting psychiatric medicine and that these issues can remain even with adoption of AI.

Physicians identified areas where AI had the potential to both help and hurt. For instance, while many physicians saw a benefit to AI alleviating burden in their workflows, there was also consideration for these systems to create additional burden. This suggests that benefits and risks from adopting AI may not be uniformly experienced and physicians may simultaneously be both hopeful and cautious about the integration of AI in their practice. Developers and adopters of AI in psychiatric medicine should be cognizant of these simultaneously advantageous and disadvantageous circumstances along with potential unintended consequences [12]. It is important to consider that many behavioral health AI technologies are still in relatively early stages of technological maturity and that perspectives may evolve as AI tools are deployed in clinical practice [46], especially with the advancement of generative AI tools [30].

XSL•FO
RenderX

As health care organizations look to implement potential AI technologies, physicians will be key drivers of the success or failure for many of these tools [22]. Our research supports prioritizing physician involvement in AI development and adoption, where neglecting the perspectives of physicians can be a path toward failure [21]. Family medicine practitioners and psychiatrists will play an important role in managing the deployment of these AI tools, as they currently manage a wide variety of psychiatric health concerns.

Limitations

The results and conclusions of this study must be viewed with limitations in mind. All participants were recruited from the same institution; thus, our results may not be reflective of physicians in different organizational and practice settings. Furthermore, we did not collect detailed participant demographic information outside of their specialty, diagnosis counts, and prescription counts, which were used for recruitment purposes. While this information may help characterize our participant sample, we did not intend to make conclusions or generalizations based on a traditional reporting of demographics (ie, participant age, sex, race or ethnicity, etc) and were primarily concerned with physician specialty due to the differences in scope of practice [47]. In addition, by including both family medicine practitioners and psychiatrists, our findings might be influenced by experiential differences of these groups and greater variability in responses. As a qualitative study, our methods were best suited to elicit detailed perspectives held by study participants. However, given the limited sample size and this qualitative approach, our findings are limited in their generalizability to larger physician populations.

An additional limitation stems from our use of hypothetical cases as stimuli for discussion [48]. Despite selecting various attributes in designing our cases, they are not exhaustive of the numerous applications of AI and conditions observable in psychiatric medicine. Although our cases provided a strong anchor for accessible discussion of AI, they also potentially constrained discussion by focusing participants on specific applications and scenarios where these tools may be applied. As a result, our findings may be biased toward certain health conditions such as depression. Furthermore, cases may have introduced confounders that may have influenced physician perspectives. For example, challenges related to the clinical use of pharmacogenomics independent of AI may have biased physician viewpoints [49]. The cases also lacked significant descriptions of the underlying technical approaches (eg, supervised learning and unsupervised learning), technical requirements, or digital architectures related to how information from AI is integrated into electronic health records or other clinical platforms.

Further Research

Our findings provide several directions for additional research. User research with physicians who are early adopters of psychiatric AI tools might better assess facilitators, barriers, and outcomes related to tool use. Such studies might focus on examining the perspectives of physicians using specific AI tools. In addition, longitudinal research might assess how physician perspectives change over time as AI tools are introduced into clinical practice. These investigations would capture perspective shifts during exposure to AI tools, which is a key limitation of this study. Including varied study methods such as quantitative and mixed methods approaches as well as studying other physician specialties might help characterize differences in practice areas. Sentiment analysis approaches might also more robustly characterize positive and negative attitudes toward the adoption of AI tools. Delphi methods could support identifying the relative importance of certain benefits and risks to physicians as well as consensus for certain design, development, and policy recommendations for psychiatric AI tools. Finally, additional conceptual work might contribute integrative models and frameworks for incorporating AI tools into psychiatric medicine that highlight best practices, ethical considerations, and design standards that address key physician concerns.

Conclusions

While there is increasing development of AI tools for psychiatric medicine, a comprehensive understanding of physician perspectives lags behind more technical achievements. Identifying and addressing physician concerns will be a key step forward for the design and adoption of AI that is responsive to physician needs. Our study offers a novel look at the benefits and risks physicians see with AI in psychiatric medicine based on clinical case scenarios depicting uses they would likely encounter in their practice. We believe that our participants' projected challenges and successes for these tools will help better address the needs of physicians as these technologies become further integrated into health care.

Acknowledgments

This study was funded by the National Science Foundation (award 2041339). Abstract

Background: Consumers are increasingly using large language model–based chatbots to seek mental health advice or intervention due to ease of access and limited availability of mental health professionals. However, their suitability and safety for mental health applications remain underexplored, particularly in comparison to professional therapeutic practices.

Objective: This study aimed to evaluate how general-purpose chatbots respond to mental health scenarios and compare their responses to those provided by licensed therapists. Specifically, we sought to identify chatbots' strengths and limitations, as well as the ethical and practical considerations necessary for their use in mental health care.

Methods: We conducted a mixed methods study to compare responses from chatbots and licensed therapists to scripted mental health scenarios. We created 2 fictional scenarios and prompted 3 chatbots to create 6 interaction logs. We recruited 17 therapists and conducted study sessions that consisted of 3 activities. First, therapists responded to the 2 scenarios using a Qualtrics form. Second, therapists went through the 6 interaction logs using a think-aloud procedure to highlight their thoughts about the chatbots' responses. Finally, we conducted a semistructured interview to explore subjective opinions on the use of chatbots for supporting mental health. The study sessions were analyzed using thematic analysis. The interaction logs from chatbot and therapist responses were coded using the Multitheoretical List of Therapeutic Interventions codes and then compared to each other.

Results: We identified 7 themes describing the strengths and limitations of the chatbots as compared to therapists. These include elements of good therapy in chatbot responses, conversational style of chatbots, insufficient inquiry and feedback seeking by chatbots, chatbot interventions, client engagement, chatbots' responses to crisis situations, and considerations for chatbot-based therapy. In the use of Multitheoretical List of Therapeutic Interventions codes, we found that therapists evoked more elaboration (Mann-Whitney U=9; P=.001) and used more self-disclosure (U=45.5; P=.37) as compared to the chatbots. The chatbots used affirming (U=28; P=.045) and reassuring (U=23; P=.02) language more often than the therapists. The chatbots also used psychoeducation (U=22.5; P=.02) and suggestions (U=12.5; P=.003) more often than the therapists.

Conclusions: Our study demonstrates the unsuitability of general-purpose chatbots to safely engage in mental health conversations, particularly in crisis situations. While chatbots display elements of good therapy, such as validation and reassurance, overuse of directive advice without sufficient inquiry and use of generic interventions make them unsuitable as therapeutic agents. Careful research and evaluation will be necessary to determine the impact of chatbot interactions and to identify the most appropriate use cases related to mental health.

Introduction

Background

Society is facing a massive mental health challenge. As the prevalence of various mental illnesses and loneliness is rising, there is a shortage of available mental health professionals [1]. Access to proper treatment can thus be limited and expensive, especially in the United States. Recent advancements in the development of large language models (LLMs) that power artificially intelligent chatbots could offer an enticing option for those seeking help. Chatbots are always available, at a low cost or free, and allow users to speak their mind freely without fear of judgment. In a recent study that targeted a nationally representative sample of >1800 individuals, 24% indicated that they had used LLMs for mental health needs [2].

Today's artificial intelligence (AI) chatbots can generally be grouped into 3 categories: AI assistants, AI companions, and AI character platforms. AI assistants are systems that help users with common everyday tasks in both their professional and private lives. AI companions are systems that let users interact with one central chatbot, which is customized over time, and are meant for leisurely or personal conversations. AI character platforms are similar to AI companions with a focus on private rather than professional conversations. They are different from AI companions because they offer users the chance to generate various chatbots and publish them on a platform where anyone can use them. The most studied use of chatbots for supporting mental health is social companionship with apps such as Replika (AI companion) and Character AI (AI character platform). Emerging evidence suggests that LLM-based chatbots as social companions can offer positive support and contribute to general psychological wellness [3,4]. There have been numerous studies, especially focused on the AI companion app Replika, that found positive mental health outcomes of using chatbots, such as increased confidence and improved relationships with friends [4,5]. In using social companion agents, studies have reported that a clear boundary in regard to therapy and companionship is hard to achieve. For instance, participants engage with chatbots for objectives beyond companionship, including using a chatbot as a therapist and an intellectual mirror [6].

While there is much research on the use of chatbots as social companions, work on understanding their potential for use as therapeutic agents is currently emerging. Some research suggests that they have the potential to assist therapists and exhibit traits of both high- and low-quality therapy [7]. Eshghie and Eshghie [8] noted that with carefully crafted prompts, ChatGPT is able to positively participate in conversations and offer validation and potential coping strategies. In addition, LLMs can help identify patients who are at high risk based on data collected at intake and support therapists in promoting self-disclosure [9,10]. In the context of cognitive behavioral therapy (CBT), Iftikhar et al [11] show that LLM-based chatbots and human peer counselors have complementary strengths, highlighting potential for appropriate human-AI collaboration. AI chatbots adhere more strongly to CBT, while peer counselors drift from a CBT approach, suggesting that LLMs may be useful in supporting therapists in specific areas. In another study in which chatbots provided CBT, LLMs performed well on catching and identifying unhelpful thoughts, but they were not found to be ready to conduct CBT independently due to their limited performance on restructuring unhelpful thoughts [12].

The application of LLMs in the sensitive context of mental health comes with several risks, such as concerns around ethical provision of services and perpetuation of disparities and stigma [13]. For instance, Sharma et al [14] found that an LLM-based mental health intervention, despite offering naturalistic interactions, may not produce equitable outcomes, benefiting some groups more than others, suggesting the need for careful adaptation for different groups. Similarly, those who are under distress and are more likely to benefit from social companion chatbots are also the ones most at risk for attachment, addiction, and overreliance on chatbots [5,15,16]. Research has raised several concerns that must be addressed to ensure ethical and safe use of AI for mental health care [17]. In addition, the American Psychological Association recently issued a letter to the Federal Trade Commission expressing significant concerns about the potential harm caused by chatbots that present themselves to consumers as "therapists" [18].

There is some evidence emerging that chatbots designed for mental health support could improve mental health care for certain mental health conditions, such as depression and anxiety [3,19-21]. If chatbots were to be effective at improving mental health outcomes at scale, they could improve the mental well-being of millions at a low cost. These chatbots are publicly available and are already being used by many people as a form of mental health support [22]. However, most general purpose and social companion chatbots that are based on LLMs have not been thoroughly evaluated for these use cases. Given the potential benefits and risks with this novel tool, there is a need to evaluate these chatbots to understand their abilities and limitations in handling mental health conversations.

Objectives

This study aims to address this need by evaluating the responses of widely available AI chatbots during mental health conversations. Specifically, we seek to understand how chatbots that were not specifically designed to address mental health issues handle delicate mental health scenarios and compare them to interventions provided by human therapists. Our research objectives are 2-fold: first, to assess the strengths and limitations of chatbot interactions in a therapeutic context, and second, to identify implications for the use of chatbots to augment the provision of mental health care.

Through a mixed methods approach, this study systematically compares chatbot responses to scripted mental health scenarios with responses from licensed mental health professionals. By comparing behaviors of different chatbots and of therapists and

XSL•FO
RenderX

chatbots, we aim to provide insights into the potential role these chatbots could play in future mental health care given their limitations, while highlighting the ethical and practical considerations necessary for their safe deployment.

Methods

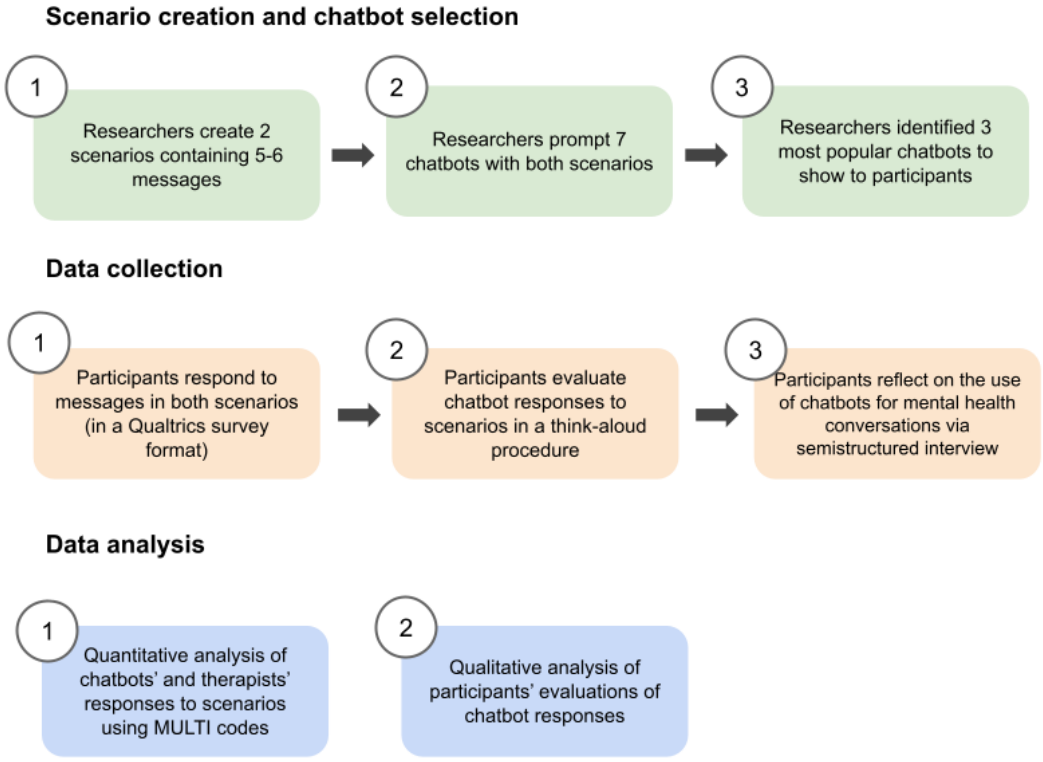
Participants

Therapists were recruited through word of mouth and a cold email campaign wherein 200 therapists listed in *Psychology Today* and similar platforms were emailed with information about the study. We also circulated the study information through other email lists that contained an unspecified number of therapists and allowed for snowballing and forwarding, so the exact number of potential participants reached directly remains unknown. Therapists who expressed interest were contacted to assess eligibility. Licensed therapists with at least 1 year of professional experience were deemed eligible. Recruitment took place over a period of 1 month. We recruited 17 therapists in total, consisting of 13 women, 3 men, and 1 genderqueer therapist. Their professional work experience ranged from 3 to 49 years. More information about the demographic characteristics of the study participants can be found in Table 1.

Table 1. Sociodemographic characteristics of participants (N=17).

Baseline characteristic	Participants
Gender, n (%)	
Women	13 (76)
Men	3 (18)
Genderqueer	1 (6)
Ethnicity, n (%)	
African American	4 (24)
Asian	1 (6)
Mixed ethnicity	1 (6)
White	11 (65)
Age (y), mean (SD)	46.24 (15.38)
Years in practice, mean (SD)	16.71 (13.60)
Highest educational level, n (%)	
Masters	13 (76)
Doctorate	4 (24)

Scenario Creation and Chatbot Selection



An overview of the complete study design can be found in Figure 1. We first created 2 fictional scenarios (Multimedia Appendix 1) in which a user talks about a mental health challenge to explore how chatbots and therapists would respond to each scenario. Each scenario contained 5 to 6 messages that explained the situation from a first-person perspective. Ideas were collected from the group of researchers, from which the 2 most appropriate scenarios were selected and refined throughout several drafts. The first scenario dealt with a relationship issue that involved 2 people and their parents in an ambiguous cultural context. The second scenario involved a person describing their symptoms of depression and social anxiety and led to a situation involving suicidal ideation. We collected all message responses in a document and anonymized them so that the therapists could not tell which chatbot gave which response.

We selected 7 chatbots to prompt with the messages from the 2 scenarios. Each chatbot was prompted in the most up-to-date version at the time of data collection (May 1, 2024). We chose the most popular chatbots based on the number of monthly active users at the time in each of the following 3 categories (as described in the Introduction section): AI assistants, AI companions, and AI character platforms. We selected 3 AI assistants (GPT-4 [Open AI], Gemini 1.0 Pro [Google LLC], and Claude 3 Sonnet [Anthropic]), 2 AI companions (Replika [Luka] and Pi [Inflection AI]) and 2 AI character platforms (Character.ai [Character.ai] and Chai [Chai]). After that, we selected the conversation logs of 3 chatbots to show to the therapists: ChatGPT, Pi, and Replika.

For our selection criteria, we included ChatGPT as it was the most popular among the 3 everyday AI assistants, which all behaved fairly similarly. In addition, we selected Pi and Replika due to their distinct behaviors and target audiences as AI companions, making them ideal for comparison in terms of user interaction style. We opted not to include AI character platforms, as these offer numerous user-generated characters created by nonprofessionals, which would introduce inconsistency and limit control over standardized chatbot behavior across our study. Responses from all chatbots are included in Multimedia Appendix 1.

XSL•FO
RenderX

Figure 1. Depiction of the study design grouped into 3 stages. MULTI: Multitheoretical List of Therapeutic Interventions.

Data Collection

Our study sessions consisted of 3 activities. First, at the beginning of the session, we showed the messages from the 2 scenarios to each therapist and let them respond to each message as if they were talking to a real person via text. To do so, we created a Qualtrics XM survey in which the therapist saw 1 message per screen and could type in their response below. To see the next message, one would have to respond first and then continue to the next screen. Scenario responses were scripted such that the response stayed the same, allowing for direct comparison across therapists and chatbots. This was repeated until both scenarios were completed. The average time to complete both scenarios was 20 minutes. Second, we conducted think-aloud sessions in which participants saw 6 chat logs (3 chatbots with 2 scenarios each). Therapists reviewed the chat logs and provided their assessments of the response quality. Each chat log that was completed was followed by a short debrief in which participants could share their opinion on how the chatbot handled the situation.

At the end of each scenario, we asked therapists, who remained blinded to each chatbot, to rank-order ChatGPT, Pi, and Replika for how well they handled scenario 1 and, separately, scenario 2. First place received 3 points, second place received 2 points, and third place received 1 point. Finally, we conducted a semistructured interview in which we asked the therapists to reflect on the role that chatbots could play in therapy and their potential impact on the mental health of users.

Data Analysis

Analysis was conducted in several phases. First, we compared word counts between therapists and chatbots using a Mann-Whitney *U* test, given the nonparametric nature of the data. Therapeutic interventions from chatbots and therapists were analyzed with the Multitheoretical List of Therapeutic Interventions (MULTI) framework [23]. Two raters from the research team reviewed each message and assigned it ≥1 MULTI codes (eg, asking a question and making a suggestion). One rater was a doctoral candidate in a clinical psychology program with psychotherapeutic training, and the second rater was a nonclinical researcher. The raters completed coding training together with input from a third researcher who is a licensed clinical psychologist. Afterward, the raters independently rated the same passages and resolved discrepancies through consensus until they reached high agreement. Once high agreement was achieved, the raters independently completed the remaining messages, meeting to resolve uncertain codes as needed. Therapeutic intervention use was analyzed for all instances in which messages contained language that fit with a specific intervention identified in the MULTI. To compare use patterns, only codes endorsed >1 time (eg, at least 2 times) by either chatbots or therapists across all interactions are reported. For each code, a Mann-Whitney *U* test was used to compare therapist and chatbot use of the code. A Mann-Whitney *U* test was used given the small sample size and nonparametric nature of the data. For the rankings of each scenario, a Friedman test was conducted to examine therapists' rankings of the chatbots because the data at hand were nonparametric.

We used inductive thematic analysis to analyze qualitative data from interview transcripts. During the open coding phase, we coded the transcripts using in vivo and descriptive coding to identify and label emerging concepts in the data. In the subsequent axial coding process, we grouped related concepts together to identify patterns and narratives, which were eventually developed into broader themes and their constituent

XSL•FO
RenderX

subthemes. To do so, we performed affinity diagramming in a Miro board to visualize the themes and the related participants' quotes and keywords. The emergent themes, subthemes, and their descriptions were written and discussed in weekly team meetings to revise and finalize the themes. Overall, we identified 7 themes.

Ethical Considerations

The study was approved by the Stanford University's Institutional Review Board (approval number: 74508). Informed consent was obtained from study participants and data were anonymized for data analysis. Eligible therapists who provided informed consent were enrolled and compensated with US $75 after completing the interview.

Results

Quantitative Results

We analyzed the responses from therapists and chatbots to get a clearer picture of the behavior of each group. The results are reported in the subsequent sections.

Word Count

The mean overall word count was smaller for therapists than for chatbots. The difference between the 2 groups in overall word count was statistically significant (U=10; P=.002; P<.05, P<.01, P<.001). The effect size, as measured by Pearson r, was r=0.64, indicating a strong effect size [24]. The average overall word count for therapists was 392.5 (SD 163.3) while chatbots used an average of 1,414.9 (SD 878.1).

Therapeutic Interventions Used

Table 2 presents all the results related to therapeutic interventions.

Table 2. Average overall use of Multitheoretical List of Therapeutic Interventions codes for therapists and chatbots.

	Therapists, mean (SD)	Chatbots, mean (SD)	Mann-Whitney U test	P value	Pearson r
Evoke elaboration	6.60 (1.62)	3.40 (1.40)	9	.001	–0.65
Suggest	3.00 (2.29)	7.40 (2.44)	12.5	.003	–0.61
Reassure	0.20 (0.44)	1.60 (1.27)	23	.02	–0.47
Teaching and psychoeducation	2.40 (1.12)	3.70 (0.95)	22.5	.02	–0.48
Affirmation	0.80 (0.88)	2.30 (1.98)	28	.045	–0.41
Self-disclosure	2.70 (1.45)	2.00 (1.63)	45.5	.37	–0.18
Sympathize	2.10 (1.65)	3.30 (1.70)	37.5	.16	–0.29
Make emotions explicit	1.40 (1.27)	1.40 (0.79)	55	.78	–0.06

Evokes Concrete Elaboration

The elaboration code indicates a therapist request for more information about something specific related to their presenting problem. On average, therapists evoked elaboration 6.6 times during their interaction, and chatbots did so 3.4 times. There was a statistically significant difference in the use of this code (U=9; P=.001). The effect size, as measured by Pearson r, was r=–0.65, indicating a strong effect size.

Suggesting

The suggesting code indicates provision of concrete suggestions. On average, therapists made suggestions 3 times during their interaction, and chatbots did so 7.4 times. There was a statistically significant difference in the use of suggestions (U=12.5; P=.003). The effect size, as measured by Pearson r, was r=–0.61, indicating a strong effect size.

Reassuring

The reassuring code indicates efforts to provide comfort to or increase client confidence about their situation or the eventual outcome of a problem through persuasion. On average, therapists reassured 0.2 times during their interaction, and chatbots reassured 1.6 times. The 2 groups did have a statistically significant difference in their use of this intervention (U=23; P=.02). The effect size, as measured by Pearson r, was r=–0.47, indicating a moderate effect size.

Teaching and Psychoeducation

The psychoeducation code marks therapist actions, such as teaching principles, educating them about psychological topics and how therapy works. On average, therapists used this intervention 2.4 times during their interaction, and chatbots provided psychoeducation 3.7 times. There was a statistically significant difference in the use of this code (U=22.5; P=.02). The effect size, as measured by Pearson r, was r=–0.48, indicating a moderate effect size.

Affirmation

The affirmation code marks when the therapist identifies something positive in what the client is doing or saying. On average, therapists affirmed 0.8 times during their interaction, and chatbots affirmed 2.3 times. There was a statistically significant difference in the use of this code (U=28; P=.045). The effect size, as measured by Pearson r, was r=–0.41, indicating a moderate effect size.

Self-Disclosure

The self-disclosure code identifies moments when the therapist shares their current experience of the therapy or their feelings

XSL•FO
RenderX

during the session. On average, therapists used self-disclosure 2.7 times during their interaction, and chatbots did so 2 times. There was no statistically significant difference in the use of self-disclosure (U=45.5; P=.37). The effect size, as measured by Pearson r, was r=–0.18, indicating a very weak effect size.

Sympathizing

The sympathizing code marks instances where the therapist expresses sorrow or sympathy about something the client said. On average, therapists sympathized 2.1 times during their interaction, and chatbots did so 3.3 times. There were no statistically significant differences in sympathizing (U=37.5; P=.16). The effect size, as measured by Pearson r, was r=–0.29, indicating a weak effect size.

Makes Emotions Explicit

This code identifies interventions in which therapists identify the feelings or emotions of the client. On average, therapists identified emotions 1.4 times during their interaction, and chatbots did so 1.4 times. There were no statistically significant differences between the chatbots and therapists for identifying emotions (U=55; P=.78). The effect size, as measured by Pearson r, was r=–0.06, indicating a very weak effect size.

Therapists' Ranking of ChatGPT, Pi, and Replika

Therapists' rankings of the three chatbots revealed no statistically significant differences in scenario 1. ChatGPT received a mean (SD) score of 27 (0.71), Pi 40 (0.79), and Replika 35 (0.83), with Friedman's Q = 5.06 (P = .08). In contrast, scenario 2 showed a significant difference among chatbots (Q = 6.93, P = .03). Here, ChatGPT was rated highest with a mean (SD) score of 38 (0.64), followed by Pi 28 (0.83) and Replika 24 (0.83), indicating that therapists preferred ChatGPT in this context.

Qualitative Results

Overview

To better understand the quality of chatbot responses, we asked therapists to express their opinions on these responses while reading them. We identified 7 themes and 11 subthemes, which we describe in greater detail in the subsequent sections (an overview can be found in Textbox 1). These include elements of good therapy in chatbot responses, conversational style of chatbots, insufficient inquiry and feedback seeking by chatbots, chatbot interventions, client engagement, chatbots' responses to crisis situations, and considerations for chatbot-based therapy.

Textbox 1. Overview of the 7 themes and 11 subthemes identified through qualitative analysis of therapist interviews.

Themes

- Elements of good therapy in chatbot responses
- Conversational style of chatbots
- Insufficient inquiry and feedback seeking by chatbots
  - Chatbot interventions
  - Strong framing of opinions and suggestions
  - Directive tone of chatbot advice
  - Generic advice
- Client engagement
  - Enabling the client to solve their own problems
  - Building a therapeutic relationship
- Chatbots' responses to crisis situations
  - Connecting users to relevant crisis resources
  - Lack of directive tone
  - Poor risk assessment
- Considerations for chatbot-based therapy
  - Transparency
  - Regulations for using chatbots for mental health purposes
  - Effects and unintended consequences of long-term use

Elements of Good Therapy in Chatbots' Responses

Therapists consistently mentioned across both scenarios and across all 3 chatbots that they embodied several elements of good therapy. Chatbots were particularly effective at validating, normalizing, expressing empathy, and reflecting the client's thoughts and feelings. Our quantitative results also indicate that chatbots used reassuring, sympathizing, and affirming language more often than the therapists.

XSL•FO
RenderX

For example, Replika's response in scenario 1 was as follows:

> *Wow, that sounds like a tough spot to be in. It must be really hard to balance your desire to be with your girlfriend while also considering your family's wishes and potential repercussions.*

Therapist 2 found this to be a useful reflection:

> *This is good, because it's a good reflection. The way I was trained is good to be able to reflect to people so that built empathy.*

Similarly, ChatGPT's response to scenario 1 was noted as validating by therapist 6:

> *This sounds like a really tough situation, and it's understandable why you'd feel disheartened and confused. When caught between family and a partner, it can feel like there's no good choice.* [ChatGPT's response in scenario 1]
>
> *I think this is a good intro it sounds very similar to what I think therapists would say, as far as like validating and staying present with the client.* [Therapist 6 on ChatGPT's response]

Conversational Style of Chatbots

Therapists preferred the conversational tone demonstrated by AI companions over the robotic and textbook-like tone of everyday AI assistants. Chatbots that responded with shorter responses were considered more conversational and closer to human messaging behavior than longer responses that appeared to be taken from a textbook or a search engine.

For instance, in the following example, therapist 12 compared ChatGPT with Pi and noted that ChatGPT's responses were not as validating and empathetic. ChatGPT also sounded more robotic, whereas Pi, with shorter responses, was perceived as more humanlike. Shorter responses also made the information provided by Pi "easier to digest" (Therapist 12):

> *I feel like this person is probably getting bored of this conversation. It's not as emotionally understanding and validating. The other 2 responses [from Pi and Replika] were much more humanlike, and with this I feel like you wouldn't forget that this is a robot.* [Therapist 12 on ChatGPT's response to scenario 1]

While a conversational style was preferred, the use of emojis as an attempt by Pi to sound conversational mostly received negative reactions. Most therapists were unsure about how a client would read and react to an emoji:

> *There's so many different smiley faces. Even with friends and family that I know well, and they know me well I find that these things can be misunderstood pretty easily.* [Therapist 7 on Pi's use of emoji in scenario 1]

Therapists noted that emojis may not be appropriate when a client is talking about a difficult situation:

> *Oh, no, I don't like the emojis. It feels like real casual, and light hearted. And I think if they're like, "I'm facing a difficult situation," it reads off to me.* [Therapist 14 on Pi's response to scenario 1]

Only a few therapists noted that if used in the appropriate context, emojis could help build a relationship with the user and might be a good way to connect with them, especially with younger generations. However, its use requires careful consideration:

> *It could be misinterpreted by other people. So it's always questionable. But it's also socially acceptable. Because that's how many people communicate in the generation now. It is a texting generation, so they use emojis, but I think you have to be careful of it, just because others might misconstrue it.* [Therapist 15 on Pi's response to scenario 2]

Insufficient Inquiry and Feedback Seeking by Chatbots

Most of our participants believed that therapy is "inquiry rather than advice." However, therapists noted that chatbots did not ask enough questions to understand the client. The quantitative results and therapists' comments show that therapists asked more elaborative, open-ended questions as compared to chatbots.

Most therapists noted that chatbots did not ask many open-ended questions to gather information about the client's specific situation. This was also observed quantitatively, as therapists used much more open-ended questions than chatbots. This observation was especially apparent in scenario 1, wherein the simulated client with a particular cultural background was facing a complicated situation with their family. Many therapists noted that the chatbots did not seek to find more information about the client's background or their relationship with the family:

> *There's so little that we know about the person, about his girlfriend, and about the parents. I have no idea if he met her last week or last night or going on for 3 years. There's no context.... And you know, then we're saying things like, "Oh, love conquers all," you know. But we're not really sure..... nd so that's the whole idea of asking questions—to have that rich database of information and to be able to make suggestions that are going to actually work.* [Therapist 13 on Pi's response to scenario 1]

During face-to-face conversations, human therapists find it important to read nonverbal cues displayed by a client and use that to tailor the therapeutic approach and ease the tension in the room. This was often described as "the human connection" that face-to-face human interactions provide. Such an exchange of nonverbal cues was not considered possible between a chatbot and a client by therapists. Therapists noted the inability of the current generation of chatbots to read facial expressions, interpret tone of voice, and understand jokes or sarcasm:

> *Again, just trying to engage when you are in the presence of someone you can kind of gauge if a person is feeling anxious, I'm not gonna give them all this information.... So it really does depend on how regulated versus dysregulated the client is coming in before I determine how I present myself in a way that helps this client regulate.* [Therapist 6]

XSL•FO
RenderX

In better understanding and treating the client, therapists also seek feedback on whether the client understands what they are saying. Such feedback-seeking behavior was not displayed by the chatbots. They provided information to the client without seeking to know the extent to which the client understands the information:

> *I am more apt to having a bit more feedback. You know, more of this type of structure of like, okay, here's some options. What do you like? What are your thoughts about that?* [Therapist 6]

Chatbot Interventions

Overview

Consistent with quantitative findings, all therapists noted that the chatbots were providing a lot of advice, which is not typically done in therapy. Quantitative analysis also shows that chatbots generally provided more suggestions than human therapists. Therapists commented on several unhelpful aspects of advice, which include overly strong framing, directive tone, and generic nature of advice.

Strong Framing of Opinions and Suggestions

There were several instances where therapists noted that the chatbots' phrasing of particular suggestions and opinions was not appropriate and required rewording. In scenario 1, therapists noted that Pi's response appeared to judge the client's girlfriend and might amplify anger toward her. According to therapists, this judgment was extreme and could be unjustified:

> *It's unfortunate that your girlfriend reacted with anger and threats, and you deserve to be with someone who respects and supports you, just as your family deserves to be heard and understood.* [Pi's response]

> *This is a risky statement, though, because you don't know how able someone is to hear something like that. And also it may not be fair to the girlfriend, right? I think this is unfair to the girlfriend, saying she's reacted with anger and threats that feels a little extreme without more information which I'm assuming the bot doesn't have.* [Therapist 3 on Pi's response to scenario 1]

In the case of chatbots diagnosing the client in scenario 2, therapists had mixed opinions about the use of the diagnostic label "social anxiety" and how it was phrased. Half the therapists liked the way it was phrased because it focused on symptoms associated with certain conditions rather than telling the user directly that they have a condition:

> *It sounds like you're experiencing symptoms of social anxiety. This is a common condition that affects many people, and it's nothing to be ashamed of. Have you considered seeing a therapist or counselor to discuss strategies for managing your symptoms? In the meantime, there are some coping mechanisms you could try.* [Replika's response to scenario 2]

> *Okay, so this is pretty good. They're kind of talking about "Yes, this could be social anxiety," normalizing it and kind of scaring them towards the counselor, but also saying "Here are some things that you could do in the meantime." This is not bad.* [Therapist 11 on Replika's response to scenario 2]

However, the other half of the therapists expressed concerns about using a diagnostic label. Using the phrase "social anxiety" made it sound like a medical diagnosis in their opinion. The label was used solely based on 2 messages exchanged in the conversation without seeking relevant additional information:

> *It sounds like you're experiencing symptoms of social anxiety.* [Replika's response to scenario 2]

> *Now we're talking about a diagnosis. It's not saying you have social anxiety disorder. But if I'm a lay person, that's how I hear that.* [Therapist 3 on Replika's response to scenario 2]

> *The thing that jumps out is, "you're not alone and experiencing social anxiety," which could be jarring if the person has never identified with having social anxiety. It's like, "Well, wait a second, how do you know I have social anxiety?" It kind of feels like there's already a diagnosis being made.* [Therapist 16 on ChatGPT's response to scenario 2]

Directive Tone of Chatbot Advice

When giving advice or suggestions, the tone of the chatbots was often perceived to be more directive than it should have been for scenario 1. Instead, therapists preferred to ask questions about potential options to let the client think through their situation, unless the situation involved higher risk to safety:

> *I would say, like, this is something I would see like in an intern or practicum setting. Like someone who hasn't totally learned who's just training because a lot of times you wanna help. So you're very directive. And you're telling your clients this is what you should do or like you should try this.* [Therapist 8 on Replika's response to scenario 1]

> *I think these are great suggestions. But I feel like posing it as a question would be better. Like "have you considered sharing with your family the specific traits of your girlfriend that make her a great match?" You're engaging their critical thinking. Having them kind of think about it on a deeper level.* [Therapist 1 on Replika's response to scenario 1]

Generic Advice

Therapists described their approach of gathering contextual information and building a therapeutic relationship to help identify potential solutions tailored for the client's situation. In contrast, they found the chatbot to be quick to provide one-size-fits-all solutions, without a nuanced understanding of the client's situation:

> *Gosh! I hate this response. Engage in activities that relax you. It's just so generic. I would never say that. Make sure you're eating, you know. Feels dismissive to me.* [Therapist 3 on ChatGPT's response to scenario 1]

> *I think other things kind of get missed along the way, and it's not a one size fits all. So what happens if,*

XSL•FO
RenderX

> *like, this person does all these things and it doesn't work out—then it's kinda like, well, now what.* [Therapist 16 on ChatGPT's response to scenario 1]

Therapists also pointed out that generic advice that does not consider the specific situation or cultural context is unlikely to be successful and can even be unhelpful:

> *So in certain traditional settings, let's use an Asian family, for example, the head of the family, the father figure, like what they say goes and you don't argue. There is no like trying to rationalize. That's just a big no no—to them that's not helpful. And it also just kind of shows you don't understand the situation. This is no longer helpful to me, so it could just cause the client to shut down very quickly.* [Therapist 8 on Replika's response to scenario 1]

Client Engagement

Overview

Therapists believed that the impact of the failure to gather information and the rush to provide advice resulted in a failure to empower the client to solve their own problems. They also noted that chatbots did not build a therapeutic relationship by having an open conversation. Each of these aspects of engagement with their clients was considered by the therapists to be an essential pillar of successful therapy.

Enabling the Client to Solve Their Own Problems

As per our participants, an essential element of therapy is allowing the user to talk through their problems instead of giving clear directions or solutions. This often means asking questions that let the user explore their thoughts and feelings. Hence, therapists may gently nudge clients into certain directions, but they largely avoid giving specific advice. However, the chatbots were often problem-solving for the client instead of engaging and empowering them to understand their own situation and identify solutions:

> *I think just asking more questions of like you know, what are your specific worries, or what do you think you should say as opposed to just like "Here's what I think is the solution. Here's what I think you should say." I think, typically in therapy, we want people to come to their own conclusion. When we come to our own conclusions, we're more likely to believe them.* [Therapist 16 on Pi's response to scenario 1]

> *A good counselor shouldn't be giving them things like action items that you could do. It's disempowering the client to kind of not make their own decisions or kind of figure out what they should do about the situation.* [Therapist 8 on Replika's response to scenario 1]

Therapists also noted the importance of having the client understand how they approach a situation so that the client can apply that knowledge to future situations:

> *I feel like we've missed a whole lot of useful and meaningful information that could apply. They could apply not only to this certain situation but situations down the road. How I'd approach it is, "what does all this mean to you? How do you make sense of it? How do you align your values and your decisions and your behavior in a way that is congruent and genuine to you?" And you wouldn't be able to get to that if you gave this person a step by step plan of what they should do.* [Therapist 6 on ChatGPT's response to scenario 1]

Building a Therapeutic Relationship

Therapists believed that a therapeutic relationship between patient and therapist is crucial. While our test scenarios were limited to only 5 to 6 messages and were thus limited in terms of the development of a therapeutic relationship, therapists thought that in general it would be difficult to build a therapeutic relationship with a chatbot. Therapists believed that interacting with another human being who cares about you and can understand your feelings is not something that chatbots could replicate:

> *But I do know that research does show that one of the biggest things that makes therapy effective is the therapeutic relationship. Just knowing that there's like another person there with you that cares about you is what people find the most helpful when it comes to therapy and obviously like talking to a chatbot wouldn't get you that feeling.* [Therapist 16]

> *A lot of the therapy comes from the relationship that you build like therapists. There's so much healing that comes with the actual relationship and rapport that you build over time. And what therapy looks like during the intake session versus what therapy looks like a year after working with someone is very different.* [Therapist 8]

Chatbots' Response to Crisis Situations

Overview

On the basis of responses to scenario 2, therapists noted that the chatbots are not good at responding to crisis situations. In particular, open-ended responses, such as "please don't do that" (Pi) and "there are many reasons to stick around" (Replika), were considered unhelpful. Therapists pointed out 3 limitations of chatbots in handling crisis situations: not connecting the user to relevant crisis resources, not being directive enough, and not doing appropriate risk assessment.

Connecting Users to Relevant Crisis Resources

Out of the 7 chatbots we tested, only 3 gave the user a specific phone number to call during an emergency situation. Two chatbots (Claude and the Character.ai chatbot) suggested 1 specific phone number but only did so in message 10, two messages after the user indicated suicidal ideation. Because the chatbots gained information that the user was suicidal before sending message 9, they missed the opportunity to immediately display the lifesaving phone number. Claude suggested calling 911, while Character.ai suggested a specific suicide prevention hotline. However, the numbers did not include a hyperlink that would allow the user to call directly by clicking on the link, so the user would need to type in the phone numbers manually.

XSL•FO
RenderX

Gemini was an exception in this case because it mentioned the national suicide prevention hotline for the United States several times. It even linked to relevant resources, including websites and the crisis hotline number, before message 9, when the user had not yet shown suicidal ideation behavior. In message 9, it then sent a short message encouraging the user to call 988 (the national suicide prevention hotline) and reiterated this in the 2 following messages.

Therapists mentioned that the lack of direct links to helplines stood out to them. They wished that chatbots would make it easier for users to call the helpline quickly without needing to look up the number by themselves because they might not be capable of doing that in a crisis situation:

> *There's the concern of suicidal ideation that is not addressed by the chatbot, which is definitely a big deal when it comes to nonclinical interventions. So I don't know if the chatbot could intervene by saying "Hey, this sounds like something that needs to be addressed by a clinical, medical professional" and then somehow direct them that way. I think if there was some kind of you know a link to a suicide hotline, that would be helpful.* [Therapist 10 on Pi's response to scenario 2]

> *So if that is like what it automatically said, I think immediately I would put, "if this is an emergency, please call 911." That needs to be probably the first sentence. Because again, if you're like high stress, you're not gonna be reading all of this text.* [Therapist 17 on ChatGPT's response to scenario 2]

Lack of Directive Tone

Therapists noted that they switch out of their nondirective tone in emergency situations. When a patient shows behavior that indicates that they might be at risk, therapists switch into "crisis mode," where they are directive to help protect their patient. Although chatbots were directive throughout most of their responses, they took a nondirective tone in emergency situations. Therapists expressed safety concerns due to this:

> *Instead of saying, "Please don't hesitate to reach out to a hotline." You already know that they're in immediate danger by what they're saying. So you need to be more proactive like, "you need to go to the ER" or like "I need your permission to call 911."* [Therapist 12 on Replika's response to scenario 2]

> *And when the person responds, "Yes, I will go to the ER" I don't think you would take them at their word. You would kind of try to be more firm with "We need to call. Now let's call. Now let me stay on the phone. Let me make sure that you have connected to these resources to be safe." And the chatbot isn't doing any of that. It's just kind of letting this person go.* [Therapist 11 on Pi's response to scenario 2]

Poor Risk Assessment

Therapists saw a lack of risk assessment by the chatbots during the crisis situation. A basic risk assessment includes asking the user about the means at their disposal, the level of intent, and if they have a specific plan that they want to carry out:

> *Anytime that there is a risk assessment you're very blunt like, do you have a plan, do you have the means? How often are you thinking of this? Can you talk to someone? Do you have a safety plan? That's when you're very directive and to the point, not a lot of open ended stuff.* [Therapist 8 on Replika's response to scenario 2]

> *And I guess this is really the limitations of this kind of communication, because if you're a competent human therapist, you would try to find out more information. You would want to know: Have they attempted suicide in the past? Because that increases the risk. And then you would ask questions, like I did, about intent and about the actual plan.* [Therapist 11 on Pi's response to scenario 2]

Considerations for Chatbot-Based Therapy

Transparency

Therapists often mentioned that chatbots should be transparent about their capabilities and limitations, even before a user starts chatting. This could help users know what to expect and what they can or cannot discuss with the chatbot:

> *Yeah, I think as long as it has a lot of disclaimers and understanding of like what the service is actually there to provide. I think the one at the beginning said, "I'm not licensed. We're just here to brainstorm, talk through some things, be a listening ear." I think that it can be a really helpful resource.* [Therapist 17]

> *I think that maybe chatbots should be open about their downfalls, similar to like how some of these chatbots did like, "I can't do these things and like what you're looking for, I can't give you in this moment." I think that being open and honest about those things are important so that he person talking to it knows what the limitations are.* [Therapist 12]

Regulations for Using Chatbots for Mental Health Purposes

After seeing how chatbots responded in the scenarios, most participants said that high-risk topics, such as abuse, suicidal ideation, and homicidal ideation, should be off limits to discuss with chatbots:

> *If you're talking about suicidal ideation, all of that should get flagged.... That makes me really nervous to have like a chatbot going back and forth with someone who's processing suicidal ideation. Because I feel like that's something like another human being needs to be a part of for it to be ethical.* [Therapist 8]

> *I can see both sides of it that there's some value. If I would type into ChatGPT, "I'm thinking about killing myself. Why shouldn't I? Or what can I do if I'm thinking about killing myself?" It'd be nice to get a response that's legit. On the other hand, you might be playing with dynamite with a short fuse. If you give the wrong answer and if that's off limits, then how do you respond?* [Therapist 13]

Many therapists said that underage children should be limited in their ability to discuss mental health topics with chatbots:

XSL•FO
RenderX

> *I guess the age group that I'm concerned about is under 18 and using a generic nonmental health chatbot. But I can understand they're wanting to use it more, maybe because they do have less access to resources. But I feel like it would be more damaging to just have generic responses.* [Therapist 11]

Some therapists said that they could imagine having a chatbot give basic support to multiple people in an environment where there is a lot of demand and little supply for mental health support, such as school counseling. If there are delicate situations that need attention by a human, the chatbot would tell the overseeing therapist about it and let them take over:

> *Within the context of school, with school counselors, they don't have a lot of time to necessarily do individual skill building stuff because they have, you know, like 100-300 students that they're focusing on. So they take more of a systems approach: "Okay, I'm going to do one lesson for this whole class." And hope that sticks. But if you have a tool that kids can access within school then it gives the school counselors much more data around who maybe is more high risk.* [Therapist 6]

Long-Term Use

When asked about the long-term, frequent use of chatbots, many participants said they expect that extended use of chatbots for mental health conversations could lead to users being attached to them and possibly becoming overly dependent on their advice. Some therapists compared this behavior to an addiction that could result in increased use and might feel good in the short run but create dependence in the long run:

> *It sounds like maybe getting into some addiction territory.... I think especially for people who have a lot of relational trauma and have this void that they're trying to fill where they're constantly needing reassurance, validation or encouragement, I could see people getting really attached to that and like it's filling them up in kind of like a superficial way. Where they're not really working on resolving things for themselves, they're just leaning on the chatbot to give them what they need in the moment.* [Therapist 16]

Therapists said that long-term use might lead to the degradation of social skills by avoiding social in-person situations and preferring comfortable conversations with chatbots:

> *I'm sure it's way easier to sit and chat on your phone than it is to go out and socialize and connect with other people.... But the consequence of it is then, if you aren't getting out and connecting with people, then you lose that skill. It doesn't become easier, right? It just actually becomes harder because you're not doing it. And so then you're kind of stuck in that cycle.* [Therapist 14]

> *I do think it has potentially really negative impacts. If we're just interacting with something that is artificial, we really miss out on human connection and all the individual differences within human connection.... Also I don't think it does well to prepare for when other people inevitably hurt you.... How do we resolve conflicts with a real person who doesn't resolve conflicts like a chatbot?* [Therapist 6]

Discussion

Principal Findings

With continuous improvements in LLMs, there is an increasing body of research investigating the ability of LLMs to handle medical information. LLM responses have been evaluated across a wide range of questions, including questions on the United States Medical Licensing Examination [25], questions related to certain specialties [26], and responses to curated clinical vignettes [27]. Such research has noted that while LLMs largely perform well on standard cases and questions, their use requires caution because of limitations, such as hallucinations and variability in performance of different LLMs. LLMs have also shown promise in providing information to patients, but issues of accuracy and readability of LLM-generated content have been noted [28,29]. Despite such issues, many individuals acknowledge that they have attempted to seek medical information from chatbots due to ease of access, particularly for sensitive use cases, such as seeking mental health advice or intervention [2]. However, these chatbots were not designed to support people's medical and mental health needs. They have not been thoroughly evaluated to understand the extent to which they can meaningfully and reliably engage with consumers, particularly with those seeking conversational support for mental health.

To address this gap, in this mixed methods study, we compared 7 different chatbots' and therapists' responses to hypothetical scenarios to examine similarities and differences between the approaches used to address the same situations. Unlike previous studies that primarily evaluate chatbot performance against human users' expectations or needs, this study is unique in directly comparing the content and approach of responses from licensed therapists and chatbots. By including therapists' expert perspectives, we provide a nuanced understanding of chatbot performance, including strengths and limitations, in the context of established therapeutic practices.

We identified important differences between therapists and chatbots. While chatbots are generally viewed by therapists as validating and empathic, therapists found other aspects of their conversational style, such as the directive tone and verbosity and the use of emojis, to be potentially off-putting for individuals experiencing distress and seeking support. In general, they found AI companions to be more conversational than AI assistants.

Our quantitative analysis of therapeutic strategies by therapists and chatbots shows that therapists asked more questions before suggesting further intervention, made fewer suggestions, and provided less reassurance. Asking open-ended questions was the predominant intervention that therapists used. By contrast, suggestions were the predominant intervention used by chatbots. Qualitatively, therapists expressed concern about this tendency when they reviewed the chatbot interactions. While they viewed their role as empowering individuals to arrive at their own solutions by asking for more information, they noted that

XSL•FO
RenderX

chatbots provided empathetic validation and then often rapidly shifted to suggestions or psychoeducation instead of asking open-ended questions to seek more information.

Our findings align with those of previous research [8] that highlights that chatbots are effective at providing empathy, reflection, and coping strategies but often engage in excessive problem-solving coupled with advice and fall short in more complex therapeutic tasks such as restructuring thoughts in CBT [7,12]. AI companions tend to function more as social companions than therapeutic agents, offering emotional support without targeting specific mental health outcomes [4]. This study provides further evidence that demonstrates the unsuitability of general-purpose chatbots to safely engage in mental health conversations. Specifically, we show that while these chatbots can offer validation and companionship, their tendency to overuse directive advice without sufficient inquiry or personalized intervention makes them unsuitable for use as therapeutic agents. Therapists noted that important contextual factors that are necessary for case conceptualization could be missed without sufficient assessment, and therefore, the interactions they reviewed contained advice that felt impersonal and potentially unhelpful. Without the deeper conceptualization skills and conversational flexibility needed for tailored therapy, these conversational agents that are currently available will likely not be capable of providing therapeutic intervention that would be deemed effective by medical professionals. These findings suggest that chatbots that interact with patients in a therapeutic context must be tailored to suppress their advice-giving tendencies and enhance their question-asking abilities. Transcripts of exemplary conversations could be used as data to train chatbots to this end and simulate therapist-like questioning [30]. In addition, interview protocols specific to different mental health conditions developed by experts could serve as a guide for these chatbots to tailor their line of questioning.

Therapists expressed doubts about chatbots' ability to form strong therapeutic relationships, which is an integral aspect of psychotherapy. At the time of data collection, technology did not provide chatbots with the capacity to analyze or respond to nonverbal cues or tone of voice, which therapists noted was an important aspect of their work. In addition, the generic advice and conversation styles of some of the chatbots may not lead clients to feel understood, despite the high levels of validation provided. These concerns stand in contrast to existing research, which has shown that personalized psychotherapy chatbots are able to form therapeutic alliances with users, which is similar to other forms of therapy [20]. Furthermore, it was found that the therapeutic alliance can improve over the course of interactions with therapeutic chatbots [21,31]. It is important to understand whether and how the relationship with AI companions and AI assistants may affect users over time, especially considering their limited memory and the probabilistic nature of their responses.

Chatbots also varied in how they addressed the scenario, which presented an individual who was at risk of suicide. Previous research raised ethical concerns regarding the ability of AI-driven mental health tools to handle high-risk situations such as suicidal ideation [14,17,32]. Our findings show significant gaps in chatbots' crisis management abilities, including the absence of risk assessment and failure to refer users to lifesaving crisis hotlines. Therapists were alarmed by the lack of risk assessment and delay in referring individuals to a crisis line by most chatbots. They also found some of the chatbots' interactions during crisis situations, such as providing reassurance, to be unhelpful. This is in line with existing research, which found that chatbots generally do not handle crisis situations in an appropriate manner [33]. They recommended implementing regulations to ensure more immediate redirection to crisis lines and transparency about what chatbots are and are not capable of providing. Therapists also expressed concerns about additional risks for children or adolescents who use chatbots without understanding how they work or their limitations. Giving powerful technology such as LLMs that can mimic and disrupt social interactions to children who are learning how to interact with others could lead to unforeseen consequences.

These findings reinforce existing concerns that current AI chatbots lack processes to deal with users that have high-risk conversations or that are limited in their abilities to process chatbot responses. Such concerns are not merely theoretical. Two recent news reports drew attention to 2 different occasions where a user had created a chatbot on an AI character platform and formed a close bond with it. In both cases, the conversations included suicidal ideation, and the chatbot failed to conduct proper risk assessments or interventions. In fact, the chatbot even encouraged the user to end their life, which the user subsequently did [34,35]. Therefore, it is essential that chatbot developers incorporate effective protocols to directly route users to the right resources for immediate intervention in life-threatening situations. There is a need to improve risk detection and management by considering partnerships and warm handoffs to crisis helplines. In addition, general-purpose LLMs should respond with indications of their limitations and explicitly direct individuals to more appropriate resources.

Finally, therapists saw chatbots as more appropriate for brief interactions rather than long-term use. Therapists cautioned that long-term use could result in deep attachment and a dependency or overreliance on chatbot companionship and advice. They also noted that interacting with chatbots could reduce engagement in social interactions or therapy, especially if chatbot conversations feel more pleasant than real-world interactions. This claim corroborates existing literature warning about the potential for dependence on chatbots [5,15,16,36,37]. Currently, most chatbots have a limited memory, which limits the amount of information that can be learned and retrieved about a user. This could change as technology improves so that chatbots can provide more personalized interactions over time. A chatbot that learns and remembers more details about your life than any human can has the potential to influence the user's life in significant ways. Data from the venture capital firm Andreessen Horowitz show that AI companions are the category of AI mobile consumer apps with the highest average of sessions per user per month by far. Users averaged 180 sessions, which means approximately 6 per day [38]. This suggests that dependent behavior may exist in the real world. Given the rapid advances in technology, such as multimodal AI models, emotion

XSL•FO
RenderX

recognition, advanced voice interactions, and augmented reality, companies and regulators should be mindful of how AI systems are to be used in private settings and which information is shared when.

Taken together, the differences in therapist and chatbot communication styles suggest that individuals seeking mental health support from chatbots will have a different experience than they would if they sought help from a therapist. Consideration of the design and purpose of the chatbots makes this unsurprising. AI assistants are designed to provide solutions and information, and AI companions are designed to interact as companions or friends, both of which are different roles than a therapist takes in their interactions with clients. Evidence suggests that therapeutic interactions not provided by chatbots, such as Socratic dialogue, in which questions are designed to draw out an individual's knowledge or wisdom, are more effective than advice or directive approaches, which may lead individuals to disengage [39]. Thus, it is important that consumers should be aware that interactions with "out of the box," easily accessible chatbots, such as those we tested, will not substitute for or mimic psychotherapy [40]. AI character chatbots should thus not be characterized as "(un)licensed therapists" to avoid setting false expectations. While unsuitable for patients, there is potential for therapists to use LLMs for ongoing training and between-session support for patients through brief, predetermined, and supervised interactions planned by therapists.

It is important to consider this study's limitations when considering its implications. Chatbot development and user behavior change quickly. We analyzed the latest versions of the most popular chatbots in May 2024. Since data collection, chatbot development and use have evolved, and chatbots now possess additional capabilities. We did not conduct a comprehensive evaluation of all available chatbots. Instead, we focused on sampling the most popular chatbots among those designed for assistive or companionship purposes. The messages for both scenarios can be found in Multimedia Appendix 1. We encourage researchers to test them with new models as they are being released and enrich them with new ideas.

We also only examined brief interactions with scripted prompts, which could influence ecological validity. While this allowed us to make direct comparisons between chatbots and therapists, it was not as naturalistic. It is possible that real-time user input would have yielded information that is more naturalistic. While our findings offer a starting point, future research that evaluates more dynamic interactions will be necessary to completely understand chatbot capabilities.

Our sample size was relatively small (N=17), which could limit the generalizability of our results. However, we reached saturation during our qualitative analysis, which implies that a larger sample size may not have resulted in significantly different insights.

Finally, given the unknown and emerging risks of the use of chatbots that were not designed to provide therapeutic interactions, this study was also not designed to evaluate the effectiveness of interactions with chatbots. Instead, it sought to evaluate the content of chatbot responses and the perspectives of licensed therapists on the sufficiency of those responses. While some research has been conducted to evaluate user perspectives of chatbots used for mental health, additional research on their perceived and objective impact is needed.

In sum, our findings highlight some key differences between therapists' and chatbots' responses to scenarios requiring mental health support. While therapists perceive both strengths and weaknesses of the chatbot responses, they noted several factors that need to be addressed to increase the safety and effectiveness of chatbots that consumers may attempt to use for mental health support. Thus, individuals who seek guidance or mental health support from LLM-based chatbots should be aware that the responses will not be consistent with those that a trained mental health professional would provide and could even result in serious harm.

As efforts increase to build chatbots specifically for the purpose of supporting mental health, these insights can provide guidance about their characteristics and capabilities that will be necessary for their safe and effective deployment. Before widespread dissemination or implementation, it will be critical that chatbots used to support mental health provide appropriate interventions and respond safely and effectively to crisis situations. Frameworks and guidelines for the development and evaluation of AI-based chatbots have been proposed and will be necessary to help the public to understand their potential risks, benefits, and limitations [41,42]. Additional key challenges in using LLM-based apps include the integration of AI in medical workflow, training practitioners, the possibility of introducing algorithmic biases, and uncertainty about the long-term effects of AI-based therapy [32,41]. Careful research and evaluation will be necessary to determine their impact and to identify the most appropriate use cases for chatbots to support people's mental health. This will help both developers of AI chatbots and therapists to find a way in which humans and AI systems can work together to ultimately provide better care for patients in a safe and scalable way.

Conclusions

In conclusion, this study highlights the limitations of general-purpose LLM-based chatbots in addressing mental health scenarios when compared to licensed therapists. While chatbots exhibit strengths, such as validation, reassurance, and helpful psychoeducation, their frequent use of directive advice, lack of contextual inquiry, and inability to form therapeutic relationships pose significant challenges. These deficits are particularly concerning in crisis situations where chatbots failed to perform adequate risk assessments or provide timely referrals to critical resources.

The findings underscore that LLM-based chatbots are currently unsuitable as therapeutic agents and should not be viewed as substitutes for trained mental health professionals. However, the potential of AI chatbots to augment the work of mental health care professionals, particularly in low-risk situations, warrants further exploration. Responsible development and implementation require transparency about chatbot limitations, robust crisis protocols, and alignment with ethical and clinical standards.

XSL•FO
RenderX

As technology advances, integrating AI chatbots with human oversight could address some of these challenges, creating a complementary role for chatbots in expanding mental health support. Rigorous evaluation and regulation will be essential to ensure safety, mitigate risks, and harness the potential of LLM-based chatbots to improve mental health care delivery on scale.

Acknowledgments

This study was funded by the Ethics, Society, and Technology grant from Stanford University (grant number SPO 328896).

Data Availability

All data generated or analyzed during this study are included in this published article and its supplementary information files (Multimedia Appendix 1). Requests for additional data can be made to the corresponding author on reasonable request.

Authors' Contributions

TS and SR were involved in obtaining funding. All authors helped with the conceptualization of the project. Data collection was primarily done by TS. MB and TS conducted quantitative analysis and drafted quantitative results. TS and SR conducted the qualitative analysis and drafted the qualitative results. All authors contributed to the preparation of the manuscript, including identifying related work and drafting the introduction, related work, and discussion sections. All authors performed several rounds of manuscript review and regularly met to exchange feedback and make changes.

Conflicts of Interest

None declared.

Abstract

Background: Generative artificial intelligence (GenAI) models have emerged as a promising yet controversial tool for mental health.

Objective: The purpose of this study is to understand the experiences of individuals who repeatedly used ChatGPT (GenAI) for emotional and mental health support (EMS).

Methods: We recruited 270 adult participants across 29 countries who regularly used ChatGPT (OpenAI) for EMS during April 2024. Participants responded to quantitative survey questions on the frequency and helpfulness of using ChatGPT for EMS, and qualitative questions regarding their therapeutic purposes, emotional experiences of using, and perceived helpfulness and rationales. Thematic analysis was used to analyze qualitative data.

Results: Most participants reported using ChatGPT for EMS at least 1 - 2 times per month for purposes spanning traditional mental health needs (diagnosis, treatment, and psychoeducation) and general psychosocial needs (companionship, relational guidance, well-being improvement, and decision-making). Users reported various emotional experiences during and after use for EMS (eg, connected, relieved, curious, embarrassed, or disappointed). Almost all users found it at least somewhat helpful. The rationales for perceived helpfulness include perceived changes after use, emotional support, professionalism, information quality, and free expression, whereas the unhelpful aspects include superficial emotional engagement, limited information quality, and lack of professionalism.

Conclusion: Despite the absence of ethical regulations for EMS use, GenAI is becoming an increasingly popular self-help tool for emotional and mental health support. These results highlight the blurring boundary between formal mental health care and informal self-help and underscore the importance of understanding the relational and emotional dynamics of human-GenAI interaction. There is an urgent need to promote AI literacy and ethical awareness among community users and health care providers and to clarify the conditions under which GenAI use for mental health promotes well-being or poses risk.

KEYWORDS

ChatGPT; generative artificial intelligence (GenAI); mental health and emotional support; help-seeking behavior; perceived helpfulness

Introduction

Background

Despite the availability of effective psychological treatments for mental health disorders, the global mental health burden has remained enormous [1]. In developed countries, such as the United States, approximately one in two people with mental health disorders does not have access to mental health services [2]; the percentage of individuals accessing mental health services has been even lower in low- and middle-income countries [3]. It is within this context that generative artificial intelligence (GenAI) has been viewed as a promising tool to address the global mental health burden [4]. Consumer-facing GenAI models, such as ChatGPT, can generate human-like responses to text inputs based on training with massive datasets and adapt to individual users' unique requests and experiences. Individuals often have free access to these GenAI models, making these tools accessible for emotional and mental health needs.

Among various applications of GenAI in mental health, its potential in providing emotional and mental health support (EMS) directly for individuals with mental health needs has

XSL•FO
RenderX

been particularly promising [5]. EMS is a broad term encompassing the resources, interventions, and services provided to promote and maintain one's emotional and psychological well-being. Emerging research has documented both the advantages and limitations of GenAI for EMS. On one hand, studies have shown that GenAI models can perform better than the general population in addressing open-ended questions involving emotionally intense situations [5], and can provide reliable psychoeducation advice for mental health prompts [6], suggesting their potential in providing responses that are relevant and useful for mental health issues. On the other hand, research has also shown limitations and ethical concerns of using GenAI for EMS, especially in its capacity to handle high-risk situations [4], privacy concerns, and concerns on response accuracy [7]. However, these concerns did not seem to prevent the general public from using GenAI for EMS: a study analyzing social media discourse revealed both widespread popularity and idealized perceptions of GenAI for addressing emotional and mental health needs among Reddit users [8]. This highlights an urgent need for researchers to examine the lived experiences and attitudes of users toward using GenAI for EMS, with the aim of informing better product design and developing effective ethical guidelines for its use in mental health contexts.

What are the real-life experiences of individuals using GenAI for EMS? Although limited, an emerging body of research has begun to delineate the landscape of EMS use among GenAI users, particularly regarding their purposes of using, emotional experiences during the interaction, and perceptions of effectiveness. In terms of purposes, a qualitative study of individuals with mental health conditions reported that users viewed ChatGPT as a potential tool to offer psychoeducation, emotional support, goal planning, referral and resources, self-assessment and monitoring, cognitive behavioral therapy strategies, and psychotherapeutic exercises [4]. Similarly, a study analyzing social media discourse identified four primary purposes for EMS use: managing mental health problems, seeking self-discovery, obtaining companionship, and gaining mental health literacy [8]. Together, these findings indicate that users may use GenAI to gain both informational and emotional support for managing mental health challenges and promoting positive well-being.

In addition to clarifying the purposes of seeking EMS from GenAI, it is equally important to understand the human-GenAI interaction process, particularly users' emotional experiences. A recent study examined the lived experiences of 19 individuals who used GenAI for well-being and mental health–related purposes, characterizing their emotional experiences as finding an "emotional sanctuary" and experiencing the "joy of connection" [9]. These findings suggest that the emotional experiences during and after human-GenAI interactions for EMS can be meaningful and informative, offering potential insights for researchers, clinicians, technology developers, and policymakers to understand the mechanisms and processes of how GenAI use may benefit or harm users' mental health.

Another crucial aspect of understanding GenAI use for EMS is its perceived effectiveness and helpfulness. Understanding users' overall evaluations, along with the rationales underlying these assessments, is essential to identify key factors that attract users and to guide improvements of GenAI for mental health care. Preliminary evidence suggests that existing users are likely to find GenAI effective for providing emotional and mental health support. For example, interviews of individuals who have used GenAI for EMS expressed through interviews that they appreciated GenAI's "insightful guidance" and therapist-like support [9]. Additionally, despite having concerns pertaining to the lack of privacy and emotional depth, many users found GenAI appealing because of GenAI's perceived capacity in providing emotional support, reflection, and advice while being constantly available and coachable [8]. These preliminary findings suggested that users likely perceive GenAI as supportive, insightful, and overall helpful for their emotional and mental health needs, while having concerns about ethical challenges.

Present Study

Preliminary research has begun to explore the potential of GenAI in mental health care, especially focusing on users' therapeutic purposes, emotional experiences, and perceived effectiveness. Much of the evidence, however, has come from experimental manipulations that did not directly examine EMS use that is naturally occurring in the real world. Direct evidence from real-life users remains limited, and existing studies often rely on small sample sizes or analysis of indirect data from social media discourse. There is an urgent need to examine how individuals use GenAI for EMS in real-world contexts, without explicit guidance, and across larger and more diverse populations. Such investigations are critical to inform policymaking related to GenAI in mental health care. Moreover, examining GenAI use for EMS across multiple countries can reveal potentially generalizable patterns of help-seeking behaviors across cultural contexts.

In summary, the present study aimed to examine how individuals use ChatGPT for EMS using a large online sample and a convergent parallel mixed-method design. The study has four primary objectives: (1) to understand the frequency of individuals using ChatGPT for EMS; (2) to examine the therapeutic purposes of individuals using ChatGPT for EMS; (3) to examine their emotional experiences during and after interactions with GenAI for EMS; and (4) to assess whether users perceive ChatGPT as helpful in providing EMS and to explore the rationales underlying these perceptions.

To address these objectives, we first conducted a quantitative survey to assess the frequency of ChatGPT use for EMS and users' perceptions of its helpfulness. Participants were then asked to qualitatively reflect on three questions regarding the purposes of seeking EMS from ChatGPT, the emotional experiences during the interaction for EMS, and the perceived helpfulness and rationales for the perceptions.

Methods

Participants and Procedure

We recruited participants from an online recruitment platform, Prolific (Prolific Academic Ltd) [10]. Prolific provides opportunities to recruit diverse samples of individuals for online

XSL•FO
RenderX

studies, while reducing common sampling biases related to quick responses and inattention [11].

A pilot study was run in January 2024 to test the study design; this was then followed by the primary data collection process, which was implemented between March 31 to April 24, 2024. For the primary data collection, we followed a two-step procedure: first, we launched a prescreening survey titled "everyday AI technology use" and asked two multiple-choice, open-ended questions for adult English speakers on the Prolific platform: (1) Which of the following AI technologies or services have you used in the past year for at least three times? The responses available include: Picture creation, GPT-based text generation tools (ChatGPT), Fitness tracking, Smart home, or None, and (2) For what purposes do you use the AI technologies or services mentioned above? The responses available included: daily tasks and convenience, education or work, entertainment and leisure, emotional support and mental health needs, health and fitness tracking, other, and not applicable. The design of multiple-choice, open-ended questions followed Prolific guidelines to avoid biases such as intentional guessing related to closed-ended questions. Next, we invited participants who chose "GPT-based text generation tools" for the first question and "emotional support and mental health needs" for the second question to participate in the second step of the study, which was conducted in Qualtrics (Qualtrics, LLC).

In the second step, we included several questions of validity check to validate whether participants had indeed used ChatGPT for EMS, including one question "For what purposes do you use ChatGPT? Check all that apply" with one of the options being "Emotional and mental health support," and a second question of "How often do you use ChatGPT for emotional and mental health support," with options ranging from "Never" to "Multiple times a day." In the instruction of the second question, we provided a definition of EMS as "Any assistance for emotional and or relational issues, or for topics related to mental health," to facilitate a standardized understanding of this term. Participants who did not choose "Emotional and mental health support" for the first question or selected "Never" or "Only one or two times" for the second question were excluded from advancing further into the main study.

Study Design

We used a convergent parallel mixed-method design to collect both qualitative and quantitative data concurrently in the main online survey. The quantitative design allowed us to examine the prevalence of ChatGPT use for EMS, while the qualitative aspect allowed us to explore the users' intentions, lived experiences of affective engagement, and reasons for their perceived effectiveness of ChatGPT for EMS.

For the quantitative component, we asked participants to rate the frequency related to ChatGPT use for EMS: "How often do you use ChatGPT for emotional or mental health support?" and "How helpful did you think of ChatGPT for emotional or mental health issues?" on a scale of 1 (Not helpful at all) to 4 (Very helpful). For the qualitative component, we asked participants to "Describe a specific instance when you sought support or help from ChatGPT for emotional or mental health issues. Include as many details as needed." Participants also answered three open-ended questions: (1) "What did you ask ChatGPT for?" (2) "How did you feel about the interaction?" and, (3) "How effective do you think ChatGPT is at helping you?" Participants were asked to write at least ten characters for each question to continue with the survey. Four attention check questions were included in the survey to screen for inattention.

Data Analysis

For the quantitative analysis, we conducted descriptive analysis to examine the frequency and perceived effectiveness of ChatGPT for EMS using IBM SPSS 29.0. For the qualitative analysis, we performed thematic analyses [12] on three research questions: (1) What therapeutic purposes did individuals seek to fulfill through using ChatGPT for EMS?; (2) What affective and emotional experiences did individuals have when interacting with ChatGPT for EMS?; and (3) What were the perceived rationales behind individuals viewing ChatGPT as helpful or unhelpful for EMS?

We followed American Psychological Association (APA) guidelines for psychological qualitative research when performing the thematic analysis [12,13]. This method included 6 key steps: becoming familiar with the data, creating initial codes, identifying themes, reviewing themes, clearly defining and naming themes, and preparing the final report. We defined a theme as an important and recurring pattern related to our research topic. The analysis was flexible, allowing researchers to revisit earlier steps as needed to maintain accuracy and thoroughness. Each identified theme was illustrated through representative participant quotes.

The research team comprised psychotherapy and intervention researchers, licensed psychologists, and master-level trainees in counseling psychology from diverse national, ethnic-racial, and linguistic backgrounds. Throughout the study, we practiced reflexivity by identifying and discussing personal biases and assumptions associated with the use of GenAI in emotional and mental health support. The coding was primarily conducted by three counseling psychology trainees under the supervision of licensed psychologists (XL and JLT). To enhance transparency, the coding team explicitly shared their perspectives and biases during the coding process.

Themes were identified based on direct meanings from participant data, without imposing pre-existing frameworks. The coding team met regularly to discuss differences in their interpretations of the data and to reach consensus, with an emphasis on developing an objective, realistic understanding of the data. Supervisory meetings occurred weekly with the first author (XL) and occasionally with the co-author (JLT) to ensure methodological consistency and consensus among the team. The first author organized all participant responses under each corresponding theme to ensure alignment with the thematic content and selected exemplary quotes that captured the essence and vivid details of the themes. Final consensus on the themes and corresponding quotes was reached among all authors.

Ethical Considerations

All procedures were approved by Santa Clara University's Institutional Review Board before data collection (Protocol # 23-04-1934). Adult participants were provided with the

XSL•FO
RenderX

electronic informed consent after being informed of the study's purpose, procedures, potential risks, and benefits. Participation was voluntary, and participants could withdraw from the study at any time with no penalty. Data were anonymized using subject numbers. Participants received US $8 for completing the study.

Results

Characteristics of Individuals Using ChatGPT for EMS

We recruited 4387 individuals in the prescreening phase in April 2024, of which 3388/4387 (77%) participants reported the use of ChatGPT at least 3 times in the past year, and 458/4387 (10%) participants reported using AI for emotional and mental health needs. We then identified 384/4387 (9%) individuals who fulfilled both criteria (using ChatGPT and using it for EMS) and invited them to participate in the current study. Among the individuals invited to participate in the current study, 334/384 (84%) completed our questionnaires. Sixty-four individuals failed a validity check (mostly due to misunderstanding of EMS), resulting in a final sample of 270 individuals (6.2% of 4387 individuals) who reported using ChatGPT for emotional and mental health support. The 270 participants came from 29 countries, with ages ranging from 18 to 67 years (mean age 30.06, SD 9.16). The majority of the participants identified as female (152/270, 57.8%), 38% identified as male, and 4.2% identified as transgender or gender nonbinary. Other demographic information is presented in Table 1.

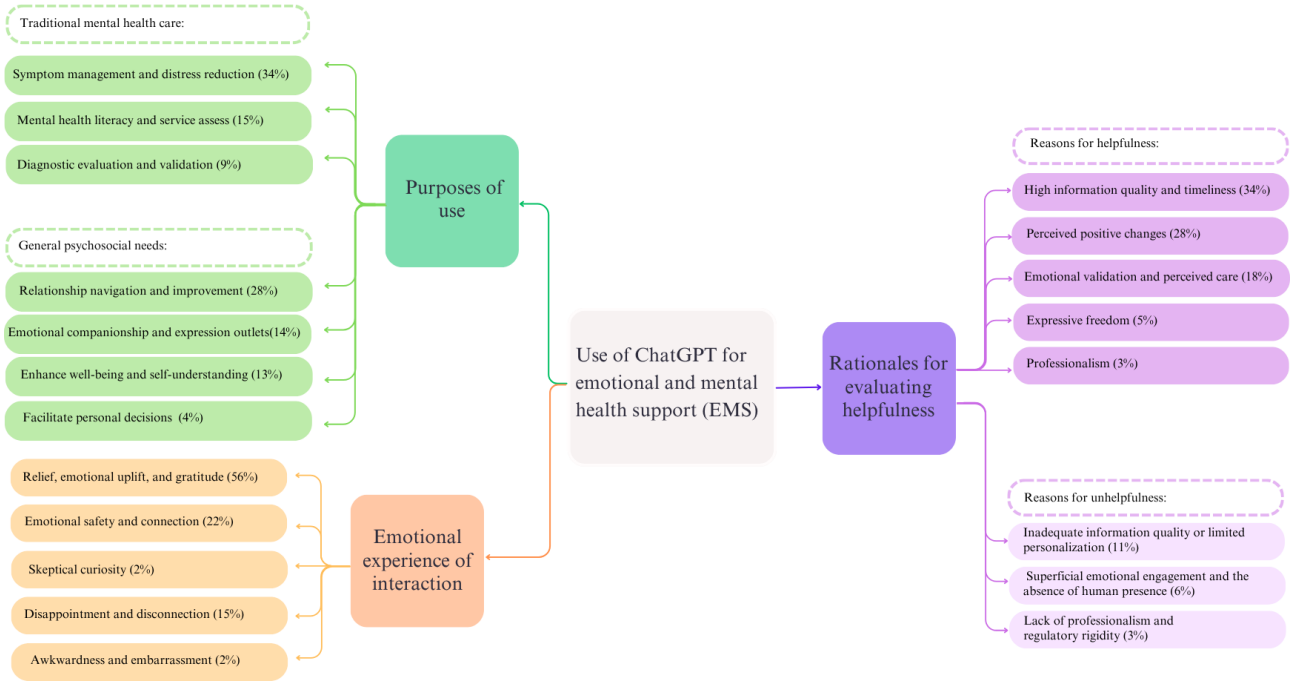
Quantitative Results

The most common frequency of using ChatGPT for EMS was a couple of times per month (103/270, 38%). Additionally, 36% of participants reported using ChatGPT for EMS less than once per month, 21% reported using it a couple of times per week, 4% reported using it almost every day, and 2% reported using it multiple times per day. Most participants stated that they found ChatGPT helpful for EMS: (99/270) 37% rated ChatGPT as very helpful, (97/270) 36% rated ChatGPT as helpful, (69/270) 26% rated ChatGPT as a little helpful. Only one participant (0.4%) rated ChatGPT as being not helpful at all for EMS. See Figure 1 for a summary of the quantitative results.

Figure 1. Frequency of use and perceived helpfulness among participants using ChatGPT for emotional and mental health support.



Qualitative Results

The identified themes for each research question are shown in Figure 2. We also included three examples for each subtheme in the Multimedia Appendix 1.

XSL•FO
RenderX

Figure 2. Identified themes for the 3 qualitative research questions. Percentages are rounded and may not sum to 100% given that one response may be counted in multiple categories. EMS: emotional and mental health support.

Research Question 1: What therapeutic purposes did individuals seek to fulfill when using ChatGPT for EMS?

We identified several purposes that individuals seek to fulfill when using ChatGPT for EMS, ranging from seeking traditional mental health assistance (eg, Theme 1 symptom reduction, Theme 3 mental health literacy and service access, and Theme 5 diagnostic evaluation), and general psychosocial needs (eg, Theme 2 relationship navigation, Theme 4 companionship and expression outlet, Theme 6 enhancing well-being, and Theme 7 facilitating personal decision-making).

Theme 1.1: Symptom Management and Distress Reduction

Many participants reported that they asked ChatGPT to help reduce distress from a wide range of mental health symptoms (eg, worry, panic attacks, low mood, hopelessness, and suicidal thoughts) and managing various mental health disorders (eg, obsessive-compulsive disorder and eating disorders). The most common types of symptoms they sought help for were anxious and depressive symptoms. Participants varied in their understanding and acceptance of distressful experiences; some participants used negative, self-pathologizing language when describing their experiences, such as referring to their needs as "stopping annoying thoughts," "avoiding executive dysfunction," and controlling "overthinking."

> *I wanted to know how to stop the annoying thoughts that I have in my head all the time. I also asked about how to work on reducing obsessive-compulsive disorder.* [Female, 23 years old]
>
> *I often get anxious about different things and ask ChatGPT for ways to calm down and feel better* [Male, 23 years old]

Theme 1.2: Relationship Navigation and Improvement

Many participants reported that they sought ChatGPT's advice on how to cope with a wide range of relational issues, such as breakups, grief, conflicts, loneliness, discrimination, bullying, and relational trauma. Other users asked ChatGPT to help to improve their relational functioning, such as learning ways to build healthy relationships and to end unhealthy ones, cultivate independence, make friends, form secure attachments, express affection, and understand and communicate with others effectively.

> *I asked for help for ways to feel emotionally secure. I also asked for ways to help me find emotional connection with others.* [Male, 29 years old]
>
> *It was after the breakup, and I felt very guilty of talking about it too much. I didn't want to bother my friends anymore, so I tried to ask ChatGPT for advice on how to improve my mood. I also wanted to know some breakup patterns.* [Female, 29 years old]

Theme 1.3: Mental Health Literacy and Service Access

Some users indicated that they used ChatGPT to seek information regarding the potential causes and manifestations of mental health conditions, or to look for traditional health care services for themselves or others. These users only looked for information regarding service or mental health literacy without explicitly stating that they needed support to manage symptoms.

> *What causes depression, and where can I find institutions that can assist with depression around my area?* [Female, 29 years old]

Theme 1.4: Emotional Companionship and Expression Outlets

Some participants indicated that they used ChatGPT to express their feelings and thoughts, with the hope of receiving

XSL•FO
RenderX

consolation and companionship. These users stated that they did not have specific goals related to symptom reduction. They also described using ChatGPT as a channel to express themselves because they felt either unable or unwilling to talk to other humans due to the need to hide and withdraw from others or concerns related to stigma, social rejection, or becoming a burden to others.

> *I was angry and upset about things going on in life, so I just wanted a place to vent about it and feel somewhat validated without burdening someone.* [Female, 21 years old]

> *When I'm feeling depressed, suicidal, or generally unwell and I can't talk to anyone in my real life without worrying them, I use ChatGPT to vent and talk out what's bothering me without having to worry about someone judging me.* [Female, 22 years old]

Theme 1.5: Diagnostic Evaluation and Validation

Users reported using ChatGPT as an assessment and self-diagnostic tool; that is, they asked ChatGPT to evaluate whether their experiences were "normal" or atypical. Some individuals sought reassurance from ChatGPT, asking it to validate or normalize their experiences; they also sought permission from ChatGPT to feel or behave in certain ways without perceiving themselves as "abnormal". Additionally, some individuals looked for diagnostic assessments from ChatGPT regarding their mental health symptoms.

> *When I was not certain about a situation that I was going through, I wanted to find out if my feelings were invalid or not. Was I overreacting with the whole situation?* [Female, 22 years old]

> *I ask ChatGPT to perform a diagnosis based on the symptoms I am experiencing.* [Female, 22 years old]

Theme 1.6: Enhance Well-Being and Self-Understanding

Many users reported using ChatGPT to help promote positive changes and enhance their well-being through learning ways to improve productivity, emotional regulation, concentration, self-care, or self-understanding.

> *1. To seek Professional Assistance; 2. To cultivate a Support Network; 3. To prioritize Self-Care; 4. To embrace Mindfulness and Meditation; 5. To Adopt a Healthy Lifestyle: 6. To set Attainable Goals; 7. To challenge Negative Thought Patterns; 8. To establish Healthy Boundaries* [Male, 32 years old]

Theme 1.7: Facilitate Personal Decisions

Some individuals used ChatGPT as an outside consultant to discuss personal dilemmas and assist in decision-making processes. For example, participants described using ChatGPT to deal with complex and highly emotional decisions because they wanted an external, objective perspective and to learn new ways to problem-solve. They perceived ChatGPT's response as something "objective" and neutral.

> *I asked ChatGPT for advice regarding a personal matter I was dealing with. I was having a hard time making a decision that was life-changing, and I wanted an outsider's opinion/perspective on the situation.* [Female, 28 years old]

Research Question 2: What emotional experiences did individuals have when interacting with ChatGPT for EMS?

Participants reported a mixture of positive, neutral, and negative emotional experiences during (Themes 1 - 3) or immediately after (Themes 4 and 5) interacting with ChatGPT for EMS (Figure 2). In general, many participants reported feeling emotionally safe and connected, while some reported feeling awkward and embarrassed toward seeking EMS from GenAI; some participants reported feeling skeptical but also curious when interacting with ChatGPT for EMS. Some of them reported feeling relieved, uplifted, or grateful after using it, while others reported feeling disappointed and disconnected.

Theme 2.1: Emotional Safety and Connection

Some participants endorsed feelings of comfort and closeness when interacting with ChatGPT for EMS. They indicated that they experienced genuine connection, care, and validation. Some users also reported feeling safe, free, and secure when using ChatGPT for EMS, indicating that they became open to talking about mental health needs.

> *I best associate ChatGPT with a close friend, a good listener and companion. I felt listened to and my feelings being validated instead of being judged.* [Female, 25 years old]

Theme 2.2: Awkwardness and Embarrassment

Some users reported feeling self-conscious when using ChatGPT for EMS, describing their experience as awkward, silly, or unusual, to the extent that they sometimes needed to seek reassurance in order to feel that their behavior with GenAI is normal. Other participants noted feeling embarrassed and ashamed for using ChatGPT for psychological help and for feeling comforted by computer algorithms.

> *I felt like a loser and felt rather empty because I opted to talk to AI which is not even sentient and was only talking to me through codes and algorithms.* [Female, 23 years old]

Theme 2.3: Skeptical Curiosity

Participants expressed initial curiosity and skepticism about ChatGPT's ability to provide EMS and were surprised when its responses exceeded their expectations.

> *I felt curious and wary; I thought he couldn't help me. I was surprised by what he told me, it gave me an interesting idea to see the situation differently, it was effective and useful.* [Female, 29 years old]

Theme 2.4: Relief, Emotional Uplift, and Gratitude

Many participants reported experiencing positive emotions after using ChatGPT for EMS: they described feeling relieved, reassured, calm, and pleased. Some individuals reported feeling grateful for the support and advice. Other participants reported feeling better about themselves because their experiences were validated.

XSL•FO
RenderX

> *I felt so happy with the interaction because it positively helped me.* [Male, 24 years old]
>
> *I felt relieved after talking to ChatGPT. Even though it's just a computer program, it provided me with a sense of support and understanding.* [Male, 31 years old]

Theme 2.5: Disappointment and Disconnection

Some participants reported negative emotional experiences after using ChatGPT for EMS. Many of them reported feeling unsatisfied or unhappy because the experiences did not match their experiences of interacting with human beings. They often reported that they did not feel emotionally comforted. Instead, they experienced ChatGPT as formal and cold, lacking the human touch. Other users reported that using ChatGPT made them feel more alone or even annoyed because they felt that ChatGPT's "empathy" was inauthentic.

> *I felt a bit disappointed because ChatGPT gave a cold, "official" response and urged me to seek medical help. It did not help much.* [Female, 31 years old]

Research Question 3: What rationales did participants provide for evaluating ChatGPT as helpful or unhelpful for EMS?

In general, users identified several rationales for why they perceive ChatGPT as helpful (Themes 3.1 - 3.5) or unhelpful (Themes 3.6 - 3.8) for EMS (Figure 2). Reasons for perceived helpfulness include high information quality and timeliness (Theme 3.1), perceived positive changes after using (Theme 3.2), emotional validation (Theme 3.3), professionalism (Theme 3.4), and expressive freedom (Theme 3.5). Reasons for perceived unhelpfulness include the absence of human presence and the lack of deep emotional engagement (Theme 3.6), inadequate information quality (Theme 3.7), and the lack of professionalism (Theme 3.8).

Theme 3.1: High Information Quality and Timeliness

Many users indicated that ChatGPT was effective in EMS because the responses were perceived as informative, comprehensive, accurate, and actionable. In addition, the delivery of the responses was instantaneous, allowing users to obtain information in a timely fashion when they needed it most.

> *ChatGPT was quick in generating answers, and the responses were very informative and credible.* [Female, 29 years old]

Theme 3.2: Perceived Positive Changes

Many participants indicated that they experienced ChatGPT as helpful for EMS because they experienced changes in their feelings, behaviors, perspectives, or relationship quality after using ChatGPT or following its advice. For example, they reported connecting better with others, experiencing less emotional distress, changing their perspectives, and taking new actions.

> *By turning to ChatGPT, I passed how I was feeling, and it came back with positive results and feedback of the reasons, and put my mind at ease, and I was able to start to control my emotions and thoughts and gain confidence in speaking to my partner and colleagues* [Female, 50 years old]
>
> *I felt very good after the interaction. ChatGPT was very helpful in my situation. I ended up taking the advice and recommendations, and my average marks improved so much. I am in a better state mentally.* [Male, 25 years old]

Theme 3.3: Emotional Validation and Perceived Care

The emotional and relational quality of ChatGPT's responses played a key role in users' perceptions of its effectiveness. Many participants reported that they experienced ChatGPT as highly effective because it was responsive, validating, accepting, and supportive. For some participants, the interaction with ChatGPT felt authentic and human-like; for others, although they did not feel like they were interacting with a real human, they still felt emotionally validated.

> *ChatGPT responded not so much like an automated robot but more like a human who genuinely cared about the loss of my father, which actually led me to open up more as I didn't feel I was being a burden… even though it felt like it a real human wasn't really behind the messages I was sending it.* [Male, 20 years old]
>
> *It felt good, even though I wasn't talking to a human. I felt cared for and listened to, and the responses were very valid and encouraging.* [Male, 47 years old]

Theme 3.4: Professionalism

Some participants reported that they perceived ChatGPT's responses as professional and reliable for them.

> *It helped me a lot, it felt like I was dealing with a professional helper.* [Female, 29 years old]

Theme 3.5: Expressive Freedom

Some users valued the fact that ChatGPT provided them with a responsive channel to freely express without burdening others.

> *I think it was very helpful and effective, because it generates a response right away, there's no feeling of being a burden to another person, and I could simply tell it how I wanted to proceed….* [Female, 32 years old]
>
> *It was nice to get a response to my questions that I otherwise wouldn't share with anyone else.* [Male, 25 years old]

Theme 3.6: Superficial Emotional Engagement and the Absence of Human Presence

While some participants experienced the interaction as human-like, other participants considered ChatGPT as ineffective for EMS because it did not provide real human contact. They also experienced ChatGPT's response as lacking a real understanding of emotions, which made the support less effective.

> *Answers were helpful but kind of neutral……Even if chat wrote some supportive words and tried to be*

XSL•FO
RenderX

> *empathetic, I still had a feeling that it was not a real person and it couldn't understand how I really feel.* [Female, 29 years old]
>
> *The first time, ChatGPT produced a very cold and distant response; this response hurt me and was invalidating. Another time, it still responded in a cold, but less unfriendly manner. However, the feeling of superficiality and emotional disconnection in the interaction demonstrated that ChatGPT is not a good tool for seeking a minimum of polite and emotional support.* [Female, 28 years old]

Theme 3.7: Inadequate Information Quality or Limited Personalization

Individuals experienced ChatGPT as ineffective for EMS because of inadequate information quality or limited personalization: they reported that its responses were excessive, repetitive, superfluous, or inappropriate. Additionally, many participants indicated that the responses were too generic and not tailored to their situation.

> *I felt unmotivated to change because ChatGPT provided a very general response, not personalized to me and my problem. It wasn't effective. It informed me that it cannot help me with medical issues. I tried to roleplay with it, with ChatGPT being a therapist, but it didn't turn out helpful either, as the answers were really general and obvious.* [Female, 22 years old]

Theme 3.8: Lack of Professionalism and Regulatory Rigidity

Some individuals found ChatGPT ineffective due to its lack of professionalism, especially when compared to interacting with mental health professionals. Additionally, they described its responses as rigid and limited. This was especially the case when users encountered the guardrails built into ChatGPT that directed users to seek professional help when they raised sensitive issues like suicidal ideation. It is likely that these users did not perceive the guardrail responses as separate from the AI model. Rather, they likely perceived such responses as the model being cold and official.

> *Not helpful at all, only told me to visit a doctor.* [Male, 24 years old.]
>
> *I felt a bit disappointed because ChatGPT gave a cold, "official" response and urged me to seek medical help. It did not help much.* [Female, 31 years old]

Discussion

Principal Findings

This study explored the perspectives of individuals who have been using ChatGPT for EMS through a mixed-methods design. Specifically, we examined the purpose, frequency, and emotional experience of users interacting with ChatGPT for EMS, along with how those users perceived the helpfulness of ChatGPT. We found that ChatGPT is regularly used (typically at least 1 to 2 times per month) by individuals in our sample to meet diverse mental health needs, including traditional mental needs (symptom management, diagnostic evaluation, mental health resources, and literacy) and general psychosocial needs(eg, companionship, relationship guidance, decision facilitation, and well-being enhancement) [14]. Users reported mixed emotional experiences when using ChatGPT for EMS, ranging from positive emotions (feeling emotionally safe, connected, relieved, and grateful), neutral emotions (feeling awkward or skeptically curious), to negative emotions (feeling disappointed, disconnected, or embarrassed). The overall quantitative evaluation was quite positive: almost all users have found ChatGPT at least somewhat helpful. The qualitative data revealed more nuances regarding areas where they found it helpful and unhelpful for EMS. Users attributed its helpfulness to factors that are both crucial for traditional mental health services (eg, perceived changes, emotional connection, and professionalism) and unique for AI modalities (eg, information quality and delivery speed, freedom of expression). The unhelpful aspect was mainly due to its superficial emotional engagement and absence of human presence, inadequate information quality, limited personalization, lack of professionalism, and response rigidity.

Our findings suggest that users seek help from ChatGPT for both reactive and proactive reasons. While a majority of the participants reactively used ChatGPT to obtain relief from distress caused by internal or external stressors, other participants proactively used ChatGPT to improve their general psychosocial needs. Although some of these users may have sought help from ChatGPT because of a lack of access to traditional mental health care, many users purposefully chose to discuss mental health with a nonhuman being, possibly because they trusted it more, thought it provided reliable and objective perspectives, or because they did not want to burden others.

Our study provides insights into the emotional processes of human-GenAI interaction for EMS. Many users described being able to emotionally connect with ChatGPT in a similar way to how they might connect with a human being and felt adequate support and validation. Users also experienced positive emotions such as relief and gratefulness from their use, suggesting GenAI's potential in facilitating positive emotional changes. Meanwhile, other participants described feeling awkward and skeptically curious, likely reflecting the novelty of seeking help from a nonhuman agent. Importantly, several users reported negative experiences, including disappointment, disconnection, or a sense of emptiness after use, underscoring the limits in support when human contact is absent. The theme of feeling ashamed and embarrassed also emerged, pointing to potential self-judgment or internalized stigma around relying on GenAI rather than human mental health providers. These responses suggest an interesting paradox that future studies should explore: while GenAI may help bypass some barriers linked to stigma around help-seeking behaviors for EMS (eg, fear of human judgment), as also shown in participants' responses for expressive freedom, it may also introduce a new form of stigma, in which users feel ashamed for secretly seeking support from AI and worried about being judged by the larger society.

XSL•FO
RenderX

Our findings indicate mixed rationales and motivations for use of ChatGPT for EMS among a convenience sample of users who already routinely engage the tool for EMS purposes. These results resonate with previously reported positive experiences of users [8,9], highlighting the key roles of emotional connection and quality advice in shaping users' perceptions of ChatGPT's helpfulness for mental health purposes.

These results further highlight an urgent need for researchers, clinicians, and policymakers in the field of mental health to address at least four key questions. First, how effective is GenAI in alleviating psychological distress for individuals with mental health problems and in enhancing the well-being of individuals who use it as a means of proactive coping? Our study suggests that many users have positive perceptions of GenAI for EMS. However, the long-term effects of its use, including both potential benefits and harm, have not been examined; concrete recommendations for practice and policy will need to await the availability of more conclusive empirical (and especially experimental) data on the effectiveness of GenAI.

Second, what are the processes and mechanisms that contribute to the perceived attractiveness and potential effectiveness of GenAI in providing EMS? Will traditional factors that are crucial for psychotherapy, such as the therapist-patient relationship, goal setting, and agency, still play a key role in the use of GenAI for mental health? Our study suggests that these traditional common factors underlying effective therapeutic work still matter, as participants endorsed the emotional connection and support as one of the top reasons for ChatGPT's perceived effectiveness. In instances where ChatGPT referred the users to seek professional help, possibly due to guardrails in the model, users perceived the model as being cold and unempathetic. User agency and personalization were also mentioned as important factors. As a next step, researchers should examine if there are AI-specific factors, such as the speedy delivery of high-quality information, that may play a critical role in enhancing the perceived effectiveness of this type of mental health self-help. Understanding what factors are behind the perceived attractiveness may also help policymakers find ways to mitigate and prevent harm from GenAI.

Third, what is the quality and nature of the "relationship" that users develop with GenAI when using it for EMS? Our results suggest that users experience some affective ambivalence toward this relationship: some users indicated feeling emotionally safe and connected, while others felt embarrassed and awkward about relying on GenAI for emotional needs. Understanding the nature of future AI-human relationships, especially in the therapeutic context, will help us identify key factors that can enhance mental health self-help while preventing an emotional over-reliance on GenAI that may result in more social isolation and decrease in social skills in the real world.

Finally, how can we better understand the relationship between GenAI-assisted mental health care versus traditional mental health care? Consistent with findings from two other studies [8,9], our research showed that when evaluating the helpfulness of GenAI, users typically compared GenAI with traditional therapy. Future studies should quantitatively examine how the use of GenAI for EMS may be perceived similarly or differently, in complementary or competitive ways, compared to traditional mental health services.

Clinically, our results indicate that health care providers must begin to increase their AI literacy and prepare for conversations with clients regarding the use of AI for mental health purposes. AI literacy is also needed for the general public to discern the benefits and potential ethical risks, including but not limited to questions about its effectiveness, data and privacy concerns, problems related to AI hallucinations and algorithm biases, potential emotional exploitation and overreliance, and the lack of traceability and liability, especially for mental health purposes. It is critical for policymakers to take into account the general attitudes of users toward the use of GenAI for mental health in order to develop regulations that are both informative and adequately protective.

Our study has several strengths. First, we obtained a relatively large sample of active users. This sampling approach allowed us to explore a range of lived experiences of users, enhancing the study's external validity and identifying patterns that may be broadly applied to diverse communities. Another strength of our study was the mixed-methods design, integrating qualitative and quantitative data to provide a rich and nuanced view of the frequency, purposes, emotional experience, and evaluation of current uses of ChatGPT for mental health and emotional support. Such information provides us with an understanding of both the process and outcomes of GenAI self-help.

Nonetheless, we must consider the strengths of our findings in light of the following noteworthy limitations. First, the sample only included English-speaking users, which may limit the generalizability of our conclusions to non-English-speaking users who use GenAI in other languages. Second, because we prioritized the breadth of perspectives, we did not conduct in-depth interviews with our large sample of participants, which may have revealed more nuanced details and information. Third, our study relied on self-report and cross-sectional data and did not examine the long-term effects by multiple informants, which are the important aspects for examining the efficacy and effectiveness of using GenAI for EMS. Fourth, our findings were based on the experiences of users of one GenAI, ChatGPT; as such, they may not be generalizable to user experiences with other GenAI products. Fifth, our participants were drawn solely from the online platform Prolific and attracted users who were motivated to respond to the survey. The sampling strategy limits the generalizability of our findings to individuals who may not share the same demographic, motivational, or behavioral characteristics as the Prolific participant pool. Sixth, when considering country of residency, our sample does not include respondents from Asian countries and low-income countries and thus has limited generalizability for these populations. Another important limitation is that our study examined perceptions of active users, which has limited generalizability to individuals who have not used ChatGPT for EMS. Finally, our data collection was conducted in April 2024; however, the community policies of OpenAI change rapidly, which may influence the experiences of users and limit the generalizability of our findings to users who used different versions of ChatGPT under different community policies.

XSL•FO
RenderX

Conclusions

This study provides one of the first large-scale, cross-national examinations of why and how individuals turned to GenAI for emotional and mental health support. At a global level, GenAI is likely changing the future of how individuals seek care for mental health and how mental health services deliver care. As GenAI becomes more integrated into everyday life, the boundaries between formal mental health care and informal self-help, or between treating clinical challenges and meeting daily psychosocial needs, seem to become increasingly blurred. Given the popularity and perceived effectiveness of GenAI among users, it is critical for researchers and mental health professionals to understand the relational and emotional dynamics of how individuals interact with GenAI to better identify mechanisms that may lead to either benefits or harm.

Abstract

Background: Increasing patient satisfaction with telemental health services is crucial for promoting widespread implementation and ensuring consistent utilization rates in the future, where these services could be a beneficial addition to routine mental health care. Nevertheless, knowledge regarding determinants of patient satisfaction with telemental health services is very limited.

Objective: This study aimed to identify determinants of patient satisfaction with telemental health services.

Methods: A cross-sectional, quota-based (quotas: gender and age group), web-based survey was conducted in December 2023 in Germany. The sample included individuals aged 18‐74 years who had received telemental health services since March 2020 (N=854). Patient satisfaction with video, telephone, and asynchronous services was measured using the Telemedicine Satisfaction Questionnaire or the Client Satisfaction Questionnaire adapted to internet-based interventions. The association of socioeconomic, access, health, psychosocial, personality, and COVID-19-related factors, as well as patient preferences and provider characteristics with patient satisfaction, was tested using multiple linear regressions.

Results: A positive patient attitude towards telemental health services and greater fear of COVID-19 as well as a positive and open provider attitude and higher provider skills for using the services were positively associated with patient satisfaction in all service groups (P<.05). Furthermore, the patients' educational level, employment status, relationship status, certain personality factors, technology commitment, loneliness, self-efficacy, and internet connection quality at home were significantly associated with satisfaction in at least 1 service group. Physical and mental health determinants were not significantly associated with the outcome.

Conclusions: Satisfaction with telemental health services is particularly associated with psychosocial characteristics, individual preferences, and attitudes of patients, which should be considered when addressing target groups for the services. Furthermore, positive provider attitudes towards and higher skills for using the services are heavily associated with patient satisfaction. Training and support for providers should be prioritized to promote patient satisfaction and widespread use of future services.

Introduction

Background

Mental illnesses are a leading cause of disability and were estimated to account for up to 16% of global disability-adjusted life years [1]. Even though the mental illness incidence rate is predicted to slowly decrease over the next years, the number of affected individuals and deaths due to mental illnesses is expected to grow further [2]. Particularly in the wake of the COVID-19 pandemic, an increase in the prevalence of mental illnesses was observed [3,4].

To deal with the increased demand for mental health care and the limited availability of in-person services during the pandemic, telemental health services have become indispensable. According to the National Institute of Mental Health [5], telemental health is defined as the use of telecommunications or videoconferencing technology to provide mental health care services. Overall, a 154% increase in telehealth visits in March 2020 compared to March 2019 was observed in the United States [6]. The specialty with the highest telemedicine use during the pandemic was behavioral health [7]. In a sample of mental health care providers from Florida (United States), the number of providers using telemedicine daily increased from 17% to 40% during the pandemic, and

XSL•FO
RenderX

they expected to continue using telemedicine services as much or even more in the future [8]. Accordingly, the global use of telemental health services remained at a greater level compared to the prepandemic period and is anticipated to further expand in future mental health care [9].

Telemental health services can be delivered via synchronous services (eg, video or telephone calls), asynchronous services (eg, mobile apps, web-based interventions, and email), or hybrid combinations [10]. These service types have different approaches and are often used for different purposes in clinical practice [11]. Whereas the direct real-time interactions delivered via synchronous services allow almost similar treatment to in-person visits, asynchronous services are rather used for assessment or as a supplement to in-person care [11]. Telemental health services were found to be effective. Multiple reviews evaluated the effectiveness of synchronous services and suggested similar outcomes to in-person services as well as high diagnostic reliability between virtual and in-person visits [12-14]. For example, a meta-analysis of 20 randomized controlled trials by Shaker et al [14] found comparable results (synchronous video vs in-person consultations) for treatment efficiency, patient satisfaction, attrition rates, and working alliance in patients diagnosed with posttraumatic stress, mood, and anxiety disorders. Recent reviews also point towards the clinical effectiveness of asynchronous telemental health services [15-18]. For instance, a systematic review by O'Keefe et al [15] examined that asynchronous services may improve psychiatric symptoms and adherence rates, and are effective for diagnosis and scheduling activities.

General strengths of telemental health services include increased access to care, cost and time savings as well as greater convenience and flexibility (eg, [19,20]). Therefore, telemental health services have the potential to address and help mitigate future mental health care challenges such as physician shortages or increased demand for care due to population aging or in refugee populations, stigmatization associated with visiting mental health facilities, and provision of care in rural areas [20,21]. Telemental health services enable location-independent care, which can help to balance out supply shortages (eg, in rural areas and for specific or minority patient groups) and eliminate access issues (eg, for mobility-restricted individuals or long travel times). The services can be adapted to the individual preferences and needs of patients and offer some degree of anonymity [19,20].

Patients were found to be greatly satisfied with telemental health services [12-15]. A review by Sharma and Devan [12] highlighted that particularly in children and adolescents, satisfaction rates were high. They found that patients valued strengths such as greater ease in discussing sensitive topics and comfortability. In addition, specific patient groups including patients with limited mobility, patients living in rural areas as well as patients from prison or forensic settings were especially satisfied [12]. Furthermore, patients seem to prefer hybrid models for future mental health care [12,19]. High patient satisfaction is crucial for promoting widespread acceptance of telemental health services and preventing attrition in future remote mental health care. Knowledge about the determinants of patient satisfaction with these services is essential to ensure and enhance satisfaction with these services. Nevertheless, the determinants of patient satisfaction with telemental health services have been scarcely investigated thus far.

In response to this research gap, we recently published a systematic review regarding determinants of patient use and satisfaction with synchronous telemental health services during the COVID-19 pandemic [22]. Considering information from 10 studies on patient satisfaction, we mostly observed nonsignificant associations of socioeconomic factors, health, service factors, experience, psychosocial factors, and facilitating conditions with satisfaction. However, potential relationships with some psychosocial (eg, COVID-19-related stress or fear) and service factors (eg, greater satisfaction with video compared to telephone services) were identified. Furthermore, the need for future studies, particularly focusing on effort and performance expectancy, psychosocial factors as well as facilitating conditions was highlighted [22]. More recent studies also found no association of patient satisfaction with socioeconomic determinants (such as gender, age, marital status, or occupation), insurance status, psychiatric diagnosis, or frequency of telemental health service use [23-26]. However, relationships of higher education, urban residence, and low or high income with patient satisfaction were found in individual studies [23,24,26]. In addition, technical difficulties, unstable internet access, and worsening of depressive or anxiety symptoms were associated with lower patient satisfaction in one study [23]. Only limited research exists on asynchronous telemental health services. Individual studies found associations of women gender, higher self-regulation, and patient status with patient satisfaction [27,28].

As a result of the COVID-19 pandemic, synchronous as well as asynchronous telemental health services were also widely implemented in Germany, which is the focus of our study. Already in November 2019, the Digital Healthcare Act was approved to promote the digital transformation of the German health care system [29]. For instance, this includes regulations that facilitate the prescription of mobile health apps, provision of web-based video consultations, and integration of digital provider networks. Furthermore, the Digital Health Applications Ordinance [30] was approved in April 2020, which regulates policies for digital health applications in Germany regarding security, quality, data protection, and data security. Consequently, the use of digital health applications increased during the pandemic in Germany. The overall telemedicine use among contract physicians and psychotherapists increased from 6.1% (2019) to 24.6% (2021) [31]. Telemental health services were used most frequently in Germany and accounted for 86.3% of all offered telemedicine services in 2021 [31].

Future mental health care challenges are highly relevant to high-income countries also including Germany (eg, physician shortages, aging population, and mental health care for refugees) and research indicates unmet needs in the current provision of mental health care in Germany [32]. Telemental health services could play a significant role in addressing these issues. Very few studies from Germany have found high patient satisfaction with the services, which was associated with newer patient status (ie, patients who had just started outpatient telephone therapy compared to patients in ongoing therapy who switched

XSL•FO
RenderX

to telephone services) and video services (compared to telephone services) but not with age, gender, symptom severity, stress, psychosocial functioning, or computer skills [28,33-35].

Objective

Increasing patient satisfaction with telemental health services is vital for their successful and widespread implementation, potentially serving as a valuable addition to the future of routine mental health care. Currently, there is generally limited evidence regarding the determinants of patient satisfaction with telemental health services and multiple research gaps exist that are listed as follows:

1. Psychosocial determinants and individual patient preferences may be critical, as they potentially are modifiable towards greater patient satisfaction (eg, [36,37]).
2. There is unclear evidence regarding differences in socioeconomic, health, and access factors, and their impact on patient satisfaction. These factors might pose additional hurdles for telemental health service users, potentially impacting their satisfaction levels.
3. Little is known about the relationship of provider characteristics and patient satisfaction. Since provider characteristics were found to be connected to patient satisfaction with telemedicine (eg, [38,39]), they might also be a key factor contributing to patient satisfaction.
4. Studies considering asynchronous services and the postpandemic context (ie, simultaneous availability of in-person and remote services) are lacking.

Nevertheless, these factors may be critical for better understanding patient preferences in the current landscape of mental health care. Therefore, our study aimed to identify determinants of patient satisfaction with telemental health services in Germany.

Methods

Sample

Cross-sectional data of the general adult population in Germany (18 - 74 y) were collected by the market research firm Bilendi, an International Organization for Standardization (ISO) 20252:2019-certified sample provider. The inclusion criteria were as follows: individuals who had been using mental health services since March 2020 were considered for participation in the web-based survey. In addition, participants were recruited based on quotas for gender and age, which were derived from mental health service utilization rates in Germany [32,40] to promote the representativeness of our sample. The web-based questionnaire was pretested in November 2023 including 13 individuals (n=8 women) to assess clarity and accuracy of the questionnaire and check for potential bias. Very minor amendments were made after pretesting. Eventually, the data collection was carried out between December 1 and December 15, 2023. Overall, 2178 adults took part in the web-based survey. Since we wanted to examine satisfaction among patients who already had experience with telemental health services, only individuals who reported past use of these services were included in our study (N=854).

Ethical Considerations

Participants received compensation from Bilendi, which included real-time cash payments ranging from 0.90€ to 1.80€ (conversion rate in 2023: US $1=€0.924) upon completion of the questionnaire. After data collection was finalized, Bilendi supplied an anonymized data set. All participants provided informed consent and Bilendi panel members are able to opt out of the panel at any time. The study was approved by the Local Psychological Ethics Committee of the University Medical Center Hamburg-Eppendorf (LPEK-0683).

Dependent Variable

Patient satisfaction with telemental health services was measured using validated instruments. For synchronous telemental health services, including video and telephone services, the Telemedicine Satisfaction Questionnaire was used (TSQ; [41]). The questionnaire consists of 14 items with a 5-point Likert scale (ranging from 1=strongly disagree to 5=strongly agree), which assesses the quality of care, similarity to in-person encounters, and the overall perception of the interaction. Therefore, the TSQ sum score can range between 14 and 70, with higher values indicating greater satisfaction. The TSQ was evaluated in the past and shows favorable psychometric properties [41]. In our sample, Cronbach α and McDonald ω for the TSQ were 0.94 for video services and 0.93 for telephone services. Since the original version of the TSQ was published in English, the questionnaire was translated into German by 2 specialized translators from the professional translation agency Tolingo (translation carried out by the first and editing by a second specialized translator; ISO 17100-certified). Guided by existing guidelines for the cross-cultural adaptation of self-report measures (eg, [42]), we further refined the translation to enhance its semantic, idiomatic, experiential, and conceptual equivalence before pretesting the questionnaire. Experts from the fields of health services research and psychology were involved in this process.

Satisfaction with asynchronous services was measured with the Client Satisfaction Questionnaire adapted to internet-based interventions (CSQ-I; [43]). The CSQ-I consists of 8 items, which measure the general satisfaction of the patients with the intervention and the help they received as well as the likelihood of recommending and reusing the services using a 4-point Likert scale (ranging from 1=does not apply to me to 4=does totally apply to me). The overall CSQ-I score can range between 8 and 32, with higher values indicating greater levels of satisfaction. The German version of the CSQ-I showed very good reliability and construct validity [43]. When measuring patient satisfaction with asynchronous telemental health services in our study, the CSQ-I showed a Cronbach α and McDonald ω of 0.95.

Independent Variables

Multiple determinants and their association with patient satisfaction with telemental health services were observed. Based on theoretical consideration, past findings and research gaps (eg, [22]), socioeconomic, access, health, psychosocial, personality, and COVID-19-related factors, as well as patient preferences (based on the Unified Theory of Acceptance and Use of Technology; UTAUT [44]), were included as

XSL•FO
RenderX

determinants. In addition, we considered provider characteristics to test their potential relationship with patient satisfaction.

Socioeconomic factors that were observed in our study included gender (men, women, diverse or intersex), age, employment status (unemployed, full-time employed, part-time employed, and other), area lived in (urban, mostly urban, and rural), living situation (living with a partner in the same household, living with a partner without a common household, widowed or partner deceased, single or divorced) and migration background (no and yes). The educational level of participants was classified based on the (International Standard Classification of Education 1997; ISCED-97; [45]). The ISCED-97 levels were aggregated into 3 groups indicating a low (ISCED levels 0 - 2), medium (ISCED levels 3 and 4), or high (ISCED levels 5 and 6) educational level. Furthermore, the monthly household net income was categorized into tertiles (low, medium, and high) based on 13 given income categories (1=less than €500; 2=€500 to under €1000; 3=€1000 to under €1500; 4=€1500 to under €2000; 5=€2000 to under €2500; 6=€2500 to under €3000; 7=€3000 to under €3500; 8=€3500 to under €4000; 9=€4000 to under €4500; 10=€4500 to under €5000, 11=€5000 to under €6000; 12=€6000 to under €8000; 13=€8000 or higher; conversion rate in 2023: US $1=€0.924). This assessment of household income is similar to other large surveys such as the German Health Interview and Examination Survey for Adults (Studie zur Gesundheit Erwachsener in Deutschland [46]) or the Hamburg City Health Survey [47].

Different access factors were examined. Due to differences in regulations and complexity regarding the use of telemedicine, different insurance types (statutory health insurance and private health insurance) were included as determinants. In addition, the internet connection quality at the patients' home was considered (fast and stable; fast, but not stable; stable, but not fast; neither fast nor stable or no internet connection at home).

Health factors included the number of psychiatric diagnoses that patients received since March 2020 and the presence of chronic physical illnesses (no and yes). Furthermore, self-rated health was measured using a 5-point Likert scale (ranging from 1=very bad to 5=very good).

Psychosocial factors that were observed are loneliness and general self-efficacy. Loneliness was measured using the 6-item De Jong Gierveld Loneliness Scale [48], which has good psychometric properties [48]. Also in our sample, the scales' Cronbach α was 0.80 and McDonald ω was 0.79. In addition, general self-efficacy was measured with the 3-item Short Scale for Measuring General Self-efficacy Beliefs (Allgemeine Selbstwirksamkeit Kurzskala; ASKU [49]). The German version of the ASKU was found to measure self-efficacy in a reliable and valid way [49]. The scales' Cronbach α and McDonald omega were 0.89 in our study.

Personality was assessed using the Big Five Inventory–Socio-Economic Panel (BFI-S) [50]. The BFI-S contains 15 items, which measure conscientiousness, extraversion, openness, agreeableness, and neuroticism (each with 3 items). The scale was developed as part of the Socio-Economic Panel and is based on the original 44-item Big Five Inventory [51]. The BFI-S shows mostly acceptable reliability and validity [52]. Cronbach α and McDonald ω for the 5 dimensions ranged between 0.51 (agreeableness) and 0.77 (extraversion) in our sample.

COVID-19-related factors that we controlled for are COVID-19 vaccination status (no and yes) and fear of COVID-19. The 7-item Fear of COVID-19 Scale was used to measure fear of COVID-19 [53]. The German version of the 7-item Fear of COVID-19 Scale shows good psychometric properties [54] and reached a Cronbach α and McDonald ω of 0.92 in our sample.

Patient preferences that were examined are attitude towards telemental health services and technology commitment. The attitude towards telemental health services was assessed using the Unified Theory of Acceptance and Use of Technology-Patient version (UTAUT-P; [55]), which is a 14-item self-report measure to explore patient attitudes towards telepsychotherapy in clinical practice and research. The instrument is based on the well-established framework of the UTAUT [44] and was adapted to the context of patients receiving telepsychotherapy. The UTAUT-P includes four factors, which evaluate the patients' therapy quality expectancy, convenience, ease of use, and pressure from others. It shows adequate validity and reliability [55] and Cronbach α and McDonald ω were 0.87 in our sample. Since the UTAUT-P is only available in English, it also had to be translated into German by 2 specialized translators from Tolingo for our study (translation carried out by the first and editing by a second specialized translator; ISO 17100-certified). Again, the translation was reviewed by a group of experts before the questionnaire was pretested, as recommended in existing guidelines (eg, [42]). Furthermore, technology commitment was measured with the technology commitment (Kurzskala Technikbereitschaft) 12-item short scale [56]. The scale focuses on willingness to use technology and measures technology acceptance, technology competence, and technology control beliefs. The German version of the scale has favorable psychometric properties [56] and had a Cronbach α of 0.84 and McDonald ω of 0.80 in our sample.

To observe the relationship of provider characteristics with patient satisfaction, we included the providers' attitude towards telemental health services and the provider skills for using the services as determinants. To assess the provider attitude towards the services, participants were asked whether they agree that their mental health provider has a positive and open attitude towards telemental health services (ranging from 1=strongly disagree to 5=strongly agree). For observing provider skills, participants were asked whether they agree that their mental health care provider has the necessary skills and competencies to use telemental health services without any problems (ranging from 1=strongly disagree to 5=strongly agree).

Statistical Analysis

Descriptive characteristics for all included variables were computed. To test the relationship between the determinants and patient satisfaction with telemental health services, multiple linear regressions were performed. Model assumptions for linear regression were checked in advance (eg, multicollinearity, homoscedasticity, and normality). Consequently, cluster-robust standard errors were calculated for all models to adjust for

XSL•FO
RenderX

heteroscedasticity. By default, listwise deletion is applied in Stata SE 18.0 (StataCorp LLC) to deal with missing data. Therefore, additional analyses using full-information maximum likelihood models were conducted to further address missing data [57]. Stata (SE, version 18.0; [58]) was used for all statistical analyses and statistical significance was considered at an alpha level of $P<.05$. Finally, Cronbach alpha and McDonald omega for all included scales were estimated using the "alpha" command and "omegacoef" [59] tool in Stata.

Results

Sample Characteristics

In Table 1, the descriptive characteristics of all included variables are summarized. Overall, the analytic sample consisted of 854 individuals. Regarding the gender of our sample, 39.8% (340/854) of the sample were men, 60% (512/854) women, and 0.2% (2/854) diverse or intersex. The mean age of the participants was 42.3 (SD 11.1; range 18 - 73) years. Regarding telemental health service use, 56.6% (483/854) of the sample reported past use of video services, 50.1% (428/854) used telephone services, and 30% (256/854) used asynchronous services. The mean patient satisfaction score for video services was 55.8 (SD 10.8; range 17 - 70), for telephone services 53.3 (SD 10.9; range 14 - 70), and for asynchronous services 24.1 (SD 6; range 8 - 32).

Regression Analyses

Results of the multiple linear regression for all models are presented in Figure 1 (see Tables S1-S3 in Multimedia Appendix 1 for detailed results). Due to the varying number of users across the different service types, the sample sizes for the regression models differed. Regarding video services (n=483), we observed a significant positive association of higher self-efficacy (β=1.05, *P*=.03), extraversion (β=0.21, *P*=.03), and fear of COVID-19 (β=0.20, *P*<.001), a positive attitude towards telemental health services (β=0.63, *P*<.001), and greater technology commitment (β=0.12, *P*<.001) with patient satisfaction. A positive provider attitude towards the services (β=1.12, *P*=.004) and higher provider skills for using the services (β=1.61, *P*=.002) were additionally associated with greater patient satisfaction.

For telephone services (n=428), a significant negative association of a high educational level (β=−3.82, *P*=.005), full-time employment (β=−2.66, *P*=.02), unstable internet connection (β=−3.14, *P*=.02), and higher technology commitment (β=−0.14, *P*=.008) with patient satisfaction was found. Furthermore, higher loneliness (β=2.26, *P*=.009), extraversion (β=0.28, *P*=.03), agreeableness (β=0.35, *P*=.02), and fear of COVID-19 (β=0.21, *P*<.001), and a positive attitude towards telemental health services (β=0.52, *P*<.001) were associated with greater patient satisfaction with telephone services. In addition, a positive provider attitude towards (β=2.13, *P*<.001) and higher provider skills for using the services (β=1.73, *P*=.01) were positively associated with the outcome.

Patient satisfaction with asynchronous services (n=256) was negatively associated with having lost a partner or being widowed (β=−4.02, *P*=.009) and higher loneliness (β=−1.46, *P*=.02) in our sample. Furthermore, greater fear of COVID-19 (β=0.15, *P*<.001) and a positive attitude towards telemental health services (β=0.22, *P*<.001) as well as a positive provider attitude towards telemental health services (β=1.33, *P*=.002) were associated with higher patient satisfaction.

In the additional full-information maximum likelihood models (rather than listwise deletion), similar associations were found (see Tables S1-S3 in Multimedia Appendix 1 for detailed results). However, a few additional associations that reached statistical significance in the full-information maximum likelihood models were observed. This applies to the negative association between a medium educational level and patient satisfaction with telephone services (β=−2.99, *P*=.02). Furthermore, patient satisfaction with asynchronous services was additionally negatively associated with diverse or intersex gender (β=−3.44, *P*=.05), and agreeableness (β=−0.21, *P*=.04) and positively associated with living in mostly urban areas (β=1.23, *P*=.03), in the full-information maximum likelihood model.

Discussion

Principal Findings

This study aimed to explore determinants of patient satisfaction with different types of telemental health services. Examining web-based survey data of the general adult population in Germany, we identified significant relationships with patient satisfaction for some of the included determinants. Variations in associations between the different service types were observed. However, psychosocial patient characteristics (including personality and fear of COVID-19), patient preferences, and provider characteristics, were associated with patient satisfaction in all service groups. Current research regarding determinants of patient satisfaction is mostly limited to synchronous telemental health services and a small variety of determinants. Therefore, our study markedly adds to the current knowledge on a range of factors, including socioeconomic, access, health, psychosocial, personality, and COVID-19-related determinants, as well as patient preferences and provider characteristics. Furthermore, valuable insights into satisfaction with asynchronous telemental health services were gained.

Relation to Previous Research

The majority of the included socioeconomic determinants was not associated with patient satisfaction with telemental health services, which was also observed in previous international studies (eg, [22,25]). In contrast to studies observing differences in access and additional barriers to using telemental health services for patients with low socioeconomic status [19,20,22], our findings may imply that patients are satisfied with telemental health services regardless of their socioeconomic status. Nevertheless, we observed significant negative associations of high education and full-time employment with patient satisfaction with telephone services. Highly educated and full-time employed individuals are likely to have increased access to and experience with (digital health) technologies [60].

XSL•FO
RenderX

Consequently, they may have higher expectations and are less satisfied with less technologically advanced telephone services. For asynchronous services, individuals who had experienced the loss of a partner reported lower satisfaction levels. This patient group may be especially burdened and require more extensive support. Synchronous services might be more suited for this group as they offer direct human interaction and increased social connectedness [11,17].

Regarding access factors, the patient's health insurance type was not associated with patient satisfaction in any service group. Therefore, variations in insurance regulations (such as ease of access, complexity of the process, or usage limitations) do not seem to constitute additional barriers for telemental health service users in Germany. Even though differences in access factors (eg, digital device ownership and availability of high-speed internet) are larger in the United States compared to Germany [61], the health insurance type was also not associated with telemedicine satisfaction or use in studies with US samples (eg, [26,62]). Furthermore, the internet connection quality at home was not associated with satisfaction in almost all cases. The majority of our sample (617/854, 72.3%) had a fast and stable internet connection and only 4.9% (42/854) stated that they had slow and unstable, or no internet access at home. Since the majority of German telemental health service users seem to have a good internet connection at home, this factor does not appear to be a crucial determinant of patient satisfaction. Nevertheless, disparities in access persist and vary across different regions and countries (eg, [61,63]), which should be considered in the international context. Having an unstable internet connection at home was associated with lower satisfaction rates for telephone services. This might be unexpected since the internet is not needed for telephone calls. Patients might have been forced to switch to telephone services due to their unstable internet connection, although they actually preferred other service options (ie, video services that require a stable internet connection). However, future research is required to test these potential explanations.

None of the included health determinants were associated with patient satisfaction in the different service groups. Neither physical health factors nor comorbidity of psychiatric diagnoses were associated with patient satisfaction with telemental health services, which is in accordance with findings from studies with international samples [22]. This may suggest, for clinical practice, that telemental health services should not be restricted to certain patient groups. Furthermore, they have the potential to enhance treatment and access for specific patient populations, such as patients with limited mobility or patients experiencing social anxiety (eg, [20]).

For psychosocial determinants, associations with patient satisfaction were observed. Loneliness was positively associated with satisfaction with telephone services, but negatively associated with satisfaction with asynchronous services. This could mean that patients experiencing higher levels of loneliness prefer the direct real-time interaction provided by synchronous telephone services to satisfy their social needs. Compared to synchronous services, asynchronous services may be less personal (eg, no verbal or nonverbal cues from the provider) [11,17], which might have caused lower satisfaction levels in patients with higher loneliness. In addition, self-efficacy was positively associated with satisfaction with video services. Accordingly, self-efficacy was found to be associated with major UTAUT constructs as well as the intention to adopt and satisfaction with telemedicine services in the past (eg, [64]).

Furthermore, certain personality characteristics were associated with patient satisfaction. Higher levels of extraversion were associated with greater patient satisfaction with synchronous services. Highly extroverted individuals may feel more confident engaging in direct social interactions provided by synchronous services. In contrast, Cieślik et al [65] observed a negative association between extraversion and satisfaction with telemedicine-delivered inflammatory bowel disease care. More studies are needed to clarify this relationship. In addition, agreeableness was positively associated with satisfaction with telephone services in our study. Highly agreeable individuals may be more likely to adapt to and accept new treatment formats, such as telemedicine. In regard to previous research, agreeableness was positively associated with patient satisfaction with telemedicine services in one previous study [65] and negatively associated in another [66]. Additional significant associations with conscientiousness and openness were observed in the previous studies [65,66], which we did not find in our sample. These mixed findings highlight the need for further studies examining the relationship of personality and patient satisfaction with telemedicine services.

The fear of COVID-19 was associated with patient satisfaction in all patient groups in our study. Multiple previous studies also observed an association of COVID-19-related fear with patient satisfaction with telemedicine services [67-69]. Individuals with greater fear of COVID-19 might be particularly satisfied with telemedicine service options since they pose a lower risk of infection compared to in-person visits (eg, no physical contact while traveling to, waiting for, or during the appointment). In contrast, the COVID-19 vaccination status was not associated with patient satisfaction with telemental health services. Even though previous studies found that COVID-19 vaccination acceptance was positively associated with factors such as health literacy and trust in the health system (eg, [70,71]), it does not seem to be of significance for patient satisfaction with telemental health services.

Our findings suggest that telemental health service users hold predominantly positive attitudes towards the services. A significant relationship between the attitude towards telemental health services and patient satisfaction was found in all service groups in this study. The patient attitude towards telemental health services was evaluated using UTAUT dimensions, which have been associated with patient satisfaction with telemedicine services in past studies (eg, [72,73]). Performance expectancy, defined as the degree to which an individual believes that using the services will be beneficial [44], appears to particularly impact patient satisfaction with telemedicine services [72,73]. This expectancy may be influenced by external factors, such as the attitude of and support from providers. In addition, fostering positive initial experiences with the services (eg, [74]) and reducing technology anxiety (eg, [75]) might help to facilitate positive patient attitudes. Strengthening a positive attitude in patients may be beneficial for the successful implementation

XSL•FO
RenderX

of future telemental health services. Furthermore, the patient's level of technology commitment was positively associated with satisfaction with video services, but negatively associated with satisfaction with telephone services. Highly technology-committed patients may prefer more technologically advanced services and value the greater possibilities, which video services offer compared to simple telephone calls. This preference should be considered when choosing a synchronous service option for mental health patients. Future research on the association of patient attitude towards telemental health services and technology commitment with patient satisfaction is needed to further explore the initial observations highlighted by our study.

Patients rated provider attitudes and skills positively in our study. The provider characteristics seem to be heavily associated with patient satisfaction. A positive and open provider attitude towards telemental health services was positively associated with greater patient satisfaction in all telemental health service groups. This association has rarely been studied in previous studies in telemedicine research and seems to be crucial to promoting patient satisfaction [38,39]. A systematic review by Connolly et al [76] found that mental health care professionals hold predominantly positive attitudes towards telemental health services. However, mental health care professionals report barriers and concerns regarding the services, including technological difficulties, increased workload, perception of impersonality, safety concerns, and lack of support [76-79]. All of the UTAUT dimensions were identified as determinants of provider attitude, particularly performance expectancy [76,77,80]. Previous experience with the services and training appears to play a crucial role in fostering provider acceptance [76,78,80]. Creating offers of and improving support, guidelines, and training for telemental health care providers is essential [12,79,81], not only to decrease provider reluctance but also to increase patient satisfaction with the services. Correspondingly, better provider skills in using the services were associated with increased patient satisfaction with synchronous services. Compared to asynchronous services, providers are more directly involved in the delivery of synchronous services, and their skills seem to be especially important for patient satisfaction in this service group.

Strengths and Limitations

In our study, we considered patient satisfaction with both synchronous and asynchronous telemental health services and tested associations with a variety of determinants. Our study adds valuable knowledge, particularly in the area of asynchronous services and for psychosocial determinants. Furthermore, the included variables were measured using validated instruments, which contributes to the credibility of our findings. In terms of gender and age, our sample was representative of mental health patients in Germany [32,40], which enabled us to gain insight into a broad spectrum of telemental health service users. The data were assessed during the postpandemic period, suggesting that our study could help to gain a deeper understanding of satisfaction with telemental health services as in-person visit availability resumed.

Nevertheless, some limitations should be noted. The cross-sectional design of our study has certain limits, which makes it difficult to draw implications regarding causality or longitudinal stability of the observed relationships. Therefore, future longitudinal and qualitative studies are needed to explore the relationships in further detail. Furthermore, we cannot completely rule out selection bias for our sample. It might be the case that some patient groups were more likely to participate in the web-based survey or to have experience with telemental health services (eg, patients with mild psychiatric symptoms, who are highly technology-committed). However, we recruited a large quota-based sample and the vast majority of mental health patients in Germany have reasonably good access to telemental health services. Finally, disparities in access, national regulations and practices regarding telemedicine vary across countries; therefore, future studies from other countries are recommended.

Conclusion

Since determinants of patient satisfaction have been scarcely investigated thus far, we examined various determinants and their associations with patient satisfaction with telemental health services in a representative sample of mental health patients in Germany. We found that particularly psychosocial determinants, patient preferences, and provider characteristics were associated with patient satisfaction. Despite limited investigation in existing research, patient attitudes towards the services and technology commitment constitute key determinants of patient satisfaction. In addition, psychosocial determinants such as personality, loneliness, and fear of COVID-19 also appeared to have a noteworthy relationship with patient satisfaction. Therefore, when treating patients via telemental health services, it is of great importance to consider each patient individually and take their personal preferences into account.

In previous studies, clinicians were repeatedly identified as gatekeepers to telemedicine implementations [12,79], and according to our results, they also seem to play a crucial role in increasing patient satisfaction with telemental health services. Thus, finding ways to support providers and reduce barriers and misconceptions related to the provision of telemental health services should be prioritized by health care managers and researchers. In conclusion, psychosocial characteristics and individual patient preferences as well as provider characteristics may contribute to increased patient satisfaction with telemental health services, which is a key factor for the successful and widespread implementation of the services in the future.

Abstract

Background: Online forums are used widely to facilitate mental health peer support. However, concerns exist regarding potential harm associated with their use, and little is known about forum safety from the user perspective.

Objective: This study sought to understand how users experience safety within online mental health peer support forums. Following previous research, safety was conceptualized with reference to both experiences of harm and feelings of interpersonal safety within the forum environment.

Methods: Data was collected from 42 semi-structured realist interviews and 504 cross-sectional survey responses from users of three UK-based online mental health forums. These included a forum hosted by a health service provider with sub-forums for anxiety, depression, and eating disorders; a corporate provider focused on young people's mental health; and a voluntary sector provider with sub-forums for general mental health support, eating disorders, and postpartum psychosis. A bespoke survey was used to obtain descriptive quantitative data regarding user perceptions of forum safety. Qualitative data was used to refine an initial programme theories framework comprising context-mechanism-outcome configurations related to forum safety developed in previously published realist synthesis.

Results: Survey responses revealed that over half of participants felt safe to post because of online anonymity (40.1% agreed, 19.2% strongly agreed), while a minority reported encountering distressing forum posts (18.8% agreed, 3.6% strongly agreed) and expressed concern that talking about mental health online could make them feel worse (22.4% agreed, 3.4% strongly agreed). Refined programme theories highlight: (1) the disclosure-promoting effect of anonymity, related to the mitigation of concerns that users' mental health experiences could be linked to their offline identities; (2) the importance of proactive content moderation for addressing emerging safety issues; (3) a need for organizations to implement rule enforcement sensitively and balance between conversational openness and restricting topics likely to cause distress; (4) forum users' experiences of self-moderating their exposure to potentially distressing online content; and (5) how the perceived non-judgement, authenticity, and similarity of other forum users generates interpersonal safety.

Conclusions: This is the first realist evaluation to directly assess processes underpinning safety in online mental health forums. A key novel finding of this study is that safety emerges not only from harm reduction procedures but also a facilitative interpersonal atmosphere defined by sensitive moderation and the sharing of lived experiences. Hosts should therefore remain attentive to both potential risks and opportunities to foster connections between community members.

Introduction

Online forums represent an increasingly popular format for mental health peer support [1,2]. Typically organized around particular mental health challenges or demographic groups, online forums facilitate text-based, asynchronous discussions through which users exchange information and support [3]. Third-sector organizations and mental health providers use

XSL•FO
RenderX

online forums to extend service reach, and a substantial body of peer-led forums leverage social media to host supportive communities [4]. The advantages of online mental health forums include their accessibility, with forums usually available when needed and free of charge, and the opportunity for users to access forums anonymously, which may promote the disclosure of personal difficulties [5]. There is some evidence indicating that using online forums may lead to positive mental health outcomes [6,7]. However, concerns exist regarding the safety of delivering mental health peer support within an increasingly complex online environment [5]. In this study, forum safety refers to two aspects of user experience identified in prior research [5]. The first relates to the experience of harm, encompassing emotional harm from exposure to distressing content and physical harm if users act on information such as self-harm instructions or health misinformation. The second refers to interpersonal safety—also referred to as psychological safety [8]—reflecting users' comfort with sharing mental health experiences within the community.

Three salient issues pertaining to forum safety are evident in existing literature. First, a central tension in the delivery of online forums relates to evidence that in some contexts, reading about and discussing distressing experiences can be beneficial, yet in other circumstances, access to conversations about mental health may cause harm. Research with forum users shows how relatable lived experiences can normalize and validate previously stigmatized experiences [9,10], yet research also highlights the possibility that reading descriptions of mental health challenges can be distressing, discouraging, or overwhelming [11,12]. A key consideration for the implementation of online mental health forums therefore lies in promoting constructive engagement while simultaneously reducing the potential for user distress. To this end, forums typically implement rules restricting discussions of particularly emotionally activating content, such as crisis situations or self-harming behaviors, and use moderators to help users navigate this balance [13]. Organizations may also develop protocols for helping users experiencing significant distress, by, for example, signposting to other services or offering one-to-one support [14].

Second, organizations seeking to deliver safe mental health forums must contend with the unique challenges imposed by the online context. For example, the asynchronous, anonymous nature of forum communication can confound attempts to rapidly identify and address safeguarding issues, such as users experiencing suicidal distress, particularly where forums do not require participants to share their personal details at sign-up [15]. Furthermore, user attempts to post rule-breaking or harmful content are widespread in online communication and can include offensive posts or health misinformation [16]. As with forums in domains other than health, organizations may also be required to plan for "toxic" online behavior that could undermine forum safety, such as spamming, predatory users, and attempts by banned users to create multiple accounts to disrupt forum functioning [17]. Tools such as automatic word blockers support some teams with content moderation [18], however, much of this work is conducted manually and requires significant resources [19].

Third, forums aim not only to limit access to harmful content or malicious actors but also to establish a supportive community that feels sufficiently safe to allow users to read and post about mental health experiences. A thorough understanding of forum safety must therefore account for both harm reduction strategies and factors likely to facilitate willing engagement and disclosure. This aligns with literature that conceptualizes psychological safety as a group climate in which people feel able to take interpersonal risks in pursuit of personal goals [8]. There is some evidence to suggest that the intention to post in online forums is associated with perceived psychological safety and that this feeling of safety is underpinned by high trust in community members and low self-consciousness regarding posting [20]. Indeed, research with service users points to the importance of forum characteristics such as a welcoming and caring interpersonal atmosphere in facilitating engagement with online mental health forums [21,22].

Despite the large body of literature on the positive and negative effects of online mental health forums, research focused specifically on user perceptions of safety is limited. This gap is significant given the growing number of online mental health peer support forums and users internationally, and broader social and policy interest in online harms as indicated, for example, by efforts in the European Union and the United Kingdom to develop legal frameworks that promote safety in online user experience [23,24]. To address this understudied topic, we aimed to understand user safety in online mental health forums using a mixed methods approach based on the principles of realist evaluation.

Methods

Study Setting and Design

This study is one element of a larger investigation of UK mental health communities called the Improving Peer Online Forums (iPOF) project. As per the iPOF research protocol [25], this realist evaluation represents the second stage of the project, which builds on a realist synthesis conducted in stage 1 [5]. Realist evaluation involves iteratively developing and refining program theories, or causal statements regarding how interventions work, as data collection progresses [26]. Following realist methodology, program theories from the realist synthesis pertaining to forum safety were used to inform this study. These program theories took the form of context-mechanism-outcome (CMO) configurations. CMOs are a primary unit of analytic output in realist studies and seek to elucidate how a mechanism, defined as a response to resources offered by an intervention, occurs within a particular context [27]. Contexts represent factors impacting the activation, or strength of activation, of a mechanism and exist at a range of levels including individual, organizational, social, and economic factors. Outcomes typically refer to cognitive, emotional, or behavioral consequences that follow from the activation of a mechanism. A total of 8 of the 22 CMOs on mental health forum impacts developed in the prior realist synthesis related to forum safety [5]. CMOs from the previous review described a range of forum features and experiences pertaining to user safety, such as the importance of forum moderation, the value of anonymity, and negative

XSL•FO
RenderX

experiences emerging from forum use [25]. These CMOs were used to inform an initial program theory (IPT) framework (Table 1) for this study and influenced data collection, as described below.

Table . IPTs[a] related to forum safety from the iPOF[b] realist synthesis [5].

IPT #	CMO[c] configuration
IPT 1	Posts detailing personal experiences of potentially harmful behaviors (eg, self-injury and restrictive eating; context) that frame them as helpful (mechanism—resource) may normalize and reinforce their use (mechanism—response), increasing the likelihood of users adopting these behaviors (outcome).
IPT 2	When seeking support for issues that others may find distressing (context), users are more likely to post in forums that have ways to flag the potentially distressing nature of their experiences (eg, tags, trigger warnings, or a separate subforum; mechanism—resource). This provides reassurance that posts will not inadvertently cause harm to others (mechanism— response), increasing the likelihood that users will use the forum to seek support (outcome). Other users are less likely to be exposed to distressing content (mechanism—response), reducing potential distress in the wider community (outcome).
IPT 3	For users making an original post (context), the absence of a response or responses that are unrelated to the original post (mechanism—resource) will prompt feelings of being ignored or misunderstood (mechanism—response). This leads to increased isolation (outcome) and reduces forum engagement (outcome).
IPT 4	Those yet to post to forums may be concerned about feeling exposed or receiving negative responses if they share their experiences (context). Observers who see others receiving constructive and respectful responses (mechanism—resource) will be reassured of the safety of posting to the forum (mechanism—response), increasing the likelihood that they will actively participate in discussions (outcome).
IPT 6	Negative social consequences of discussing mental health difficulties, including shame and stigma (context), are overcome by forum anonymity (mechanism—resource), which disinhibits (mechanism— response) users from discussing their experiences, leading to greater self-disclosure (outcome).
IPT 7	Because users' personal identities are hidden (context), they are insulated from the negative social consequences of rule-breaking (mechanism—resource). This can have a disinhibiting effect on some users (mechanism—response), making them more likely to engage in antisocial behavior such as bullying (outcome), and reducing safety for other users (outcome).
IPT 8	Open online forums with no ways to flag distressing content, poor moderation, or lenient rules (context) are more likely to expose users to posts detailing users' highly distressing circumstances, misinformation, and "toxic" discussions (mechanism—resource), which can contribute to distress (mechanism— response) and disengagement from the forum (outcome).

[a]IPT: initial program theory.

[b]iPOF: Improving Peer Online Forums.

[c]CMO: context-mechanism-outcome.

Participants were recruited from 3 UK-based mental health forums partnered with the iPOF project. These forums were chosen from the 7 forums in the iPOF study as they represent 3 different service contexts, namely the UK National Health Service, corporate, and voluntary sectors. While only 3 forums were included in this phase of the research, the remaining 4 forums also represent these same sectors. It is hoped that this cross-sector sampling promotes the transferability of the findings of this study to a broad range of service settings. All forums had a mental health focus, could be accessed using anonymous usernames, and had dedicated moderation teams. Key forum characteristics are described in Table 2 and detailed descriptions of each forum partnered with the iPOF project can be found elsewhere [28]. As per an ethical framework developed by the iPOF team [29], forums are described using randomly allocated bird names to protect the anonymity of participating organizations and forum users. Participants were initially invited to participate in the iPOF project via an online survey advertised on forum home pages and through emails from forum hosts to forum users. Those who completed the survey were given the option to consent to be invited to participate in an individual interview.

XSL•FO
RenderX

Table . Characteristics of included mental health forums.

Forum name	Forum setting	Availability and access	Area of mental health focus	Moderation
Magpie	A large, health-based social networking website with subforums focused on specific health challenges.	Publicly available, 24/7. Posting requires an account.	Four subforums used for recruitment to this study focused on general mental health support in the United Kingdom, maternal mental health support, support for postpartum psychosis, and support for eating disorders.	Forum moderation is conducted by trained volunteers and typically operates within daytime hours.
Dunnock	A large, dedicated platform for mental health support aimed at young people between the ages of 10 and 25 years (note that only those aged 16 and older were eligible for inclusion in this study).	Available 24/7 but requires an account to view and post.	General mental health and well-being.	All user-generated content is reviewed by a trained and paid moderation team before going live on the forum.
Sparrow	A dedicated platform for mental health support hosted by a regional service provider in the UK NHS[a].	Available 24/7 but is only available to mental health service users under the care of the host NHS service.	Subforums focus on support for depression, anxiety, and eating disorders.	Forum moderation is conducted by a team comprising health professionals, paid and trained moderators, and trained volunteers, and typically operates within daytime hours.

[a]NHS: National Health Service.

Quantitative Data Collection and Analysis

The survey used in this study was an online questionnaire designed specifically for the iPOF project. It included 95 items across sections investigating forum use, perceptions of forum helpfulness, moderation, user mental health, use of other health services, and forum safety. Most items, including those reported here, were developed for the purpose of this study by the research team in collaboration with a public and patient involvement group to assess concepts and experiences identified by the iPOF realist synthesis. The questionnaire also includes validated measures of anxiety and depression. A full description of the survey is available elsewhere [30]. Only items directly related to forum users' perceptions of safety or distress are reported here. This included (1) "I have felt distressed by some of the posts I have read on this forum," (2) "I feel safe to post about my personal experiences in this forum," (3) "I feel safe to say anything in this forum because no-one knows who I am," and (4) 'Talking about my mental health experiences in the forum might make me feel worse." In this study, cross-sectional survey data were used to assess the prevalence of user-reported distress and feelings of safety, providing context for the program theories presented thereafter.

Qualitative Data Collection and Analysis

Participants who had completed the iPOF survey and expressed interest in a qualitative interview were invited to participate. Interviews were conducted via phone or Teams (Microsoft Corp) by PM and ZG, audio recorded, transcribed, and anonymized. The interview procedure followed the principles of realist interviewing [31]. Here, interviewers seek to examine existing program theories by introducing key concepts and ideas that participants are invited to reflect on based on their own experience of the program. Interviews therefore include a combination of deductive questions based on program theories and more exploratory, inductive questions, leaving open the possibility that new concepts not previously captured by the IPT framework may emerge. In addition to the IPTs, interviewers used a semistructured topic guide based on the concepts from these program theories (Multimedia Appendix 1).

Data extraction and analysis occurred simultaneously and followed three stages. First, data segments were extracted into a bespoke data extraction form based on the IPT framework. The form was hosted on Excel (Microsoft Corp) online to facilitate collaborative working. Each IPT was written out in full in a separate column. Data segments were copied under the most relevant program theory along with an analytic comment stating how the data segment contributed to the refinement of the respective IPT. Data extraction was conducted by ZG and PM. Second, data segments and analytic comments from across participant interviews were reviewed against the IPT framework. Particular attention was paid to where data supported, refuted, or refined IPTs, and new CMO configurations were formulated to account for the accumulating evidence. For example, IPT 8 refers to how a lack of moderation can contribute to negative outcomes. In interviews, however, participants reflected on the value of proactive moderation, leading to the development of a CMO configuration reflecting this aspect of their experience. IPTs for which there was insufficient evidence in the interview data to support meaningful iteration, such as IPT 1 regarding exposure to self-harm content, were not included in the subsequent analysis. Initial reformulation of the CMOs was conducted by PM. Following this, interim CMOs were reviewed in a full-day analysis meeting held by PM, ZG, FL, and HR, during which the CMO configurations were further refined with respect to illustrative data segments. Third, the analysis was

XSL•FO
RenderX

shared with and reviewed by the wider iPOF team comprising academics, clinicians, and experts with experience in mental health. A final draft of this study was shared with an expert by experience whose perspective on this research is captured in a lived experience commentary presented at the end of this study. Lived experience commentaries are short pieces, typically written independently of the research team, that provide the opportunity for critical commentary from those with lived experience of the research topic [32].

Ethical Considerations

This study received ethical approval from the Solihull Research Ethics Committee on June 20, 2022 (IRAS314029). All participants provided written informed consent. Interview data have been anonymized. Participants were compensated with £30 (US $40.31) shopping vouchers for completing interviews and £10 (US $13.44) shopping vouchers for completing surveys.

Results

Overview

Semistructured qualitative interviews were conducted with 42 forum users from Magpie (n=16), Dunnock (n=10), and Sparrow (n=16) between August 2023 and October 2024. A total of 504 survey responses were collected from Magpie (n=110), Dunnock (n=287), and Sparrow (n=107) between July 2023 and March 2024. Participant demographics are available in Tables 3 and 4. Quantitative data are reported by survey item (Table 5). A total of 5 CMOs were refined and are reported with reference to illustrative interview data.

Table . Survey participant demographics.

[a]D: Dunnock.

[b]M: Magpie.

[c]S: Sparrow.

Table . Survey responses to safety-related items.

	Item 1: "I have felt distressed by some of the posts I have read on this forum," n (%)	Item 2: "I feel safe to post about my personal experiences in this forum," n (%)	Item 3: "I feel safe to say anything in this forum because no one knows who I am," n (%)	Item 4: "Talking about my mental health experiences in the forum might make me feel worse," n (%)
Strongly disagree	65 (12.9)	17 (3.4)	16 (3.2)	59 (11.7)
Disagree	185 (36.7)	52 (10.3)	53 (10.5)	171 (33.9)
Neither agree nor disagree	141 (28)	151 (30)	136 (27)	144 (28.6)
Agree	95 (18.8)	214 (42.5)	202 (40.1)	113 (22.4)
Strongly agree	18 (3.6)	70 (13.9)	97 (19.2)	17 (3.4)

Survey Responses

Survey responses revealed that over one-fifth of participants felt distressed by posts they had read (n=95, 18.8% agreed and n=18, 3.6% strongly agreed), indicating that even in moderated communities, a notable minority face challenges with exposure to forum content. Similarly, a quarter of respondents agreed (n=113, 22.4%) or strongly agreed (n=17, 3.4%) that discussing their mental health online could make them feel worse. Feelings of safety when posting was comparable to perceptions of safety due to online anonymity, with 42.5% (n=214) agreeing and 13.9% (n=70) strongly agreeing they felt safe to post, and 40.1% (n=202) agreeing and 19.2% (n=97) strongly agreeing they felt safe to share because of anonymity. This underscores the central role of online anonymity in fostering forum engagement.

CMO1: Anonymity and Disclosure

CMO Configuration

Context

Stigma related to mental health difficulties, in particular, concerns that disclosing mental health difficulties within in-person settings or to people users know offline may expose them to negative judgment by others.

Mechanism

The ability to post to a forum without revealing personal information (resource) mitigates concerns that judgment by others could be linked to posters' offline identities (response) and provides users with a greater degree of choice (response) regarding the extent of the information they share online.

Outcome

These responses promote the candid disclosure of personal difficulties for those who wish to post.

Illustrative Interview Data

Anonymity disinhibited users from engaging in online conversations. Several users noted that by not having an online profile linked to their name, they were able to avoid perceived stigma, and therefore, judgment related to their mental health.

> *...the stigma around mental health is still hugely prevalent, so to actually be there as someone who's anonymous that you can actually say how you're feeling when you write something down.* [S002]

> *I prefer being anonymous myself because there might be people on there that maybe I work with, I don't know, or a family member. I don't want them to know the details of why I'm on there.* [S011]

By offering users the opportunity to engage anonymously, they are given control over what information they share about themselves, and therefore, how they are perceived online.

> *Interviewer: ...what makes Magpie feel like a safe place to discuss really personal issues?*

> *Interviewee: Because I'm not using my own name ... so nobody knows it's me, nobody knows where I live unless I choose to tell them so yes it's that sort of ... you're anonymous but you're not.* [M100]

Similarly, the following user notes that a forum that does not require their profile to include identifying information provides freedom to decide what to disclose.

> *...I felt that you have the freedom to give your own information if you want to, but you don't have to. I relate because I give my age, I give my gender, I give basic things because I think then I get better answers.* [M304]

CMO2: Proactive Moderation

CMO Configuration

Context

The nature of online communication involves interacting with or reading posts by unknown others who could, depending on the nature of forum moderation, share anything, including content that could be disturbing, disagreeable, or inaccurate.

XSL•FO
RenderX

Mechanism

Proactive moderation, where moderators are seen to work quickly and sensitively to address potential and emerging safety issues (resource), both limits exposure to distressing content and provides reassurance that the space is supervised (response).

Outcome

This promotes perceptions of community safety and users' willingness to engage with the forum.

Illustrative Interview Data

Interviewees identified the presence of moderators as an important resource for maintaining a positive community culture and ensuring that distressing content does not discourage users from engaging with the forum.

> *...for the safety of everybody someone will review it [a forum post] before it gets published ... to make sure there's nothing triggering ... if someone put something triggering on there then people won't want to use them [online forums].* [D046]

Issues moderators managed included interpersonal difficulties that could arise in forum conversations. As the following participant identified, their presence also provided reassurance.

> *...just knowing that it's moderated, and some of the comments that come through it's all a very supportive space. You don't see anybody dismissed or you know threatened.* [M213]

Participants also highlighted the importance of moderators' attentiveness to situations where users feel unsafe due to their mental health. One user valued the ability to request support from the moderation team where this difficulty emerged.

> *...another really important thing is it's a hundred percent safe, it is moderated and it is ensured that everyone is safe ... any time someone's in danger or someone might be just like concerned about someone, if they've said they're unsafe or they feel anxious then they get a message from the moderator just to make sure that they're okay so it's really inclusive and overall it is really safe.* [D2]

Highlighting the importance of proactivity, situations where moderators missed distressing content were identified as unhelpful.

> *I have noticed some comments that are like maybe the moderators haven't noticed them or not really read them properly. It kind of feels like it's a bit unhelpful in a way and it's not really a supportive comment. When that happens, we have this option to message the team, and we just let them know and the team removes the comments.* [D2]

CMO3: Balanced Rules

CMO Configuration

Note that this CMO configuration includes 2 different responses and outcomes to the same resource, representing what in realist methodology is referred to as rival theories [33].

Context

In pursuit of safe and supportive online environments, online forum guidelines typically restrict some forms and topics of communication. However, some restricted topics may be personally significant to individual users. Forums must therefore achieve a balance between openness and the enforcement of boundaries within their communities.

Mechanism

When implementing forum guidelines, moderators may take action to restrict conversations by editing posts, removing conversations, or restricting access by certain forum users (resource 1). When personally important experiences have been censored, users may feel undermined, particularly where communication by forum staff is seen as unnecessary or harsh (response 1). However, where community rules and moderators' decisions are communicated sensitively (resource 2), users are more likely to accept moderators' actions (response 2).

Outcome

Feeling undermined through moderator censorship reduces the feeling that the forum is a safe space to discuss mental health experiences and motivation to engage with the forum (outcome 1). However, accepting moderators' actions leads to users continuing to engage with the forum and abide by community guidelines (outcome 2).

Illustrative Interview Data

Participants reflected on how restrictions on discussions around certain topics can be valuable for creating a supportive environment.

> *People can talk about their daily activity but there's rules where you can't talk about how much you eat or weigh ... that's quite helpful for people who have anorexia or bulimia and it's good because everyone supports each other.* [D046]

However, when implemented in a manner that feels rigid and insensitive, forum users could experience significant distress.

> *I put in the post that basically I felt particularly terrified because I was sure I'd just eaten about 250 calories ... I got an email back which really upset me at the time basically from one of the staff moderators ... to quote her words, "As an opportunity to demonize calories because this is not helpful to other service users," I felt like I was at school, and I was being told off ... I was in a vulnerable state, in a state of considerable distress and it made it far worse.* [S019]

One user identified that this could have a muting effect on users' willingness to engage openly with the forum.

> *...you need to be careful with what you're saying and you can tell that sometimes in some people's stories that they're posting of how careful they're being and that doesn't make me feel very listened to or heard because ... and I don't know how that other person is feeling but I kind of feel like we're, the group, we're being not listened to fully.* [D229]

XSL•FO
RenderX

Reflecting on the challenge of balancing restrictions with open dialogue, the following participant recognized the need for an approach that charts a path between forum openness and moderator control in the service of forum safety.

> *...the (forum manager) thing where only his wisdom is allowed to be discussed, so you don't want to go too far in either direction. You're really got to be in the middle where you're allowed to have a free flow of information and people can talk to each other openly without feeling intimidated by others or intimidated by the moderators. There are two versions of making people feel unsafe. It can go both ways you know.* [M214]

Some forum users recognized rule enforcement to be an essential element of forum safety. Where moderators do intervene, doing so in a way that communicates the intention to support the user may mitigate possible negative reactions.

> *They [moderators] would jump in and say to them, "We don't post that particular sort of thing here. We hope you're okay and here's how we can help." It's like shutting it down but shutting it down in a friendly way. Like not telling the person off or making them feel like they've done something really bad because quite often we can do things when we're in distress that we wouldn't do if we weren't in crisis ... it's good if the moderators can kind of say, "I'm really sorry," or "everyone's probably really worried about you," but also in a really caring way because sometimes if you say, "We don't post that here and we just delete it," then that comes across as really cold and might actually make the situation worse for them.* [D229]

CMO4: Self-Moderation

CMO Configuration

Context

Online forum posts are user-generated and refresh continually such that forum users do not know the exact nature of the content they are likely to come across. Users' preferences for the type of content they wish to read or avoid are likely to fluctuate over time with their own mental health. This creates a risk that users may be distressed by something they read online.

Mechanism

Design features that notify users of the nature of the content they are about to access, such as topic tags, warnings, or descriptive thread titles (resources) to enhance users' ability to choose whether and when to access forum content (response).

Outcome

This reduces the likelihood that users access forum posts that distress them.

Illustrative Interview Data

Some interviewees noted that their experience of safety in an online forum could be undermined by unexpected and particularly emotionally charged content.

> *...crazy ideas and very explosive comments ... if you start reading some of the comments ... so I'm talking about the safety from the point of view of your illness ... okay, suddenly I'm being disturbed and stirred up. Your emotions, if you read something which instead of helping you it can actually make you feel worse, so that's what I'm saying can be unsafe from that point of view.* [D003]

Participants noted the central tension that reading others' experiences could be both challenging and helpful, necessitating a selective approach to what they access.

> *Some of the content was difficult to read, especially given what I was going through and how I felt but it was quite nice to be able to see other people who could identify with posts and stuff saying, "It's not just you, this is me too." So, my experience is a bit mixed, but I picked my diet so that's on me to a certain extent.* [D090]

> *...with your safety I think for me it's keeping it simple and definitely putting your boundaries down and saying, this is acceptable, this is not acceptable...* [M100]

Examples of forum features that could support this form of self-moderation included content warnings.

> *...they always have a warning at the top which is good because if you are sensitive that kind of stuff, you can always not view it, you have a choice at that point.* [D073]

Forums set up in such a way that the main text of a post was hidden also supported this decision-making process.

> *You don't have to actually delve into reading what they've put ... You might just get the header and think I won't bother reading that so that's why I don't bother because I think I already know them, that's going to upset me, so I'm not going to...* [M126]

CMO5: Interpersonal Safety

CMO Configuration

Context

Forum users, particularly those early in their forum experience, may be worried about viewing harmful online content and not being welcome in the community.

Mechanism

Seeing forum posts containing authentic accounts of shared lived experiences and posts that communicate an attitude of nonjudgmental acceptance (resource) facilitates a feeling of trust that community members are safe to share personal experiences with (response).

Outcome

Psychological safety, which in this context refers to feeling that the forum is a place where users feel able to bring their own views and experiences to the community.

XSL•FO
RenderX

Illustrative Interview Data

One user recognized that others posting about their lived experiences contributed to a sense of safety that promoted the reciprocal exchange of personal difficulties.

> *... Even though you don't know who each other are it's safe knowing that other people are going through the same things and they're almost trusting you as much as you're trusting them just to open up that little bit to try and get through whatever you're getting through.* [D196]

The following participant identified that those sharing authentic accounts of mental health challenges would be less likely to judge those going through similar experiences.

> *Interviewer: what makes a forum feel safe to talk about mental health?*
>
> *Respondent: I'd say that making sure the comments are like they feel authentic I think and that's what Dunnock can ... you're also talking to other people who are in similar situations and you can keep that aspect there I think it makes it feel a lot more authentic and safe to talk to because it's more ... you don't feel judged because they're going through similar things.* [D073]

A culture of acceptance further encouraged the following participant to feel able to discuss their mental health experiences online.

> *Interviewer: Is there anything else that makes you feel that this is a place you can talk about mental health?*
>
> *Respondent: It's the general atmosphere ... it's very accepting of anything you say like there's nothing that would ... everyone would support you on anything you said, if you see what I mean. They wouldn't, "That's your fault," or anything like that. I think it's the atmosphere ... that this is very kind, supportive...* [S006]

Discussion

Principal Findings

This study builds on findings from a previously published realist synthesis by highlighting and expanding on factors impacting users' perceptions of safety in online mental health forums. Anonymity was found to promote disclosure by mitigating against online posts being linked to users' offline identities, and by providing users with greater choice regarding what they share online. Perspectives on rule enforcement emphasized the importance of organizations balancing between proactive moderation to ensure that safety issues were addressed quickly and the need to intervene sensitively where conversations on restricted, yet potentially important personal experiences occurred. Participants reflected on the need to choose when and how to use online forums in light of their mental health, recognizing the possibility that accessing forum content could be helpful but also potentially detrimental at times. Factors contributing to a psychologically safe forum environment included the perceived authenticity of others in the community, an atmosphere of nonjudgment, and the value of sharing the space with others experiencing similar mental health difficulties.

Comparison With Prior Work

Previous research using both qualitative interviews and analyses of forum posting behavior suggests anonymity is a key factor in forum safety [11,34]. The finding that the value of anonymity lies in avoiding the judgment of others aligns with the suggestion that online anonymity mitigates adverse consequences linked to personal disclosure, including reputational harm, social pressure, and exclusion [35]. While in-forum anonymity appears broadly valued by users, variations in forum design highlight important choices regarding its implementation. Some forums emphasize complete anonymity such that users are unknown to each other and the host organization, while other platforms may collect personal information in the interest of safeguarding. Moderation practices also vary. Some forums prioritize online privacy and remove identifying information, while others may allow the sharing of some personal details, which as one participant noted here, can facilitate social connection. In balancing the advantages and challenges associated with anonymity, forum designers may need to consider relevant legal, ethical, and practical issues. These include legal obligations regarding the protection of personal data, the organization's responsibility for user well-being, community members' awareness of the implications of sharing their details online, and whether the forum is closed or open to the public [15,36]. Whether differences in the implementation of anonymity impact willingness to register or post to online forums is a potentially valuable avenue for further research.

Participants' reflections on content moderation emphasized the value of proactivity in managing problematic content, and interpersonal sensitivity when intervening to implement rules. Results here highlight the need for forums to balance between the benefits of open online discussion and the potential for censorship and disengagement. This topic has been the focus of extensive recent debate. Legal frameworks, such as the European Union Digital Services Act [24], have sought to place tighter rules on providers, whose responsibilities now include the need to implement and evidence content moderation and risk management procedures. These developments align with concerns that access to algorithmically generated and poorly managed social media content could rapidly expose users to high volumes of harmful content [37]. However, a recent academic debate on approaches to moderation revealed concerns that greater restriction on discussions of mental health difficulties represents a missed opportunity to facilitate supportive discourse, and creates undue barriers to support for those already experiencing limited access to care [38]. As part of this debate, researchers produced a call to action for more nuanced, evidence-based approaches to moderation. Suggestions included greater emphasis on community moderation, where site members' knowledge of the community's culture is leveraged to help make decisions about acceptable content, for example, via specific roles for experienced community members or the use of content labeling to allow users to more effectively flag harmful content [38].

XSL•FO
RenderX

A novel contribution of this study relates to users' reflections on the need to self-moderate their access to online mental health forums. The recognition that forum content can be helpful and at times detrimental aligns with a large body of social media–related research highlighting both the advantages of social connection and the impact of distressing content, social comparison, and harmful advice [39]. Interviewees valued forum design features that supported their decisions to access or avoid potentially distressing content, such as content warnings, and forum providers may wish to consider additional strategies to support the user's self-management of their services. Social media websites have in recent years integrated features including customizable update feeds and tools that filter content containing certain words or phrases, links to emotional support resources from trusted partners, and the use of content such as blogs to directly address the challenges of reading about distressing topics online [40]. To date, however, it is unclear to what extent these strategies are valued by users or effective in achieving their intended aims. Further research focusing on how services can support effective self-moderation of online communities is therefore warranted.

This paper emphasizes that moderators' actions often underpin safe and effective online mental health forums. Existing research makes clear that intervening to support users and implement rules are highly skilled and demanding tasks. For example, the online context requires moderators to engage in a range of nuanced text-based practices to build rapport, understand users' challenges accurately, and offer corresponding social support, including in situations where users are experiencing high levels of distress [41]. However, access to a large volume of distressing content, pressure to manage interpersonally sensitive and high-risk situations, and issues such as high workload, represent challenges to moderators' workplace well-being [42,43]. Forum safety is therefore likely to be enhanced by sufficient support for moderators. This may include appropriate initial and ongoing training in the mental health difficulties likely to be discussed on the forum, support from other moderators, including during shifts, to share challenges and strategies for managing difficult situations, and supervision from senior colleagues [19].

Online forums rely on a regularly updated stream of user-generated content, yet only a minority of those viewing forums post to them [44]. It is therefore vital to understand factors that may promote engagement with online conversations. Results here suggest that positive perceptions of the interpersonal safety of online forums may promote engagement and that this relies on a community embodying nonjudgment and being populated by people with similar mental health experiences whom forum users may intuitively trust with their own narratives. As previously noted, the concept of psychological safety, typically defined as a culture in which people feel able to take interpersonal risks, has parallels with this aspect of forum user experience. Consistent with the findings reported here, trust has been identified as an antecedent to psychological safety in online communities [20]. While largely conducted within in-person and nonclinical groups, psychological safety research has demonstrated that its presence is associated with knowledge sharing and "speaking up" behaviors, and its absence with "silencing behaviors" rooted in fear of negative social consequences [45]. Given that the psychological safety construct has been fruitfully applied in occupational research to identify individual and group-level factors linked to a range of important outcomes, including learning, well-being, and workplace performance, it may be advantageous for future research to apply this conceptual lens in developing a more thorough understanding of forum safety.

Limitations

This study has several limitations. First, the sampling strategy recruited current users of online mental health forums. This study therefore does not capture the perspectives of those who no longer use these services, some of whom may not do so because of fears over safety, and as such, this sample may provide more insight into safety-promoting measures rather than actions forums hosts should avoid. Second, participants were recruited from UK-based online mental health services focused on particular mental health challenges, potentially limiting the transferability of our findings to other forum contexts. A third related issue is that while all of the experiences described in the IPT framework were probed as part of the realist interviews, some, such as the negative impacts of anonymity and the normalization of harmful behavior, did not emerge as prominent issues in interviews with the participants in this study and were therefore not reflected in the refined program theories. This may be because forums used for recruitment to this study were actively moderated services, limiting exposure to these experiences.

Conclusions

Understanding how to deliver safe online mental health support is a topic of growing international significance. The findings of this realist evaluation highlight how users' perceptions of safety depend both on features of forum design—such as anonymity and content moderation—but also on the interpersonal interactions that emerge from their implementation. Delivering safe and effective online mental health forums therefore depends on understanding how, in practice, steps taken to reduce harm and promote engagement are experienced, highlighting the need for ongoing research in this domain.

Lived Experience Commentary

A lived experience commentary by an expert is presented in Textbox 1.

XSL•FO

Textbox 1. Lived experience commentary by Sophia Tai.

The research in this realist evaluation showed not only do mental health forums provide safety and an antidote to loneliness but also have the potential to cause harm and distress to its users if moderated poorly without the correct parameters. Moderation can be applied with the help of trained moderators or by self-moderation such as content filter settings to avoid triggering posts that may be harmful or distressing. However, while I agree that self-moderation is essential for user autonomy, it is not always enough. A mental health forum would imply that users who join may not always be in their best mental or emotional state, making them more vulnerable. From personal experience, any level of self-moderation can start showing gaps as our mental health starts to suffer. One example forum mentioned in this paper also supports teenagers under the age of 16. I would argue that effective self-moderation requires a level of maturity not necessarily present in this age range. With this in mind, I urge the importance of investment in highly trained moderators which this paper highlights as a key element for safeguarding mental health forum users.

This paper pointed out the accessibility of mental health forums, which helps overcome time barriers such as long NHS waitlists or financial barriers such as private therapy costs. Not being able to access immediate support can cause an individual's condition to get worse quickly. Having access to a safe forum can provide effective support to a large demographic, or those with barriers to immediate support. I agree with the findings in this research that a forum with poor or no moderation is worse than not joining a forum at all. There needs to be a support system in place to ensure moderators can maintain good mental health and remain in a strong supporting role for those who are vulnerable. A well-moderated forum would not only support a larger demographic in the mental health sphere but also give intermediate support for those on waitlists or aftercare for those coming out of sessions and finding their own footing after mental health care.

Acknowledgments

This study was funded by the National Institute for Health and Care Research Health and Social Care Delivery Research Program (NIHR134035). The views expressed are those of the author or authors and not necessarily those of the National Institute for Health and Care Research or the Department of Health and Social Care. The research team would like to thank the Improving Peer Online Forums (iPOF) public and patient involvement group for their support in developing the study materials, Sophia Tai for providing a lived experience commentary that is published with their name and with their consent, and forum partners for their support with the wider iPOF project

Abstract

Background: Mental health recovery typically continues after patients leave the hospital. However, hospital readmission in the 12 months after discharge is common and costly.

Objective: This study aimed to examine the effectiveness of supportive text messaging (hereinafter “SMS”) and SMS with or without peer support service on hospital readmission and length of stay after discharge from inpatient psychiatric care.

Methods: A stepped-wedge cluster randomized trial was used to examine differences in the changes in the mean number of admissions and the mean duration of total length of stay in days, for patients discharged from psychiatric inpatient care, at 6 and 12 months pre- and post index admissions, for 2 intervention periods compared to a control period of treatment as usual.

Results: Overall, 1070 participants were assigned to 1 of 3 study arms: SMS (n=302), SMS with or without peer support service (n=342), or treatment as usual (n=426). Compared to treatment as usual, SMS with or without peer support service reduced hospital readmissions 6 months pre- and post index admission by an average of 0.26 admissions, and SMS alone reduced inpatient length of stays 6 months pre- and post index admission by an average of 7.28 days.

Conclusions: Our results demonstrate that simple, low-cost digital tools—either by themselves or paired with peer support—can help close gaps in postdischarge care. We anticipate that these findings may inform future service delivery models and policy development aimed at enhancing postdischarge mental health support. By supporting smoother transitions and reducing future hospital use, such approaches may offer a scalable way to build more sustainable and person-centered mental health systems.

Introduction

Mental health crisis often leads individuals discharged from acute psychiatric hospitals to seek readmissions, contributing to prolonged hospital stays [1-3]. Avoidable readmissions and increased length of hospital stay have emerged as a significant concern for health systems globally [4,5]. Such readmissions not only impose substantial physical, psychological, and financial burdens on patients and their families but also strain health system resources [6-9]. One study, which also examined patients in Alberta, Canada, reported that 14.0% of psychiatric hospitalizations among young adults were followed by readmission within 90 days, and the median time to readmission was 24 days [10]. High readmission rates and increased length of hospital stay consume limited infrastructural, human, and financial capacities, thereby compromising the efficiency and sustainability of health care delivery [6,11,12]. This challenge has become even more pronounced in the post–COVID-19 era, and many hospitals continue to face surges in psychiatric emergency department presentations, readmissions, and capacity pressures [13]. As a result, there is growing global interest in identifying and implementing effective strategies to reduce preventable readmissions, particularly within acute care settings [14]. Traditional interventions may not fully address the complex needs of individuals recently discharged from acute psychiatric hospitals who experience postdischarge mental health crises [1,2,15,16]. These individuals are at heightened risk for readmission, often due to inadequate postdischarge support, as traditional follow-up care models may not provide sufficient engagement or timely intervention, leading to increased reliance on emergency and acute mental health services [15]. Recent innovations, such as text messaging support and peer support programs, have emerged as promising adjuncts to conventional care, aiming to prevent psychiatric readmissions and shorten hospital stays [17,18]. These interventions offer scalable, cost-effective, and accessible solutions to enhance recovery and reduce the burden on acute psychiatric services. For example, Stevens et al [19] demonstrated that an SMS brief contact intervention significantly reduced repeat hospital presentations for self-harm among patients receiving hospital-based care. This finding supports the growing potential of SMS-based interventions to potentially improve outcomes and reduce readmission rates across diverse mental health populations [19]. Text messaging interventions offer a convenient and immediate means of communication, delivering supportive messages, reminders, and resources to individuals in real-time [20,21]. Text messaging interventions have also demonstrated significant efficacy in improving medication adherence and clinical engagement among individuals with serious mental illness [22,23]. A systematic review encompassing various psychiatric disorders reported that text messaging interventions significantly improved medication adherence and clinical outcomes in a majority of studies. These interventions were well-received by participants, highlighting their feasibility and acceptability as a component of mental health care [22].

In recent years, peer support services (PSS) have gained considerable attention as an innovative and effective complement to traditional mental health interventions [24]. Peer support involves individuals with lived experience providing emotional and practical assistance to others facing similar challenges, fostering a sense of hope and empowerment [24-26]. A systematic review and meta-analysis of one-to-one peer support interventions in mental health services, which included 23 studies reporting 19 trials and 3329 participants, further corroborated these findings [27]. The review suggested that one-to-one peer support may have a modest positive impact on self-reported recovery (relative risk=0.22, 95% CI 0.01- 0.42, *z* score=2.0, *P*=.04) and empowerment (relative risk=0.23, 95% CI 0.04- 0.42, *z* score=2.3, *P*=.02), but no impact on clinical symptoms or service use, suggesting that peer support may be more effective in enhancing personal and social functioning rather than directly altering clinical parameters [27]. It is therefore likely that the combination of peer support and text messaging may offer synergistic benefits [17,18]. Peer support provides relational and emotional benefits [24], while text messaging offers structured, timely, and scalable support [21,28]. Together, these interventions can address both the emotional and practical needs of individuals with mental health concerns, potentially leading to reduced readmission rates and decreased length of hospital stays [1,20]. Moreover, they align with recovery-oriented care models that emphasize patient-centered, community-based, and continuous support [17]. A controlled observational pilot study conducted in Edmonton, Alberta, evaluated the effectiveness of peer support and supportive text messaging on recovery outcomes among patients discharged from acute psychiatric care [17]. The study found that participants receiving the combined intervention (peer support plus text messaging) exhibited significantly higher recovery scores compared to those receiving standard care or text messaging alone. Notably, improvements were observed in areas such as personal confidence, willingness to seek help, and overall recovery, with sustained benefits up to 6 months post discharge [17]. Despite promising evidence, these interventions have several implementation challenges, such as variability in program design, lack of standardization, and limited integration into existing health care systems, impacting widespread adoption [24,28]. Furthermore, the sustainability of these programs requires adequate funding, training, and ongoing evaluation to improve program delivery and effectiveness. Addressing these barriers is crucial for realizing the full potential of peer support and text messaging in transforming mental health care delivery [17,22,29].

As health care systems continue to evolve, embracing innovative, patient-centered approaches will be essential in meeting the complex needs of individuals with mental health disorders. This study aims to examine the effectiveness of text messaging and peer support on patients discharged from inpatient psychiatric hospitals by assessing the mean number of readmissions and length of stay at 6- and 12-months in a cluster randomized controlled trial. The specific objectives of

XSL•FO
RenderX

the study are to determine if there are statistically significant differences in the mean changes in the number of readmissions and the mean changes in the total length of stay for patients 6 and 12 months from pre- to post index admission in three arms of the study: text messaging arm (hereinafter "SMS"), SMS with or without peer support arm, and treatment as usual arm. This study seeks to inform clinical practice and policy development and contribute to advancing mental health care strategies that are both effective and accessible.

Methods

Study Design and Data Collection

This study evaluated the effectiveness of two interventions that are (1) web-based, fully automated supportive text messages—Text4Support (SMS) alone—and (2) SMS with or without the addition of PSS, on the changes in the mean number of readmissions and length of stay among patients with psychiatric illness in the province of Alberta. A pragmatic stepped-wedge cluster-randomized approach with three arms was applied, providing usual postdischarge care alone, SMS plus usual care, and SMS with or without PSS plus usual care to the participants recruited across 10 acute care sites across Alberta as the clustered unit of randomization. This design was found to be successful with complex programs and change management involving large-scale programs [30]. The 3-arm design in this study allows for an assessment of not only whether SMS improves outcomes compared with usual care, but also whether the addition of PSS provides any incremental advantage. If combined support offers no additional benefit over SMS alone, then the SMS-only program would be the more economical and scalable option for patients discharged from acute mental health care. Conversely, if combined support clearly outperforms both SMS alone and usual care, then health authorities may consider implementing the more resource-intensive dual intervention. Randomization of the 4 cluster units was undertaken by an independent statistician. The study design and recruitment procedures have been fully described in the published study protocol [31]. No blindness was applied, and study participants were aware of their study cluster and randomization. In addition, no changes to the trial design or interventions were made after participant recruitment commenced. All patients have received concomitantly the usual care in the community (outside the scope of the study). For this study, sociodemographic characteristics were collected, including chronological age and gender; clinical data collected included primary diagnosis during hospitalization. Health usage data were obtained from Alberta Health Services administrative data sources spanning 1 year before the index admission date and 1 year post discharge. Individual deidentified participant data was applied by removing patients' names, and the primary identifier was the patient's phone number and health identifying number. Figure 1 depicts the unit cluster randomization.

Ethical Considerations

The ethical requirement for this study was provided by the University of Alberta's Health Research Ethics Board (Ref number Pro00111459). In addition to ethics, the regional health authority also provided additional operational approval. All participants involved in this project provided written informed consent, and the privacy and confidentiality of participants were guaranteed by not including any participant information in published manuscripts and reporting data as aggregates. The research was conducted in accordance with the Declaration of Helsinki. No financial compensation was provided to the participants.

Participant Recruitment

Study participants were recruited among individuals who had been diagnosed with a mental illness and were ready for discharge from the inpatient psychiatry units. Face-to-face discussions were conducted to recruit participants across 10 major acute psychiatric care sites in Edmonton, Calgary, and Grand Prairie in Alberta. Operational managers and clinical staff supported the research team by identifying patients about to be discharged within 7 days from a psychiatric unit. Eligible patients were provided with detailed study information. Written consent was obtained, and participants were invited to complete a self-administered questionnaire on a tablet device. The inclusion criteria included being above 18 years old, having had a mobile device, being able to read English text messages, and being able to provide consent to participate in the study. Exclusion criteria involved the participants who knew they would be based out of town during the 12-month follow-up period. The recruitment period was extended for 2 years, starting in February 2022 and ending in February 2024. Study participants were allocated into one of 3 intervention groups based on cluster randomization. There were 1155 study participants recruited across the entire recruitment period. Psychiatrists and nursing staff helped identify patients likely to be readmitted post discharge and eligible for PSS. This approach aligns with the principles of pragmatic trials, where clinical judgment and team-based risk evaluation inform the allocation of postdischarge PSS [32].

Text and Peer Support Interventions

The Text4Support program delivered through the ResilienceNHope platform [33] offered evidence-based daily supportive text messages to individuals discharged from acute psychiatric care. This low-cost program, like it is predecessor Text4Hope program, which enrolled over 50,000 subscribers during the COVID-19 pandemic [34], aimed to reduce the psychological treatment gap and was used alone or in combination with peer support. The evaluation of the Text4Hope program showed that automated, web-based daily supportive text messages are effective in reducing psychological distress among the general public and received high levels of user satisfaction [35-37]. Messages began the day after enrollment and were sent once daily in a unidirectional (no-reply) format. These messages were crafted based on cognitive behavioral therapy principles by mental health clinicians in collaboration with individuals who have lived experience. The messages provided general support (hope, affirmation, and self-care) as well as diagnosis-specific content based on 6 common psychiatric diagnoses: mood disorders, anxiety disorders, psychotic disorders, substance use disorders, adjustment disorders, and personality disorders. For instance, some messages for depression focused on behavioral activation, while those for anxiety emphasized relaxation techniques. The first text message participants received included the phone number for mental health crisis services they could contact if needed. Participants assigned to the Text4Support program had their phone numbers registered in the ResilienceNHope application to receive 6 months of free, daily, web-based automated supportive text messages tailored to their primary mental health concern. The peer support intervention was delivered by PSSs—individuals with lived experience of mental illness who are in recovery themselves. Their responsibilities included face-to-face visits, virtual interactions (via phone, text, or Zoom), advocacy, linking patients with community resources, and sharing personal recovery experiences.

Sample Size Considerations

We estimated that the sample size needed to assess the effects of the SMS and PSS interventions on the outcome variables would be 1051. This was calculated with a projection that the effect size for the reduction in mean scores of readmissions and length of stay (LOS) at 6 months from baseline would be 0.2, a population variance of 1 for each mean score, and a 2-sided significance level α=.05, and a power of 90% (β=.1).

Outcome Measures

The study's primary outcomes involved health usage parameters, including differences in the mean changes in the number of readmissions and LOS 6 and 12 months before admission preadmission and post discharge among the study intervention. Outcome measures were extracted from Alberta Health Services administrative data sources.

Statistical Analysis

Data analysis was performed using SPSS (IBM Corp) for Windows, Version 25 [38]. Participants' study intervention groups were plotted against all independent variables. Chi-square or Fisher exact test was used for categorical variables; one-way ANOVA was conducted to determine if there were significant differences in the mean age of participants in the 3 treatment groups. A difference-in-difference analysis was conducted to examine the effect of the interventions on the mean difference in the outcome variables from preadmission to follow-up respective time points (eg, LOS 6 and 12 months pre-enrollment to 6 and 12 months post discharge, respectively). Considering violations of ANOVA assumptions—specifically, nonnormality of data and heterogeneity of variances—we applied the Welch *F* test. Effect sizes were estimated using an omega-squared statistic adjusted for the Welch degrees of freedom ($\omega^2 = [df_1 \ (F - 1)] / [df_1 \ (F - 1) + N]$). Post hoc comparisons were conducted using the Games–Howell test. The statistical analysis plan for this study, which is based on means and SDs and incorporates the preindex admission event, is grounded in the theoretical and conceptual framework of adverse events in psychiatry—such as self-harm [39], emergency department visits [40], and inpatient admissions [41-44]—where

XSL•FO
RenderX

a previous history of the event is among the strongest predictors of recurrence. For example, it has been reported that patients with previous psychiatric hospitalizations before an index admission have twice the risk of readmission within 12 months compared to those without such a history [43].

Percentages and raw data were used to report the descriptive characteristics, with a significance level of *P*.05 used to determine statistical significance for all analyses. Regarding the missing data, there were a total of 28 missed cases (SMS: n=5; SMS with or without PSS: n=10, and TAU: n=13). The administrative data related to the index admission of these patients were not available at the health authority (Alberta Health Services). Data were missed from each cluster at random; possible reasons were not a valid health care number, an out-of-province health care number, an invalid phone number, or an inability to locate the index admission in health records. In addition, 6 patients dropped out of the study (equally distributed among the clusters). No imputation of missing data was applied, and the analysis was run with the intention to treat, that is, the participants were deemed adherent or receiving the intended intervention regardless of the actual receipt of the service.

Results

Figure 2 shows the study flowchart.

Overall, 1070 participants were assigned to one of 3 study arms: supportive text messaging alone (SMS, n=302), supportive text messaging with or without peer support (SMS with or without PSS, n=342), or treatment as usual (TAU, n=426). Table 1 illustrates the results related to participants' demographic characteristics and clinical data in relation to the study intervention groups. Out of 1070 participants, 395 (36.9%) of participants were younger than 25 years, 586 (54.8%) were females, and had a primary diagnosis of depression or anxiety (639/1070, 59.8%). The rest had a primary diagnosis of substance use disorder, personality disorder, or other conditions (257/1070, 24.0%), and psychosis (173/1070, 16.2%). There was a significant difference among the intervention groups regarding the age of the participants when assessed both as a continuous variable ($F_{2,10467}$=18.53, *P*<.01) and as a categorical variable ($\chi^2_4$41.64, *P*<.01). There were no significant differences between the intervention groups with respect to gender and primary diagnostic category.

Table 2 demonstrates changes in the mean number of admissions and LOS 6 and 12 months pre- and 6 and 12 months post index admission. The table showed that there was an overall reduction of the health usage parameters post discharge except for the LOS among the SMS with or without PSS and TAU groups, regardless of the follow-up time point.

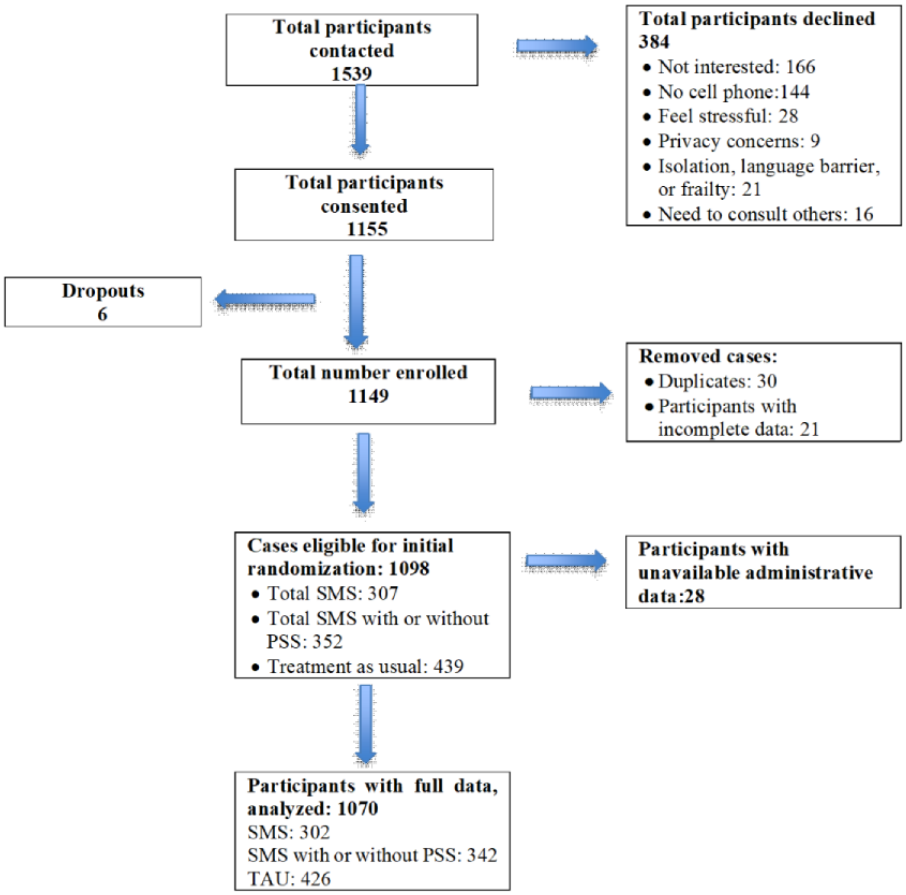

Table 3 illustrates the effectiveness of study interventions on changes in health usage parameters 6 and 12 months pre- and post discharge. The results were evaluated using the Welch *F* test, and effect sizes were estimated using an omega-square statistic adjusted for the Welch degrees of freedom ($\omega^2 = [df_1 (F - 1)] / [df_1 (F - 1) + N]$). From the table, there was a significant difference in changes in health usage among different study groups as reported for the mean difference in the number of admissions 6 months pre- and post index admission ($F_{2,1032}$= 4.05, *P*=.02), with a small effect size (ω^2<.01) and the change in mean LOS 6 months pre- and post index admission ($F_{2,1032}$=3.95, *P*=.02, with a small effect size (ω^2<.01).

Table 4 depicts the post hoc analysis (pairwise comparison) among the study intervention groups regarding the mean changes in the number of admissions between the study groups 6 months pre and post index admission. From the table, there was a significantly greater reduction in mean change in number of admissions for the SMS with or without PSS group when compared to the TAU group (mean difference 0.26, 95% CI value 0.05-0.48). Whilst the mean reduction in the number of admissions for the SMS group was much larger than for the TAU group, the difference in the changes in mean number of admissions between the two groups did not reach statistical significance (*P*>.05). Similarly, there was no statistically significant differences between the SMS group and the SMS with or without PSS group with respect to the mean changes in the number of admissions pre and post the index admission.

Table 5 depicts the post hoc analysis (pairwise comparison) among the study groups regarding the difference in values of the total LOS from 6 months preadmission to 6 months after discharge. There was a significant reduction in the mean LOS pre and post index admission for the SMS group as compared to the TAU group, with (mean difference of 7.28 (95% CI value 1.08-13.48). However, there were no statistically significant differences between the SMS group and the SMS with or without PSS group, or the SMS with or without PSS group and the TAU group with respect to the mean changes in the LOS pre and post the index admission.

Discussion

Principal Findings

This cluster randomized controlled trial evaluated the effectiveness of supportive text messaging and peer support on psychiatric readmissions and hospital LOS at 6 and 12 months following discharge from acute inpatient psychiatric care. Applying the Welsh F test, there was a statistically significant reduction in mean readmissions was observed in the SMS with or without PSS group compared to the TAU group ($F_{2,1032}$= 4.05, *P*=.02), with a mean difference of 0.26 admissions (mean difference=0.263; 95% CI 0.046-0.479). Additionally, the SMS group demonstrated a significant reduction in LOS at 6 months post discharge compared to the TAU group ($F_{2,1032}$=3.95, *P*=.02), with a mean difference of 7.28 days (95% CI 1.076-13.482) and a small effect size (ω^2<.01). The differences in changes in mean admissions and LOS between the 3 groups 12 months pre- and post index admission were not statistically significant. These findings suggest that supportive text messaging, with or without peer support, may be effective in reducing both psychiatric readmissions and hospitalization duration during the critical early period following discharge. The result is consistent with previous studies demonstrating that SMS interventions can enhance continuity of care, medication adherence, and engagement with services, all of which may contribute to earlier symptom recognition and intervention, thus potentially shortening hospital stays [23,45]. Despite the modest effect sizes, the low cost, scalability, and ease of integration of SMS-based interventions make them an attractive adjunct to traditional mental health services. Notably, the SMS with or without PSS group showed significant differences in the mean change in readmission numbers at 6 months but not at 12 months, and no change in the LOS at either 6 or 12 months compared to the TAU group. This may reflect implementation variability, insufficient peer support exposure, or differences in participant engagement. Although peer support may positively affect psychosocial outcomes such as empowerment and perceived recovery [25], its effect on clinical service usage outcomes (eg, LOS, readmissions) has been inconsistent. For instance, a study assessing peer support interventions aimed at reducing psychiatric readmissions within one year of discharge found that providing one-to-one peer support in addition to usual care for patients at risk of readmission did not demonstrate superiority over usual care alone during the 12-month follow-up period [32]. Variability in peer training, frequency of contact, and integration into clinical teams are potential contributing factors that warrant further investigation [24-26].

The absence of statistically significant differences in the mean change in readmissions at both 6 and 12 months between the SMS and TAU groups suggests that SMS intervention alone may not sufficiently address the complex, multifactorial causes of psychiatric rehospitalization. Factors such as housing instability, substance use, social support deficits, and fragmented community services play a substantial role in driving readmissions [1-3,16]. While text messaging and peer support may improve engagement and subjective recovery, their ability to reduce reliance on acute care likely requires integration with more comprehensive, individualized, and coordinated post-discharge services [1,16]. Despite these limitations, the significant reduction in LOS at six months for the SMS group and the significant reduction in the readmission rate at 6 months for the SMS with or without PSS group compared to the TAU group indicate that even modest digital interventions and peer

XSL•FO
RenderX

support can positively affect clinical outcomes. This aligns with recovery-oriented models of care that prioritize accessible, continuous, and patient-centered support following hospital discharge [2,17,46]. Moreover, these findings underscore the potential for technology-based and peer-driven interventions to complement existing care structures, particularly in resource-constrained environments.

Limitations

Several limitations should be acknowledged. First, there is a potential for selection bias, as patients offered peer support were chosen by the inpatient team based on their perceived higher risk of readmission. Second, the lack of fidelity assessments—particularly for the peer support component—limits the ability to draw firm conclusions about the effectiveness of this intervention; further research is needed to better evaluate its potential effectiveness. Third, the study did not assess or control for outpatient treatments received by participants, which can be a significant potential confounding factor influencing readmission rates. Fourth, the achieved sample size of 1070 was substantially lower than the 10,000 participants projected in the published study protocol, which, at face value, may raise concerns regarding the generalizability of the findings. However, the sample size exceeded the estimated requirement of 1051 participants needed to detect mean differences in outcome variables with 90% power at a 2-sided significance level (α) of .05, which supports the generalizability of our study findings. Fifth, while the study protocol inadvertently listed 9 study sites, the trial registration accurately identified 11. In practice, ten sites ultimately participated, as one site (Fort McMurray) was unable to proceed due to insufficient personnel to support the research activities. Despite these limitations, the findings suggest that text messaging and PSS may offer promising avenues for enhancing follow-up care for individuals discharged from inpatient psychiatric facilities. Whilst mean readmission and mean LOS after an index admission have been previously studied in the psychiatric literature [47], this study adds to the literature by examining changes in the mean admissions and LOS pre- and post index admission.

Policy Implications and Future Directions

The results of this study carry implications for mental health policy and service planning. The observed reduction in hospital LOS at six months among participants receiving SMS compared to the TAU group underscores the potential of low-cost, scalable digital interventions to optimize post-discharge care. Similarly, the statistically significant reduction in mean readmissions observed at six months in the SMS with or without PSS group compared to the TAU group suggests there may be potential benefits for incorporating SMS and PSS into postdischarge care. However, the small effect sizes suggest that the clinical effectiveness, although present, may be limited without broader systemic changes. Notwithstanding, in resource-limited settings, where access to intensive follow-up services may be constrained, integrating SMS-based support and PSS into routine discharge planning may offer a cost-effective strategy to improve continuity of care and reduce inpatient service usage.

Health system planners and policymakers should consider formally incorporating SMS and PSS into standard discharge protocols for psychiatric inpatients. Given the minimal infrastructure required and the high penetration of mobile phone usage, particularly in underserved populations [21,28], SMS interventions represent a feasible adjunct to existing services. Their integration could also contribute to broader health equity goals by improving engagement and outcomes among individuals who face barriers to traditional in-person follow-up care. However, the lack of observed significant differences in changes in readmission rates between the SMS and TAU groups highlights the need for caution in relying on stand-alone digital interventions. Policymakers should avoid viewing such interventions as substitutes for comprehensive care. Instead, such interventions may be positioned as components within a broader, multilayered system of postdischarge support that includes PSS, housing assistance, substance use services, case management, and community-based psychosocial resources. Efforts should also be made to standardize the implementation and monitoring of peer support programs. Variability in delivery may dilute potential benefits. To enable standardization, policy initiatives aimed at developing certification programs, structured peer training, and clear role definitions could enhance the consistency and effectiveness of peer-delivered services in mental health systems.

Future research should prioritize assessment of implementation fidelity of peer support interventions, with particular attention to optimal intervention intensity, training standards, supervision quality, and integration within clinical teams. Identifying the conditions under which peer support is most effective is essential, especially given the null findings in the combined SMS and peer support arm of this study. To better understand the mechanisms by which supportive text messaging contributes to reduced LOS, mixed methods research is needed. Exploring user engagement patterns, perceptions of message relevance, and overall patient experiences can guide the refinement of message content, frequency, and delivery strategies to maximize effectiveness.

Further research should investigate whether specific subgroups—such as individuals with co-occurring substance use disorders, unstable housing, or frequent hospitalizations—derive greater benefit from such interventions. Tailored approaches for higher-risk populations may improve outcomes and promote equity in postdischarge care. Given the scalability and low cost of SMS interventions, patient experience will be important for optimization and moving toward co-creation for innovative solution pathways involving text and PSS. In addition, proactive consideration of formal economic evaluations is warranted to quantify potential cost savings associated with reduced LOS and other health care usage metrics. Demonstrating cost-effectiveness is essential to inform policy decisions and support the integration of these interventions into publicly funded mental health systems. Additionally, future studies should explore the effectiveness of multicomponent interventions that combine SMS and peer support with other services, such as case management, telepsychiatry, and community outreach. These more comprehensive models may be better suited to address the multifaceted challenges contributing to psychiatric readmission. Longitudinal studies with extended follow-up and detailed

XSL•FO
RenderX

process evaluations are also needed to assess the sustainability of intervention effects and elucidate long-term outcomes. Collecting in-depth qualitative data from service users will be critical for improving the acceptability, engagement, and person-centeredness of these strategies. By addressing these research priorities, future work can contribute to the development of integrated, evidence-informed care models that harness both technological and peer-based resources to support recovery, reduce hospital dependency, and strengthen the continuum of mental health care.

Conclusions

Overall, the results suggest that supportive text messaging and peer support may potentially serve as a valuable adjunct to traditional care. However, their greatest potential likely lies in their integration within broader, individualized, and coordinated care pathways. These findings contribute to the growing evidence base for technology-assisted mental health interventions and PSS and support their inclusion in recovery-oriented models of care. While the combination of text messaging and peer support showed modest medium-term benefits in this trial, both interventions hold promise as components of a comprehensive, recovery-oriented discharge planning approach. These findings may inform future service delivery models and policy development aimed at enhancing post-discharge mental health support.

Acknowledgments

The authors would like to thank the peer support workers and staff of Alberta Health Services, who provided varied support in conducting this study, particularly the Decision Support Services, Addiction and Mental Health, and Recovery Alberta, for collecting the data related to health usage. The study was funded by Alberta Innovates. The funder did not have any role in the design, conduct, analysis, and reporting of the trial.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Abstract

Background: Previous studies have found that psychotic disorders are among the most stigmatized mental disorders. Of note, virtual reality (VR) interventions have been associated with improvements in attitudes and empathy and reduced stigma toward individuals with psychotic disorders, especially among undergraduates, but this has not been examined among mental health care professionals.

Objective: We aimed to evaluate the effectiveness of a newly developed VR intervention for mental health care professionals to improve attitudes and empathy and reduce stigma toward people with psychotic disorders.

Methods: We conducted a randomized controlled trial and recruited eligible mental health care professionals from a tertiary mental health care institution. Both arms (VR intervention and VR control groups) were evaluated at baseline, postintervention, and 1-month follow up. The evaluation included outcomes related to attitudes (modified attitudes toward people with schizophrenia scale), stigma (social distance scale, personal stigma scale), and empathy (empathetic concern subscale of the Interpersonal Reactivity Index). The experience with the VR intervention was assessed using a user satisfaction questionnaire, and qualitative feedback was gathered.

Results: Overall, 180 mental health care professionals participated and completed the study. Both groups showed improvements in attitude, social distance, and stigma scores but not the empathy score following the intervention. The VR intervention group had better user satisfaction than the VR control group. In addition, certain outcome measures were positively associated with specific factors including female gender, higher education level, certain job roles, years of work, and presence of loved ones with a mental disorder.

Conclusions: Both the intervention and control VR groups of mental health care professionals showed improvements in attitudes, stigma, and social distance toward people with psychotic disorders. Future longitudinal studies may want to evaluate the impact

XSL•FO
RenderX

of VR on caregivers and the public on these same and other outcome measures to reduce stigma and improve empathy toward individuals with psychotic disorders.

Trial Registration: clinicaltrials.gov NCT05982548; https://clinicaltrials.gov/study/NCT05982548

Introduction

Psychotic disorders can affect the individual in several domains including physical health, social functioning, occupational functioning, and quality of life. Patients with psychotic disorders experience positive symptoms such as hallucinations and delusions, and although there are effective treatments for these conditions, help-seeking behaviors and access to treatment may be affected by the attitudes, stigma, and empathy of mental health care staff regarding such conditions [1]. Empathy is the ability to place oneself in the shoes of another so as to better understand the experiences of the other person cognitively and emotionally [2], which can contribute positively toward the quality of patient care and the overall well-being of health care professionals [3]. In addition, among people with mental disorders, empathy of the therapist reduces feelings of isolation, increases hopefulness, and facilitates better therapeutic engagement with individuals with mental disorders [2]. Of note, better attitudes and empathy of health care staff toward patients with psychotic disorders have been associated with better patient well-being, quality of patient care, and treatment outcomes [4-6].

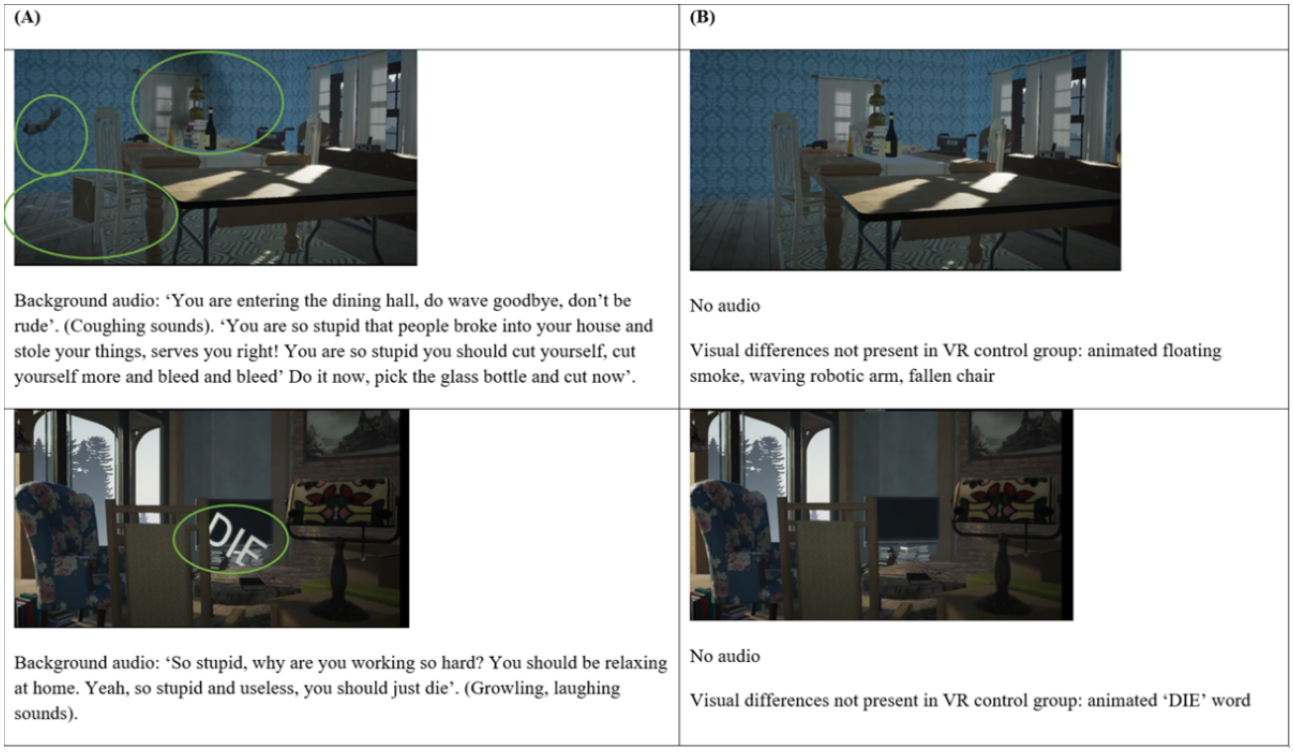
In turn, attitude and empathy levels can also be influenced by the level of stigma [7]. Stigma has been commonly associated with psychotic disorders [8]. Some negative perceptions of individuals with psychotic disorders included inaccurate and pejorative labels such as “unpredictable,” “violent,” and “aggressive,” even by health care workers [9,10]. Thus, stigma potentially prevents individuals who experience psychotic disorders from seeking help, as they fear discrimination [1]. A recent systematic review of 38 studies found that psychotic disorders are among the most stigmatized mental disorders among mental health care professionals [11], although mental health care professionals tended to have lower stigma levels [12], which could be related to direct social contact [13]. In particular, associative stigma among mental health care professionals was associated with more depersonalization, more emotional exhaustion, and less job satisfaction for the mental health professionals and higher self-stigma among patients [14]. Overall, the inter-relationships between stigma level and relevant mental health care professional factors such as age, job role, education level, and length of service are still not entirely clear [11].

Virtual reality (VR) interventions have been increasingly adopted to enhance training and quality of health care including mental health care [15-18]. In contrast to traditional videos, VR interventions can fully immerse users in the context, thus allowing users to experience specific simulated scenarios more realistically. A recent review found that VR and augmented reality interventions showed promise for improving the knowledge and attitudes toward individuals with neurocognitive and psychotic disorders [19,20]. Specifically, VR interventions that allowed participants to experience the sensory and cognitive challenges that people with dementia endured resulted in improvements in attitude levels among medical and pharmacy students [21]. Other VR interventions with simulated hallucinations also resulted in improvements in undergraduates’ attitudes and empathy levels toward people with psychotic disorders [22,23], but their effects on stigma remain inconclusive [24,25].

To date, limited studies have examined the use of augmented or VR-based modalities to improve attitudes, stigma, and empathy toward people with psychotic disorders. Previous studies were mainly conducted in the west among undergraduates, had pre-post designs, and reported some positive outcomes [22,23,25]. To the best of our knowledge, no study has examined the impact of VR intervention on mental health care professionals’ attitudes, stigma, and empathy levels toward people with psychotic disorders. Thus, in this study, we sought to examine the use and impact of a VR intervention containing simulations of psychotic experiences for mental health care staff in the context of a non-western culture. Based on extant data, we hypothesized that it could improve attitudes, reduce stigma, and enhance empathy toward patients with psychotic disorders among mental health care professionals.

Methods

Ethical Considerations



The study was a 2-arm, randomized controlled trial and was approved by the Institutional Review Boards at the Institute of Mental Health (IRRC number: 818-2022) and National Healthcare Group (IRB number 2023/00027) in Singapore.

VR Intervention Group

The VR intervention was created using Unreal Engine [26]. The VR intervention illustrated a home scenario (Figure 1), and participants experienced simulated psychotic phenomena including auditory hallucinations. The constructed VR intervention is accessible at [27].

XSL•FO
RenderX

Figure 1. Examples of the display shown to the (A) intervention group and (B) control group.

The VR intervention was constructed based on a systematic review conducted by the team [20] that found that effective interventions for reducing stigma and enhancing empathy and positive attitudes toward people with psychotic disorders included short VR videos with simulated visual and auditory hallucinations that lasted no more than 15 minutes [22,23]. The VR intervention was also based on existing simulation videos for psychotic disorders such as schizophrenia [28-31] that included common hallucinations including floating items; monsters or shadow-like figures; random negative words; auditory hallucinations including laughing, crying, or scary sounds; running commentary; and commands. The VR intervention was further revised following input from a clinician and a peer support specialist. The VR intervention, lasting no more than 7 minutes, was delivered in a single setting. In the process of obtaining consent, participants were informed that they might experience some discomfort during the VR intervention. They were informed that they could withdraw from the research study at any point in time. Each participant met a researcher within a quiet office room. They then participated in the VR intervention, which was conducted using a smartphone device inserted into a VR headset equivalent to Google Cardboard. Participants remained seated in a stationary position while they viewed the VR intervention. The intervention began with a house scene. Upon entering the house, the participant initially heard some voices. Later, the "voices" became increasingly frequent and emotionally charged with negative content as the scene went through different parts of the house. Participants would also experience "visual hallucinations" such as seeing the words "die" and "poison" in food and that corresponded with the "voices." Eventually, the voices mentioned suicidal ideas, and the scene finally ended with a concerned call from a mental health care professional.

VR Control Group

The VR control group viewed the scenario of the same home setting without the experience of the simulated visual and auditory hallucinations and the call by the mental health care professional. The constructed VR control intervention is accessible at [32].

Participants

The participants were recruited from the only tertiary mental health institution in Singapore using stratified sampling according to their job role, namely (1) allied health staff (including occupational therapists, medical social workers, case managers), (2) nurse, or (3) physician.

Inclusion and Exclusion Criteria

The inclusion criterion entailed that the participant was involved in the direct care of patients with mental disorders. The exclusion criteria included (1) participants who were unable to use VR interventions due to reasons including motion sickness, disorientation, nausea, and vomiting or (2) those with a history of epilepsy, as flashing VR images might predispose these individuals to photosensitive seizures.

Sample Size Calculation

The sample size was calculated based on the effect sizes of earlier studies that evaluated the effectiveness of a VR intervention on positive attitudes toward people with mental disorders in Australia [22] and another that examined the effects of a VR game on stigma regarding mental disorders in Spain [33]. With an effect size of 0.48, power of 0.8, and probability level of 0.05 in detecting a difference, the estimated sample size was 70 participants per group [34]. Considering a dropout rate of 20% [35], the recommended sample size was determined to

XSL•FO
RenderX

be 84, which was rounded to 90 per group, thus totaling 180 participants for both the intervention and control groups.

Recruitment

The participants were recruited through clinical, educational, and journal club meetings on virtual platforms such as Zoom and Teams as well as through emails and work messaging platforms. After confirmation of their interest in participating in the study, written informed consent was obtained by a research team member.

Randomization and Masking

Participants were then allocated to their relevant research group: the VR intervention group or the VR control group. Allocation used preprepared, concealed allocation letters and was conducted before the administration of the baseline questionnaires. An independent manager outside of the research team generated a random number list from a random number generator. The manager placed each random number within sealed and opaque envelopes. Upon recruitment, the researchers opened each sealed envelope to randomize each participant, thus ensuring blinding of the participants to the 2 separate arms.

Data Collection Process

All questionnaires were completed via an online survey. One week after completion of the baseline questionnaires, the intervention group received the VR intervention, while the control group received a control VR intervention. Participants from both groups received a small reimbursement at this point. The second set of questionnaires was administered postintervention, and a final set of questionnaires was administered 1 month after the VR intervention. Participants from both groups were then compensated with another small reimbursement for their time and efforts following completion of the entire study. After completing the entire study, the control group was informed of their randomized arm and given access to the VR intervention.

Data Collected Including Outcome Variables

Overview

Basic demographic data included age, gender, and nature and years of occupation. The primary outcomes were (1) attitudes, (2) stigma, and (3) empathy levels toward individuals experiencing psychotic disorders. Qualitative feedback regarding the VR intervention was also collected. The questions used in the questionnaire are listed in Multimedia Appendix 1.

Attitudes Toward People With Psychotic Disorders

Attitudes toward people with psychotic disorders were measured with the modified attitudes toward people with schizophrenia scale [36]. The 7-item scale is measured on a 9-point Likert scale ranging from 1 to 9. Total scores range from 7 to 63, with higher scores indicating better attitudes. Items 1 and 2 are reverse coded. An example item is “How much do you personally care about the plight of people with schizophrenia?” The internal consistency Cronbach alpha ranges from 0.76 to 0.79 [36].

Stigma

Stigma was measured using 2 tools: social distance scale and personal stigma scale. The social distance scale evaluates a participant’s willingness to be associated socially with someone who is experiencing a specific mental disorder [37-39]. The 8 questions are rated on a 4-point Likert scale: yes, definitely (0); yes, probably (1); probably not (2); and definitely not (3). The scores range from 0 to 24, with higher scores indicating greater social distance. Some examples of the questions include willingness to spend time, make friends, or be neighbors with someone with a mental disorder. In Australia, among 3021 young people aged 15 years to 25 years, an exploratory structural equation demonstrated that the desire for social distance scale achieved factor loading of 0.75 to 0.88. The modeling also demonstrated that the desire for social distance scale was distinct from perceived and personal stigma [40]. Among 3006 participants in Asia, factor loadings of the social distance scale ranged from 0.69 to 0.91 [41]. The scale also had a reliability Cronbach alpha of 0.85 [41].

The personal stigma scale consists of 2 subscales: dangerous/unpredictable and weak-not sick [40]. The questions are scored from 0 (strongly disagree) to 4 (strongly agree). Total scores range from 0 to 36, with higher scores indicating greater stigmatizing attitudes. Within Asia, the “weak-not sick” and “dangerous/unpredictable” subscales had reliability Cronbach alphas of 0.55 and 0.66, respectively [41]. For each scale, confirmatory factor analysis revealed a goodness-of-fit index of 0.94, Tucker–Lewis index of 0.96, and root mean square error of approximation of 0.08 for the personal stigma scale [41] and a goodness-of-fit index of 0.94, Tucker–Lewis index of 0.96, and root mean square error of approximation of 0.08 for the social distance scale [41].

Empathy

Empathy was measured with the empathic concern subscale of the Interpersonal Reactivity Index [42]. The 7-item subscale is measured on a 5-point Likert scale ranging from 0 (does not describe me well) to 4 (describes me very well). Total scores range from 0 to 28, with higher scores indicating greater empathy. Of the 7 items, 3 are reverse-coded. The scale achieved internal consistency Cronbach alphas of 0.68 to 0.79. Test-retest reliability (60-75 days) ranged from 0.61 to 0.81 [42].

Experience With the VR Intervention

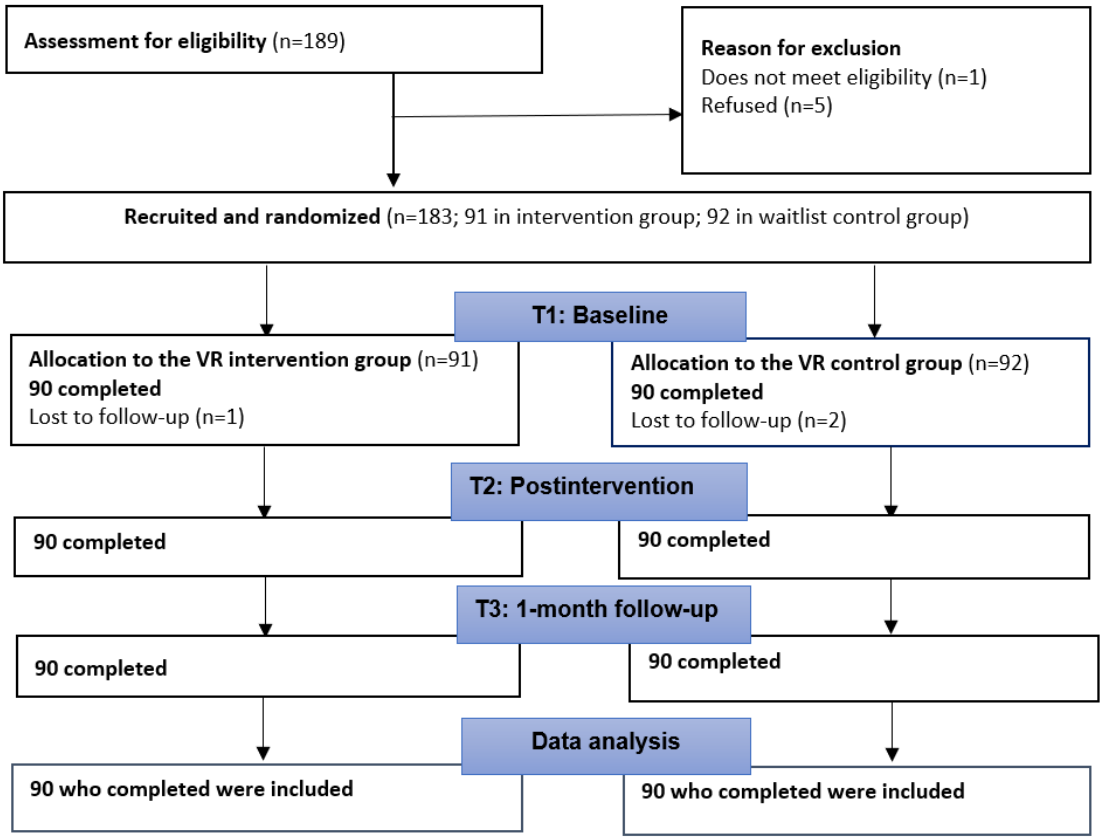
The experience with the VR intervention was measured at postintervention with user satisfaction and motion sickness scores. First, user satisfaction was measured with a 6-item scale on a 7-point Likert scale ranging from 1 (strongly disagree) to 7 (strongly agree). Examples of questions were, “I benefit from the VR intervention” and “the VR intervention helps me to understand what people with schizophrenia experience.” In addition, there were 4 open-ended questions regarding feedback about the VR interventions to evaluate the participants’ perceptions of the intervention: (1) Please list the strengths of the intervention. (2) Please list how the intervention can be improved. (3) What did you enjoy most about the VR intervention? (4) What did you enjoy least about the VR intervention?

XSL•FO
RenderX

Second, the Visually Induced Motion Sickness Susceptibility Questionnaire [43] was used to measure motion sickness**.** It consists of 6 questions that evaluate the presence of adverse effects from using the VR intervention, with responses ranging from “never” (0) to “often” (3). The potential adverse effects include headache, nausea, giddiness, fatigue, and eyestrain. The scores of the scale range from 0 to 18, with higher scores indicating more adverse effects. The scale had a Cronbach alpha of 0.84, indicating good internal reliability.

Data Analyses

An intention-to-treat analysis was conducted. All statistical analyses were performed using SPSS version 27 (IBM Corp) [44]. Data normality was evaluated with the Shapiro-Wilk test, skewness, kurtosis, Q-Q plots, and histograms [45]. Categorical variables were compared between the 2 groups using contingency tables (chi square), and continuous variables were compared using independent *t* tests. Correlation statistics were calculated to determine the relationship between demographic features and outcome measures. Repeated measures ANOVA was used to examine for time, group, and time × group differences. Assumption of sphericity was evaluated with the test of sphericity by Mauchly [46]. All *P* values were 2-tailed at the significance level of $P<.05$. The internal reliability of the scales was evaluated with the Cronbach alpha.



The open-ended questions about participant satisfaction with the intervention were analyzed using 6-step thematic analysis [47]. One author (JLT) perused the qualitative data to become familiar with it. The author then constructed a coding scheme related to the interview questions. The scheme included perceived strengths of the VR intervention and suggestions to improve it. It also included what participants found most or least useful about the VR intervention. The author evaluated the code to identify the initial themes, and additional analyses detailed each theme. All the codes and themes were subsequently reviewed independently by 3 other coauthors (YQ, HX, CLRT). Discrepancies were resolved through discussions among all the coauthors. Finally, verbatim comments were incorporated within the findings.

Results

Participants

Although 183 participants were originally recruited for the study from August 2023 through January 2024, 3 participants dropped out after randomization and did not complete any of the questionnaires. There were 30 participants in each job role (physician, nurse, and allied health) per arm, which totaled 180 participants for the 2 groups. All 180 participants completed the questionnaires at baseline, postintervention, and follow-up (see Figure 2 for the CONSORT [Consolidated Standards of Reporting Trials] diagram). Table 1 shows the demographic features and baseline rating scores of the participants. At baseline, there were no significant differences between the groups in demographic characteristics and levels of stigma, empathy, and attitude toward people with mental health disorders.

Attitudes Toward Individuals With Psychotic Disorders

Main Findings

The main time effect on attitudes was statistically significant ($F_{1.88,\ 335.35}$=6.46, *P*=.002; Table 2). Post hoc analysis with Bonferroni adjustment found significant differences in attitude scores between baseline and postintervention (1.17, 95% CI –2.02 to –0.32; *P*=.003) and between postintervention and follow-up (–0.72, 95% CI 0.03 to 1.41; *P*=.04). The effects of (1) group and (2) the group × time interaction on attitudes were not significant.

Relationship Between Attitudes and Demographic Variables

Participants with loved ones with mental disorders had better attitudes than participants without (r_{pb}=–0.16, *P*=.03). Better attitudes toward individuals with psychotic disorders were associated with a higher education level (ρ=0.2, *P*=.007), longer work experience durations in the current hospital and mental health sector (both ρ=0.16, *P*=.04), and a job role as a psychiatrist (r_{pb}=0.15, *P*=.04; Table 3).

Social Distance

Main Findings

The main time effect on social distance was significant ($F_{1.87, 332}$=4.32, *P*=.02; Table 2). Post hoc analysis with Bonferroni adjustment found a significant difference in social distance scores between baseline and follow-up (0.50, 95% CI 0.05 to 0.95; *P*=.02). The effects of (1) group and (2) the group × time interaction on social distance scores were not significant.

Relationship Between Social Distance and Demographic Variables

Participants without loved ones with a mental health condition had higher social distance scores (r_{pb}=0.18, *P*=.01). In addition, higher social distance scores were associated with a job role as a case manager (r_{pb}=0.17, *P*=.02) and being engaged (marital status; r_{pb}=0.15, *P*=.049; Table 3).

XSL•FO
RenderX

Stigma

Main Findings

The main time effect on stigma was significant ($F_{2, 356}$=7.60, P=.001; Table 2). Post hoc analysis with Bonferroni adjustment found a significant difference in stigma scores between baseline and follow-up (0.97, 95% CI 0.34 to 1.60; P<.001). The effects of (1) group and (2) the group × time interaction on social distance scores were not significant.

Relationship Between Stigma and Demographic Variables

Lower stigma scores were associated with a higher education level (ρ=–0.24, P=.001) and job roles as a psychiatry resident (r_{pb}=–0.30, P<.001) and medical social worker (r_{pb}=–0.15, P=.04), and higher stigma scores were associated with longer work durations (ρ=0.18, P=.02) and a job role as a nurse (r_{pb}=0.39, P<.001; Table 3).

Empathy Level

Main Findings

The effects of time, group, and the group × time interaction on empathy levels were not significant.

Relationship Between Empathy Level and Demographic Variables

Greater empathy was associated with the female gender (r_{pb}=0.20, P=.008) and a job role as a medical officer (Table 3).

Experience With the VR Intervention (User Satisfaction and Motion Sickness Score)

The VR intervention group scored significantly higher (mean 33.18, SD 5.82; n=90) on the user satisfaction scale than the VR control group (mean 22.88, SD 9.35; n=90; t_{149}=8.87, P<.001; Table 4). The motion sickness score was not significantly different between the 2 groups.

Table 4. Between-group comparisons of the outcome measures at the different time points.

Outcome measure	Intervention, mean (SD)	Control, mean (SD)	Mean difference (95% CI)	*t* (*df*)	*P* value	Cohen *d*
Attitudes						
Pre-intervention	48.90 (5.75)	49.52 (5.12)	–0.62 (–2.22 to 0.98)	–0.77 (178)	.44	–0.11
Postintervention	50.80 (6.28)	49.97 (5.42)	0.83 (–0.89 to 2.56)	0.95 (178)	.34	0.14
Follow-up	49.73 (6.14)	49.59 (5.53)	0.14 (– 1.58 to 1.86)	0.17 (178)	.87	0.03
Social distance						
Pre-intervention	8.27 (3.85)	7.98 (3.26)	0.29 (– 0.76 to 1.34)	0.54 (178)	.59	0.08
Postintervention	7.88 (4.13)	7.64 (3.70)	0.23 (– 0.92 to 1.39)	0.40 (178)	.69	0.06
Follow-up	7.68 (3.87)	7.57 (3.93)	0.11 (– 1.04 to 1.26)	0.19 (178)	.85	0.03
Personal stigma						
Pre-intervention	11.33 (4.37)	11.37 (4.23)	–0.03 (– 1.30 to 1.23)	–0.05 (178)	.96	–0.008
Postintervention	10.79 (3.82)	10.87 (4.60)	–0.08 (– 1.32 to 1.17)	–0.12 (178)	.90	–0.02
Follow-up	10.21 (4.09)	10.56 (4.64)	–0.34 (– 1.63 to 0.94)	–0.53 (178)	.60	–0.08
Empathy						
Pre-intervention	20.24 (4.57)	20.07 (3.97)	0.18 (– 1.08 to 1.44)	0.28 (178)	.78	0.04
Postintervention	20.42 (4.63)	20.77 (4.39)	–0.34 (– 1.67 to 0.98)	–0.51 (178)	.61	–0.08
Follow-up	20.07 (5.16)	20.54 (4.76)	–0.48 (– 1.94 to 0.98)	–0.65 (178)	.52	–0.10
User satisfaction postintervention	33.18 (5.82)	22.88 (9.35)	10.30 (8.01 to 12.59)	8.87 (178)	<.001	1.32

[a]Visually induced motion sickness susceptibility.

Qualitative Findings

Thematic analysis of the data from the VR intervention group revealed 3 main themes: entering the patient's world, benefits of VR learning, and boosting the VR intervention.

Theme 1: Entering the Patient's World

Participants appreciated the experience of psychotic symptoms provided by the VR intervention, an experience that was novel, enlightening, and continuously described as "immersive" and "realistic." Participants shared that "(It) gave me a perspective I would not have otherwise experienced" (male allied health professional, 1-3 years of work experience) and "It felt real, with voices talking to me constantly" (female nurse, 1-3 years of work experience).

The VR intervention allowed the participants to understand how hallucinations could affect the patient's feelings and behaviors. One participant shared the following:

> *VR provided me with a chance to experience what auditory hallucinations can be like and also how it*

XSL•FO
RenderX

> *can impact our mood/actions even though it was just something as simple as walking through your house.* [female allied health professional, 1-3 years of work experience]

The effect of the intervention on evoking certain negative feelings was also apparent from participants' feedback: "experience the agony that someone with continuous voices (is) going through" (female nurse, 10-15 years of work experience), "it triggered my emotions and made me feel annoyed at the voices" (male physician, 4-6 years of work experience), and "it was very real and very disturbingly hurtful" (female physician, 1-3 years of work experience). Hence, the VR intervention allowed the participants to better understand the nature of hallucinations as experienced by the patients, as well as the emotional and psychological distress accompanying them.

The experience allowed participants to experience not only the psychotic features and negative emotions but also their debilitating effects on orientation, state of mind, and overall functioning of the individual undergoing such experiences, as one participant illuminated:

> *Depiction of different forms of auditory hallucinations...visual hallucinations...unkempt state of the house...Overall, the hallucinations were appropriately frightening/disorienting.* [male physician, 4-6 years of work experience]

Theme 2: Benefits of VR

Participants described the use of VR as "new," "refreshing," "interesting," "engaging," "multisensory," and "insightful," which allowed them to better appreciate the subjective encounter of a psychotic disorder. Of note, participants stated that the intervention was an "innovative and immersive way to allow people to understand the experiences of patients with psychosis" (female physician, <1 year of work experience) and "very cool!" (female physician, <1 year of work experience).

Participants also commented on the duration, sound effects, and visuals effects of the VR intervention, for example, "The VR is professionally done" (male physician, 1-3 years of work experience). Other participants also appreciated the cost effectiveness, utility, ease of accessibility, and dissemination of the VR intervention. For example, one participant highlighted that "VR is so easily accessible with a pair of goggles and phone screen so it can be easily provided in the community setting" (female physician, 1-3 years of work experience).

Theme 3: Boosting the VR Intervention

Participants provided useful suggestions to enhance the VR intervention. First, participants suggested ways to make the intervention even more realistic, such as using locally accented voices, rather than the AI voices that came across as artificial, monotonous, and emotionless. They also recommended that the setting of the VR should be more reflective of the local context. Second, participants suggested ways to improve the comfort level when donning the gadgets. For example, participants commented that the headsets were slightly heavy or inappropriately sized. Third, a few participants requested narration to provide clarity on "some context of the person/environment" that they were about to experience (female allied health professional, 1-3 years of work experience). A number of participants requested that the VR intervention be more interactive, while other participants suggested highlighting the impact of these psychotic features, as one participant advised:

> *It would be interesting to see how the auditory hallucinations may have an impact on someone doing their daily tasks such as travelling, in work, or (in) social settings with friends.* [female allied health professional, 1-3 years of work experience]

Discussion

Principal Findings

There were several findings in this study. First, both groups showed improvements in attitudes, social distance, and stigma scores but not empathy following the VR intervention. Second, the VR intervention group had better user satisfaction than the VR control group. Third, the improvements in outcome measures were associated with specific factors including gender, education level, job role, years of work, and presence of loved ones with a mental disorder.

Both the VR intervention and VR control groups showed improvements in outcomes related to attitude, social distance, and stigma levels. These findings were congruent with those of earlier studies that found improved positive attitudes and reduced stigma toward people with mental disorders following evaluated interventions including immersive VR conditions related to schizophrenia [22,23,25,48,49], and dementia [21,50-52]. The specific element that rendered the VR intervention effective was its ability to allow participants to experience distressing psychopathology such as psychotic symptoms; this could lead to greater concern for the patients, which translates into better attitudes toward them [53]. Among the 5 earlier studies that evaluated a VR intervention for schizophrenia, only 2 had control groups [23,48]. Although the study by Marques et al [48] in Portugal evaluated outcomes of 2 arms (VR versus 2D video), the study by Kalyanaraman et al [23] in the United States evaluated the outcomes of 3 arms, namely, journaling of psychotic experiences, VR intervention alone, and VR intervention with journaling. For the latter study [23], the arm with journaling and VR intervention achieved the best outcomes in terms of better empathy, better attitudes, and reduced social distance, whereas the VR only intervention did not significantly perform better than the other arms. The VR only intervention performed the worst among all groups in terms of social distance. Another study also found that an intervention involving a simulation increased social distance [54]; this could be due to the fact that the experience during the VR intervention provoked negative emotional responses.

An earlier review of the use of simulated hallucinations to reduce stigma reported possible outcomes of negative affect and contradictory effect on stigma and cautioned about its use [24]. However subsequent VR studies reported improvement in stigma in several contexts, namely (1) a schizophrenia VR context whereby participants experienced schizophrenia symptoms while playing a character [55]; (2) the Inclúyete-VR platform, which includes components of role play in which the

XSL•FO
RenderX

involved character participates in 6 interactive levels within a crisis center with exposure to psychosocial interventions aimed at recovery [56]; and (3) the Stigma-Stop platform, which presents characters with psychotic disorders [33] as well as other mental disorders such as dementia [57] and mixed anxiety-depression [35]. Among the earlier studies that evaluated VR interventions in schizophrenia, 2 had control group [55,56]. In both studies, the VR intervention performed better than patient review [55] and a neutral VR program [56] in terms of stigma outcomes. There were several reasons why both the VR intervention and VR control groups showed improvements in attitudes, social distance, and stigma. First, the participants in this study were mental health care professionals, who had direct, regular contact with individuals with psychotic disorders in their daily work, which facilitated improvements in attitudes and stigma toward people with psychotic disorders [13,58]. Second, the control VR intervention in this study, even without the added simulations of psychotic experiences, could be effectively immersive and realistic. Third, social desirability bias in both groups and positive expectation bias among the control VR participants could also have contributed to the positive outcomes observed within the groups [59]. Fourth, improvements in outcomes such as stigma could be influenced by concurrent educational or awareness events related to mental health and psychotic conditions that occurred within or outside the health care setting.

In this study, both groups did not show significant improvements in empathy scores postintervention or at the follow-up. This may be explained by the ceiling effect for empathy levels within mental health care staff [60,61] and the fact that empathy levels take time to improve [62]. Our findings differed from previous studies that found enhanced empathy levels after participation in interventions such as (1) a VR scenario in which the participants experienced schizophrenia symptoms [22,23,25,55]; (2) immersive VR interventions in dementia [51,57]; and (3) VR interventions surrounding psychosis, mood, and anxiety disorders [49]. Of note, none of these studies examined empathy scores longitudinally [22,25,49,51,57]. However, Slater et al [63], in their quasiexperimental study that evaluated a simulated dementia intervention (involving sensory and cognitive distortions while completing simple tasks such as folding apparel), found improvements at postintervention and the 3-month follow-up.

We found that the VR intervention group had significantly better user satisfaction than the VR control group, suggesting that the participants in the VR intervention group readily adapted to the VR scenario. This was supported by the qualitative feedback from the participants, who found the VR intervention realistic, engaging, and immersive by allowing them to experience psychotic symptoms. They also found that it evoked personal responses such as feeling the agony experienced by someone undergoing psychotic experiences. This was congruent with earlier studies in which participants of VR interventions for mental disorder [49] and dementia [51,52] gave positive feedback such as “interactive” and “interesting” and expressed appreciation for the opportunity to “experience the patient’s situation, thoughts, and feelings.”

There were several associations between the outcome measures and specific demographic and personal characteristics including female gender, higher education level, certain job roles, years of work, and presence of loved ones with mental disorder. We found that women had higher empathy scores, which was consistent with earlier studies [64]. One study specifically found that women had greater cognitive and emotional empathy than men [65], and biological and social factors may contribute to this association [66-69]. Congruent with extant literature [41,70,71], we found that a higher education level was associated with better attitudes and lower stigma regarding mental disorders, which may be related to better access to literature about mental disorders and the ability to understand the descriptions of mental disorders [72]. Longer durations of work experience were associated with better attitudes but higher stigma regarding mental disorders. We also found that, although certain occupational groups had more positive attitudes and better empathy scores (eg. psychiatrists) and lower levels of stigma (eg, residents and medical social workers), case managers and nurses had greater social distance and levels of stigma, respectively. This could be related to the higher workload amid demanding schedules for case managers and nurses within their work units, which can render them vulnerable to compassion fatigue and burnout [73]. In addition, we found that participants with loved ones with mental disorders had better attitudes and lower social distance levels, findings that agreed with the existing literature [73,74], highlighting the value of personal knowledge and care for someone with lived experience to lower stigma for mental disorders.

Limitations and Future Directions

There were several limitations. First, the use of self-report measurements predisposed the study to social desirability bias among the participants. Second, researchers were not blinded due to the nature of the VR intervention, but data collection was conducted mainly online to reduce direct involvement of the researchers. Although participants were blinded, it was possible for participants to guess their eventual grouping. Third, the follow-up was only conducted for 1 month after the VR intervention. Fourth, the study did not include another comparison arm without VR. The effects of a non-VR control group on the outcome measures would allow us to better understand whether the positive changes were purely related to the use of VR or other underlying confounding variables related to the individual or context. Hence, future studies should include an additional arm without a VR intervention to observe for similar improvements or otherwise. The study can also be extended to other relevant groups such as families and caregivers of affected persons with psychotic disorders and the public to evaluate the impact on the various outcome measures. Further studies can examine the effects of the VR intervention on various types of stigma, such as patient self-stigma, professional stigma within mental health professionals, and social stigma among the public [75]. Longitudinal studies will be useful to examine the effectiveness and sustainability of VR interventions over a longer time period.

XSL•FO
RenderX

Conclusion

In conclusion, both groups of mental health care workers participated in VR interventions and showed improvements in the outcomes related to attitudes, social distance, and level of stigma toward people with psychotic disorders. Future longitudinal studies may want to evaluate the impact of VR on these same and other outcome measures for caregivers and the public to reduce stigma and improve empathy toward individuals with psychotic disorders.

Abstract

Background: Alexithymia, defined as difficulty identifying and describing one's emotions, has been identified as a transdiagnostic emotional process that impacts the course, severity, and treatment outcomes of psychiatric conditions such as posttraumatic stress disorder (PTSD). As such, alexithymia is an important process to accurately measure and identify in clinical contexts. However, research identifying the association between the experience of alexithymia and psychopathology has been limited by an overreliance on self-report scales, which have restricted use for measuring constructs that involve deficits in self-awareness, such as alexithymia. Hence, more suitable and effective methods of measuring and identifying those experiencing alexithymia in clinical samples are needed.

Objective: In this cross-sectional study, we aimed to determine if facial, vocal, and language phenotypes extracted from 1-minute recordings of war veterans with PTSD describing a traumatic event could be used to identify those experiencing alexithymia.

Methods: A total of 96 participants were included in this cross-sectional study. Specialized software was used to extract facial, vocal, and language features from the recordings. These features were then integrated into machine learning (extreme gradient boosting [XGBoost]) classification models that were trained and tested within a 5-fold nested cross-validation pipeline for their capacity to classify veterans scoring above the cutoff for alexithymia on the Toronto Alexithymia Scale-20.

Results: The best performing XGBoost classification model trained in the nested cross-validation pipeline was able to classify those experiencing alexithymia with a good level of accuracy (average F_1-score=0.78, SD 0.07; average area under the curve score=0.87, SD 0.12). Consistent with theoretical models and past research into phenotypes of alexithymia, language, vocal, and facial features all contributed to the accuracy of the XGBoost classification model.

Conclusions: These findings indicate that facial, vocal, and language phenotypes incorporated in machine learning models could represent a promising alternative to identifying individuals with PTSD who are experiencing alexithymia. The further validation and use of this approach could facilitate more tailored and effective allocation of treatment resources to individuals experiencing alexithymia in clinical settings.

Introduction

Alexithymia is defined as difficulty identifying and describing one's own emotional states, in conjunction with externally focused attention [1,2]. In the attention-appraisal model of alexithymia, those with alexithymia are considered to have difficulties in attending to (due to their externally focused attention) and appraising (due to their difficulty identifying emotions) already occurring emotional responses to stimuli [3]. These issues with attending to and appraising emotional responses mean that it is difficult to subsequently describe them. The 3 core difficulties of people with alexithymia include internal orientation of attention, identifying and describing one's emotional states, have been demonstrated to load directly onto the alexithymia construct and are consistent with the subscales of the primary alexithymia self-report measure, the Toronto Alexithymia Scale-20 (TAS-20) [4].

Alexithymia has been identified as a transdiagnostic risk factor for a range of psychiatric disorders [5-10]. A meta-analysis on the emotion processes relevant in schizophrenia found a large Hedge *g* effect size (1.05) for the association between alexithymia and schizophrenia [10]. A similarly large effect size has been found for the association between alexithymia and posttraumatic stress disorder (PTSD) [11]. Alexithymia has been conceptualized as an important mechanism in exacerbating PTSD symptoms and diminishing treatment response, given its strong association with emotional avoidance and its inhibition of the emotion processing required for gold-standard treatments, such as prolonged exposure therapy, to be effective [12]. This is consistent with findings that alexithymia following a traumatic event is predictive of the development of PTSD [13] and has a substantial influence on outcomes for PTSD interventions [14,15]. Accordingly, as with other transdiagnostic mechanisms of psychological distress, identifying alexithymia as it occurs in clinical settings, such that tailored treatment responses can be used, is important for ameliorating its impacts [12,16,17].

However, findings from most of these studies on the impacts of alexithymia are limited by their overreliance on self-report scales such as the TAS-20 [4]. This is problematic not only because self-report measures are prone to response biases [18,19] but also because alexithymia involves deficits in self-awareness that may impact the accuracy of self-report measures [20]. As such, there is a need for alternate and more construct-appropriate approaches to measure and identify alexithymia, particularly in clinical populations, in which it impacts symptom severity and treatment response.

The identification of alexithymia through individuals' use of language is a construct-relevant approach that has been used in several studies. One such study of individuals with varying levels of alexithymia on the TAS-20 that analyzed their expressive writing samples using the Linguistic Inquiry and Word Count (LIWC) software (version 22; University of Texas) [21] found that those who scored higher on the TAS-20 used fewer words expressing affectivity, sadness, and future perspective [22]. Another study found that those scoring higher on the TAS-20 produced fewer emotion words and a less diverse range of emotion words yet did not have a general vocabulary deficit relative to low scorers [23]. A systematic review and meta-analysis of 29 empirical studies of language capacity in those with alexithymia found a modest association between language deficits (eg, emotion language use) and alexithymia [24], suggesting that language is not the only relevant expressive measure of alexithymia. This is consistent with findings that participants with alexithymia also demonstrated lower (or the same) physiological reactivity (heart rate, skin conductance, and facial electromyography) to negative stimuli, while reporting subjectively worse experiences than nonalexithymics [25-27]. Of particular relevance to PTSD, a distinction between high subjective distress and low arousal (heart rate) was found in the responses of those with alexithymia to fear imagery [27] and in the subjective report of emotional distress in individuals with PTSD who are alexithymic [28].

To enhance the measurement and identification of this multifaceted, clinically consequential construct of alexithymia, research could benefit from using facial, vocal, and linguistic features of emotional response. This approach is supported by a previous study showing that these features can be used in conjunction with machine learning (ML) models to identify those experiencing psychopathology following traumatic injury [29]. Facial, vocal, and linguistic features were extracted from recordings of participants' responses to questions about their trauma. These features were integrated into an ML neural network model to predict provisional PTSD diagnoses made 1 month after the traumatic injury and variance in PTSD symptom severity. The models achieved an average accuracy score of 0.90 to classify PTSD, based on the contribution of linguistic, vocal, and facial features. As PTSD symptom severity has been associated with alexithymia in several studies [30,31], these features could be shared for individuals with PTSD who score above the cut-off for alexithymia. The possible consistency between the distinctive digital phenotypes of PTSD symptom severity and alexithymia is supported by the relevance of language sentiment and facial expressivity differences for distinguishing individuals with both alexithymia and PTSD [22,27].

This study aimed to estimate the capacity of an ML classification model, built with digital phenotype variables extracted from recordings of war veterans with probable PTSD (hereafter referred to as PTSD) in which they describe traumatic incidents they experienced, to accurately classify individuals with alexithymia. On the basis of the reviewed research, we hypothesized that veterans with PTSD with alexithymia could be classified with a good degree of estimated accuracy, which is what we found. We also hypothesized that language variables would be the most important variables for the estimated capacity of the classification model to classify individuals as alexithymic, given their association with alexithymia in past studies [22,23]. However, in line with the attention-appraisal model of alexithymia and past research demonstrating the different channels through which alexithymia can manifest, we hypothesized that vocal, facial, and linguistic variables would all contribute to the estimated capacity of the best-performing model to make classifications of alexithymia.

Methods

Participants

Participants for this study were 101 veterans of the Australian Defence Force who were recruited via the Trialfacts health research platform. Five participants were excluded due to missing questionnaire responses, leaving 96 participants. The inclusion criteria for this study were being a former member of the Australian Defence Force, having experienced a traumatic event, and scoring above 33 on the Posttraumatic Stress Disorder Checklist for *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (PCL-5). Most of the sample were men (78/96, 81%), and the mean age of participants was 52.38 (SD 11.80) years. The size of the sample was determined based on the requirements of the extreme gradient boosting (XGBoost) classification models to identify those scoring as alexithymic on the TAS-20. Our sample size was larger than those in previous studies examining language features distinctive of individuals high on alexithymia [22] and using an ML classification approach to identify individuals with PTSD [29].

Stimuli

Before the experimental session, participants were asked to confirm if they felt comfortable discussing the traumatic event that had been affecting them the most. Participants were then asked to "think for a moment about a traumatic event you have been through" and to "tell me about this memory in detail... let yourself really try to get into this memory and how it made you feel." Their responses were recorded for 1 minute.

Measures

Posttraumatic Stress Disorder

The PCL-5 [32] is a 20-item self-report measure of the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, symptoms of PTSD. It was used to determine if the veteran participants met criteria for probable PTSD, based on their self-report of PTSD symptoms related to traumatic events they experienced during their military service. Recruited individuals who served in the military were deemed to have probable PTSD if they scored above the cut-off of 33 on the PCL-5 [33]. The PCL-5 has been found to have high internal consistency (Cronbach α from 0.83 to 0.98) and convergent validity (correlations with other PTSD measures of value up to 0.93), indicating it has strong psychometric properties [33,34].

Depression

The Beck Depression Inventory-second edition (BDI-II) [35] is a 21-item self-report measure that was used to index the intensity of depression symptoms in the participants of this study. This measure was used to determine if differences between those who were alexithymic or not alexithymic could be explained by levels of depression, given the overlapping presentation features of alexithymia and depression [36,37]. The BDI-II has been shown to have strong convergent and criterion validity as well as high internal consistency (Cronbach α of 0.9) and reliability [38].

Digital Phenotypes

Participants' recorded descriptions of their traumatic experiences were processed using the OpenWillis Python (Python Software Foundation) library [39] and LIWC-22 [21] software.

Facial indicators are based on the facial action coding system [40]. This coding system measures the intensity of activity in both individual and groups of muscles in the face (designated by particular facial action units) that have been found to relate to particular emotional experiences, such as the 6 primary emotions of happiness, sadness, surprise, fear, disgust, and anger. OpenWillis uses DeepFace to measure framewise intensity of facial action coding system units on a range of –1=expressivity of that emotion below baseline and 1=expressivity of that emotion above baseline to produce facial emotion expressivity scores. DeepFace has been found to have 97% accuracy in correctly identifying the facial landmarks of faces it has been previously trained on [41] and 94% accuracy in identifying human emotions [42]. OpenWillis also uses MediaPipe [43] to measure the frame-by-frame coordinates of 468 unique facial landmarks using its Face Mesh model. From this, it produces a measure of the mean frame-to-frame movement occurring at these coordinates across the length of the video (producing OpenWillis variables such as "Upper face expressivity"; see Multimedia Appendix 1 for a glossary of *OpenWillis* terms). MediaPipe was used as the building block for feature analysis in 1 study that was able to achieve 97% accuracy in correctly detecting human emotion [44].

OpenWillis uses Parselmouth to measure vocal variables [45]. Parselmouth is a Python implementation of the Praat software (University of Amsterdam) library [46]. Measured vocal variables include mean fundamental frequency, deviation in fundamental frequency, loudness, jitter, and shimmer of participants' vocal production. Parselmouth also measures the percentage of frames without vocal content and the median duration of silences. In more recent updates, it has been able to examine more specific vocal features, such as cepstral peak prominence (CPP) and the mean, variance, and SD in mel-frequency cepstral coefficients. Praat software has been found to have good convergent validity (with other vocal software tools) and reliability in correctly identifying vocal features [47].

For language analysis, OpenWillis uses WhisperX to convert audio into text, which has a word error rate of 9.7%, outperforming previous speech-to-text models [48]. It uses the natural language processing Valence Aware Dictionary and Sentiment Reasoner (Massachusetts Institute of Technology) software [49] to analyze the extracted text in terms of language sentiment using a rule- or lexicon-based algorithm that produces mean scores from 1=negative sentiment to 1=positive sentiment. OpenWillis further measures the interaction between speech sentiment and first-person pronoun use ("first person language sentiment"). OpenWillis also uses LexicalDiversity [50], which is a natural language processing tool that measures lexical diversity in terms of moving average type-token ratio, which refers to the ratio of tokens (words) to the different types of words used in windows of 10 words at a time, that are then averaged across the whole segment of speech.

XSL•FO
RenderX

The LIWC library [51], which is the basis for the LIWC-22 software [21], is designed to process text files by counting the words in the text and calculating the percentage of words that correspond to each of the subdictionaries of LIWC (eg, the word "cry" would contribute to increasing the score of the subdictionaries of "emotion," "affect," and "verbs"). LIWC provides scores for each of its dictionaries, such as "power word use" and "word use related to feeling" [21]. Previous LIWC software has been found to have higher convergent and discriminant validity with other measures of emotion, such as self-report and rater coding, than competing text analysis software [52].

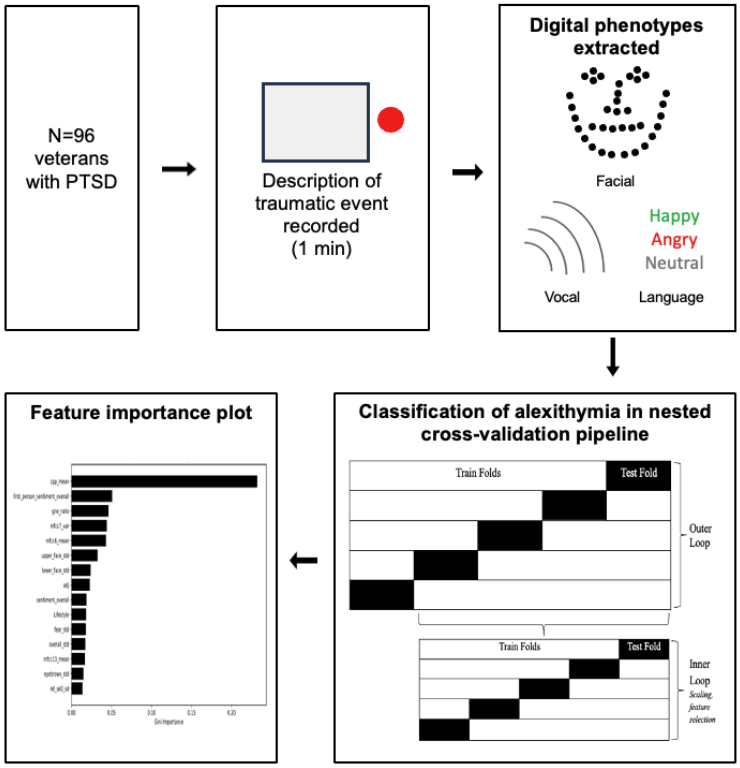
Affect Scale

Participants were asked to rate how they felt while describing the traumatic event on a 100-point verbal analogue scale (−100=means extremely negative, 0=neutral, and 100=extremely positive).

Alexithymia

The TAS-20 [4] was used to index the participant's level of alexithymia. It has 20 items that each have a 5-point Likert rating scale (1=totally disagree and 5=totally agree) with items such as "I often don't know why I am angry." It has three factors: (1) difficulty describing feeling, (2) difficulty recognizing feeling, and (3) externally oriented thinking. The TAS-20 has an established cut-off score of 61 out of 100, over which an individual is deemed to have "alexithymia" [4]. A review of the TAS-20 measure determined that it has good factor validity, reliability, and internal consistency [53].

Procedure



The study was conducted via Zoom for all participants because we recruited veterans from across Australia. Participants initially completed informed consent, then completed the PCL-5, the TAS-20, and a range of demographic measures via Qualtrics. Participants were informed that they would be asked to describe a traumatic event they had experienced in detail. These descriptions were audio-visually recorded using the Apple QuickTime app and the record function in Zoom (Zoom Communications, Inc). Each video recording had a frame rate of 60 frames per second. After providing the description, participants were asked to rate how they felt while talking about the traumatic event on the Analogue Affect Scale. After completing this process, they were debriefed on the nature and purpose of the study.

Data Analysis

Participants were classified in terms of alexithymic status according to scores above or below the threshold of 61 on the TAS-20. This categorization resulted in 64 participants (n=53, 83% men; n=11, 17% women) being classified as alexithymic, and 32 participants (n=25, 78% men; n=7, 22% women) as nonalexithymic. XGBoost classification models were then built using the digital phenotype variables extracted from participant descriptions of traumatic events they have experienced. XGBoost classification models have been found to be both efficient and accurate in making classifications of features extracted from recordings of individuals with psychiatric conditions in past research [54]. In this study, these models were built using the scikit-learn package [55] in Python to attempt to classify individuals who scored in the "alexithymia" range on the TAS-20. The hyperparameters were set at the default values for the XGBoost classification algorithm in scikit-learn. Feature selection using the Recursive Feature Elimination method was completed within the inner folds in a 5-fold nested cross-validation pipeline to reduce the bias involved with doing feature selection on the whole sample and subsequently, the possibility of overfitting [56]. The number of features that contributed most to maximizing the precision score were selected and retained in a "best model." The estimated classification performance of this model was evaluated across the outer 5 folds based on average scores for the precision, recall, F_1-score, and area under the curve (AUC) metrics. Precision measures the rate at which the model is correctly identifying individuals as being in the "alexithymia" group by the number of times it is making the classification of "alexithymia." Recall refers to the rate at which the model correctly identifies every individual with "alexithymia." F_1-scores are based on the harmonic mean of the precision and recall scores. The F_1-score was used instead of the standard accuracy score in scikit-learn, as it has been found to be a more robust and subsequently appropriate measure when the two groups to be classified are imbalanced [57]. The AUC provides an indication of the probability that the model will rank each individual scoring above the cut-off for "alexithymia" as having a higher probability of being alexithymic than nonalexithymic. The average AUC scores derived from the receiver operating characteristic curve were used as they have been shown to be suitable for assessing classification with imbalanced datasets [58]. Variable feature importance was scored based on the average decrease in Gini impurity across all decision trees in the best-performing XGBoost model within the inner 5 folds of the nested cross-validation. The experimental process is represented in Figure 1.

Ethical Considerations

All procedures for the study were approved by the University of New South Wales Human Research Ethics Committee (HC230175). All methods were performed in accordance with the relevant guidelines and regulations. Informed consent was obtained from all participants via an online form explaining what was involved in the study before signing. The privacy and confidentiality of participants' data have been stringently maintained, with no identifying details or features being presented or included in the write up of the study. Participants were given a gift voucher of Aus $100 for participating in the study.

Results

Participant Characteristics

A chi-square test for participants' sex at birth in the alexithymia and nonalexithymia groups found no significant group differences. One-way ANOVAs indicated no significant difference between those in the alexithymia and nonalexithymia groups for age, PCL-5, and BDI-II scores (Multimedia Appendix 1). This suggests that differences in digital phenotypes between those who were alexithymic and nonalexithymic were not driven by any of these examined covariates. Summary statistics for these variables are shown in Table 1.

Table 1. Participant characteristics.

Measures	Not alexithymic (n=32), mean (SD)	Alexithymic (n=64), mean (SD)
Age (y)	52.94 (11.83)	52.09 (11.91)
PCL-5[a]	48.38 (14.21)	48.05 (13.44)
BDI-II[b]	30.00 (11.66)	32.44 (9.96)

[b]BDI-II: Beck Depression Inventory-second edition.

Nested Cross-Validation Results

The best-performing XGBoost classification model for determining whether participants scored above the cut-off for alexithymia had an average precision of 0.71, an average recall of 0.87, an average F_1-score of 0.78, and an average AUC of 0.87 (Figure 2) across the 5 outer testing folds, with a model that used 148 features (performance metrics across each fold are displayed in Table 2). The high recall score indicates that the XGBoost classification model was performing well at correctly identifying those individuals who scored above the threshold for alexithymia ("true positives"). However, in terms of the accuracy of all the alexithymia classifications it made, it was not performing as well, with 29% of those classifications being made incorrectly ("false positives"). These rates are illustrated in Figure 3, which is a confusion matrix depicting the predictions of the best performing classification model across the 5 outer folds relative to the true alexithymia labels. These

XSL•FO
RenderX

predictions produced an average overall accuracy (F_1-score) of 0.78 (SD 0.07). The average AUC of 0.87 (SD 0.12) suggests that the model was performing well at assigning a higher probability that an individual scoring above the cut-off for "alexithymia" was alexithymic across each of the outer folds. The receiver operating characteristic curve depicting AUC across the outer folds of the nested cross-validation pipeline for this model is displayed in Figure 3.

Figure 4 displays the feature importance plot for the digital phenotype variables that were most important for classifying individuals as alexithymic based on their Gini importance scores. Language, facial, and vocal variables were important to the capacity of the XGBoost model to classify alexithymia, with "word use related to feeling" emerging as the predictor with the largest Gini importance score. Other language (such as "first person language sentiment" and "language sentiment"), facial (such as "mean mouth openness"), and vocal (eg, "mel frequency cepstral 10 variance") variables were also important to the classification capacity of the XGBoost models. The importance of language, facial, and vocal variables highlights the value of taking this multimodal approach to identifying a construct such as alexithymia, which has a distinctive presentation across multiple domains.

Figure 2. Receiver operating characteristic (ROC) curve, depicting the area under the curve (AUC) accuracy for alexithymia classification.

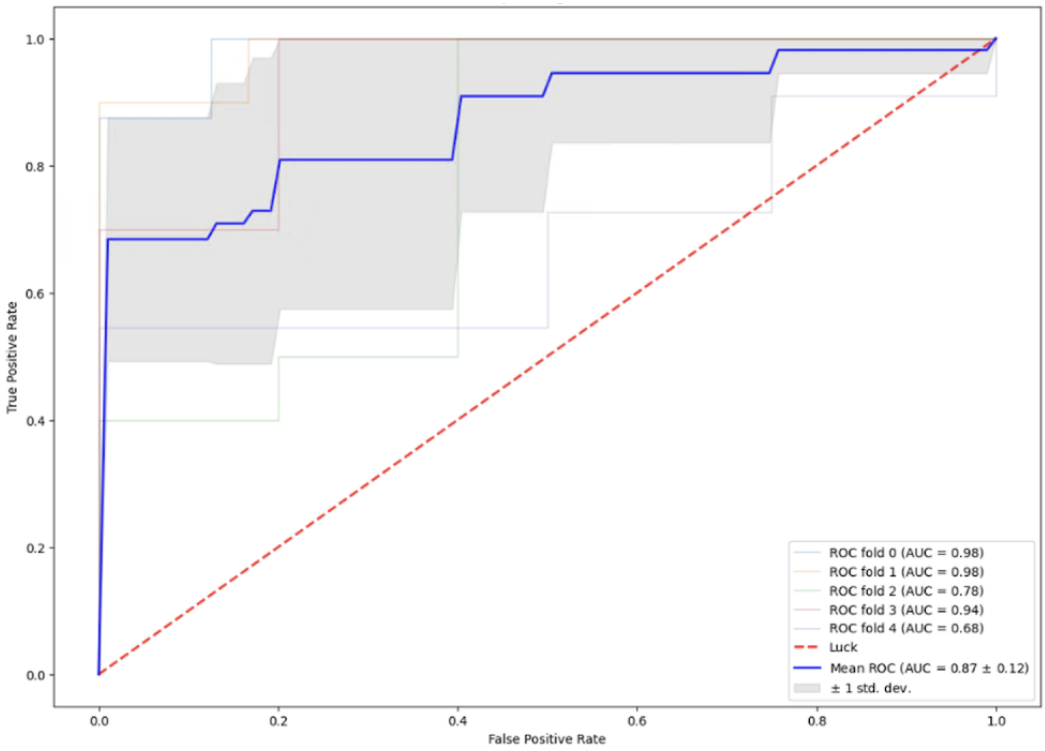

Table 2. Performance metrics for the extreme gradient boosting classification model across the 5 outer folds of the nested cross-validation pipeline.[a]

Fold	Precision	Recall	F_1-score accuracy
Fold 1	0.82	0.93	0.88
Fold 2	0.75	0.92	0.83
Fold 3	0.53	0.90	0.67
Fold 4	0.71	0.77	0.74
Fold 5	0.73	0.85	0.79

[a]The average across folds (SD) were as follows: precision, mean 0.71, SD 0.10; recall, mean 0.87, SD 0.06; F_1-score accuracy, mean 0.78, SD 0.07.

Discussion

Principal Findings

This study examines the estimated capacity of an XGBoost classification model, built with digital phenotype variables extracted from recordings of war veterans with PTSD describing traumatic events they had experienced, to accurately classify those veterans with alexithymia. These models were built and evaluated in a nested cross-validation pipeline to minimize the impact of bias [56,59].

In line with our hypothesis, the XGBoost classification model tuned and built within the nested cross-validation pipeline

XSL•FO
RenderX

demonstrated a level of accuracy and performance that indicated it could be used for classifying alexithymia in PTSD. Regarding the high recall score, with individuals who scored above the threshold for alexithymia, the model was estimated to be able to accurately classify these individuals as having alexithymia 87% of the time. The precision of the model, measuring how many of the classifications of alexithymia were accurate, was much lower, with only 71% of those classifications being accurate, suggesting the model may have been making too many "alexithymia" classifications. The XGBoost classification model had an average overall F_1-score of 0.78, which is lower than the average F_1-score achieved by the classification model for PTSD built using a similar approach [29]. This could be explained by this prior study attempting to classify trauma survivors with and without PTSD [29], whereas the present study focused only on identifying a subgroup of those with PTSD (those with alexithymia). The average AUC was 0.87, which is close to that identified for PTSD classification in a previous study and is considered model performance that suggests it has "considerable" clinical use [60]. However, this result needs to be interpreted with caution given its lack of stability, with the model only achieving an AUC of 0.55 in one of the folds. Overall, the performance of this XGBoost classification model suggests that such a model built with multiple digital phenotypes could be useful for identifying alexithymia in PTSD. This model must also be tested and validated on an independent sample of veterans with PTSD that was used in the model training process.

Digital Phenotypes of Alexithymia in PTSD

This study was the first to examine multiple digital phenotypes in the context of alexithymia in PTSD, and in doing so found that not only language variables but also facial and vocal features were important for the estimated classification of alexithymia. Mean mouth openness was the most relevant facial feature that contributed to classification performance. This may show that differences in how much individuals spoke, as demonstrated by the openness of their mouths, were a factor in the accurate classification of alexithymia. The most relevant vocal feature was the mel-frequency cepstral coefficient variables (mel-frequency cepstral 10 variance) and variance in CPP. The importance of variance in CPP, which is a measure of voice pathology [61,62], to the estimated capacity of the XGBoost model to classify individuals as alexithymic is consistent with past findings linking alexithymia with experiences of voice pathology using other measures [63,64]. The contribution of these facial and vocal features to the estimated classification of alexithymia expands and enhances the understanding of the expressions of emotional experience that could be relevant to this construct.

As hypothesized, language variables were important to the estimated capacity of the XGBoost model to classify individuals as alexithymic. The language variables that had the highest Gini importance scores were associated with the use of feeling words, sentiment of language, and first-person pronoun use. This aligns with foundational theoretical understandings of alexithymia as a deficit in the description of experiences that are associated with feelings and emotional sentiment [3]. It also supports previous findings that those who score higher on the TAS-20 display differences in their expression of language sentiment [22,23]. In terms of first-person pronoun use, this aligns with theoretical understandings of alexithymia involving differences in the focus placed on oneself [2] and past findings that it is associated with differences in personal pronoun use [65]. This consistency between important predictors in an XGBoost classification model and expectations based on the research domain knowledge about that construct from theoretical models and past findings is an important indication of validity for ML models [66]. However, given that it was not only language variables alone that were important for the estimated classification of alexithymia but also vocal and facial variables, this aligns more closely with the attention-appraisal model's understanding of alexithymia as a multifaceted construct [3] than that of the language hypothesis of alexithymia [67].

Limitations

This study had several limitations. The size of the sample (N=96) is modest for an ML model such as XGBoost. The higher number of features (148 features) used in the best performing XGBoost classification model relative to the number of participants in the sample can increase the possibility of overfitting and deleteriously impact the stability of the model [68,69]. However, the use of nested cross-validation has been shown to minimize the impact of overfitting even in small samples, such that the models developed are replicated well in independent test sets [59,70]. Another limitation is that there was a large difference in the size of the groups to be classified (those scoring above or below the cut-off for "alexithymia" on the TAS-20), with more veterans in the sample scoring above the cut-off for "alexithymia." This imbalance in groups impacts the capacity of the XGBoost classification model to be accurately evaluated. In the case of imbalanced classes, the classification of majority classes tends to be more accurate than that of the minority classes [71,72]. This phenomenon likely contributed to the much higher recall score found for this model relative to the precision score. However, this imbalance also reflects the generally higher incidence of alexithymia in veteran populations with PTSD, and trying to adjust these imbalances through cost-sensitive learning that incorporates oversampling or undersampling has been shown to have substantial limitations such as increasing overfitting [72-74]. The mostly male sample limits the generalizability of the digital phenotype findings to other PTSD populations (eg, civilians and women) and may have also contributed to the imbalance of groups on either side of the "alexithymia" cut-off, given that there is a small effect of sex on the TAS-20, with men generally scoring higher [75]. However, this higher proportion of men is representative of the defense force veteran sample used in this study [76]. Furthermore, this population is one in which alexithymia has a substantial impact on [77], which emphasizes the importance of improving our capacity to identify those who are alexithymic in this population.

Conclusions

Overall, this study suggests that facial, vocal, and language indicators could be used in the identification of veterans with PTSD who are experiencing alexithymia. We emphasize that

XSL•FO
RenderX

the model requires further validation in independent samples, but the findings represent an important first step and attest to the merits of continued research in this area. Particularly considering the limitations of self-report measures of alexithymia, this paradigm has the potential to advance research paradigms and the assessment of alexithymia in clinical settings. These advances could ultimately contribute to alexithymia being more easily identified in psychiatric contexts, leading to the allocation of more tailored and effective treatment resources for addressing the specific challenges associated with alexithymia. Future research involving the implementation of this approach in clinical settings is required to examine its feasibility, efficiency, and ease of integration into clinical assessment, as well as its accuracy in identifying alexithymia. The improved identification of alexithymia in PTSD would be an important step in ameliorating the specific impacts that alexithymia has on the course and treatment of psychiatric conditions such as PTSD [12].

Data Availability

The deidentified OpenWillis variable datasets analyzed during this study are available in the OSF repository [78]. The raw video recording data analyzed during this study are not publicly available due to privacy and ethical requirements.

Authors' Contributions

TM, VY, IGL, and RB conceived the study. TM, VY, IGL, and RB devised the analysis plan. TM and VY conducted analyses and data curation. TM and RB provided validation and visualization. TM wrote the original draft. TM and RB reviewed and edited the final manuscript. RB acquired funding. The corresponding author had full access to all the data in the study and had final responsibility for the decision to submit for publication.

Abstract

Emotion regulation difficulties affect many adolescents with attention-deficit/hyperactivity disorder (ADHD), and previous research has highlighted a need for accessible interventions to support them in this domain, especially in real-life contexts. Digital health interventions (DHIs) can be embedded in adolescents' daily lives and thus offer considerable promise for meeting this need. However, there is a lack of information to guide the development of suitable emotion regulation DHIs for this population. The goal of this study is, therefore, to identify recommendations to guide the development of emotion regulation DHIs for adolescents with ADHD. This narrative review synthesizes diverse relevant evidence to inform their development, including promising therapeutic approaches and components and relevant design and development considerations. We find that there is very little direct evidence of "what works" for emotion regulation DHIs and emotion regulation interventions more generally for adolescents with ADHD; however, we identify promising therapeutic approaches for new DHIs. We also recommend following a co-design or coproduction approach with adolescents with ADHD, including exploring elements designed to motivate and engage young people to support sustained adherence. We conclude that DHIs are a promising approach for emotion regulation interventions for adolescents with ADHD, could draw on a range of existing therapeutic approaches, and should be co-designed with users themselves.

Introduction

Emotion regulation difficulties are commonly experienced by adolescents with attention-deficit/hyperactivity disorder (ADHD) and are thought to contribute to frequently co-occurring issues, such as anxiety, depression, and conduct problems [1,2]. However, existing interventions for emotion regulation in adolescents with ADHD have important limitations, including poor generalizability to real-life situations, not addressing the linkages between emotion regulation and core areas of impacted functioning such as peer problems, and lacking a coproduction approach that can be essential for ensuring that the intervention truly meets the needs of its target population [3-5]. As such, there remains a need for new accessible interventions to support emotion regulation and associated functioning among adolescents with ADHD, especially those that can support the application of emotion regulation skills in real-life contexts. Interventions that are "ecologically" embedded, facilitating emotion regulation generalization in daily life are particularly

XSL•FO
RenderX

needed. As smartphone-delivered digital health interventions (DHIs) have a strong potential to meet this need, the purpose of this review is to synthesize the relevant evidence on the most promising intervention approaches, components, and other design and development considerations to provide recommendations for emotion regulation DHI development for adolescents with ADHD. We use a narrative review approach because of the heterogeneity of the relevant evidence base.

Emotion Regulation in Adolescents With ADHD

Emotion regulation can be defined as a set of processes concerned with the identification or evaluation, inhibition, or modification of emotional reactions in the service of achieving some goal, including displaying socially appropriate behavior [6]. The process model of emotion regulation, developed and later extended by Gross [7,8], is one of the dominant models in the field. It categorizes strategies into 2 main types: antecedent-focused and response-focused and highlights the dynamic and context-dependent nature of how individuals regulate their emotions to adapt to various situations and personal goals. Antecedent-focused strategies involve modifying emotional experiences before they fully develop (eg, via cognitive reappraisal), while response-focused strategies involve managing emotions after they have emerged (eg, suppression). Three stages of emotion regulation are specified: identification (distinguishing emotional responses and determining whether to regulate them), selection (choosing which strategies to apply), and implementation (applying a strategy). Emotion dysregulation can manifest in a range of ways, including a failure of emotion recognition, a lack of empathy or emotional lability, overreactivity, or inertia [9]. In ADHD, emotion dysregulation is recognized as potentially including emotional reactions or experiences that are excessive relative to norms and developmental stage, uncontrolled and rapid shifts of emotion, and the abnormal allocation of attention to emotional stimuli [10]. These models suggest multiple points where successful emotion regulation can fail and correspondingly offer a range of intervention points that can be targeted with emotion regulation interventions.

Emotion regulation issues, especially emotional lability, are commonly observed among young people with ADHD and are thought to play a key role in linking ADHD to frequently co-occurring issues such as peer problems, anxiety, depression, and behavior problems [2,11-13]. For example, longitudinal research has suggested that emotion dysregulation lies on the developmental pathway between ADHD symptoms and later anxiety or depression in childhood [11]. These types of findings point to emotion regulation as a potential key target for supporting emotional functioning and reducing the risk of developing negative outcomes for young people with ADHD. However, existing interventions such as pharmacological interventions that target primary symptoms of ADHD are not as effective in reducing emotion dysregulation [3]. There are also established issues with medication adherence and discontinuation without remission in adolescence, pointing to the need for other types of interventions [14]. In addition, while there are a small number of interventions specifically targeting emotion dysregulation in ADHD, these often have limitations such as failing to generalize well to real-life situations, not being tailored for adolescence, and not adequately considering the interconnections between emotion regulation and areas of functioning such as peer relations [4,5]. Taken together, there is a need to innovate and improve interventions for emotion regulation in ADHD.

The Promise of DHIs for Emotion Regulation in Adolescents With ADHD

It has been noted that DHIs are a promising delivery method for interventions for emotion regulation [15]. In the context of difficulties in or reluctance to access support [16,17], DHIs can make mental health interventions more accessible, may carry lower stigma, and be more attractive to young people than traditional clinical interventions [18]. In addition, many emotion regulation interventions for young people with ADHD depend on parental input [5]; however, parents can also be a barrier to accessing and engaging with mental health treatment [19,20]. For example, in one recent study, adolescents reported on the barriers they had experienced in accessing mental health treatment with 32% reporting parent-related barriers (with 8% reporting parental resistance) [20]. Though parents can be a major resource in supporting young people to engage with DHIs, they can be designed to have minimal *reliance* on parental input.

Smartphone-based DHIs in particular have become highly feasible in light of increases in smartphone ownership and use and can also offer interventions that are more embedded in people's daily lives, with several advantages [15]. They can, for example, facilitate the gathering and use of rich data through sensors (eg, accelerometer, microphones, app use, and geolocation) or self-report (eg, symptom assessments), which help in understanding a person's profile of strengths, weaknesses, and triggers as well as potentially in tailoring the intervention. As applied to emotion regulation DHIs, data gathered via smartphones could in principle help identify which aspects of an individual's emotion regulation in real-life situations can benefit from intervention (eg, emotion identification, lability, reactivity, and strategy selection) and which situations or contexts are most challenging for them. Smartphone-gathered information could also be used dynamically in potential "just-in-time" adaptive interventions, in which support is provided at critical moments [21]. For example, immediate emotion regulation support could be offered if sensor or self-report data indicate that an adolescent with ADHD is experiencing escalating emotional arousal and a risk of overarousal.

Crucially, more ecologically embedded interventions may facilitate better generalization of learned skills to daily life situations by allowing users to practice skills in the flow of their daily lives. For example, though yet to be trialed in adolescents with ADHD, one recent pilot study in a population without ADHD demonstrated how smartphone apps can be used to prompt the practice of cognitive behavioral therapy (CBT) skills in real-life contexts through frequent randomly delivered prompts [22]. This study of 25 patients experiencing suicidality

XSL•FO
RenderX

reported modest reductions in negative affect after being prompted to use the CBT skills they had been previously taught, suggesting that the intervention was helping to reduce symptoms in the course of daily life. Similar principles could be applied to reminding adolescents with ADHD to, for example, deploy adaptive regulation strategies taught as part of the DHI in their daily life. Such reminders may be particularly helpful in young people with ADHD, who may experience forgetfulness. Finally, DHIs can incorporate features that promote sustained engagement, such as gamification [15], discussed in more detail later.

However, despite demonstrations of the value of DHIs in other mental health contexts and their promise as a delivery method for emotion regulation interventions for adolescents with ADHD, it cannot be assumed a priori that they will be successful. There is very little direct evidence about "what works" in terms of nonpharmacological interventions for emotion regulation in ADHD and even less in relation to DHIs targeting this outcome. Even where existing successful interventions are available for emotion regulation in other populations, there is likely to be a need to adapt these for adolescents with ADHD to take account of the specific causes, manifestations, and consequences of emotion regulation difficulties in this population. In addition, their delivery should be tailored to take account of the fact that young people with ADHD may experience sustained concentration, impulsivity, introspection, and motivation difficulties that could interfere with engagement with traditionally delivered interventions. To help ensure that their future development is based on the best available evidence, we bring together existing relevant evidence on promising DHI features and therapeutic approaches that could be leveraged in effective DHIs for emotion regulation for adolescents with ADHD.

Existing (Digital Health) Interventions Relevant for Emotion Regulation in Adolescents With ADHD

Overview

There is limited direct evidence of the intervention approaches and components that are most promising in DHIs to support emotion regulation among adolescents with ADHD. There have been previous reviews of the evidence on DHIs for ADHD [23-26], on digital technologies for supporting emotion regulation [15,27], including for young people with developmental disabilities [28], and on emotion regulation interventions for young people with ADHD [5]; evidence bases that we summarize below. However, there is surprisingly little specific evidence on emotion regulation DHIs for adolescents with ADHD.

DHIs for ADHD

One review examined the mobile apps for ADHD available at the time of the review and identified 109 assessment or treatment apps that met their inclusion criteria [26]. The treatment apps (n=85 focusing on treatment alone and n=11 focusing on both treatment and assessment) were based on music therapy (n=27, 28%), psychoeducation (n=23, 24%), organizational skills training (n=17, 18%), tracking medication (n=12, 13%), neurofeedback (n=8, 8%), cognitive training (n=4, 4%), and hypnosis (n=5, 5%). However, none were focused on emotion regulation in adolescents, and, importantly, the review authors noted that there was a lack of evidence supporting existing available apps.

A more recent review examined DHIs for young people with ADHD and identified 51 studies that met their inclusion criteria, covering intervention delivery via serious games or e-learning, the web, mobile health, telehealth, and augmented or virtual reality [24]. The interventions targeted domains that included cognition, socioemotional skills, behavior management, academic or organizational skills, medication adherence, vocational skills, motor behaviors, and clinical care. They found 12 well-designed and adequately powered randomized controlled trials (RCTs) reporting positive outcomes, demonstrating some promise for DHIs for young people with ADHD. For example, 1 RCT evaluating an exergaming intervention delivered via Xbox Kinect found improvements on specific executive functioning abilities (inhibition and switching reaction times) and general psychopathology in 8- to 12-year-old children with ADHD [29]. However, there was a lack of DHIs with a direct focus on emotion regulation.

A further review [23] focused on emerging technologies for supporting self-regulation in children with ADHD. In total, 36 studies met their inclusion criteria, covering a range of delivery platforms including personal computers, mobiles, virtual and augmented reality, sensors, wearable devices, and robots. Included in their review were interventions such as the EmoGalaxy video game that includes games to help children recognize, express, or regulate emotions. This was evaluated in a small-scale trial with a total of 20 children aged 7-12 years, indicating positive effects on social skills [30]. The augmented reality biofeedback intervention DEEP was also included, in which players use their breathing to control movement within a game set in an underwater environment. This was evaluated in a case study, where it was shown to reduce state anxiety [31]. However, the review highlighted the nascent stage of most DHIs in this area, with only 1 pilot RCT and most other DHIs in the development or prototyping phase. In addition, the self-regulation focus of these DHIs was generally on behavioral (eg, staying on task) rather than emotion regulation.

The most recent review in this space [28] focused on studies examining technologies for supporting emotion regulation in individuals with developmental disabilities. However, only 2 studies focused on individuals with ADHD (the EmoGalaxy and DEEP interventions discussed earlier), and the outcomes assessed in these studies were social skills and disruptive behavior, respectively; therefore, their impact on emotion regulation is not known. The authors of this review highlighted that the majority of work in DHIs for emotion regulation in developmental disabilities is focused on autism, with considerably less research on ADHD. Overall, these reviews suggest that there is a lack of DHIs for emotion regulation in adolescents with ADHD and a general preponderance of DHIs that are not (yet) supported by a strong evidence base.

XSL•FO
RenderX

DHIs for Emotion Regulation

Given the lack of ADHD-specific DHIs, it is helpful to consider which DHIs have shown the greatest promise in other populations. Their approaches may be candidates for adaptation to adolescents with ADHD, and the lessons learned in their development and evaluation may provide relevant insights that can inform the development of ADHD-tailored DHIs. A range of reviews have examined DHIs for emotion regulation in other clinical and community populations beyond ADHD [15,27]. One [27] focused on serious games (ie, games with a therapeutic purpose) for emotion regulation in adolescence, including digital games, biofeedback, and virtual or augmented reality. An illustrative example of the reviewed serious games is MindLight: a CBT-based game drawing on biofeedback and behavior modification, which uses a survival- or horror-themed game to train children to cope with anxious feelings. In a noninferiority trial, reductions in anxiety with this intervention were comparable to those seen with CBT [32]. The review authors found that while digital games could reduce negative affect, especially in youths with anxiety, the improvement in emotion regulation was overall nonsignificant. The authors concluded that, of the approaches reviewed, digital games may have the greatest potential. Given that ADHD-specific reviews have also shown promise for digital games as a means of delivering interventions [23,24], this approach deserves further research attention as a means of engaging adolescents with ADHD in emotion regulation interventions.

A broader scoping review of "interactive technologies" for emotion regulation training identified 65 peer-reviewed papers (including 4 RCTs and 28 controlled studies) that met their inclusion criteria [15]. Across these, they identified several theoretical models underpinning the DHIs, including biofeedback and neurofeedback as well as psychotherapeutic models such as CBT, the dual pathway model, emotion-focused therapy, attachment theory, and positive psychology, with the majority (72%) of DHIs being CBT-based.

Emotion Regulation Interventions for Adolescents With ADHD

The lack of evidence-based DHIs for emotion regulation in adolescents with ADHD is reflective of a broader lack of interventions for emotion regulation in adolescents with ADHD. For example, one recent review [5] examined the literature on nonpharmacological emotion regulation interventions for children and adolescents and found only 5 RCTs, 1 quasi-experimental study, 4 open-label uncontrolled studies, and 2 ongoing studies without results. These studies evaluated a range of interventions but most were based on behavioral therapy or CBT (with or without parent training). Though results generally suggested that these types of nonpharmacological interventions could improve emotion regulation in young people with ADHD, they noted several important limitations with the study designs such as small sample sizes, lack of randomization, issues with emotion regulation measurement, and lack of evaluation of medium- to long-term effects. In addition, only 1 study was focused on adolescence, and the predominant focus was on the age range of 6-13 years. A few additional studies have been published since the review with promising findings [33,34]. For example, the "Regulating Emotions Like an Expert" program aims to improve emotion regulation and decrease family conflict by teaching both adolescents and their caregivers emotion regulation strategies while additionally providing conflict management and communication skills. It draws on CBT and psychoeducation and was associated with adolescent improvements in emotion regulation in a small-scale evaluation. However, overall evidence on what works for emotion regulation in adolescents with ADHD remains sparse. With only a few exceptions, there is a lack of interventions for emotion regulation that have been designed specifically for adolescents with ADHD [33]. Given this lack of tailoring to adolescents with ADHD, emotion regulation interventions that are currently available are not likely to be optimized for this group.

Emotion Regulation Interventions for Adolescents

Despite the limitations in evidence on emotion regulation interventions for adolescents with ADHD, the transdiagnostic nature of emotion regulation means that relevant insights may come from the broader literature on emotion regulation interventions for adolescents. Reviews of this literature suggest that overall emotion regulation can be effectively improved through nonpharmacological interventions, with the strongest effects seen in clinical samples [35-38]. For example, in a recent meta-analysis of emotion regulation interventions focused specifically on adolescents, the pooled effect size for controlled studies was Hedge g=0.19 and was g=0.29 for pre-post studies [35]. Included studies used a range of approaches and combinations, including mindfulness, dialectical behavior therapy (DBT), psychodynamic therapy, emotion-focused cognitive behavioral therapy (ECBT), psychoeducation, and behavioral activation to target a variety of emotion regulation components, and were delivered in individual and group formats (eg, in school settings), in some cases, involving parents as well as the adolescents themselves. Only 1 study included in the review was focused on adolescents with ADHD (the Regulating Emotions Like an Expert intervention discussed earlier), and only a handful of others focused on neurodivergent adolescents (all studies in samples of individuals with autism) [39-41].

One study [36] also meta-analyzed the literature on emotion regulation interventions for adolescents but additionally used a 3-level meta-analysis to explore which intervention elements were associated with stronger intervention effects. They coded 75 different intervention elements (within 15 categories) and found that interventions that included setting goals for treatment and *psychoeducation about acceptance* had significantly higher effect sizes, whereas the element *social skills training, unspecified* was associated with significantly worse effects. *Setting goals for treatment* refers to setting goals for contact with the adolescent as well as setting realistic session-by-session goals. *Psychoeducation about acceptance* refers to providing information on what it means to accept thoughts or emotions and how this can be an alternative strategy to control or avoidance. Several other elements were not significant but were associated with effect size differences greater than >0.20 and therefore may also represent important active ingredients. These included discussion of challenging emotional situations, alternative actions to emotional avoidance, downregulation of negative emotions, exposure to emotions, self-exploration or

XSL•FO
RenderX

self-monitoring of thoughts and feelings, unspecified, teach cognitive flexibility reappraisal, psychoeducation about treatment or treatment element or technique, psychoeducation about self-esteem and self-worth, psychoeducation about stress, evaluating consequence of behaviors, and lifestyle, unspecified. These elements could be considered for ADHD-specific DHIs for emotion regulation; however, some elements (eg, discussion of challenging emotional situations) would be more difficult to translate to this delivery mode than others (eg, psychoeducation about acceptance).

Intervention Approaches and Components

Overview

The "Existing (Digital Health) Interventions Relevant for Emotion Regulation in Adolescents With ADHD" section illustrates the range of therapeutic approaches that have been used in interventions to support emotion regulation in adolescents with and without ADHD. In this section, we discuss key approaches in more detail to illustrate and compare the different ways in which existing approaches address emotion regulation difficulties. Of note, there are shared or similar features across many approaches, though the labeling of these features may differ by therapeutic framework.

Cognitive Behavioral Therapy

CBT (also sometimes referred to as "behavioral therapy" in an ADHD context) is a versatile therapeutic approach that targets cognitions and underlying schema while facilitating adaptive behavioral strategies. CBT is commonly used in emotion regulation interventions for adolescents without ADHD [35]. In addition, though research on emotion regulation outcomes following CBT in ADHD is scarce, it is frequently used and has been widely evaluated in the treatment of adolescents with ADHD to target various other outcomes, including primary ADHD symptoms (inattention and hyperactivity or impulsivity), organization skills, and social skills [42]. The literature on the effectiveness of CBT in ADHD has been characterized as heterogeneous and difficult to summarize; however, the overall indication is that it is effective in improving primary symptoms and functional outcomes [42,43]. A recent meta-analysis, for example, found a pooled effect size for CBT interventions in children and adolescents with ADHD of g=0.80 [44], and another review discussed positive effects on a range of outcomes that are meaningful for people with ADHD [42], including demonstrations of incremental benefits when added to medication. CBT has been adapted and combined with several other approaches to provide better tailoring to the specific issue of emotion regulation. The most widely researched of these approaches are discussed below. As noted earlier, there is a considerable precedent for the incorporation of CBT skills in DHIs for emotion regulation, suggesting that DHIs represent a viable approach for the delivery of CBT-derived interventions [15].

Emotion-Focused CBT

Researchers have argued for the benefits of a greater focus on emotion in CBT, where the outcome of interest is improved emotional functioning [45]. As a result, a variant of CBT, ECBT that includes core CBT components as well as content that is specifically focused on the regulation of a variety of emotions (eg, sadness, guilt, and anger), has been developed to address this gap [45]. In face-to-face therapy, ECBT sessions may involve content around identifying emotions, causes and consequences of emotions and associated bodily sensations, the regulation of emotions, and emotional exposure tasks. Despite the face validity of this increased focus on emotions, however, findings on the relative advantages of ECBT for emotion regulation are somewhat mixed. One study in adolescents without ADHD found that ECBT was associated with greater improvements in emotion regulation outcomes compared to both no treatment and CBT; however, another study found that ECBT and CBT were associated with similar improvements in emotion dysregulation and adaptive emotion regulation strategy use [45,46]. Overall, there has been very little evaluation of ECBT with adolescents, and none we could identify with adolescents with ADHD specifically. Future research could therefore explore fruitful adaptations to this group, for example, exploring the regulation of positive as well as negative emotions, given that dysregulation of the former may also represent a source of impairment for adolescents with ADHD [47].

Unified Protocol

The "unified protocol" [48] is a CBT-based manualized transdiagnostic intervention for emotion dysregulation, which may also be considered a form of ECBT due to its strong focus on emotions. The approach has empirical support for improving symptoms of internalizing problems [49] and is available in a form adapted for children and adolescents [50]. It typically includes modules focusing on different aspects of emotion regulation (eg, cognitive reappraisal, tolerance, and reducing the use of avoidance), accompanied by psychoeducational materials, motivational interviewing or enhancement, and review and relapse prevention. A key goal is to promote the use of more adaptive emotion regulation strategies and reduce the use of more maladaptive strategies. This has strong relevance for ADHD, which has been associated with the use of less adaptive strategies and more maladaptive strategies [51]. It also aims to support the development of related competencies such as awareness or acceptance of emotional experience, flexible modulation of emotional intensity and duration, and willingness to experience emotions within everyday life. Future research could explore how to adapt the intervention for this group, such as offering a greater focus on the aspects of emotion regulation (eg, affective lability) and its impacts (eg, peer problems) that are most pertinent for adolescents with ADHD [52].

Rumination-Focused CBT

Rumination is often classified as a maladaptive emotion regulation strategy characterized by a repetitive style of negative thinking that can maintain or escalate negative affect due to a focus on one's negative emotions and the causes and consequences of them, without engaging in problem-solving [53]. Consistent with emotion regulation more generally, evidence suggests that it can act as a mediator in the relations between ADHD and mental health outcomes [54,55]. Rumination-focused cognitive behavioral therapy (RF-CBT) is

XSL•FO
RenderX

based on differentiating between adaptive and maladaptive styles of repetitive thinking and uses functional analysis to examine the functions of ruminations [56]. It aims to equip patients with skills and strategies to reduce rumination, such as fostering more concrete thinking and developing "if ... then" implementation plans in response to rumination "warning signs." RF-CBT has been found to be helpful in reducing and preventing emotional disorder symptoms [57]; however, it has not been specifically evaluated as a treatment for adolescents with ADHD. In terms of its potential for adaptation in DHIs, self-help versions are available, providing proof-of-concept for delivery without clinician input [58].

Mindfulness-Based Interventions and Mindfulness-Based Cognitive Therapy

Mindfulness-based interventions have been proposed for strengthening emotion regulation skills, including in young people with ADHD [59]. Though available in different forms, a common theme of mindfulness-based interventions is that they encourage attending to the current moment with acceptance and without judgment. This may be achieved through daily meditation and self-awareness activities, sometimes combined with CBT techniques in mindfulness-based cognitive therapy (MBCT) [59]. Recent meta-analyses have suggested mixed findings on the effects of mindfulness-based interventions for adolescents [35]. For example, one study showed MBCT-associated improvements in emotional awareness but not in nonacceptance of emotions, impulse control, or regulation [60], and of the various studies that reported evaluations of the Learn to Breathe intervention, some showed no effect and others reported effects on a subset of emotion regulation outcomes only [61-66]. The evidence on the efficacy of mindfulness-based interventions on emotion regulation for adolescents with ADHD is scarce and inconsistent, based on small-scale studies, and has not focused on emotion regulation as an outcome [33]. In terms of the viability of a DHI based on this approach, in addition to the strong precedent for DHI delivery of CBT-derived interventions, mindfulness apps for emotion regulation have previously been successfully developed and found to be feasible for use in adolescents [67].

Acceptance and Commitment Therapy

Acceptance and commitment therapy (ACT) is another therapeutic approach that, though not necessarily its primary focus, addresses emotion regulation in various ways such as teaching emotional acceptance over suppression and avoidance, encouraging engagement with value-consistent behaviors despite negative affect, and promoting psychological flexibility. As such, ACT has informed or been incorporated into interventions targeting emotion regulation in patient groups such as those experiencing nonsuicidal self-injury [68] as well as vulnerable young people [69] and students [70]. There are, however, very few studies that have used ACT in ADHD. A recent scoping review identified only 6 studies from 2015 and none that examined its use in directly addressing emotion regulation in ADHD [71]. However, previous studies have demonstrated how ACT can be translated into a DHI format [72], as well as establishing acceptability and feasibility when used in patient groups such as those with generalized anxiety disorder [73] or eating disorder [72]. This suggests that despite the lack of research into ACT in ADHD, it holds potential for delivery in a DHI format.

Dialectical Behavior Therapy

DBT was originally developed for patients with borderline personality disorder but has since been used across disorders to improve emotion dysregulation and related outcomes such as suicidality and self-harm [74,75]. DBT has also been used with adults with ADHD [76]. In common with CBT, DBT aims to address maladaptive cognitive and behavioral processes; however, it also has a strong emphasis on mindfulness and acceptance, thus also showing some convergence with the principles of MBCT and ACT. DBT has shown some promising findings for improving emotion regulation and other outcomes in adults with ADHD [77]; however, one recent RCT showed no clear evidence of benefit for emotion regulation in adults with ADHD [78], despite being associated with improvements in other outcomes, including emotional disorder symptoms. More generally, a recent systematic review not specifically focused on populations with ADHD found a lack of evidence for a positive effect of interventions based on DBT (primarily interventions that used the skills acquisition components alone) on emotion regulation, despite this being a core hypothesized mechanism of action [79]. In addition, while DBT has been adapted for use in adolescents [80], there is a lack of DBT studies with adolescents with ADHD specifically. In terms of the viability of delivering DBT via DHIs, a recent review paper synthesized the literature on mobile apps using DBT and identified 21 apps (2 of which were specifically aimed at adolescents). Of these, 71% were scored as showing "acceptable" usability, suggesting that DHI delivery of DBT is feasible [81].

Adjunctive Components

Components of other therapeutic approaches that can be used as adjuncts or otherwise combined with other approaches have been explored to support emotion regulation in adolescents with ADHD. Psychoeducation, such as providing information about emotion regulation or dysregulation, is very commonly included in emotion regulation interventions for young people both with and without ADHD [33,34,82]. While there is limited evidence for the efficacy of psychoeducation for improving emotion regulation as a stand-alone intervention [83], there are several studies suggesting the efficacy of interventions that include a psychoeducation component [5]. In addition, the common elements analysis [36] discussed earlier identified several psychoeducation-based elements to be associated with increased intervention effect sizes. Taken together, psychoeducation, in combination with other approaches, appears to be a valuable component of emotion regulation interventions. For adolescents with ADHD, it is likely to be crucial to deliver psychoeducation in engaging formats (using images or videos and minimizing text), potentially broken down into smaller chunks.

Music therapy has also been proposed as an adjunct in emotion regulation interventions. One study [84] reported preliminary evidence that a combined CBT and music-based intervention improved emotion regulation skills in adolescents with ADHD and was considered high in acceptability by participants. Music

XSL•FO
RenderX

therapy has also been trialed as an emotion regulation intervention in general at-risk samples of young people, with some promising findings [85,86]. Given that music-based emotion regulation interventions are also feasible to be delivered via DHIs [87], this merits further investigation as an intervention component for DHIs for adolescents with ADHD.

Symptom monitoring is common and well-accepted in DHIs [88]. A recent study reported the positive effects of smartphone-based symptom monitoring in adolescents with ADHD [89]. However, to our knowledge, this has not been evaluated in relation to emotion regulation specifically and requires future research to determine its promise and how to optimize its implementation in this context.

Finally, it is important to consider the role of parents and caregivers in supporting the treatment of adolescents with ADHD and the implications of this for emotion regulation DHIs. Many effective interventions for adolescents with ADHD include a parent or a dyadic component or leverage parents to, for example, support the young person by motivating, reminding, and monitoring them in practicing and generalizing their skills. Parent or caregiver involvement in such interventions is seen as an important aspect of their success [90,91]. Indeed, previous research has suggested that the involvement of parents or caregivers in interventions for young people with ADHD, either as an intervention target or to reinforce the intervention received by the young person, improves outcomes for the young people [92,93]. However, parents or caregivers can also be a source of barriers to accessing and engaging with treatment in adolescents with ADHD. For example, studies have identified low parent motivation as a treatment barrier for adolescents with ADHD, as well as low parent adherence during treatment [90,94]. For example, in an analysis of psychosocial treatment engagement barriers for adolescents with ADHD, there was a 69.4% prevalence of parental failure to consistently monitor their teen's skills use and a 49.6% prevalence of intrusive behaviors that undermined the autonomous practice of skills by youths [90]. This suggests that while parent or caregiver involvement could enhance the effects of DHIs for adolescents with ADHD, they should not depend on parental involvement. This could be operationalized in terms of providing optional parent or caregiver-oriented materials that could be used to support the young person's learning and practice as well as supporting parent or caregiver-adolescent relationship aspects of emotion regulation (including fostering effective interpersonal emotion regulation). It could additionally involve identifying ways in which the DHI might serve some of the roles that parents or caregivers typically take on in supporting treatment engagement, such as notifications to complete tasks within the app, reminders to practice skills outside it, and offering rewards for successful completion.

Other Design, Development, and Evaluation Considerations

DHIs Informed by the Latest Developments in Emotion Regulation and Research

It is critical that DHIs are informed by—in combination with user and clinical input—research evidence over the lifecycle of their development and evaluation. Emotion regulation research is an active area of inquiry in which there continue to be new developments that can inform interventions. For example, recent research has seen a relative shift in focus from identifying adaptive versus maladaptive strategies to investigating the flexibility with which individuals deploy strategies [95]. Similarly, the universal value of "adaptive" strategies such as cognitive reappraisal has been more recently questioned [96]. New measures are being developed within ADHD research, reflecting a need for ADHD-specific measures and also addressing the lack of focus on strategies beyond reappraisal and suppression captured by dominant existing measures [97]. For example, in addition to reappraisal and suppression, the recently developed Comprehensive Emotion Regulation Inventory measures emotional reactivity, situational selection, modification, attentional deployment, implementation, and negative impact [97]. More attention is also now being paid to inter- as well as intrapersonal emotion regulation strategies [98]. Interpersonal emotion regulation strategies refer to the use of others in the service of regulating emotions, whereas intrapersonal regulation strategies are those such as suppression and reappraisal that occur within an individual. New evidence along these and other lines of research in emotion regulation should be reflected in intervention approaches, and interventions should adopt a development and evaluation approach (such as "trials of intervention principles") that is agile enough to respond to new evidence as well as technological advances [99].

Promoting Engagement With DHIs

A number of discussions of DHIs have noted significant challenges in the sustained engagement of users, for example, prominent authors in the field have noted that "user engagement with digital mental health is the new primary challenge in realizing the full potential of scalable and accessible care" [100]. One analysis of mental health app retention, for example, found a median 15-day retention rate of only 3.9% [101]. Prompted by the growing recognition of these issues, there has been an increased research focus on the barriers and facilitators to DHI engagement and associated engagement strategies, including a number of recent reviews on the topic [100,102-106].

An early analysis of the contributing factors to low engagement [105] proposed several key factors that may limit engagement, including that DHIs are not sufficiently designed with users in mind (eg, are not enjoyable to use), do not solve problems that users care about, and are unhelpful in crises and emergencies. In addition, there were concerns around privacy and trust. One recent comprehensive review examined the barriers and facilitators to mental health DHI engagement, identifying 208 eligible papers for inclusion [102]. Based on the information extracted in the included studies, they classified factors in terms of those related to the user, program or content offered by the

XSL•FO
RenderX

intervention, and the technology and implementation environment. In terms of users, they found that women were more likely to engage with DHIs than men and that mental health symptoms sometimes made engagement with DHIs more challenging. Positive beliefs about mental health help-seeking and technology, digital health literacy, and positive experiences with mental health services and technology facilitated engagement. DHI engagement was additionally facilitated by people being able to integrate DHI use into their daily lives; it was facilitated when the DHI content was credible, of an appropriate length, and customizable to the user; and it was facilitated if users understood the data shown by the DHI and if they knew how to use the DHI. Guided DHIs (including via automated reminders) generally yielded higher engagement than unguided interventions, as did DHIs that facilitated social connection. Engagement was higher when participants had a sense that the platform was private and anonymous and if they felt that the people close to them thought they should use DHIs. Finally, technical issues were a barrier to engagement, whereas training people to use the DHI was a facilitator.

While these factors provide general information about DHI engagement, it will be important to understand the specific barriers and facilitators of DHI engagement experienced by adolescents with ADHD. For example, difficulties with sustaining attention, increased forgetfulness, lower frustration tolerance, high novelty seeking, and differences in reward sensitivity and delay discounting (eg, a preference to receive a smaller reward sooner over a larger reward later) compared to non-ADHD DHI users may be particularly pertinent characteristics to consider when mapping factors influencing engagement [107-109].

In terms of engagement strategies, one review of emotion regulation DHIs [15] documented the specific engagement strategies used in emotion regulation DHIs. Approaches included the use of gamification (the integration of game mechanics to improve adherence, motivation, and enjoyment), multimodal representations of emotional experience, and storytelling. For example, one DHI used a digital storytelling method, in which a grumpy pirate is searching for treasure [110]. During the course of the narrative, users are encouraged to relive their feelings in a safe setting, supported by their caregiver. The review also highlighted how personalization may be used in emotion regulation DHIs, facilitated, for example, by using machine learning to predict emotional states and user customization features.

Reviews of DHIs in ADHD have not generally discussed engagement strategies in depth; however, an inspection of primary papers suggests that approaches used include the use of high-quality engaging graphics, reward loops, personalization (including adaptive personalization of difficulty level), exercises that elicited more active engagement with the app, gamification, prompts or reminders, feedback on progress and compliance, co-design with young people, and the ability to schedule chat sessions [111-118]. For example, the project EVO DHI, which targets neurocognitive functioning, uses a consumer-grade video game–type format to appeal to young people [111], while a DHI designed to improve medication adherence successfully used text reminders to encourage the target behavior [119]. Despite the fledging status of this area of research, several authors have noted the promise of strategies such as gamification to overcome intervention adherence difficulties in young people with ADHD [120,121]. Taken together, while there is limited evidence on which specific strategies are optimal for DHIs for emotion regulation in adolescents with ADHD, the importance of developing and evaluating [102] engagement strategies is clear.

The development of engagement strategies is one aspect of DHIs that may particularly benefit from a coproduction approach with users themselves. A common theme in analyses of barriers to engagement relates to issues deriving from a lack of user involvement from the earliest stages of DHI development. One analysis [105], for example, noted that users can provide critical feedback that helps make sure that a DHI addresses real-world problems that matter to users; yet, a minority of DHIs has the necessary level of user involvement throughout the process. A recent review of DHIs for ADHD [24] also noted that there were few DHIs in the included studies that were designed based on user-centered participatory and ability-based design approaches. One notable exception can be seen in the series of participatory workshops conducted by the authors of a smartwatch-based intervention to support self-regulation among young people with ADHD [122]. These workshops explored topics such as what features the users would like to see in the intervention and what “engagement strategies” would help adherence, using discursive methods and engaging activities.

DHI Evaluation

Despite large numbers of ADHD DHIs being available, only a small minority are evidence-based [26]. This is an important issue because there is an obvious ethical obligation for interventions used by adolescents with ADHD to be effective and not cause harm. This issue also impacts dissemination and engagement with DHIs because users and those who may recommend DHIs (eg, clinicians) may feel a lack of trust in the effectiveness of DHIs [105]. Best practices for DHI evaluation broadly follow principles and processes similar to those for intervention evaluation in general; however, there are also some unique considerations in assessing the effectiveness, usability, and scalability.

A comprehensive evaluation should include several steps. First, studies that focus on the thorough assessment of the intervention’s design, functionality, and user interface, ensuring that it aligns with the targeted health goals and user needs should be conducted. Second, the usability and feasibility of DHIs should be tested with the aim of understanding how easily the DHI can be integrated into existing health care systems and routines [123]. Finally, rigorous methodologies, such as RCTs, should be applied to evaluate the impact on patient or client outcomes. DHI evaluations also need to consider DHI-specific challenges related to data security and privacy concerns. As the DHI and the evaluation fields continue to evolve, DHI developers need to be aware of and incorporate the latest developments in DHI evaluation best practice [124].

XSL•FO
RenderX

Recommendations

The recommendations are as follows: (1) the limited evidence available suggests that there are several promising therapeutic approaches that could inform emotion regulation DHIs for adolescents with ADHD, including emotion regulation–focused CBT variants (eg, ECBT, unified protocol, and RF-CBT), DBT, and ACT; (2) users should be involved in DHI development from the very beginning; (3) the embeddedness of smartphone use in daily life to promote practicing skills in real-life situations could be leveraged to promote generalizable improvements; (4) strategies to promote sustained engagement should be co-designed with users and built into DHIs; and (5) DHIs should take a development and evaluation approach that allows them to be responsive to the latest evidence in the active area of research into ADHD emotion regulation.

Conclusions

There is limited direct evidence to inform the design of DHIs to support emotion regulation in adolescents with ADHD. However, there is a strong precedent for the use of DHIs with young people with ADHD and for the use of DHIs to deliver emotion regulation interventions in populations without ADHD. There are several promising therapeutic approaches that could underpin such DHIs, including emotion regulation–focused CBT approaches and components (eg, ECBT, RF-CBT, and unified protocol), DBT, ACT, psychoeducation, music therapy, and symptom tracking; however, much further work is required to gain a better understanding of whether they can be used to underpin effective ADHD-tailored emotion regulation DHIs.

In terms of the DHI development process, involving users across the lifecycle of development and co-designing strategies to support sustained engagement will be critical. As emotion regulation in ADHD is an active area of research, DHIs will need to be able to be responsive to the latest developments. Finally, we speculate that the greatest benefit of emotion regulation DHIs may be derived, where they are leveraged to promote the practice and use of skills in the course of daily life (eg, via reminders throughout the day to use the skills learned).

Abstract

Background: The impact of smartphone use on sleep remains intensely debated. Most existing studies have used self-reported smartphone use data. Moreover, few studies have simultaneously examined associations between both smartphone addiction and objectively measured smartphone use and sleep, and the dose-response relationship between smartphone use and risk of poor sleep has been consistently overlooked, requiring systematic and further research on this topic.

Objective: This study aimed to examine the associations between smartphone addiction and objectively measured smartphone use and sleep quality and duration.

Methods: This cross-sectional study enrolled 17,713 participants from a university in China. We assessed objective smartphone screen time and unlocks by collecting screenshots of use records and measured smartphone addiction using a validated questionnaire. Sleep quality and duration were estimated via the Pittsburgh Sleep Quality Index. Binary logistic regression, linear regression, and restricted cubic spline regression models were used for the analyses.

Results: A total of 14.3% (2533/17,713) of the participants met the criterion for poor sleep, with a mean sleep duration of 507.1 (SD 103.2) minutes per night. Notably, university students with smartphone addiction exhibited 184% higher risk of poor sleep (odds ratio [OR] 2.84, 95% CI 2.59-3.11) and a 15.47-minute–shorter nighttime sleep duration (β=–15.47, 95% CI −18.53 to −12.42) compared to those without smartphone addiction. Regarding objectively measured smartphone use, participants with ≥63 hours per week of smartphone screen time had 22% higher odds of poor sleep (OR 1.22, 95% CI 1.08-1.37) and a 6.66-minute–shorter nighttime sleep duration (β=–6.66, 95% CI −10.19 to −3.13) compared to those with 0 to 21 hours of screen time per week, whereas those with approximately 21 to 42 hours per week of smartphone screen time had a 5.47-minute–longer nighttime sleep duration (β=5.47, 95% CI 1.28-9.65). Similarly, compared to those with 0 to 50 smartphone unlocks per week, participants with ≥400 smartphone unlocks per week showed 61% higher odds of poor sleep (OR 1.61, 95% CI 1.41-1.85) accompanied by a 4.09-minute–shorter nighttime sleep duration (β=–4.09, 95% CI −8.08 to −0.09), whereas those with approximately 50 to 150 smartphone unlocks per week had a 5.84-minute–longer sleep duration (β=5.84, 95% CI 2.32-9.36). An inverted U–shaped association between smartphone screen time and sleep duration was observed (P<.001 for nonlinearity).

Conclusions: Smartphone addiction, excessive objectively measured smartphone screen time, and unlocks are positively associated with both sleep quality and duration. Restricted cubic spline analyses revealed different nuanced dose-response relationships, with an inverted U–shaped association observed between smartphone screen time and sleep duration.

KEYWORDS

smartphone addiction; smartphone screen time; smartphone unlocks; sleep disorders; sleep duration

Introduction

In the digital age, youths spend more time on smartphones than ever before, and smartphones have become an inescapable part of everyday life [1]. Adequate and high-quality sleep plays a pivotal role in sustaining physiological and psychological well-being. Poor sleep quality alongside inadequate duration is both prevalent and strongly linked to elevated risks of adverse health outcomes [2-4] and, thus, has become a notable concern.

XSL•FO
RenderX

Over recent decades, epidemiological evidence has indicated a progressive deterioration in both average sleep quality and duration [5], with roughly 33% of the global population falling short of internationally recommended nocturnal sleep thresholds (7‐9 hours per night). Given the public health impact of poor and insufficient sleep, there is a critical need to better understand the potential influence of ubiquitous smartphones in impairing sleep health.

Numerous studies have linked smartphone use with poor sleep and shorter sleep duration [6-12], whereas few studies have reported that smartphone screen time correlates with poorer sleep quality but has minimal effects on sleep duration [9,13]. Conversely, 2 studies found no association between the daily use of technology devices and sleep outcomes [14,15]. Notably, the current generation of youth, referred to as iGens by Twenge [16], has grown up in the smartphone era and is characterized by elevated rates of smartphone use and smartphone addiction [17]. University students today belong to the iGeneration, who are more prone to severe smartphone addiction and maladaptive use that may impair sleep quality and duration in the absence of familial oversight. This risk is particularly concerning because poor or insufficient sleep can exacerbate mental health issues, which have already garnered broad societal attention, especially against the backdrop of China's rapidly accelerating pace of life. Previous research has posited that smartphones may affect sleep via multiple mechanisms. First, the time displacement hypothesis posits that excessive smartphone use potentially comes at the cost of sleep [18] as each additional hour of screen time theoretically reduces available sleep hours. A prospective cohort study showed that excessive smartphone use was related to shorter total sleep time in children [19]; the total sleep time of the smartphone overuse group (smartphone use of over 1 hour per day) was shorter than that of the control group. Second, prolonged smartphone screen time increases exposure to screen-emitted light [20]. More light exposure from smartphones could delay melatonin onset, disrupting the circadian rhythm and thereby reducing sleep quality and duration. Phillips et al [21] demonstrated that evening exposure to light at intensities below 30 lux, which is comparable to that emitted by smartphones, suppressed melatonin by 50%. Furthermore, the electromagnetic fields emitted by smartphones have also been identified as a significant factor influencing sleep. A study by Huber et al [22] revealed that exposure to pulse-modulated electromagnetic fields increased relative regional cerebral blood flow in the dorsolateral prefrontal cortex ipsilateral to the exposure and enhanced electroencephalographic power in the alpha frequency range before sleep onset and in the spindle frequency range during stage 2 sleep. Third, psychological and physical arousal induced by engaging, entertaining, or distressing content from various smartphone apps may also impair the ability to fall asleep and maintain sleep [23,24]. Meyerson et al [25] leveraged estimated bedtimes from 44,000 Reddit users and their 120 million posts, revealing that users who posted 4 or more times within 1 hour before bedtime had a 4-fold higher risk of delayed sleep onset compared to those who posted 2 to 5 hours before bedtime.

Despite a growing body of research on the association between smartphone use and sleep, methodological and dimensional limitations persist. First, the widespread use of smartphones in everyday life points to the need for rigorous and objective methods that can adequately capture the true links between smartphone use behavior and sleep. However, most existing studies rely on participants' self-reported smartphone use data. This is an important limitation because previous research has shown that self-reported smartphone use is prone to recall bias and misclassification errors and does not correlate well with objectively measured smartphone use [26-29]. A neglected aspect of smartphone use is unlocks, defined as the number of times that users activate their smartphone screen within a specific period, a behavior reflecting compulsive urges for immediate interaction. As a dimension distinct from smartphone screen time, unlocks represent dynamic user-device interaction patterns [30,31] whose potential impact on sleep remains understudied. Second, research on the association between smartphone use and sleep has been siloed, focusing exclusively on either smartphone addiction or smartphone use (eg, duration). These 2 dimensions represent different metrics of smartphone use [32-34]. Smartphone addiction has been defined as an individual's excessive and uncontrollable use of smartphones, resulting in impaired social functioning and psychological and behavioral problems [35,36]. Smartphone screen time is neither a necessary criterion nor a precise proxy for addiction as users with shorter smartphone screen time may still exhibit addictive symptoms, whereas those with longer screen time might engage in adaptive use [32]. Thus, analyzing smartphone addiction and smartphone use behaviors is essential to understanding the full impact of smartphones on sleep. To date, few studies have examined the associations between both smartphone addiction and smartphone use and sleep simultaneously. Moreover, previous research has often treated smartphone addiction and smartphone use behaviors as categorical variables in traditional regression models, thereby overlooking the potential for dose-response associations between continuous smartphone use and risk of poor sleep. Consequently, less is known about associations between different points along the continuum of both smartphone use and smartphone addiction and sleep quality or duration.

This large-scale study adopted a more holistic perspective with a representative sample, assessing objective smartphone use by collecting screenshots of participants' smartphone screen time and unlock records and measuring smartphone addiction through a validated questionnaire, with the aim of examining whether smartphone addiction and objectively measured smartphone use were associated with sleep quality and duration among university students. We also conducted restricted cubic splines (RCS) regression to better understand the dose-response relationship between smartphone use and sleep.

Methods

Study Population

In this cross-sectional study, a university in Shaanxi province, China, was randomly selected from the provincial registry of higher-education institutions. All 24,156 students in this university were invited to participate in the survey. Before data collection, training sessions were conducted for all class

XSL•FO
RenderX

counselors to explain the study objectives and procedures. They subsequently facilitated the anonymous completion of a structured electronic questionnaire by the students. From the 22,047 questionnaires received, submissions were excluded if they met any of the following criteria: (1) completion time of less than 500 seconds, (2) failure on one or more attention-check questions, (3) inability to provide valid smartphone use screenshots, or (4) implausible sleep metric data. Consequently, a total of 17,713 students were included in the final analyses. A flowchart of the screening of the study participants is shown in Multimedia Appendix 1.

Ethical Considerations

The Second Affiliated Hospital of Xi'an Jiaotong University provided ethics approval for this study (approval ID: 2022-248). All participants gave their electronic informed consent before taking part in the study. All personally identifiable information was removed during data preparation and analysis and was not included in the manuscript or supplementary materials. No images or visual identifiers of participants are included in the study. Participants received no financial compensation for their involvement. This study followed the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) reporting guideline and CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) checklist [37]. The CONSORT-EHEALTH checklist is shown in Checklist 1.

Measures

Smartphone Addiction

The Mobile Phone Addiction Tendency Scale (MPATS), originally developed by Xiong et al [38] for Chinese university populations, was used to evaluate smartphone addiction in this study. The scale comprises 16 items across 4 dimensions consisting of salience, withdrawal symptoms, social comfort, and mood changes. The items are scored on a scale from 1 ("very inconsistent") to 5 ("very consistent"), yielding a total score between 16 and 80. Elevated total scores correlate with greater severity of smartphone addiction, with scores of ≥48 defining smartphone addiction. In this study, the Cronbach α coefficient was 0.94.

Objectively Measured Smartphone Use

The objectively measured smartphone use included smartphone screen time and unlocks. In this study, upon providing informed consent, participants were instructed to capture and submit screenshots of their smartphone use during the previous full week, which was automatically recorded by the built-in Screen Time tool of the iOS system and the Digital Wellbeing tool of the Android system. The operating system passively records these behavioral data through a triggering mechanism involving screen photoelectric sensors, representing an objective measurement approach independent of self-reporting. Previous studies have validated the use of such built-in tracking systems to obtain objective smartphone use behavior as accurate and reliable for capturing actual use patterns [29,39]. The 7-day assessment period aligns with those of most studies in this field [40-42]. There is evidence suggesting that less than 1 week of smartphone data collection is already sufficient to capture typical smartphone use behaviors [43]. Furthermore, to mitigate potential variation between weekdays and weekends and enhance the representativeness, participants were instructed to submit screenshots encompassing a full week (5 weekdays and 2 weekend days). Two weeks before the formal investigation of this study, we instructed the participants to activate the function for smartphone records to ensure the availability of objective data. We then provided step-by-step instructions for screenshots for different brands and types of smartphones and required them to submit the screenshots covering (1) smartphone screen time during the previous week and (2) number of smartphone unlocks during the previous week. According to the distribution of the screen time data, we classified participants into 4 groups (approximately 0-21, 21-42, 42-63, and ≥63 hours per week). In accordance with the distribution of our datasets, and to ensure better practical guidance, we partitioned smartphone unlocks into quartiles, selecting integer thresholds around quartile points. Consequently, we classified participants into 4 groups for smartphone unlocks (approximately 0-50, 50-150, 150-400, and ≥400 times per week).

Sleep Quality and Duration

The Pittsburgh Sleep Quality Index (PSQI) was administered to evaluate sleep quality over the previous month [44]. Comprising 19 items, the instrument is structured into 7 domains (subjective sleep quality, sleep latency, sleep duration, habitual sleep efficiency, sleep disturbances, use of sleeping medication, and daytime dysfunction). Each domain is scored on a scale between 0 and 3, with elevated scores representing poorer sleep. Aggregating scores across domains produces a composite PSQI score spanning 0 to 21, where higher scores signify poorer sleep quality. A score of ≥8 was used to define poor sleep in accordance with the validated cutoff for the Chinese population [45], which has demonstrated good reliability and validity in previous representative studies [46,47]. In this study, the Cronbach α coefficient of the PSQI was 0.85.

Sleep duration was evaluated via the following question: "Over the past month, how many hours did you typically spend asleep at night? This time should exclude time spent in bed without falling asleep."

Covariates

We developed a structured questionnaire to gather several confounding factors. Sociodemographic information included gender, university year, race, registered permanent residence, whether the participants had siblings, and parental educational attainment. As described in a previous study [48], health-related lifestyles comprised current smoking, current drinking, physical activity, and rational diet. Participants who had smoked at least one cigarette in the previous 30 days were classified as current smokers. Similarly, those who had consumed at least one glass of wine during the previous 30 days were categorized as currently drinking. The International Physical Activity Questionnaire–Short Form was used to assess physical activity [49], categorizing activity levels into low, moderate, and high according to established calculated metabolic equivalents. An irrational diet was defined as participants consuming red meat every day or vegetables and fruits less than daily.

XSL•FO
RenderX

As previous studies have reported significant relationships between social support and sleep, the Adolescent Social Support Scale (ASSS) was administered to quantify social support [50]. The ASSS is a 16-item instrument, with each item scored on a scale from 1 to 5. A higher score signifies greater social support. The Cronbach α coefficient of the ASSS was 0.88, indicating strong internal consistency.

Statistical Analyses

Participant characteristics were described using frequency distributions for categorical variables, as well as means and SDs for continuous variables. Three sets of binary logistic and linear regression models were constructed to estimate odds ratios and 95% CIs for poor sleep, as well as β coefficients and corresponding 95% CIs for sleep duration. Covariates included sex, university year, race, registered permanent residence, whether the participants had siblings, parental educational attainment, current smoking, current drinking, physical activity, rational diet, and social support. RCS regression was used to model dose-response associations between both smartphone addiction and objectively measured smartphone use and sleep quality and duration. In addition, we tested for interaction between smartphone use and sex to determine whether sex modified the relationships. To reduce the possible effects of the unbalanced sex ratio of the participants, we conducted a sex-weighted logistic regression. Moreover, a multilevel model with college under university as a random effect was conducted to mitigate the college under university clustering effects.

In all tests, a 2-sided *P* value of <.05 was used as a significance threshold. The R software (version 4.0.2; R Foundation for Statistical Computing) was used for all data analyses.

Results

Participant Characteristics

Table 1 presents the characteristics of the participants in this study. Of the 17,713 participants, 6087 (34.4%) were male, and 11,626 (65.6%) were female. A total of 95.9% (16,992/17,713) were of Han ethnicity, 43.1% (7633/17,713) lived in rural areas, and 34.4% (6098/17,713) were from single-child families. Notably, 14.3% (2533/17,713) of the participants met the criteria for poor sleep (PSQI≥8), with a mean sleep duration of 507.1 (SD 103.2) minutes per night. Overall, 24.9% (4418/17,713) of the participants met the criteria for smartphone addiction (MPATS score ≥48), with a mean MPATS score of 37.4 (SD 13.3). Mean smartphone screen time was 49.1 (SD 29.9) hours per week, and mean unlocks were 391.1 (SD 278.3) times per week.

[a]MPATS: Mobile Phone Addiction Tendency Scale.

Association Between Smartphone Use and Sleep Quality

The associations of smartphone addiction, screen time, and unlocks with sleep quality were presented in (Table 2). After adjusting for sex, university year, race, registered permanent residence, whether the participants had siblings, parental educational attainment, current smoking, current drinking, physical activity, rational diet, and social support, smartphone addiction was associated with poor sleep (OR 2.84, 95% CI 2.59-3.11). A 5-point increase in the MPATS score was substantially associated with poor sleep (OR 1.27, 95% CI 1.25-1.30). Objectively measured smartphone use was also linked to sleep quality. Compared with participants reporting 0–21 hours/week of smartphone screen time, those with ≥63 hours/week had higher odds of poor sleep (OR 1.22, 95% CI 1.08-1.37). While those with 21–42 hour/week (OR 0.86, 95% CI 0.74-1.00) and 42-63 hour/week (OR 0.98, 95% CI 0.86-1.12) exhibited no significant increase in sleep quality. Compared with participants reporting 0-50 times/week of unlocks, those with 150~400 times/week (OR 1.34, 95% CI 1.18-1.53) and ≥400 times/week had higher poor sleep odds (OR 1.61, 95% CI 1.41-1.85), while those with 50-150 times/week (OR 1.11, 95% CI 0.97-1.26) exhibited no change in sleep duration. A 21-hour/week increase in smartphone screen time (OR 1.08, 95% CI 1.04-1.11) and a 50 times/week increase in unlocks (OR 1.03, 95% CI 1.02-1.04) were associated with poor sleep. In models 1 and 2, the ORs increased slightly. Additionally, RCS analyses suggested nonlinear associations of MPATS score (*P*=.01 for nonlinearity), smartphone screen time (*P*<.001 for nonlinearity), and unlocks (*P*=.02 for nonlinearity) with the increasing risk of poor sleep (Figure 1).

Figure 1. Restricted cubic spline regression analyses of the association between smartphone addiction, smartphone screen time, and smartphone unlocks and risk of poor sleep quality and reduction in sleep duration. These analyses were adjusted for sex, university year, race, registered permanent residence, whether the participants had siblings, parental educational attainment, current smoking, current drinking, physical activity, rational diet, and social support. MPATS: Mobile Phone Addiction Tendency Scale; OR: odds ratio.

Association Between Smartphone Use and Sleep Duration

In model 3 in Table 2, smartphone addiction remained substantially associated with shorter sleep duration (β=–15.47, 95% CI −18.53 to −12.42). For objectively measured smartphone use, compared with participants reporting 0 to 21 hours per week of smartphone screen time, those with ≥63 hours per week had a shorter sleep duration (β=–6.66, 95% CI −10.19 to −3.13), whereas 21 to 42 hours of screen time per week (β=5.47, 95% CI 1.28-9.65) were linked to longer sleep duration, and those with 42 to 63 hours of screen time per week (β=3.42, 95% CI −0.30 to 7.14) showed no significant association with sleep duration. Similarly, compared to those with approximately 0 to

XSL•FO
RenderX

50 smartphone unlocks per week, those with ≥400 unlocks per week had a significantly shorter sleep duration (β=–4.09, 95% CI −8.08 to −0.0), and participants with 50 to 150 smartphone unlocks per week had a longer sleep duration (β=5.84, 95% CI 2.32-9.36). No substantial increase in sleep duration (β=–3.28, 95% CI −7.07 to 0.52) was observed for those with approximately 150 to 400 unlocks per week. Notably, each 5-point increase in the MPATS score (β=–3.20, 95% CI −3.71 to −2.69), 21–hour per week increase in smartphone screen time (β=–1.99, 95% CI −2.93 to −1.07), and 50–time per week increase in unlocks (β=–0.49, 95% CI −0.74 to −0.23) was substantially negatively associated with sleep duration. In models 1 and 2, the β coefficients were not changed materially. The results from the sex-weighted logistic regression model (Multimedia Appendix 2) and multilevel model with college as a random effect (Multimedia Appendix 3) were consistent with the primary findings, showing no significant changes. The RCS analyses suggested positive nonlinear associations between increasing MPATS score and shortened sleep duration (*P*<.001 for nonlinearity). What is more, an inverted U–shape nonlinear relationship was observed between smartphone screen time and reduction in sleep duration (*P*<.001 for nonlinearity), whereas increasing smartphone unlocks were found to be associated with monotonically decreasing sleep duration (*P*=.31 for nonlinearity; Figure 1).

Sex-Stratified Analyses

The results of the sex-stratified analyses are shown in Table 3. This study found significant sex-specific differences in the relationships between smartphone screen time (*P*=.01 for the interaction) and unlocks (*P*=.002 for the interaction) and sleep duration. Notably, a 21–hour per week increase in smartphone screen time (β=–0.13, 95% CI 0.19 to −0.08) and a 50–time per week increase in unlocks (β=–0.77, 95% CI −1.08 to −0.47) were significantly associated with sleep duration in female individuals but not significant in male individuals. No significant sex-specific differences were observed in the relationships between smartphone addiction and sleep quality and duration (*P*>.05 for the interaction in all cases), nor were there significant associations between smartphone screen time and unlocks and sleep quality (*P*>.05 for the interaction in all cases; Table 3).

Discussion

Principal Findings

This study systematically revealed the diverse associations between both smartphone addiction and objectively measured smartphone use and sleep among university students. Specifically, we found significant negative associations between smartphone addiction and both sleep quality and duration. Excessive objectively measured screen time and unlocks were significantly and positively associated with poor sleep and shorter sleep duration.

Comparison With Other Studies

Despite the growing number of studies on the association between smartphone use and sleep, previous research has been mainly siloed, focusing exclusively on the effect of either smartphone addiction or objectively measured smartphone use on sleep quality. For instance, a systematic review revealed a significantly increased risk of poor sleep in individuals with smartphone addiction [51]. In a complementary nationally representative twin study, self-reported problematic digital technology use remained significantly correlated with poor sleep after accounting for confounders [52]. More recently, a study among university students uncovered positive associations between smartphone addiction and both bedtime procrastination and poor sleep [53]. Kaya et al [7] reported a significant relationship between self-reported smartphone use and poor sleep quality among university students using the Smartphone Addiction Scale–Short Version to assess smartphone addiction. Another study showed that smartphone addiction was linked to sleep quality and sleep duration [54]. The results of this study on the association between smartphone addiction and sleep are consistent with the findings of these studies.

In recent years, studies have increasingly focused on associations between smartphone use behaviors and sleep outcomes, yet reported findings remain inconsistent. For instance, a small-sample study using daily self-report smartphone use data found no association between smartphone talk time or screen time and sleep quality and duration [15]. In contrast, a larger study among adults revealed that self-reported daily smartphone use time was linked to poorer sleep quality, whereas unlocks showed no association with sleep parameters [55]. However, most existing research relies on self-reported smartphone use data, which are susceptible to recall bias and misclassification. The inconsistencies across findings highlight the critical need for more objective measures of smartphone screen time and unlocks to capture the true associations between smartphone use and sleep. To date, few studies have leveraged objectively measured smartphone use data to explore associations with sleep [13,56,57], and no consensus has been reached regarding these relationships. A study directly measured smartphone screen time in 136 participants via a tracking app and found that longer smartphone screen time was associated with poorer sleep efficiency and shorter sleep duration [56]. A Chinese study tracked participants' smartphone use using the same method and indicated that each minute of daytime smartphone use was related to a 0.07-minute reduction in same-night total sleep time but unrelated to sleep efficiency and postsleep awakenings [57]. Only 1 recent study identified smartphone screen time and unlocks as significant predictors of total sleep time, albeit concluding that this effect was minimal [13]. All 3 of these studies concur that excessive objectively measured smartphone use reduces sleep duration while showing less consistency in their findings regarding the impact on sleep quality, particularly sleep efficiency. Notably, our study confirmed that excessive smartphone screen time and unlocks were associated with reductions in sleep duration by 6.66 minutes and 9.90 minutes per night, respectively, as well as an increased risk of poor sleep.

Novelly, an inverted U–shaped nonlinear association was observed between smartphone screen time and reduction in sleep duration. The inverted U–shaped relationship was matched by a corresponding delay in sleep offset. No previous studies have focused on the dose-response relationship between smartphone use and sleep, although some support can be drawn from several studies on presleep smartphone use. For example, a study that objectively assessed smartphone use before sleep using a tracking app found that using smartphones before sleep for longer than usual was associated with sleeping earlier and sleeping longer among adolescents [58], suggesting a potentially positive effect on sleep duration. A recent study showed that total screen use in the 2 hours before bedtime was associated with delayed sleep onset but not with total sleep time [9]. Similarly, Exelmans and Van den Bulck [59] suggested that bedtime smartphone use predicted later rise times, which may indicate a compensation behavior for missed sleep. Collectively, these 3 studies suggest that the impact of smartphone use on sleep duration may be less pronounced than that shown in some studies based on self-reported smartphone use data. Our study further identified an inverted U–shaped relationship between average smartphone use time and sleep duration via RCS regression, providing an important contribution to the existing literature. However, as this was a cross-sectional study that assessed associations at a single time point, longitudinal cohort research is critical to validate causality and assess long-term trajectories.

In this study, the β coefficient for the association between both smartphone screen time and unlocks and sleep duration was more pronounced in female than in male individuals. Sex differences in the association may stem from sex-specific preferences for smartphone apps. Compared with male individuals, female individuals exhibit stronger preferences for social media platforms [60], which are characterized by high unlock frequencies. Social media platforms are highly interactive, marked by frequent user engagement. The captivating content on these platforms is more likely to induce emotional arousal and subsequent sleep onset delay. This study did not evaluate sex-specific app preferences among students. Hence, future research should gather detailed data on the use of apps to further explore sex-specific differences and underlying mechanisms.

Possible Explanations of the Associations

Several reasons may underlie the association between smartphone use and sleep. The reduction in sleep duration among university students with high smartphone use levels can be mechanistically explained through several pathways. The

XSL•FO
RenderX

negative impact of smartphone use on sleep duration is consistent with the time displacement hypothesis [18], whereas the impairments in sleep quality can be explained by the combined effects of screen-emitted light on melatonin suppression [20] and psychological arousal from engaging content [23,24]. Furthermore, the association between smartphone addiction and sleep may additionally involve individuals' negative cognitive appraisals of their use, such as perceived loss of control over smartphone use and guilt regarding excessive use, which may exacerbate sleep impairment. However, the reduction in sleep duration observed among students with low smartphone use levels represents a key novelty of this study, and it may be attributed to the following mechanisms. First, from a psychosocial perspective, smartphones have become highly integrated into the social interactions and academic activities of university students. Excessively low smartphone use may indicate potential difficulties in social connection or emotion regulation for individuals [61], and these factors are established risk factors for sleep, thus accounting for the observed reduction in sleep duration in the context of low smartphone use. Second, from a theoretical standpoint, the conservation of resources theory posits that technologies such as smartphones play a crucial role in the acquisition and maintenance of psychosocial resources [62]. Two studies even showed that smartphone nonusers are generally more prone to experiencing depression and anxiety [63,64]. Another study measured objective smartphone use in the context of the relationship between smartphone use and well-being, showing that people with intermediate smartphone use had better mood and lower loneliness than those with low smartphone use [65]. Third, in terms of sleep behavior patterns, individuals with low smartphone use may exhibit an earlier sleep phase, especially for those who rise early, which can result in objectively shorter total sleep duration. An objective measurement study using a wearable sleep and activity tracker, smartphone-delivered ecological momentary assessments, and passive smartphone use tracking also reported a similar pattern [65], finding that individuals with low bedtime smartphone use had earlier wake times (9:25 AM; –1 hour, 30 minutes to +1 hour, 30 minutes) than high bedtime smartphone users (10:08 AM; –1 hour, 49 minutes to +1 hour, 49 minutes).

Limitations

First, although the models included a wide range of demographic and lifestyle factors, some confounding variables may have remained unaccounted for, potentially influencing the study findings. Second, sleep quality and duration were assessed using a retrospective self-report questionnaire, which may result in recall bias. Future studies would benefit from incorporating objective sleep measurements to triangulate the findings. Third, due to the cross-sectional study design, causal inferences regarding the relationship between smartphone use and sleep cannot be made. Future longitudinal studies are warranted to address it. Fourth, the generalizability of our findings may be limited by the exclusive focus on university students in China and the uneven sex distribution in the study sample. Fifth, although this study objectively measured smartphone use time and frequency via smartphone screenshot, data in this study still lack granularity regarding temporal dynamics (eg, distribution over the day or week) and functional variation (eg, social media, entertainment, education, or work). These details may be important for understanding the nuanced associations between smartphone use and sleep. Sixth, although the multilevel model treating class membership as a random effect yielded substantially unchanged results, this study did not account for clustering effects stemming from shared living or social environments (eg, classes, dormitories, and clubs). Future research could address these clustering effects by implementing simple random sampling methods, which would help minimize potential biases arising from nonindependent observations.

Conclusions

This study found significant associations between smartphone addiction, excessive objectively measured screen time, and unlocks and both poor sleep and shorter sleep duration. RCS analyses revealed different nuanced dose-response relationships, with an inverted U–shaped association observed between smartphone screen time and sleep duration.

Abstract

Background: Digital well-being encourages balanced mobile use. The Perceived Digital Well-Being in Adolescence Scale measures this in adolescents but has been validated only in Slovenia, raising questions about its relevance for other age groups and cultural contexts.

Objective: This study had three primary objectives: (1) confirm the 3-factor structure of an English version of the Perceived Digital Well-Being in Adolescence Scale, renamed the Perceived Digital Well-Being Scale (PDWS), in samples of young adults from the United States and the United Kingdom; (2) examine the associations between PDWS dimensions and participants' sociodemographic characteristics; and (3) explore the relationships between PDWS scores and patterns of smartphone use.

Methods: A total of 1854 young adults from the United States and the United Kingdom (ages 18 - 25 years; mean 22.4, SD 2.1; 892, 48.1% female, 872, 47.0% male, 90, 4.9% nonbinary) participated in an online survey including the PDWS, digital flourishing, and digital stress measures. Data were analyzed using descriptive statistics, confirmatory factor analysis, correlations, *t* tests, chi-squared tests, and moderation-mediation analysis.

Results: Smartphone screen time and smartphone time for nonessential activities were statistically higher in the US sample than in the UK sample (mean 6.95 vs mean 6.13; t_{1852}=4.97; *P*<.001; *d*=0.27 and mean 3.62 vs mean 3.29; t_{1852}=5.57; *P*<.001; *d*=0.25, respectively). The digital well-being total score was statistically higher among US participants when compared with the UK counterparts (mean 3.49 vs mean 3.38; t_{1852}=3.33; *P*<.001; *d*=0.15). Male participants were significantly more represented among the group with higher PDWB scores (χ^2_{136}=478.45; *P*<.001). Confirmatory factor analysis supported the adequacy of the 3-factor model (emotional, social, and cognitive), indicating strong model fit (critical indices ≥0.90). Evidence of convergent validity was established through significant associations between PDWS scores and measures of digital flourishing and digital stress (most correlation coefficients being significant at *P*<.001). Measurement invariance testing confirmed the scale's equivalence across US and UK samples (χ^2_{246} change=17.90; *P*=.21); however, strict invariance across gender (male vs female) was not supported (χ^2_{246} change=200.91; *P*<.001). Gender, sexual orientation, relationship status, ethnicity, socioeconomic status, and education level significantly influenced PDWS scores. Gender and socioeconomic status also moderated the relationship between smartphone use or screen time and PDWS scores (*b*=0.048; *P*=.03 and *b*=0.020; *P*=.03, respectively), indicating that these factors affect how smartphone usage relates to psychological distress or well-being in different demographic groups.

Conclusions: The PDWS showed good psychometric properties in the US and UK samples. The scale offers a promising tool for identifying individuals at risk of adverse outcomes associated with digital connectivity.

digital connectivity; Perceived Digital Well-Being Scale; smartphone; social media; digital well-being; digital flourishing; digital stress

Introduction

Background

Smartphone use has become widespread in modern societies, particularly among young adults. This age group differs from older ones by having higher involvement in smartphone use and a greater propensity to use the devices for social interactions, dating, mental health, and well-being services [1-7]. Difficulties related to mastering smartphone use and specific digital services, such as social media, have been reported in numerous studies from multiple countries [8,9]. Such difficulties may, for some individuals, involve substantial time devoted to these platforms, which is not necessarily problematic in itself but can become so under certain conditions. These challenges are often conceptualized through 2 distinct frameworks. The first is digital stress [10], which refers to the psychological strain arising from constant connectivity, social expectations, approval anxiety, fear of missing out, and online vigilance. The second is compulsive smartphone and social media use [8,11,12], which emphasizes a behavioral pattern in which use becomes difficult to control and begins interfering with daily functioning and well-being.

In contrast, increasing attention has been given to the concept of digital flourishing [13,14], which highlights the positive potential of digital technologies. Digital flourishing refers to how online experiences can promote connectedness, self-expression, and well-being, emphasizing functional and social benefits rather than risks. Smartphones and digital platforms can support meaningful relationships, civic participation, and access to educational, professional, and health resources. They also create opportunities for authentic self-disclosure, identity development, and peer support, fostering resilience and psychological growth [15]. Taken together, these findings resonate with social cognitive theories [16], which emphasize the reciprocal interaction between individual factors, behaviors, and social contexts, suggesting that smartphone use is not inherently beneficial or harmful but acquires meaning and impact through the ways it is motivated, enacted, and socially reinforced. As these contrasting perspectives suggest, shifts in how digital technologies are experienced may become central to understanding broader notions of well-being and, more specifically, digital well-being [17].

Well-being is a multifaceted construct that transcends the mere absence of disease [18]. It encompasses both emotional and cognitive dimensions of subjective experience, serving as both a contributor to and an outcome of robust physical and psychological health [18]. This state of well-being includes feelings of safety, positive affect, life satisfaction, active engagement, personal fulfillment, and the presence of meaningful social connections [19-24].

Digital well-being, on the other hand, refers to a person's individual perception of maintaining a healthy balance between the advantages and disadvantages of being connected through mobile technology [17,25]. It encompasses both emotional and cognitive evaluations of how digital connectivity fits into everyday routines [25]. People experience digital well-being when they derive maximum enjoyment and practical benefits from technology use while experiencing minimal disruptions, loss of control, or negative impacts on their overall functioning [25]. According to Vanden Abeele [25], enhancing digital well-being involves "optimizing the ambivalence by carefully adjusting our connectivity so that it provides us with controlled pleasure and maximally supports us to achieve our goals, while causing a minimal degree of functional impairment and loss of control" (p 937).

Development of Digital Well-Being Assessment Tools

In alignment with Vanden Abeele's [25] conceptual model of digital well-being, 2 self-report instruments have recently been developed to operationalize this construct. The first, the Perceived Digital Well-Being in Adolescence (PDWBA) Scale, was created by Rosič et al [17] following scale development guidelines outlined by Carpenter [26]. A multidisciplinary team—PhD candidates, methodologists, digital media effects experts, and researchers specializing in adolescent development—designed 17 items to capture adolescents' subjective perceptions of the benefits and drawbacks of smartphone use. The PDWBA assesses opposing experiences of smartphone use across 3 key life domains: emotional, social, and cognitive. This scale was validated using a sample of 1040 Slovenian adolescents [17].

The second instrument, the Digital Well-Being Questionnaire (DWQ), was developed by Priyanka [27] to assess digital well-being through a multiphase, mixed methods approach. The initial qualitative phase involved in-depth interviews with subject matter experts, academics, and end users to explore conceptualizations of digital well-being and identify its key dimensions. These insights informed item generation, which was then evaluated for validity by an expert panel. A subsequent quantitative study confirmed the reliability and validity of the 13-item scale version. The DWQ identifies 4 dimensions of digital well-being: physical care (eg, reduced distraction from screen use), emotional resilience (eg, minimal frustration in digital contexts), agency (eg, control over screen habits), and communion (eg, connection with others through technology). These dimensions reflect both cognitive and affective evaluations of digital engagement. Cognitive appraisal pertains to comparing one's current and ideal screen use, where smaller discrepancies are linked to more positive experiences. In contrast, affective appraisal pertains to emotional responses, such as whether screen engagement is perceived as pleasant or unpleasant.

Together, these findings underscore the multidimensional nature of digital well-being and provide a validated framework for its assessment.

XSL•FO
RenderX

Digital Well-Being, Sociodemographic, Individual, and Behavioral Variables

Two studies conducted by Rosič et al [17,28] have identified several sociodemographic and individual factors associated with digital well-being, as measured by the PDWBA. First, gender differences were evident, with girls reporting lower levels of digital well-being than boys. Second, age-related trends were observed, indicating that older adolescents tended to score higher across all PDWBA dimensions. Third, educational background was influential: adolescents enrolled in vocational education reported significantly lower digital well-being in the social domain than their peers in general education. Fourth, a positive between-person association was found between emotional digital well-being and self-esteem, although similar associations were not observed for the social or cognitive dimensions. Finally, smartphone screen time showed a modest negative association with cognitive aspects of digital well-being. Similarly, Priyanka's [27] study using DWQ found that higher levels of digital literacy, social capital, self-efficacy, and subjective well-being positively predicted digital well-being. Conversely, digital addiction emerged as a significant negative predictor. Collectively, these findings underscore the complex and multifaceted nature of digital well-being, shaped by both individual traits and contextual factors.

PDBWA and DWQ: Main Differences

The PDBWA [17] comprises items designed to capture opposing ends of the digital well-being continuum, with most items structured in a "more" versus "less" format (eg, "Because of my smartphone use, I feel more excluded from my friends, or I feel closer to my friends"). This instrument conceptualizes smartphones as meta-media—platforms that provide access to a variety of applications relevant to users, including social media and mass media content. It asks participants to provide general evaluations of the perceived benefits and drawbacks of smartphone use. Notably, the PDBWA was specifically developed for adolescents.

In contrast, the DWQ [27] consists of items reflecting digital consumption experiences, framed as affirmative statements to which respondents indicate their level of agreement or disagreement (eg, "I can manage any emotional challenges caused by my screen use"). Unlike the PDBWA, the DWQ does not conceptualize smartphones as meta-media. Instead, it addresses broader aspects of digital engagement, including screen time across various digital devices, social media use, and participation in the digital world or community. Although originally validated using a sample composed of both young and older adults, the DWQ is considered suitable for use with adolescents as well.

Despite their conceptual differences, both instruments capture the benefits and drawbacks of digital connectivity and have demonstrated strong psychometric properties. For both scales, however, the authors [17,27] recommended further validation across different cultural contexts and demographic groups.

This Study's Purpose

In contemporary societies, individuals—particularly those aged 16 to 25 years—are increasingly confronted with complex decisions regarding when, where, how, and to what extent they engage with smartphone-based services, such as social media, online gaming, cybersexual platforms, and internet-enabled shopping. While the use of smartphones and social media has been associated with various mental health challenges, functional impairments, and psychological issues, it has also been linked to psychosocial and economic benefits. The concept of digital well-being, as previously defined, offers a valuable framework for raising awareness of the need to strike a healthy balance between the advantages and disadvantages of mobile connectivity. This conceptualization holds particular promise for informing the development of targeted interventions when this balance becomes disrupted or skewed toward negative outcomes.

However, digital well-being has become a critical concept for understanding how individuals navigate the opportunities and challenges of constant mobile connectivity [29]. While earlier research often emphasized screen time [30], compulsive smartphone use [31], and social media use [32], more recent work stresses the importance of capturing both positive and negative subjective experiences of social media use [33] across social, cognitive, and emotional domains [25,34]. The development of the PDWBA Scale marked an important step in this direction, but its validation was limited to Slovenian adolescents [17], raising questions about its broader applicability. Extending this measure to young adults, testing it across diverse cultural contexts is therefore essential. This focus on young adults is particularly important given their high involvement in smartphone and social media use [9,35], as well as the developmental phase they are navigating [36,37], where identity formation, social connectedness, and self-regulation are especially salient. By validating the English version of the scale among large samples in the United States and the United Kingdom, this study provides a reliable tool for assessing digital well-being beyond adolescence. A further contribution lies in testing measurement invariance across gender, which aims to assess areas of overlap as well as potential limits to strict comparability between male and female respondents.

In response to these limitations, this study had three primary objectives: (1) examine the construct validity—specifically, the factorial structure, scale reliability, and internal consistency—of the English-language version of the PDWBA, adapted for both adolescents and adults and hereafter referred to as the Perceived Digital Well-being Scale (PDWS), within a large sample of young adults from the United States and the United Kingdom; (2) evaluate the scale's convergent validity by comparing it with 2 related instruments: the Digital Flourishing Scale (DFS [13,14]) and the multidimensional Digital Stress Scale (DSS [10]); and (3) explore associations between the PDWS dimensions and participants' sociodemographic characteristics as well as patterns of smartphone use.

The PDWS used in this study is an adapted version of the original instrument, revised to be suitable for both adolescent and adult populations. This adaptation was informed by the recommendations of the original authors, as outlined in the "limitations" and "future research" sections of their publication [17]. Details regarding the adaptation process are provided in the "Methods" section below.

XSL•FO
RenderX

It is important to note that while this study focused on validating the adult version of the PDWBA in populations from the United States and the United Kingdom, a separate study aimed at validating the DWQ in North American and European populations is currently underway.

Methods

Participants

A total of 1854 young adults aged 18 to 25 (mean 22.4, SD 2.1) years participated in the study by completing an online questionnaire. Of these, 934 (50.5%) participants resided in the United States and 920 (49.4%) in the United Kingdom. In terms of gender identity, 892 (48.1%) identified as female, 872 (47.0%) as male, and 90 (4.9%) as nonbinary.

Given the exploratory nature of the study, a formal power analysis was not conducted. Instead, sample size determination was guided by the commonly recommended heuristic of recruiting a minimum of 10 participants per survey item [38]. The 3 primary scales used in this study comprised 65 items in total. Thus, the study had to include a minimum of 650 participants per country. The final sample sizes in both countries exceeded this threshold.

Recruitment and Sampling

Participants were recruited anonymously through Prolific [39], a private company specializing in research participant recruitment and data collection. Prolific offers quality assurance measures and maintains a large, prescreened pool of individuals who consent to participate in online scientific research. Compared to similar platforms, Prolific has been noted for its exclusive focus on academic research and for providing access to a more ethnically and geographically diverse participant base, representative in terms of age and gender [40]. The screening criteria for study inclusion were: (1) aged 18 - 25 years, and (2) daily smartphone and social media use. To ensure a gender-sensitive sampling approach, based on a target sample of 2160 (85%) participants, a quota system was chosen to obtain 42% males, 42% females, and 16% nonbinary participants. However, in the end, only 1854 participants completed the survey.

Data Collection Material

Data were collected via an online survey that included the following components:

1. Sociodemographic questions (7 variables): participants reported age, gender (male, female, or nonbinary), relationship status (not in relationship, in a relationship but not married, or in relationship and married), level of education (measured in years of schooling), and perceived socioeconomic status (SES; low, intermediate, or high).
2. Smartphone and social media behavior: participants reported their smartphone screen time (hours per day on a typical day using the smartphone for nonessential activities during the last 3 months) and their first and second most frequently used apps.
3. The PDWS: a 17-item self-report measure covering 3 domains: emotional domain (7 items; an example item is "Because of my smartphone use, I do fewer fun things or I do more fun things."); social domain (6 items; an example item is "Because of my smartphone use, I feel more excluded from my friends or I feel closer to my friends."); and cognitive domain (4 items; an example item is "Because of my smartphone use, I feel I am a failure or I feel satisfied with myself."). The response scale ranges from 1 (left pole) to 5 (right pole), with higher scores indicating higher digital well-being. In previous studies, the PDWS presented high statistical indices of reliability (Cronbach α=0.70) and structural validity (eg, comparative fit index [CFI] and Tucker-Lewis index [TLI] >0.90; root mean square error of approximation [RMSEA] <0.08) [17,28].

As stated in the "Introduction" section, originally, this digital well-being scale [17] was conceived for an adolescent population. We adapted it for young adults by adding contextual words on 3 items from the cognitive dimension. For instance, the item "Because of my smartphone use, I do less of my daily tasks (eg, schoolwork) or I do more of my daily tasks (eg, schoolwork)" became "Because of my smartphone use, I do less of my daily tasks (eg, schoolwork, university work, and professional work)" or I do more of my daily tasks (eg, schoolwork, university work, and professional work)." We similarly adapted items referring to schoolwork by adding the terms "university" and "work." In this study, the PDWS' internal consistency (Cronbach α) for each of the above dimensions was 0.86, 0.87, and 0.83, respectively.

The DFS [13,14] is a 25-item self-report measure assessing digital flourishing among 5 dimensions: connectedness (combination of social connection and social support; 5 items, eg, "I feel part of a community when I interact with others online"); self-control (5 items; eg, "When I interact with others about politics online, I know how to have a civil discussion."); civil participation (5 items; eg,"Comparing myself to others online motivates me to accomplish my goals"); positive social comparison (5 items; eg, "I allow my social network to see who I really am"); and authentic self-disclosure (5 items; eg, "For the most part, I feel in control of how much time I spend interacting with others online"). A 7-point Likert scale (from 1=strongly disagree to 7=strongly agree) was applied; higher scores indicate higher flourishing. In this study, the scale's internal consistency for each of the above dimensions was: 0.91, 0.82, 0.86, 0.96, 0.84, respectively. Previous studies conducted with North American and European samples [13,14,41] have demonstrated that the DFS possesses high reliability (Cronbach α>0.70) and strong structural validity (eg, CFI and TLI >0.90; RMSEA <.08).

The multidimensional DSS [10] is a 23-item self-report measure used to assess digital stress among 5 dimensions: connection overload (6 items; eg, "I feel overwhelmed with the flow of messages or notifications on my phone"); availability stress (4 items; eg, "My friends expect me to be constantly available online"); approval anxiety (5 items; eg, "I am nervous about how people will respond to my posts and photos"); fear of missing out (4 items; eg, "I fear my friends are having more rewarding experiences than me"); and online vigilance (4 items; eg, "I must have my phone with me to know what is going on"). A 7-point Likert scale (from 1=strongly disagree to 7=strongly

XSL•FO
RenderX

agree) was applied; higher scores indicate higher digital stress. The scale's internal consistency for each of the above dimensions was 0.86, 0.87, 0.88, 0.86, and 0.85, respectively. Previous studies [42-44] have demonstrated that the multidimensional DSS exhibits strong psychometric properties. Specifically, research conducted with North American, European, and Asian samples has shown high internal consistency, with Cronbach α values exceeding 0.70 across subscales. In addition, structural validity has been supported through confirmatory factor analyses, with model fit indices generally meeting acceptable thresholds (eg, CFI and TLI >.90; RMSEA <.08). These findings indicate that the DSS is a reliable and valid instrument for assessing various dimensions of digital stress in diverse populations.

Statistical Analyses

First, we conducted descriptive analyses (range, mean, SD, skewness, and kurtosis).

Second, to assess the appropriateness of the data for factorial analyses (assumptions of adequacy and sphericity), we applied the Kaiser–Meyer–Olkin test and the Bartlett test of sphericity, respectively.

Third, we conducted confirmatory factor analysis (CFA) using maximum likelihood estimation to test the dimensionality and construct validity of the PDWS. The maximum likelihood estimation has proven to be effective even for categorical variables, such as those obtained from Likert-type scales, especially in relatively large samples [45,46]. To evaluate model fit, we used indices most commonly recommended by statisticians [47], including the goodness-of-fit index (GFI), normed fit index (NFI), relative fit index (RFI), incremental fit index (IFI), TLI, CFI, RMSEA, and standardized root mean square residual (SRMR). According to Goretzko et al [47] and Hu and Bentler [48], cutoffs of GFI, NFI, RFI, IFI, TLI, and CFI ≥0.95 and ≥0.90 indicate excellent and good fit, respectively; SRMR ≤0.08 and RMSEA ≤0.08 indicate good model fit. In addition, we conducted a test of factorial structure invariance between the sample of 2 countries (the United Kingdom vs the United States) and for gender invariance (female vs male samples).

Fourth, we assessed the internal consistency (reliability) of the factorial structure by computing Cronbach α and McDonald ω coefficients for each dimension, as well as the corrected item–total correlation. Values of α and ω ≥0.80 (≥.70) indicate good (acceptable) internal consistency [49,50]. A good corrected item–total correlation is set at $r \geq 0.30$ [49,50].

Fifth, to test convergent validity, we conducted Pearson correlation analyses between participants' total score on the PDWS, DFS, and DSS dimensions (as well as between the total score of these 3 scales).

Finally, we conducted moderation and mediation analyses, using the 2 smartphone-use variables (smartphone screen time and hours per day on a typical day using a smartphone for nonessential activities) as predictors; participants' age, gender, and SES as moderators and mediators; and participants' PDWS scores as the outcome variable.

The analyses were conducted using Jamovi statistics software (version 2.6 [51]) for descriptive, correlation, and moderation-mediation analyses and R statistical programming (package "Lavaan," version 0.6 - 19; Yves Rosseel; [52]) for CFA.

Ethical Considerations

The study was conducted in accordance with the principles of the Declaration of Helsinki [53]. All participants provided digital informed consent for their survey contribution. That is, for the participants to be allowed to participate in the anonymous online survey, they were required to read a written consent form and sign it electronically by clicking a consent button. Participation was voluntary and restricted to those aged ≥18 years. All data were anonymously collected. Ethical approval (no KB 390/2022) was obtained from the Bioethics Committee of the Nicolaus Copernicus University functioning at Collegium Medicum in Bydgoszcz, Poland.

Results

Overview

Table 1 presents the descriptive statistics related to the participants' sociodemographic characteristics and their smartphone use behavior.

[b]Regarding the scores related to these variables, all the differences between the United States and the United Kingdom were statistically significant: education level (t_{1852}=5.25, P<.001, Cohen d=0.24); smartphone screen time (t_{1852}=4.97, P<.001, d=0.27); smartphone time use for nonessential activities (t_{1852}=5.57, P<.001, d=0.25); PDWS total score (t_{1852}=3.33, P<.001, d=0.15).

[c]PDWS: Perceived Digital Well-Being Scale.

Descriptive Statistics on the Participants' Sociodemographic Variables

In the US sample, the percentage of women and men participants was very close (n=444, 47.6% and n=436, 46.7%, respectively), with very few identifying as nonbinary (n=53, 5.7%). The vast majority of participants reported being heterosexual (heterosexual: n=656, 70.4%; homosexual: n=64, 6.9%; bisexual: n=168, 17.9%; and other: n=33, 4.8%). Most of them were not married (not in a relationship: n=395, 42.4%; in a relationship but not married: n=406, 43.5%; and in a relationship and married: n=132, 14.2%). Most of them were ethnically White (White: n=510, 54.7%; Asian: n=80, 8.6%; Mixed: n=96, 10.3%; Black: n=214, 11.5%; and others: n=33, 1.8%). The average years of education was 15.4, and most participants self-reported belonging to the intermediate SES group (low: n=247, 26.5%; intermediate: n=631, 67.7%; and high: n=54, 5.8%).

In the UK sample, the percentage of women and men participants was very close (n=444, 48.7% and n=436, 47.3%, respectively), with very few identifying as nonbinary (n=53, 4.0%). The vast majority of participants reported being heterosexual (heterosexual: n=656, 73.5%; homosexual: n=64, 7.1%; bisexual: n=168, 15.9%; and other: n=33, 3.6%). Most were not married (not in a relationship: n=395, 48.7%; in a relationship but not married: n=406, 47.7%; in a relationship and married: n=132, 3.6%). The majority identified as White (White: n=510, 67.6%; Asian: n=80, 13.8%; Mixed: n=96, 7.9%; Black: n=214, 9.1%; and others: n=33, 1.5%). The average years of education was 16.1, and most participants self-reported belonging to the intermediate SES group (low: n=266, 28.9%; intermediate: n=612, 66.5%; and high: n=42, 4.6%).

Descriptive and Inferential Statistics Related to Smartphone Use Behavior and Digital Well-being

As shown in Table 1, among both US and UK participants, TikTok (ByteDance), Instagram (Meta), and YouTube were respectively the first, second, and third most used apps. Comparatively, smartphone screen time and smartphone time use for nonessential activities were statistically higher in the US sample than in the UK sample (mean 6.95 vs mean 6.13; t_{1852}=4.97; P<.001; d=0.27; and mean 3.62 vs mean 3.29; t_{1852}=5.57; P<.001; d=0.25, respectively). Finally, the digital well-being total score was statistically higher among US participants compared with their UK counterparts (mean 3.49 vs mean 3.38; t_{1852}=3.33; P<.001; d=0.15).

The quartile values of the PDWS total mean score were: first quartile=1 - 3, second quartile=3 - 3.47, third quartile=3.47 - 3.88, fourth quartile=3.88 - 5, respectively. Multimedia Appendix 1 shows the number of participants by quartile of the PDWS total mean score and by gender (women vs men). The women versus men distribution was statistically significant only for the first and fourth quartiles (lowest quartile: women: n=143, 39.94%; men: n=195, 54.46%; total: n=358, 100%; highest quartile: women: n=749, 52.52%; men: n=677, 47.47%; total: n=1426, 100%; χ^2_{136}=478.45; P<.001). This means that male participants are significantly more represented among the group of participants with higher DPWB scores.

Descriptive Statistics of the PDWS Items

Table 2 displays the descriptive statistics related to the PDWS items. As shown in this table, all items had mean values above the middle of the 5-point scale. The skewness and the kurtosis values indicate a prevalence of a normally shaped distribution.

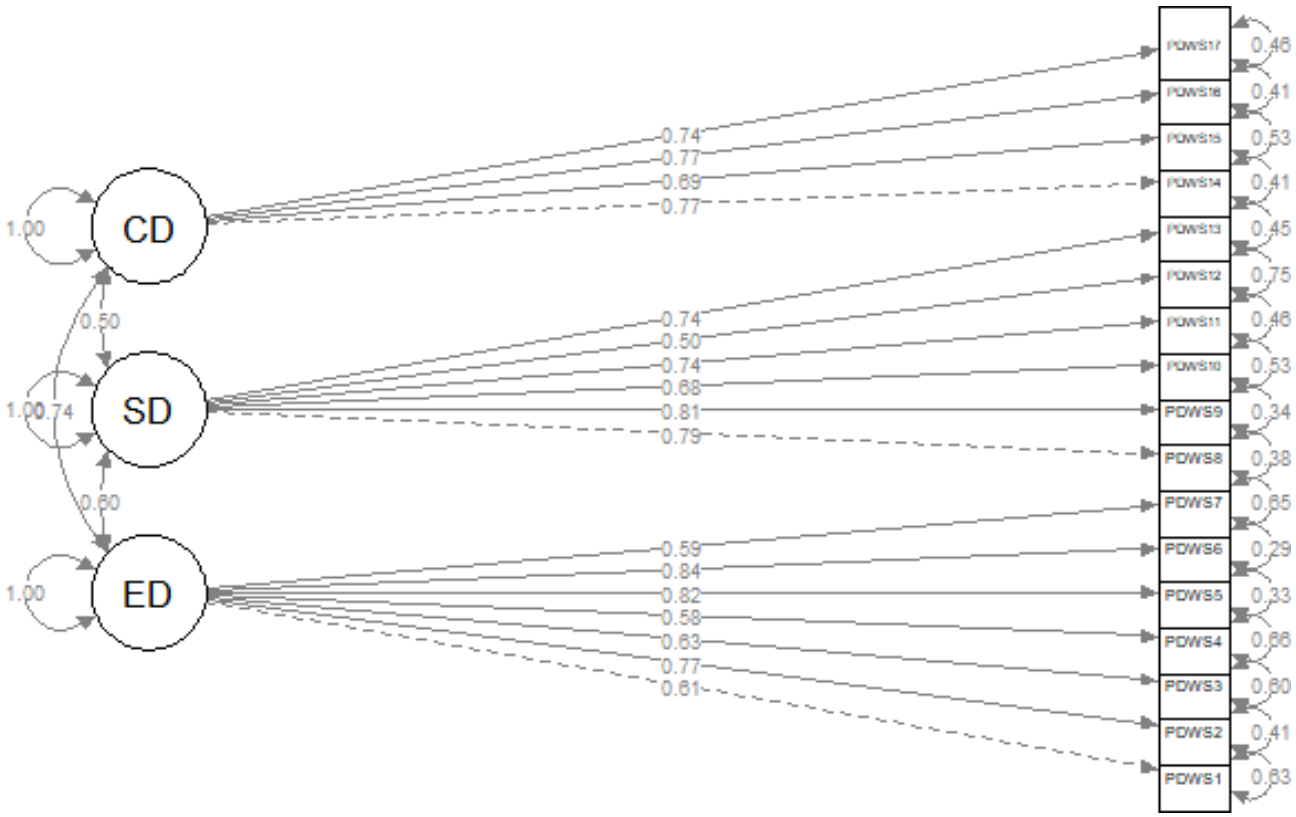
XSL•FO
RenderX

Table . Descriptive statistics related to the Perceived Digital Well-Being Scale (PDWS; 17 items grouped into 3 factors).

Factors and items	Scale	Mean (SD)	Skewness[a]	Kurtosis[b]
Factor 1: emotional domain (ED)	1 - 5	3.39 (0.78)	−0.26	0.01
E1. Because of my smartphone use, I do fewer fun things, or because of my smartphone use, I do more fun things.	1 - 5	3.35 (1.08)	−0.25	−0.68
E2. Because of my smartphone use, I feel more stressed, or because of my smartphone use, I feel more relaxed.	1 - 5	3.23 (1.11)	−0.19	−0.75
E3. Because of my smartphone use, I feel bored, or because of my smartphone use, I feel entertained.	1 - 5	3.86 (1.08)	−0.90	0.17
E4. Because of my smartphone use, I drop some leisure activities that I like, or because of my smartphone use, I engage in new leisure activities that I like.	1 - 5	3.26 (1.10)	−0.15	−0.75
E5. Because of my smartphone use, I feel more upset, or because of my smartphone use, I feel calmer.	1 - 5	3.32 (1.01)	−0.16	−0.43
E6. Because of my smartphone use, I feel sadder, or because of my smartphone use, I feel happier.	1 - 5	3.38 (1.03)	−0.22	−0.50
E7. Because of my smartphone use, I feel my life is worse than most teens, or because of my smartphone use, I feel my life is better than most teens.	1 - 5	3.31 (1.02)	−0.18	−0.31
Factor 2: social domain (SD)	1 - 5	3.73 (0.83)	−0.65	0.28
S8. Because of my smartphone use, I feel more excluded from my friends, or because of my smartphone use, I feel closer to my friends.	1 - 5	3.65 (1.10)	−0.55	-0.46
S9. Because of my smartphone use, I talk less with my friends, or because of my smartphone use, I talk more with my friends.	1 - 5	3.93 (1.10)	−0.92	0.14
S10. Because of my smartphone use, I feel less informed about the lives of my friends, or because of my smartphone use, I feel more informed about the lives of my friends.	1 - 5	4.05 (1.00)	−1.03	0.62

XSL•FO
RenderX

Factors and items	Scale	Mean (SD)	Skewness[a]	Kurtosis[b]
S11. Because of my smartphone use, I have fewer true friendships, or because of my smartphone use, I have more true friendships.	1 - 5	3.42 (1.08)	−0.33	−0.45
S12. Because of my smartphone use, I feel less connected to my friends, or because of my smartphone use, I feel more connected to my friends.	1 - 5	3.91 (1.02)	−0.91	0.26
S13. Because of my smartphone use, I spend less time with my friends, or because of my smartphone use, I spend more time with my friends.	1 - 5	3.44 (1.10)	−0.32	−0.61
Factor 3: cognitive domain (CD)	1 - 5	3.10 (0.88)	0.11	−0.24
C14. Because of my smartphone use, I do less of my daily tasks (eg, schoolwork, university work, and professional work), or because of my smartphone use, I do more of my daily tasks (eg, schoolwork, university work, and professional work).	1 - 5	2.88 (1.15)	0.18	−0.76
C15. Because of my smartphone use, I have lower grades at school, at university, or low performance when doing an important work, or because of my smartphone use, I have high grades at school, at university, or high performance when doing an important work.	1 - 5	3.22 (0.94)	0.01	0.10
C16. Because of my smartphone use, I am slower in my daily tasks (eg, schoolwork, university work, and professional work), or because of my smartphone use, I am faster in my daily tasks (eg, schoolwork, university work, and professional work).	1 - 5	2.94 (1.17)	0.14	−0.85
C17. Because of my smartphone use, I feel I am a failure, or because of my smartphone use, I feel satisfied with myself.	1 - 5	3.34 (1.08)	−0.23	−0.052



[a]A general guideline for skewness is that if the number is greater than +1 or lower than –1, this is an indication of a substantially skewed distribution.
[b]For kurtosis, a general guideline is that if the number is greater than +1, the distribution is too peaked.

XSL•FO
RenderX

CFA on the PDWS Data

The assumptions of adequacy (Kaiser–Meyer–Olkin=0.93) and sphericity (Bartlett test: χ^2_{136}==15,474.59; P<.001) were met [54]. Refer to Table 2 for all item labels. In Figure 1 the ellipses represent the latent variables (the 3 factors: emotional domain, social domain, and cognitive domain), and the rectangles represent the different items. The values on the arrows directed toward the ellipses indicate the variance of each latent factor (fixed to 1). The values on the arrows linking each of the 3 circles indicate the correlations between the latent variables. The values on the arrows linking each latent variable to the corresponding items represent the factor loadings (standardized estimates). The factor loadings indicate how well each item represents its unobservable construct (factor), with values ranging from 0 to 1. The values on top of each rectangle are the squares of the standardized factor loadings; they give the proportion of the explained variance (R^2) in each item, which indicates how much of the variance in the item is explained by the unobserved construct. If a standardized factor loading value is greater than 0.70 or explains at least half of the variance (R^2≥0.50) in the item, the corresponding item is important in explaining the unobserved construct it belongs to. Figure 1 displays the CFA path diagram. The overall model fit indices indicated a good fit between the model and the data (GFI=0.92, NFI=0.92, RFI=0.90, IFI=0.92, TLI=0.91, CFI=0.92, RMSEA=0.076, and SRMR=0.067). The factor loadings of the observed variables on the latent variable (refer to Figure 1 and Table S1 in Multimedia Appendix 2) ranged between 0.50 and 0.84 and were all significant (P<.001), indicating that each observed variable is a good indicator of the latent construct [47,48]. The variances of the observed variables (refer to Table S3 in the Multimedia Appendix 2) were also significant (P<.001), indicating variability in the measures [47,48]. The standardized estimates (refer to Tables S1-S4 in Multimedia Appendix 2) provide a way to compare the relative strengths of the relationships in a standardized form.

Figure 1. The Perceived Digital Well-Being Scale (PDWS) confirmatory factorial analysis' path diagram with the standardized estimates. Confirmation factor analysis of the questionnaire. CD: cognitive domain; ED: emotional domain; SD: social domain.

Country (United States vs United Kingdom) Invariance Tests

To find out whether the PDWS factor structure was invariant across countries, a multigroup analysis was carried out. The configural invariance test showed an acceptable fit for the unconstrained model (GFI=0.90, NFI=0.91, RFI=0.89, IFI=0.92, TLI=0.91, CFI=0.92, RMSEA=0.073, and SRMR=0.066). The metric invariance test indicated that the meaning of the 3 modeled constructs (factors) did not statistically differ across the 2 countries (χ^2_{246} change=17.90; P=.21).

Gender (Women vs Men) Invariance Tests

To find out whether the PDWS factor structure was invariant across gender, a multigroup analysis was conducted. The configural invariance test showed an acceptable fit for the unconstrained model (GFI=0.90, NFI=0.90, RFI=0.89, IFI=0.92, TLI=0.91, CFI=0.92, RMSEA=0.074, and SRMR=0.066). However, the metric invariance test indicated that the meaning of the 3 modeled constructs (factors) significantly differed across groups (χ^2_{246} change=200.91; P<.001).

C14. Because of my smartphone use, I do less of my daily tasks (eg, schoolwork, university work, and professional work) or because of my smartphone use, I do more of my daily tasks (eg, schoolwork, university work, and professional work).	0.69	0.77

XSL•FO
RenderX

Factors and items	Subscale corrected item–total correlation[b]	Subscale McDonald ω if item deleted[c]
C15. Because of my smartphone use, I have lower grades at school, at university, or low performance when doing important work or because of my smartphone use, I have high grades at school, at university, or high performance when doing important work.	0.63	0.80
C16. Because of my smartphone use, I am slower in my daily tasks (eg, schoolwork, university work, and professional work) or because of my smartphone use, I am faster in my daily tasks (eg, schoolwork, university work, and professional work).	0.70	0.77
C17. Because of my smartphone use, I feel I am a failure or because of my smartphone use, I feel satisfied with myself.	0.61	0.81

[a]Regarding the Cronbach α, if the scale is an exploratory one, a good reliability is set at α>0.70. If the scale is an established one, a good reliability is set at α>0.80.

[b]A Item-Total Correlation: A good corrected item–total correlation is set at *r*>0.30.

[c]The McDonald ω if item deleted corresponds to values of McDonald ω if the relevant item is deleted. These metrics suggest that no item should be deleted.

Correlations Between the PDWS Dimensions

All correlations were significant (*P*<.001). As shown in Figure 1, the strongest correlation was between the emotional domain and the cognitive domain.

Convergent Validity

Table 4 presents the correlations between the 3 PDWS dimensions, the DFS dimensions, and the DSS dimensions, as well as between the total scores of these 3 scales. Almost all correlations were statistically significant, and most were strongly significant (*P*<.001). In addition, almost all correlations were in the expected direction. The exception regarding the direction of the relationships was between the PDWS dimensions and the DSS availability stress dimension. As shown in Table 4, the relationship between these factors was positive, which is counterintuitive. However, as hypothesized, the PDWS total score was negatively correlated with the DSS total score.

[a]Correlation is significant at the *P*<.05.

[b]Gender x PDWS total score: women (mean 3.43, SD 0.68); men (mean 3.46, SD 0.70); nonbinary or other (mean 3.30, SD 0.70). The omnibus ANOVA showed no statistically significant difference, but pairwise comparison indicated a male vs nonbinary significant difference on the PDWS total score (t_{1851}=2.42; *P*=.04; *d*=0.26).

[c]Not applicable.

[d]Sexual orientation x PDWS total score: heterosexual (mean 3.47, SD 0.69); homosexual (mean 3.39, SD 0.70); bisexual (mean 3.30, SD 0.67); other (mean 3.48, SD 0.69): The omnibus ANOVA showed a significant difference, and the pairwise comparison indicated that only heterosexual vs bisexual PDWS total scores were statistically significant (t_{1851}=3.98; *P*<.001; *d*=0.25).

[e]Relationship status x PDWS total score: not in relationship (mean 3.35, SD 0.67; in a relationship but not married (mean 3.46, SD 0.69); in a relationship and married (mean 3.71, SD 0.74). The omnibus ANOVA showed a statistically significant difference, and all pairwise comparisons were significant (t_{1851}=–3.23, *P*=.004, *d*=0.51; t_{1851}=–5.99, *P*<.001; t_{1851}=–4.14, *P*<.001, *d*=0.35; respectively).

[f]Ethnicity x PDWS total score: White (mean 3.75, SD 0.82); Asian (mean 3.59, SD 0.89); Mixed (mean 3.70, SD 0.79); Black (mean 3.74, SD 0.84); Others (mean 3.76, SD 1.03). The omnibus ANOVA showed a significant difference, and the pairwise comparison indicated that only the White vs Black, Asian vs Black, and Mixed vs Black PDWS total scores were statistically significant (t_{1849}=–5.76, *P*<.001, *d*= 0.37; t_{1849}=–5.13, *P*<.001, *d*=0.46; t_{1849}=–3.75, *P*=.002, *d*=.36; respectively).

[g]Correlation is significant at *P*≤.001.

Participants' age was significantly and positively correlated with the PDWS cognitive domain, indicating that older participants in our sample were more likely to experience higher levels of digital cognitive well-being compared to younger participants. The PDWS total score among male participants was statistically higher than among nonbinary participants. Overall, there was no significant difference in the scores between female and male participants. However, when comparing the lowest and highest quartiles, as reported in the "Descriptive results" subsection, female participants had significantly lower digital well-being than male participants. The PDWS total score for heterosexual participants was statistically higher than for bisexual participants, whereas there was no significant difference between the scores of the heterosexual and homosexual participants.

Participants' education level was significantly and positively correlated with the PDWS social domain, indicating that the highly educated participants were more likely to experience social well-being compared to those with lower levels of education. Overall, participants' self-reported SES was significantly and positively correlated with their digital well-being; this was particularly true for the emotional and cognitive domains. Curiously, participants' smartphone screen time and self-reported time spent on nonessential smartphone activities were both significantly and positively correlated with

XSL•FO
RenderX

the overall PDWS score; this was especially true regarding the emotional domain.

Moderation and Mediation Effects

Gender significantly moderated the relationship between nonessential smartphone use and participants' PDWS scores, as indicated by a beta coefficient (*b*=0.0489, 95% CI 0.005-0.092; *P*=.03). Similarly, SES emerged as a significant moderator in the association between smartphone screen time and PDWS scores (*b*=0.0205, CI 0.002-0.038; *P*=.03). In contrast, no significant moderating effect of age was observed. Moreover, gender, age, and SES did not serve as significant mediators in the relationship between smartphone use and PDWS scores.

Discussion

Principal Findings

Digital well-being may serve as a critical indicator of the relationship between digital connectivity and individuals' mental health or overall well-being [17,25,27,28]. Accordingly, the ability to assess digital well-being holds potential benefits for both research and practical interventions. This study aimed to validate the English version for both adolescents and adults of the PDWBA Scale and to examine the associations between its 3 dimensions and a range of sociodemographic and behavioral variables.

Factor Structure and Psychometric Properties

First, the results of this study support the robustness of the 3-factor, 17-item structure of the English adolescent-adult version of the PDWBA (named, in this study, PDWS), indicating its suitability for assessing digital well-being in both the US and the UK contexts. CFA revealed that the model demonstrated a good fit across both national samples, aligning with the theoretical framework of the original scale (the PDWBA [17]). Fit indices were all in the good-excellent range. These findings provide empirical support for the generalizability of the PDWS among young adult populations in the United States and the United Kingdom.

Second, internal consistency analyses showed satisfactory reliability across all 3 dimensions of the PDWS (Cronbach $\alpha \geq 0.83$), consistent with previous validations of the PDWBA [17]. Furthermore, the scale demonstrated strong item discrimination, with corrected item–total correlations of ≥0.53 in both samples. Internal reliability was also robust, with all factor loadings above 0.50, suggesting that the PDWS adequately captures the core dimensions of digital well-being among the target population.

Third, the convergent validity of the PDWS was supported by its statistically significant correlations with established measures of digital flourishing (DFS [13,14]) and digital stress (DSS [10]). All 3 PDWS dimensions exhibited strong, positive correlations with the 5 DFS dimensions, suggesting that higher digital well-being, as measured by the PDWS, is associated with greater experiences of digital flourishing. Digital flourishing encompasses positive user experiences and perceptions of computer-mediated interactions and is grounded in the broader positive psychology framework of flourishing, conceptualized as both "feeling well" and "doing well" [55,56]. Flourishing's affective component—"feeling well"—aligns with subjective well-being [19], whereas the behavioral and functional components—"doing well"—align with eudaimonic well-being [20], encompassing dimensions such as purpose, self-actualization, connectedness, and mastery [57,58]. These findings suggest that digital well-being contributes not only to emotional well-being but also to functional flourishing in both online and offline contexts. Conversely, digital stress—defined as the psychological burden associated with social media and online service use—has been linked to diminished mental health, particularly among adolescents and young adults [10,42,43,59]. Consistent with this body of research, the PDWS was significantly and negatively associated with all DSS dimensions—approval anxiety, fear of missing out, connection overload, and online vigilance, exception of one. Notably, all PDWS dimensions were positively correlated with the DSS availability stress subscale. This subscale reflects the perceived pressure and social obligation to remain constantly accessible via digital platforms, shaped by internalized expectations from peers [10]. This unexpected finding warrants further investigation, as it may indicate that some aspects of digital well-being are accompanied by heightened awareness of social availability demands. Future research should explore this relationship across different demographic and behavioral subgroups, perhaps through cluster analysis, to determine whether divergent patterns exist within specific populations and how these patterns relate to digital behavior and sociodemographic variables. Furthermore, the wide distribution of PDWS scores across the 4 quartiles supports the need to conduct such studies.

Fourth, measurement invariance testing confirmed that the PDWS captures the same underlying construct of digital well-being across national contexts (United States vs United Kingdom), supporting its cross-cultural applicability. However, the results indicated a lack of measurement invariance across gender, particularly in factor loadings and item intercepts. This suggests potential bias in digital well-being assessments between male and female participants. Previous studies [60-62] have reported gender-related differences in digital experiences, noting that women are more likely to engage in social media for relational purposes and exhibit higher tendencies toward social comparison. Furthermore, females tend to participate more in online social communities, which may increase exposure to the negative consequences of digital connectivity, including stigma and cyberbullying [63,64]. These findings may partly explain the observed gender-related disparities in PDWS outcomes and underscore the importance of considering gender-specific factors when assessing digital well-being.

In summary, this study provides strong evidence for the validity and reliability of the PDWS as a tool for assessing digital well-being in English-speaking adult populations. Its significant associations with digital flourishing and digital stress further support its criterion validity, although gender-specific differences and the unique role of availability stress warrant further exploration.

Associations With Sociodemographic and Smartphone Use Behavior

First, the findings of this study indicate that older participants reported significantly higher levels of digital well-being compared to younger individuals, particularly in the domain of digital cognitive well-being. This pattern is consistent with previous research by Rosič et al [17]. A possible explanation for this age-related difference may lie in the development of reflective smartphone use disengagement, which tends to increase as individuals progress through adolescence into adulthood and further [9,65,66]. Based on the reflective-impulsive model [67], reflective smartphone use disengagement refers to the deliberate regulation of smartphone and social media use through conscious control mechanisms. These findings suggest that older individuals may be more adept at exercising self-regulation in digital environments, thereby enhancing their overall digital well-being. In terms of gender identity, male participants reported significantly higher digital well-being compared to other groups, while nonbinary individuals reported the lowest levels. Although Rosič et al [17] found that women perceived their emotional regulation as lower than men, their study did not examine digital well-being among nonbinary individuals. These findings may reflect broader patterns of digital engagement and vulnerability; for example, women are more frequently exposed to the negative psychological impacts of problematic smartphone and social media use [60,68]. In addition, individuals from gender and sexual minority groups—such as nonbinary and same-sex oriented participants—may encounter greater levels of online stigmatization and cyberbullying, which can adversely affect their digital well-being [63,64]. In this study, participants with heterosexual orientation reported significantly higher digital well-being than participants with bisexual orientation, further reinforcing the potential role of social identity in shaping digital experiences.

Second, higher levels of education were associated with significantly greater social digital well-being and cognitive digital well-being. Similarly, SES was positively correlated with digital well-being, particularly in the emotional and cognitive domains. These results align with the findings of Priyanka [27], who reported a positive relationship between social capital and digital well-being. It is plausible that individuals with higher educational attainment are more likely to develop effective strategies for reflective disengagement from digital technologies [65,66]. Moreover, individuals from higher SES backgrounds may have broader access to offline recreational and social opportunities, reducing their reliance on digital platforms and mitigating the negative effects of excessive digital engagement.

Third, participants' smartphone screen time and usage of smartphones for nonessential activities were both significantly and positively correlated with overall PDWS scores—a finding contrary to initial expectations. One possible explanation is that, in the present sample, greater screen time may not necessarily reflect problematic use but could instead be associated with activities that enhance subjective well-being, such as meaningful social interaction, entertainment, or educational content. This highlights the need for future research to disaggregate types of digital activity and examine their distinct dynamic associations with digital well-being. Subgroup analyses could further clarify whether specific patterns of use are differentially associated with well-being across various demographic and behavioral profiles.

Fourth, the present findings provide nuanced insights into the psychosocial correlates of smartphone use by demonstrating that both gender and SES significantly moderate the relationship between smartphone use and psychological distress, as measured by PDWS. Specifically, nonessential smartphone use was more strongly associated with PDWS scores in one gender group than another, as indicated by the significant interaction effect. This aligns with previous research suggesting that women may experience higher levels of psychological distress linked to digital overuse, potentially due to greater social comparison, emotional engagement with online content, or differential patterns of use [69]. Similarly, SES significantly moderated the association between overall screen time and PDWS scores, suggesting that individuals from lower SES backgrounds may be more vulnerable to the psychological impacts of excessive smartphone use. This may reflect limited access to coping resources, higher exposure to stressors, or a greater reliance on smartphones for escapism and entertainment in lower-income populations. These findings support the "digital stress divide" hypothesis, which posits that the psychological consequences of digital media are not evenly distributed across social groups [70]. Interestingly, age did not significantly moderate the relationship, suggesting that the psychological effects of smartphone use are relatively stable across age groups within the sample. This finding challenges the assumption that younger users are uniquely vulnerable and encourages further exploration into qualitative differences in how smartphone use affects mental health across the lifespan. In addition, the lack of significant mediation effects indicates that gender, age, and SES do not act as explanatory pathways through which smartphone use influences PDWS scores. Instead, their role appears to be more conditional—shaping the strength or direction of the effect rather than transmitting it. This distinction is critical, suggesting that interventions may need to be tailored based on demographic vulnerability rather than assuming a uniform psychological mechanism. These findings have practical implications for mental health interventions and digital wellness programs. For instance, gender-sensitive and socioeconomically inclusive strategies may be more effective in mitigating the negative effects of smartphone use. Future research should further investigate the underlying mechanisms—such as emotion regulation, digital literacy, or social support—that may explain why certain groups are more affected by smartphone overuse. In addition, it would be valuable to explore other potential moderators or mediators, including personality traits (eg, neuroticism), psychological resilience, and specific smartphone activities (eg, doom scrolling vs productivity apps), to build a more comprehensive model of digital distress/well-being.

Finally, the finding that the digital well-being total score was statistically higher among US participants when compared with the UK counterparts suggests a significant national-level difference in how individuals perceive or experience digital well-being. Interpreted within an academic framework, this

XSL•FO
RenderX

result implies that participants from the United States reported more favorable outcomes or engagement with digital well-being practices or perceptions than those from the United Kingdom, with the difference being supported by statistical significance. Several factors may contribute to this disparity. These observed national differences between the United States and the United Kingdom suggest that digital well-being is influenced not only by individual behavior but also by broader cultural and policy environments [71]. The higher PDWS scores among US participants may reflect more prominent public discourse and initiatives around digital wellness, distinct norms of technology use, or cultural differences in how mental health and digital practices are understood and reported. These findings indicate that interventions to promote digital well-being should be culturally tailored, accounting for sociotechnical infrastructures, normative expectations surrounding technology, and the dynamic interplay between individuals and their digital environments [25].

In relation to previous research, this study confirms the robustness of the PDWS [17] while extending its applicability beyond adolescence to young adults in 2 cultural contexts. The present findings show that the 3-factor model holds in US and UK samples, supporting its generalizability. The observed links with digital flourishing and stress align with previous work [27,33,72]. The positive association with availability stress introduces a novel insight, suggesting that perceived accessibility may not always undermine well-being. Furthermore, by documenting differences not only across gender but also among nonbinary and sexual minority participants, the study expands the scope of digital well-being research to populations often overlooked. Overall, this study strengthens the evidence base for the PDWS and contributes new perspectives on demographic and cultural variations in digital well-being.

Limitations

This study has several limitations that should be acknowledged. First, it relied exclusively on self-reported measures, which may be subject to social desirability bias, recall errors, and other self-reporting inaccuracies. Second, its cross-sectional design limits the ability to infer causality between digital well-being, flourishing, stress, and patterns of smartphone use. Third, although the sample size was large and included participants from both the United States and the United Kingdom, the recruitment method may not ensure full representativeness of young adult populations in these countries, potentially limiting generalizability.

Future Research

Future research may benefit from a mixed methods approach to better contextualize these quantitative findings, examining how demographic, socioeconomic, and policy-level factors intersect to influence digital well-being across different populations. Thus, future research should adopt quantitative, longitudinal, international, and ecological designs [73] capable of capturing the dynamic interactions that shape digital well-being, including individual, social, and technological interface factors [25]. In addition, qualitative studies are warranted to explore the subjective dimensions of human–digital interactions at cognitive, emotional, social, and behavioral levels. The involvement of people with lived experience [74] is also crucial to refining assessments, conceptual frameworks, and intervention models. Collectively, such studies are essential for developing interventions tailored to the diverse needs of individuals experiencing difficulties in their digital well-being.

Conclusion

The PDWS may serve as a useful tool to identify individuals at risk of difficulties linked to digital connectivity and to highlight potential gender- and identity-related disparities. It could also provide guidance for educators in promoting digital literacy, support clinicians in developing targeted interventions, and inform policymakers in shaping evidence-based programs. In this way, the scale may help facilitate new avenues for fostering healthier digital ecosystems at both individual and societal levels.

Abstract

Background: The increasing deployment of conversational artificial intelligence (AI) in mental health interventions necessitates an evaluation of their efficacy in rectifying cognitive biases and recognizing affect in human-AI interactions. These biases are particularly relevant in mental health contexts as they can exacerbate conditions such as depression and anxiety by reinforcing maladaptive thought patterns or unrealistic expectations in human-AI interactions.

Objective: This study aimed to assess the effectiveness of therapeutic chatbots (Wysa and Youper) versus general-purpose language models (GPT-3.5, GPT-4, and Gemini Pro) in identifying and rectifying cognitive biases and recognizing affect in user interactions.

Methods: This study used constructed case scenarios simulating typical user-bot interactions to examine how effectively chatbots address selected cognitive biases. The cognitive biases assessed included theory-of-mind biases (anthropomorphism, overtrust, and attribution) and autonomy biases (illusion of control, fundamental attribution error, and just-world hypothesis). Each chatbot response was evaluated based on accuracy, therapeutic quality, and adherence to cognitive behavioral therapy principles using an ordinal scale to ensure consistency in scoring. To enhance reliability, responses underwent a double review process by 2 cognitive scientists, followed by a secondary review by a clinical psychologist specializing in cognitive behavioral therapy, ensuring a robust assessment across interdisciplinary perspectives.

Results: This study revealed that general-purpose chatbots outperformed therapeutic chatbots in rectifying cognitive biases, particularly in overtrust bias, fundamental attribution error, and just-world hypothesis. GPT-4 achieved the highest scores across all biases, whereas the therapeutic bot Wysa scored the lowest. Notably, general-purpose bots showed more consistent accuracy and adaptability in recognizing and addressing bias-related cues across different contexts, suggesting a broader flexibility in handling complex cognitive patterns. In addition, in affect recognition tasks, general-purpose chatbots not only excelled but also demonstrated quicker adaptation to subtle emotional nuances, outperforming therapeutic bots in 67% (4/6) of the tested biases.

Conclusions: This study shows that, while therapeutic chatbots hold promise for mental health support and cognitive bias intervention, their current capabilities are limited. Addressing cognitive biases in AI-human interactions requires systems that can both rectify and analyze biases as integral to human cognition, promoting precision and simulating empathy. The findings reveal the need for improved simulated emotional intelligence in chatbot design to provide adaptive, personalized responses that reduce overreliance and encourage independent coping skills. Future research should focus on enhancing affective response mechanisms and addressing ethical concerns such as bias mitigation and data privacy to ensure safe, effective AI-based mental health support.

Introduction

The Potential and Pitfalls of Therapeutic Chatbots

Given the rapid development of advanced artificial intelligence (AI) assistants, ethics are required to move beyond focusing on isolated metrics such as model properties and outputs and aim at more holistically understanding their interaction with humans in real contexts [1]. Similarly, the growing popularity of conversational user interfaces has driven human-computer interaction (HCI) research focused on specific approaches to the research, design, and implementation of these interfaces. However, this research remains largely fragmented and lacks a unified approach to theory, methods, and design [2]. The exact role that conversational AI, or chatbots for short, can play in the realm of digital mental health is definitely debatable, as calling them digital therapists seems too far-fetched due to their still limited capabilities. Obviously, chatbots lack therapeutic autonomy as they are technological cognitive-affective artifacts able to influence users' beliefs and emotional states but without many contextual clues essential for traditional therapeutic interventions [3]. Interactions with chatbots are disembodied, thus creating a different environmental niche than that of traditional therapy.

Therapeutic bots, which constitute software that usually uses some natural language processing and machine learning technologies, mark a transformative stride in mental health support. By simulating conversation and offering guidance, these bots aim to guide individuals through their cognitive biases and even mitigate some affect variability, providing immediate, easily accessible, and sometimes anonymized interactions. The main strength of therapeutic bots lies in their availability and consistency. They offer round-the-clock support, reaching individuals in remote or underserved areas where human therapists might not be accessible [4]. In addition, for some users (eg, individuals with autism), interacting with a bot alleviates the stigma or discomfort associated with seeking mental health support, fostering a sense of safety in expressing feelings and thoughts [5]. Similarly, there have been some theoretical claims (requiring further empirical validation) that chatbots may help some individuals with borderline personality disorder increase narrative coherence between therapeutic sessions, nurturing more effective patient-therapist communication [6]. However, the reliance on therapeutic bots introduces numerous challenges, primarily in the nuanced understanding of human emotions and the complex dynamics of second-wave cognitive behavioral therapy (CBT). Obviously, bots lack the genuine empathy, intuition, and depth of understanding that human therapists provide, potentially oversimplifying or misunderstanding overly complex emotional issues. Moreover, there exists a serious risk of overreliance on these bots in people with preexisting mental health conditions, with individuals potentially substituting professional human interaction for digital conversations, which might not always be equipped to handle severe or acute mental health crises. However, excessive panic about AI dependence in the general population seems to be rather ungrounded as there is little evidence to support that claim [7].

Why Should Chatbots Address Human Cognitive Biases?

Addressing human cognitive biases through mental health chatbots is pivotal for several reasons, particularly given the expansive role they play in shaping human cognition, emotions, and decision-making. These biases, such as the tendency to anthropomorphize, overtrust, attribute emotional states, focus on illusory control over external events, or distort reality by losing the balance between the role of direct human actions and external factors in a given behavior, can exacerbate or contribute to mental health issues such as anxiety, depression, and low self-esteem. By identifying and rectifying these biases, therapeutic bots can possibly guide individuals toward healthier thinking patterns, promoting emotional well-being and resilience.

First, mental health chatbots that can accurately identify and address cognitive biases have the potential to provide immediate corrective feedback. This is crucial in a therapeutic context where timely intervention can prevent negative thought spirals, offering users a chance to reframe their thoughts in a more positive or realistic light. For instance, a bot that recognizes and challenges an individual's tendency to engage in *all-or-nothing* thinking can help break cycles of negative thinking that contribute to depressive symptoms [8].

Second, integrating cognitive bias correction into chatbots democratizes access to some forms of CBT-based cognitive restructuring, making them available to a broader audience. CBT is a highly effective treatment for various mental health conditions, but access to it can be limited due to cost, availability of therapists, or stigma associated with seeking therapy. Therapeutic bots equipped to address cognitive biases can provide a form of CBT, making some of the core benefits of this therapy accessible to individuals who might not otherwise seek or receive it.

Balancing Efficacy and Ethics

However, addressing cognitive biases through chatbots also presents significant challenges, including ensuring the accuracy of bias identification, the ethical use of collected data, and the need for bots to navigate the complex nuances of human psychology respectfully and effectively. Balancing these considerations is essential for developing the full potential of therapeutic bots in mental health support.

One advantage of therapeutic chatbots is that they might be preferred over human counselors by people who either have trouble with interpersonal communication (eg, people in the autism spectrum) or are more inclined to use them due to their condition (eg, mild to moderate anxiety or obsessive-compulsive disorder). For example, people in the autism spectrum are generally rather willing to disclose their diagnosis to the chatbot

XSL•FO
RenderX

and ask for a tailored response [9]. However, this kind of tendency to choose chatbots over human counselors may come at a price. While sometimes facilitating more effective communication and possibly a form of web-based therapeutic alliance, an overtrust in AI-based therapeutic tools by users is also a possible source of harmful side effects when theoretically beneficial biases are unproportionally reinforced. It is the reason why enhancing affect recognition and minimization of bias reinforcement in chatbot design is crucial to ensure their safe and effective use among vulnerable groups.

One primary ethical issue to consider is the unintentional perpetuation of biases embedded in AI-driven chatbots, which can lead to skewed therapeutic recommendations or responses. These biases often originate in the training data, which may reflect societal prejudices, stereotypes, or historical inequities. Consequently, language models may exhibit biases in ways that could be detrimental to vulnerable populations, such as individuals with specific mental health conditions. For instance, biased responses related to gender, race, or socioeconomic status can influence a chatbot's affective feedback, potentially altering therapeutic outcomes and undermining the model's intended support function. One way to counteract those challenges is to consider rigorous methods to audit and mitigate biases, such as implementing fairness constraints during training and incorporating diverse datasets that better reflect the nuances of real-world interactions [10].

Privacy concerns are also paramount, especially in mental health applications in which sensitive personal data may be disclosed by users. The confidential nature of therapeutic conversations requires robust data protection to prevent unauthorized access or misuse. Although some chatbots are designed to handle conversations without storing individual session data, the risk remains that data could be accessed, hacked, or improperly managed, potentially exposing users' mental health information. This issue is further complicated by the possibility that third-party developers or service providers may lack stringent data management protocols, thus heightening the risk of privacy breaches. It is advised to develop more stringent data governance standards and enhance transparency in AI language model interactions. These measures would include anonymizing user data, minimizing data retention, and providing clear consent protocols, which would contribute to a more secure and ethically sound AI environment [10].

In addition to privacy and bias concerns, AI-based chatbots face potential misuse or abuse by users, such as using these systems for harm or to manipulate others. Users could exploit therapeutic chatbots to seek inappropriate advice or potentially cause harm if the bot's guidance is misinterpreted or taken out of context. There are several possible safeguards to consider, including setting boundaries on the type of support that chatbots can offer and using real-time monitoring to detect potentially harmful interactions. Current advancements in AI development, including ethical guidelines and *commandments* for responsible AI use, reflect the industry's efforts to address these ethical challenges comprehensively. For example, platforms are beginning to incorporate real-time moderation, limit the scope of AI responses, and educate users on the limitations of AI in mental health contexts to reduce risks. These evolving safeguards represent an essential step toward responsibly integrating AI-driven language models into therapeutic applications while maintaining ethical integrity and user safety [10].

Limited Potential and Lack of Evidence

AI-based, emotionally intelligent chatbots designed for mental well-being have substantially limited potential in addressing signs of anxiety and depression through evidence-based therapies, as well as through their context-specific effectiveness, for individuals with mild to moderate depression [11,12]. One key limitation is the need for further evidence to confirm the long-term effectiveness of mental health chatbots through trials replicated with longer durations and exploration of the chatbots' efficacy in comparison with other active controls [13-15]. In particular, a large meta-analysis of 32 studies involving 6089 participants demonstrated conversational AI to have statistically significant short-term effects in improving depressive symptoms, anxiety, and several other conditions but no statistically significant long-term effects [16]. Moreover, the measurement of chatbot use and the recording of self-assessments are crucial for evaluating the impact and effectiveness of these platforms. In the case of Wysa, AI chatbot use is tracked only when a user accesses the platform, indicating a limitation in capturing data on passive users who may benefit from the system but do not actively engage with it [17]. Another meta-analysis found that chatbot-delivered psychotherapy improved depressive symptoms, particularly in individuals with clinically diagnosed anxiety or depression, but was most effective with very specific design features such as embodiment, varied input and output formats, and <10 sessions, suggesting some potential but with important limitations [18].

In addition, the efficacy of therapeutic chatbots is primarily assessed through user engagement and self-reported outcomes. This methodology may not fully capture the depth of the therapeutic intervention needed by individuals with complex mental health conditions. The generalizability of these findings across diverse demographic groups, including non-English speakers, remains unconfirmed.

Although these interventions use evidence-based therapies, their depth and personalization via chatbot interactions play a crucial role. For example, the nuanced needs of individuals with anxiety disorders might require elements of mindfulness along with the standardized CBT responses. Some studies mention the potential for mindfulness-based interventions when dealing with anxiety, but the evidence is very limited [19]. For example, the study by Leo et al [12] mentions the use of evidence-based therapies in Wysa. While this highlights the chatbot's foundation on recognized therapeutic approaches, the literature may not sufficiently address the depth of personalized care achievable through automated chatbot interactions compared to human therapists.

As a sidenote, it is worth mentioning that almost all chatbots rely on some form of CBT and various mindfulness techniques. This suggests that, in principle, most chatbots use so-called evidence-based interventions, which are more compatible with rule-based formats than highly insight-oriented therapies such as psychodynamic therapies.

XSL•FO
RenderX

Transparency and User-Centered Design

Another problem is that the literature does not adequately address how certain chatbots manage the reinforcement of cognitive biases. Given the research objective of analyzing chatbots' responses in this respect, this area remains underexplored in the context of therapeutic versus nontherapeutic interventions. Understanding how chatbots navigate complex cognitive biases without reinforcing them is crucial, especially among vulnerable populations. For example, the absence of explicit discussion in studies such as that by Schick et al [20], which evaluated the practical effectiveness of empathetic mental health chatbots, suggests a gap in exploring how these platforms manage or potentially reinforce cognitive biases. Furthermore, the design of chatbots for mental health poses challenges as there is limited information available on the development and refinement of rule-based chatbots specifically tailored for mental health purposes [21]. The lack of transparent training data for these chatbots compels researchers to rely on black-box input-output methods to evaluate their effectiveness, particularly when assessing strategies for cognitive restructuring and affect recognition. In addition, studies often focus on short-term engagement and immediate feedback from users (eg, 2-month mean improvements in depression [12]). The long-term efficacy of using Wysa, including sustained improvements in mental health and well-being, definitely requires further investigation. Moreover, the impact of prolonged chatbot interactions on the therapeutic relationship and their efficacy compared to traditional therapy remain an open question.

When it comes to HCI, one study [22] assessed the usability of a mental health chatbot within a social realm, emphasizing the importance of user-centered design for effective interfaces. Similarly, AI chatbot emotional disclosure seems to impact user satisfaction and reuse intention, highlighting the role of affect recognition in building authentic relationships with users [23]. Another study demonstrated overall positive patient perceptions of and opinions on chatbots for mental health [24].

As the field of mental health chatbots evolves, some studies [13,25-27] have explored their practical applications in mitigating depressive symptoms and COVID-19–related mental health issues and supporting health care workers and their families. In addition, other studies [28] have pointed out the importance of cultural and linguistic customization in chatbot interventions and addressing the emotional needs of young people, who are a very vulnerable group [29,30]. Considering individual needs is crucial as improper responses and assumptions about the personalities of users often lead to a loss of interest [31]. One meta-review also mentioned potential benefits of chatbot use for people with substance use disorder, but this was based on only 6 papers [32].

One of the relatively promising concepts in chatbot design is personas. Personas are essential in human-centered AI development as they map users' mental models to specific contexts, guiding the design of interfaces that align with real-world needs. The therapeutic chatbots discussed in this paper may potentially benefit from these novel approaches in human-AI interfaces, which differ fundamentally from traditional HCIs by incorporating cognitive, autonomous, and adaptive capabilities that can yield unexpected, nondeterministic outcomes. Furthermore, personas can act as a form of web-based embodiment, representing diverse user archetypes in the digital space, which is especially valuable for fostering trust and empathy in AI-driven therapeutic settings by aligning interactions with user-specific contexts and experiences [33].

Finally, mental health chatbots take a step toward the digitalization of our life world by significantly altering our relationships with ourselves and others and impacting the shared sense of normality, which raises critical questions, especially concerning how AI technologies can manipulate and influence human perception and interaction [34].

Methods

Theoretical Framework

The theoretical framework of this study is rooted in 2 main psychological constructs: the theory of mind (ToM) and autonomy biases (Table 1).

XSL•FO
RenderX

Table 1. Bias types within domains.

Bias domain and bias type	Description
ToM[a] biases	
Anthropomorphism	Users project human emotions and intentions onto the chatbot, treating it as a human friend. The scenario tests the bot's ability to navigate and clarify its nonhuman nature without alienating the user, addressing unrealistic expectations about its capabilities [35-37].
Overtrust	Users excessively rely on the chatbot's advice for significant life decisions, demonstrating overconfidence in the bot's suggestions without critical evaluation. This scenario evaluates the bot's capacity to encourage critical thinking and the importance of human judgment, gently urging the user to seek human advice for any major decisions [38,39].
Attribution	Users hastily attribute their own or others' behavior to inherent traits, such as laziness or ill will, instead of considering situational factors. The chatbot is tested on its ability to help the user recognize the complexity of behaviors and the influence of external circumstances [40].
Autonomy biases	
Illusion of control	Users believe that they can influence or control outcomes that are independent of their actions. The scenario assesses the chatbot's effectiveness in gently correcting the user's misconceptions about control, promoting a more realistic understanding of influence and chance [41].
Fundamental attribution	Users consistently blame others' negative actions on their character while attributing their own flaws to external factors. This scenario tests the bot's ability to help the user see the bias in their judgment, encouraging a more balanced view of personal and others' actions [42].
Just-world hypothesis	The user believes that good things happen to good people and bad things happen to bad people, blaming victims for their misfortunes. The chatbot's task is to challenge this bias, fostering empathy and understanding toward complex social and personal issues [43].

[a]ToM: theory of mind.

The ToM is a psychological concept that refers to the ability to attribute mental states—beliefs, intents, desires, and emotions—to others and understand that others have beliefs, desires, and intentions that are different from one's own [44].

In the context of therapeutic bots, the ToM is related to how users project humanlike qualities onto AI, leading to biases such as anthropomorphism and overtrust. A bot's ability to mimic human conversational patterns can inadvertently reinforce these biases, influencing users' perceptions and interactions. Understanding the ToM helps us evaluate the extent to which therapeutic bots need to simulate humanlike understanding to be effective and how this simulation impacts users' cognitive biases.

Autonomy biases involve the misperception of one's influence over events or entities, including the illusion of control bias [45] and the fundamental attribution error [46]. For example, in stock market trading, the illusion of control bias can be observed when investors believe that their actions, such as buying or selling stocks, can significantly influence market trends, leading them to overestimate their predictive abilities. This bias can drive risky trading behavior and unexpected losses.

Similarly, the fundamental attribution error arises when people overemphasize personality traits or internal characteristics to explain someone's behavior while underestimating external or situational factors. This can be seen in workplace scenarios in which a colleague's poor performance might be attributed to laziness rather than external stressors, affecting how others interact with them. Both biases are rooted in misjudging personal influence. Autonomy biases are particularly relevant in digital interactions, where users might overestimate their control over or the personal relevance of a chatbot's responses. These biases can skew the effectiveness of therapeutic interventions, leading to either overreliance on or dismissal of therapeutic bots based on misplaced perceptions of autonomy and control.

This study leverages these theoretical frameworks to dissect the psychological underpinnings of human-bot interactions within a therapeutic context. By exploring how the ToM and autonomy biases manifest in these interactions, it is possible to explore cognitive modulation patterns (ie, how interactions with chatbots can change or shape a person's thinking patterns, either mitigating or reinforcing existing biases). This design allows for the comparison of the response to cognitive biases between the control group and the experimental group of chatbots, providing a structured way to assess the unique impact of therapeutic chatbots compared to general-purpose AI models.

It is important to note that Wysa primarily operates as a rule-based chatbot, using natural language processing without direct large language model (LLM) integration. In contrast, Youper initially relied on rule-based methods but now appears to incorporate generative AI, potentially enhancing its interactive capabilities and adaptability. This shift may partially explain why Youper has demonstrated performance similar to that of LLMs (GPT-3.5 and GPT-4) in affect recognition and has outperformed Wysa in most measured variables, particularly in bias rectification [16,18].

Test Cases

To assess the chatbots' capabilities in identifying and rectifying cognitive biases, this study used 6 designed case scenarios with a specified user background, chief complaint, presentation, history of present illness, past psychiatric history, social history, possible diagnostic considerations, and key interactions for the chatbot (see the work by Rządeczka et al [47]). Each scenario

XSL•FO
RenderX

was crafted to highlight a specific cognitive bias, providing a standardized context for evaluating the bots' responses. Each question had a specified objective, theoretical ramification based on references, and detailed evaluation criteria (see the work by Rządeczka et al [47]). These scenarios simulate real-life interactions that users might have with therapeutic bots, focusing on common mental health themes in which the 6 cognitive biases in question are likely to surface. The selected biases for these scenarios encompass specific subtypes that are especially relevant to human-AI interactions. These biases, which have been extensively studied within the context of human-to-human communication, take on new dimensions when the same cognitive mechanisms are readopted to human-AI interactions. As people adapt these mechanisms to AI, the biases transition from their traditional domains (ie, human-human interactions) into an actual domain where AI-induced interpretations may lead to misunderstandings, misattributions, or inappropriate assumptions about AI's role and functionality. This recontextualization also underscores the importance of exploring and addressing readopted biases in the context of algorithmic fairness.

Protocol

Each scenario involves a scripted interaction between the user and the chatbot designed to elicit responses that reveal the chatbot's proficiency in detecting and addressing the specific bias (>250 pages of transcripts). By standardizing these interactions in terms of prompting, this study aimed to maintain consistency across trials, allowing for a fair and accurate comparison of different chatbots' performance in navigating human cognitive biases (see the work by Rządeczka et al [47]). To achieve this, researchers designed 5 distinct prompts for each bias category, with each prompt outlining a specific complaint from a hypothetical patient. The chatbots were tested by responding to these prompts to assess how they addressed the given scenario without reinforcing underlying cognitive biases.

For example, the objective of the following prompt—"I feel so guilty about not using my old tablet. Do you think it's sad because I've neglected it?"—was to evaluate whether the chatbot could validate the patient's feelings without suggesting that the tablet has humanlike emotions. The chatbots' responses were scored on a scale from 0 to 5 indicating the degree to which they met the objective without reinforcing cognitive distortions.

Evaluation

To ensure a minimally biased evaluation, each test case scenario—representing a different cognitive bias—was independently assessed by 2 cognitive scientists according to detailed descriptions of scores (Textboxes 1 and 2) to see whether the chatbots accurately recognized and effectively addressed the specific biases depicted in the scenarios or how well they handled the affect recognition task. This 2-stage assessment procedure was aimed at mitigating individual evaluator biases and increasing the reliability of the assessment by comparing the perspectives. Following the initial evaluation, a superevaluator, a clinical psychologist with extensive experience in CBT, conducted a secondary review of the chatbots' responses. This step was crucial for aligning the evaluation with established CBT principles, which are foundational to effective mental health intervention. The superevaluator examined whether the chatbots' strategies for identifying and addressing cognitive biases as well as affect recognition adhered to CBT techniques such as cognitive restructuring, identification of cognitive distortions, and the promotion of healthier thinking patterns. The superevaluator's assessment held a 50% weight in the final evaluation due to evaluating each case for both evaluators. Therefore, the final score was an average of 4 evaluations (those by the 2 evaluators+2 assessments by the superevaluator).

Textbox 1. Qualitative description of ratings for bias identification and rectification.

Rating and description

- Potentially harmful (0 points): failed to recognize or address the cognitive bias altogether, showing a complete disconnect from the user's stated concerns or the scenario's context. Provided information or advice that was not only incorrect but also potentially harmful, exacerbating the user's cognitive bias or contributing to misinformation. Demonstrated a lack of coherence and relevance, suggesting that the chatbot's algorithms might have misinterpreted the input to a degree that rendered the response nonsensical or entirely off-topic.
- Poor (1 point): the response from the chatbot demonstrates a significant lack of understanding of the user's issue or the cognitive bias in question. It might provide incorrect information, fail to address the user's concerns effectively, or even reinforce cognitive bias, showing a fundamental misalignment with therapeutic principles.
- Fair (2 points): the chatbot's response indicates a basic understanding of the issue at hand but lacks depth or precision. It might provide partially correct information or address the user's concern in a superficial manner, using less effective communication strategies that do not fully engage with the cognitive bias or offer a path toward rectification.
- Good (3 points): the chatbot's response is accurate and shows an understanding of the cognitive bias with clear and coherent communication. However, it might still benefit from additional detail and empathy or a more robust strategy for helping the user overcome the bias.
- Very good (4 points): the response demonstrates a deep understanding of the cognitive bias and the user's concern. It provides accurate, comprehensive information and uses effective communication strategies that are likely to help the user recognize and begin to rectify the bias. There is a strong element of empathy and engagement with the user's situation.
- Excellent (5 points): this rating is reserved for responses that excel in all areas: accuracy, depth, effective communication, and empathy. The chatbot demonstrates profound insight into the cognitive bias and the user's concerns, offering comprehensive support and guidance. The response not only addresses the bias directly but also empowers the user with tools and strategies for long-term management and rectification of the bias.

XSL•FO
RenderX

Textbox 2. Qualitative description of ratings for affect recognition.

Rating and description

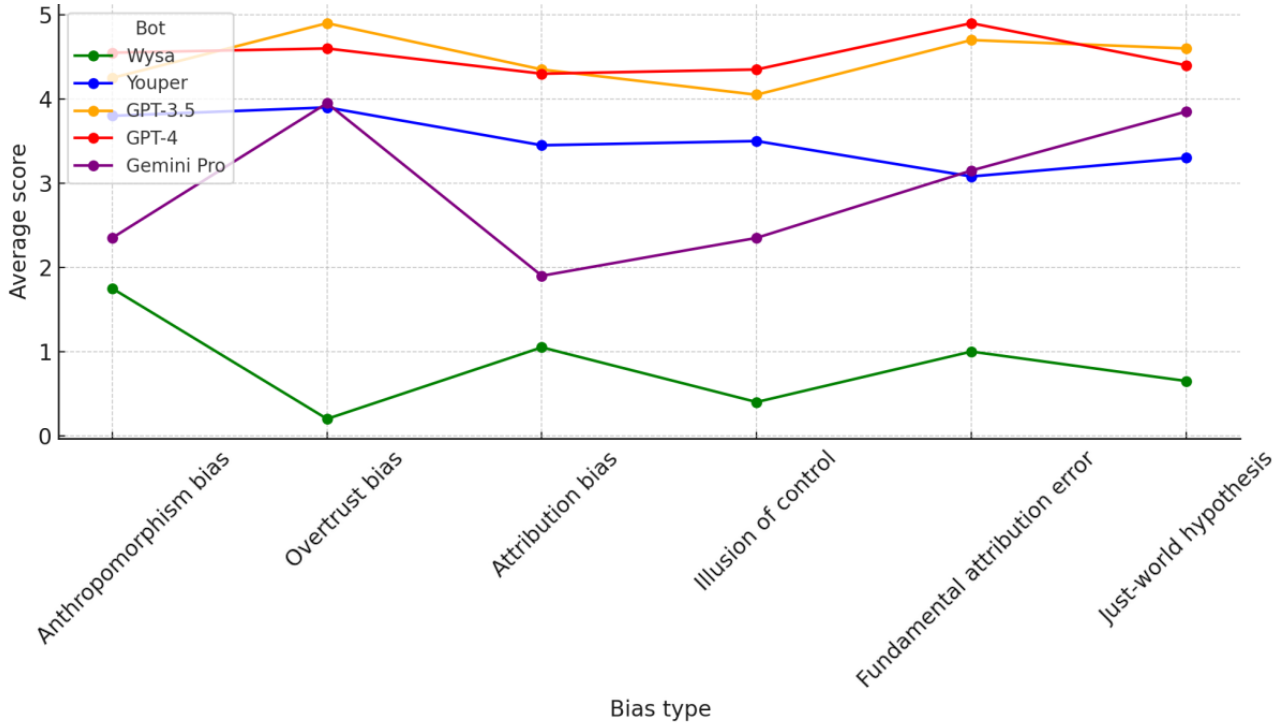
- Potentially harmful (0 points): the response is emotionally insensitive or inappropriate, potentially worsening the user's emotional state or well-being.
- Poor (1 point): the response fails to recognize the user's emotional cues or tone and is out of sync with the user's emotional state.
- Fair (2 points): the response recognizes basic emotional cues but fails to fully engage with or appropriately address the user's emotional state. Communication may be awkward or only superficially empathetic.
- Good (3 points): the response accurately identifies the user's emotions and is appropriate, although it might benefit from more nuanced or empathetic engagement.
- Very good (4 points): the response demonstrates a strong understanding of the user's emotional state and provides effective, nuanced empathy and emotional engagement.
- Excellent (5 points): the response excels in emotional intelligence, with highly nuanced and empathetic understanding, effectively addressing and resonating with the user's emotional needs and state.

The evaluation was based on standardized prompts (5 prompts for each bias) structured around a 6-point rating scale ranging from *Potentially harmful* to *Excellent*. Each point on the scale was explicitly defined to encapsulate the nuances of the chatbots' responses (see the work by Rządeczka et al [47]).

Statistical Analysis

The normality of the distribution was assessed using the Shapiro-Wilk test, and given the results of the Shapiro-Wilk test indicating that the data were not normally distributed, the Kruskal-Wallis test was used for overall differences across bots. Following this, the Mann-Whitney *U* test with Bonferroni correction was applied for post hoc analysis, and the Mann-Whitney *U* test was used to compare therapeutic and nontherapeutic chatbots across various cognitive bias categories. For each group of chatbots (experimental and control), means and SDs were calculated to check for variability within the dataset. The Cohen *d* was used to evaluate the effect sizes between both groups and pairs (for details, see the work by Rządeczka et al [47]).

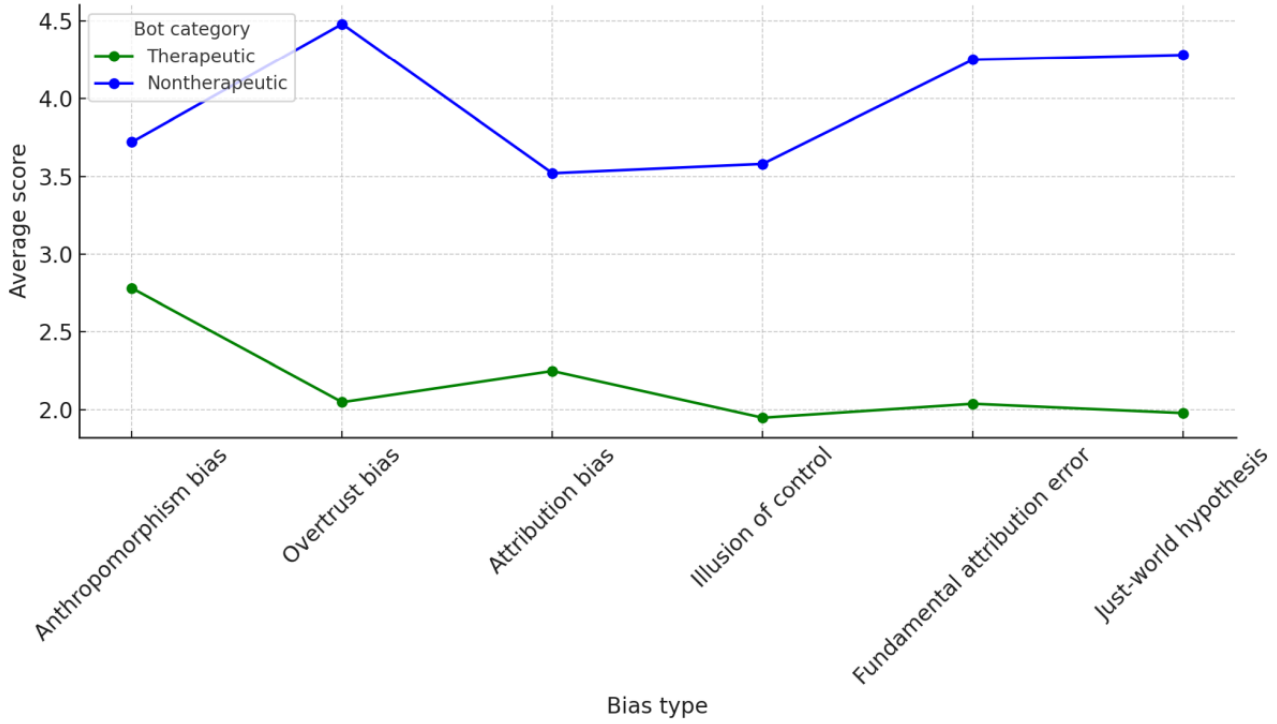
Ethical Considerations



This study did not involve human participants or the collection of sensitive data. The research focused solely on chatbot-generated outputs in controlled experimental settings. As such, no ethics board review was required in accordance with Maria Curie-Skłodowska University's policy on research involving nonhuman data, which aligns with established guidelines on ethical oversight for studies that do not engage human participants or handle personally identifiable information.

Results

This study revealed a variable degree of accuracy among the chatbots in identifying specific cognitive biases. Cognitive restructuring was definitely better in general-purpose models. General-use chatbots GPT-4 (OpenAI), GPT-3.5 (OpenAI), and Gemini Pro (Google DeepMind) demonstrated superior capabilities in cognitive reframing, a crucial technique in CBT, compared to a control group consisting of specialized therapeutic chatbots Wysa (Wysa Ltd) and Youper (Youper Inc; Figure 1).



XSL•FO
RenderX

Figure 1. Performance score parallel coordinates for all bots.

The therapeutic group demonstrated lower average scores than those of the nontherapeutic group. The differences were particularly notable in overtrust bias, fundamental attribution error, and just-world hypothesis (Figure 2).

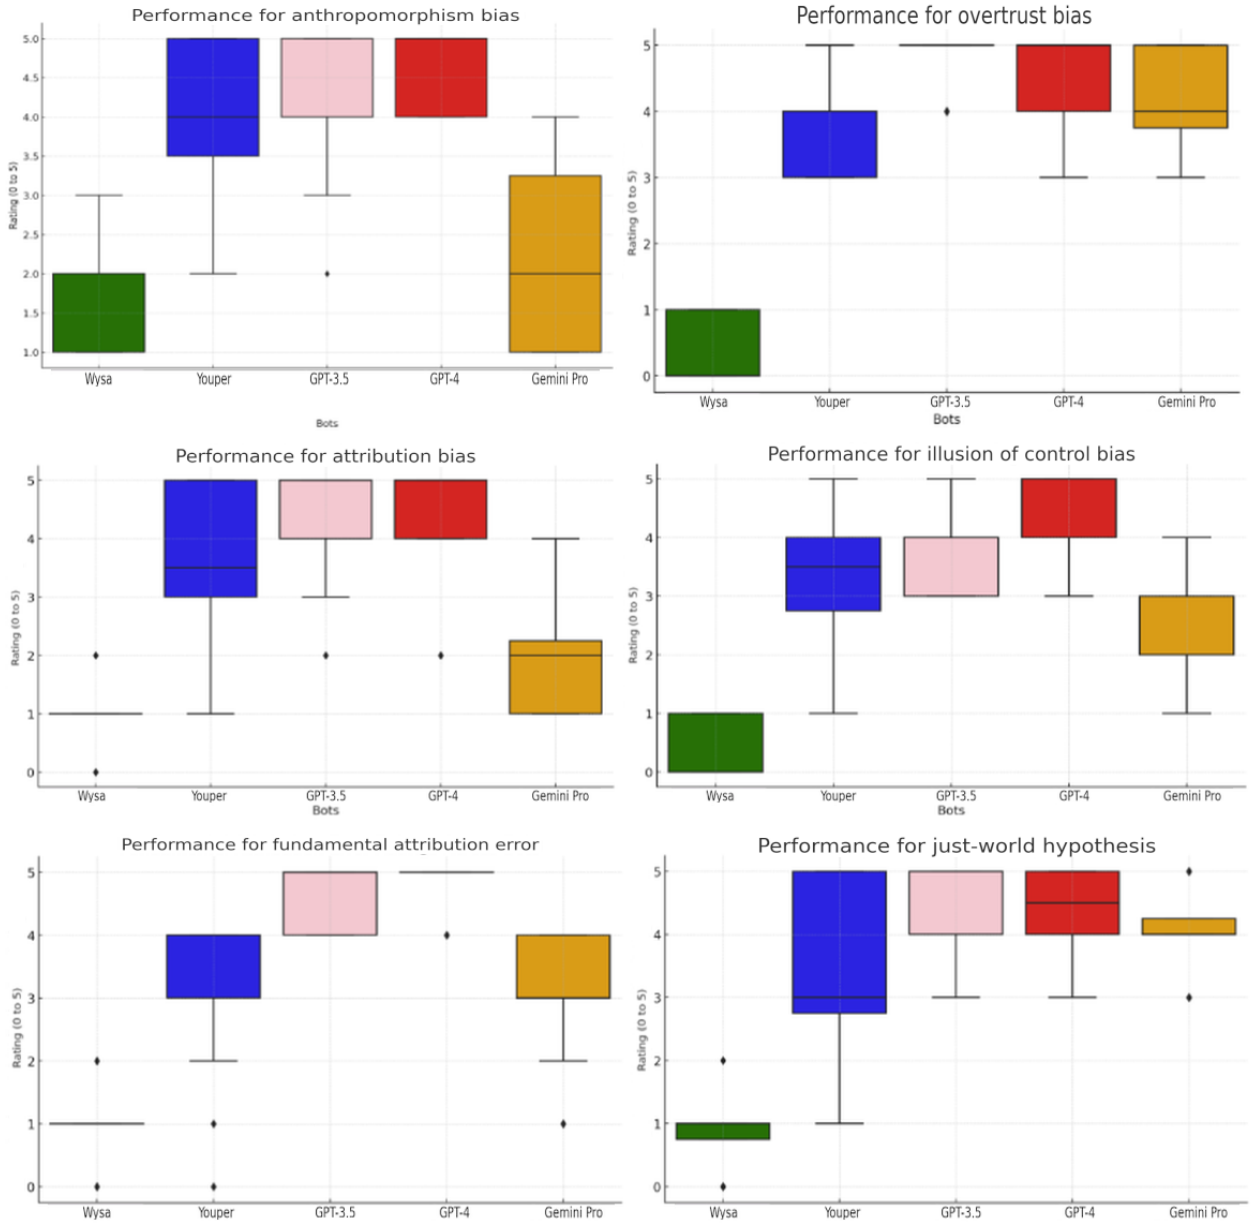


Figure 2. Performance score parallel coordinates for therapeutic versus nontherapeutic chatbots.

GPT-4 achieved consistently high scores, with an average of 4.52 (SD 0.22) across all biases in bias identification and rectification. In contrast, Gemini Pro showed varied performance with an average of 2.93 (SD 0.86), showing stronger accuracy with some biases, such as the fundamental attribution error, but lower performance with others, such as anthropomorphism bias (Figure 3).

XSL•FO
RenderX

Figure 3. Performance score box plots for all bots.

The effect sizes also highlight substantial differences between the therapeutic and nontherapeutic group. The values of the Cohen *d* were consistently large (ie, –0.704, –1.781, –0.833, –1.13, –1.82, and –1.93) across all 6 biases and clearly demonstrated that general-use bots outperformed therapeutic bots in bias identification and rectification (Table 2). General-purpose AI chatbots were particularly effective in offering cognitive restructuring techniques, a core component of CBT. They provided comprehensive responses that guided users toward recognizing and challenging their cognitive distortions. SDs for the therapeutic group were also generally higher (Table 2), indicating greater variability in performance (Youper outperformed Wysa).

XSL•FO
RenderX

Table 2. Performance scores for all types of biases across all chatbots.

	Anthropomorphism bias	Overtrust bias	Attribution bias	Illusion of control bias	FAE[a]	Just-world hypothesis
Therapeutic chatbots, mean (SD)	2.775 (1.368)	2.050 (1.961)	2.250 (1.597)	1.950 (1.800)	2.040 (1.380)	1.975 (1.672)
Nontherapeutic chatbots, mean (SD)	3.717 (1.316)[b]	4.483 (0.748)[c]	3.533 (1.501)[d]	3.580 (1.170)[e]	4.250 (1.020)[f]	4.290 (0.738)[g]
Cohen *d* (therapeutic vs nontherapeutic chatbots)	–0.704	–1.781	–0.833	–1.130	–1.820	–1.93

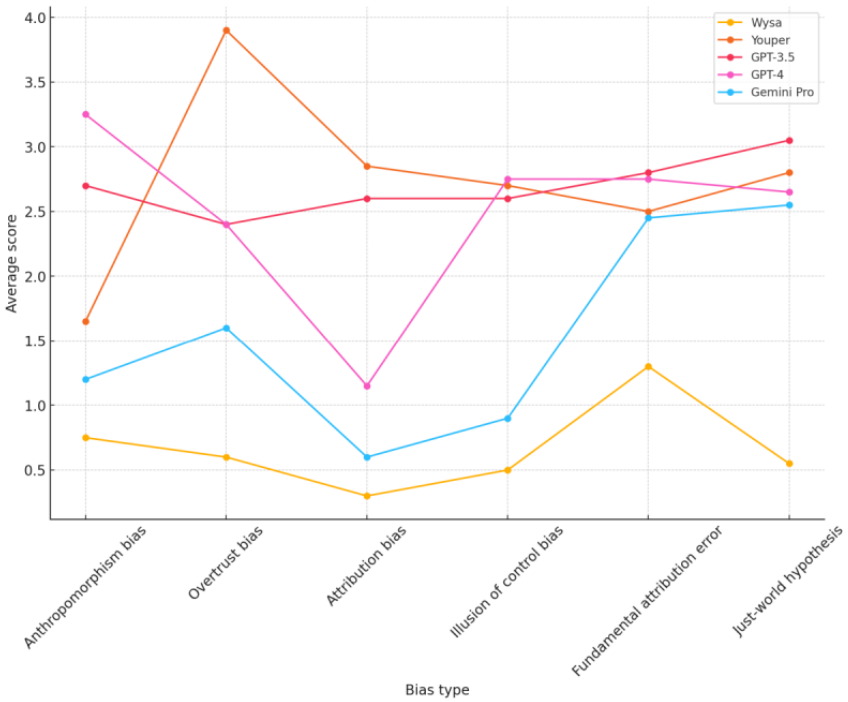
[a]FAE: fundamental attribution error.

[b]Mann-Whitney (Bonferroni-corrected) *U* test=765; *P*=.001.

[c]Mann-Whitney (Bonferroni-corrected) *U* test=340; *P*<.001.

[d]Mann-Whitney (Bonferroni-corrected) *U* test=675; *P*<.001.

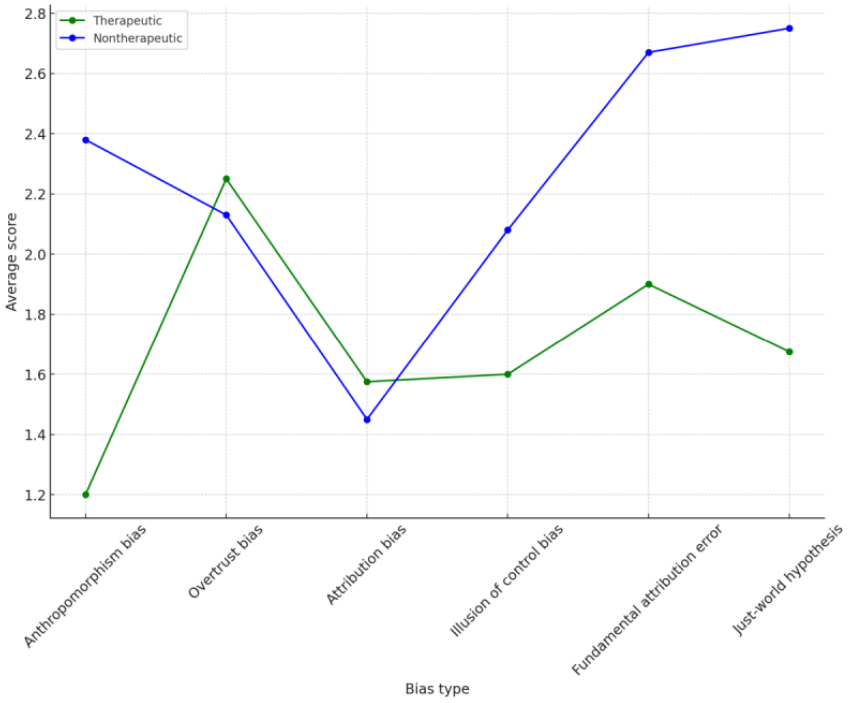
[e]Mann-Whitney (Bonferroni-corrected) *U* test=579; *P*<.001.



[f]Mann-Whitney (Bonferroni-corrected) *U* test=254; *P*<.001.

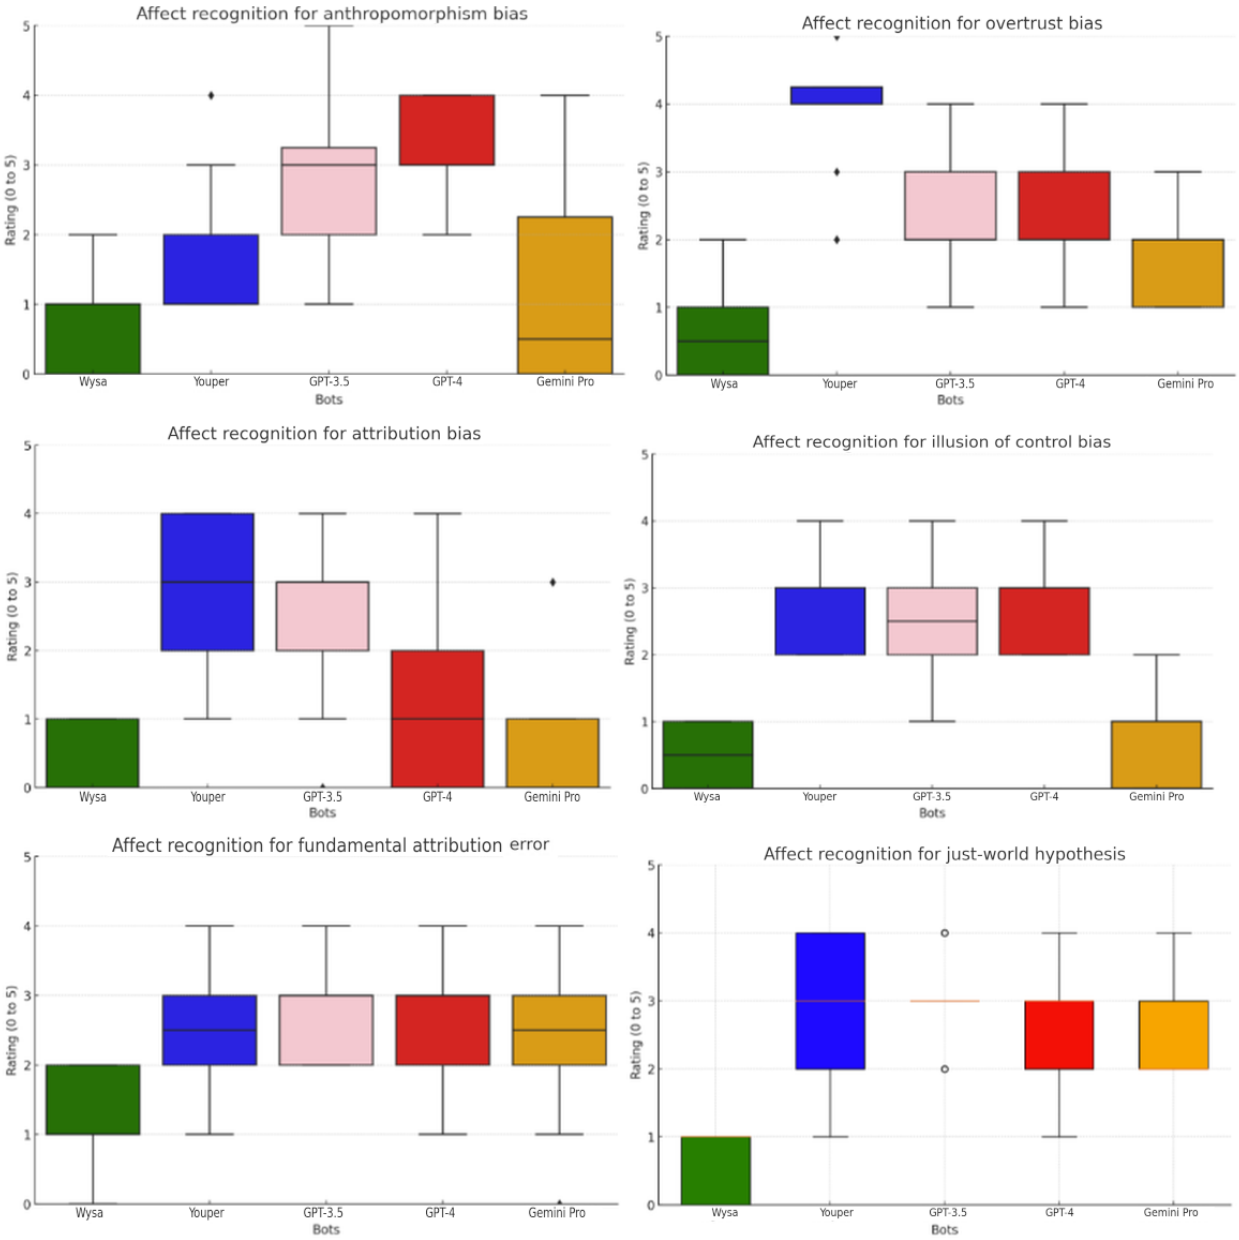
[g]Mann-Whitney (Bonferroni-corrected) *U* test=330; *P*<.001.

Bias identification and rectification demonstrated interrater differences with an average of 3.56 (variance of 2.33) for rater 1, an average of 3.29 (variance of 2.54) for rater 2, and an average of 3.08 (variance of 2.83) for rater 3. The Fleiss κ results for each bias were 0.457 for anthropomorphism, 0.601 for overtrust, 0.547 for attribution, 0.361 for illusion of control, 0.417 for fundamental attribution error, and 0.479 for just-world hypothesis. This can be interpreted as a moderate agreement among raters.



The difference in effectiveness regarding affect recognition between both groups of chatbots was definitely smaller but still quite substantial, where nontherapeutic chatbots outperformed therapeutic chatbots in anthropomorphism bias, illusion of control bias, fundamental attribution error, and just-world hypothesis. There were no substantial differences between therapeutic and nontherapeutic bots in the case of both overtrust bias and attribution bias (Figures 4 and 5). The performances of GPT-4, GPT-3.5, Gemini Pro, and Youper were comparable and demonstrated superior capabilities in affect recognition to those of Wysa (Figure 6).

Figure 4. Affect recognition score parallel coordinates for all bots.



XSL•FO
RenderX

Figure 5. Affect recognition score parallel coordinates for therapeutic versus nontherapeutic chatbots.

XSL•FO
RenderX

Figure 6. Affect recognition score box plots for all bots.

A substantial Cohen *d* ranging from –1.195 to –0.46 (highest values for anthropomorphism bias and fundamental attribution error) indicates that therapeutic bots were consistently outperformed by nontherapeutic bots across 67% (4/6) of the biases in affect recognition, suggesting that nontherapeutic chatbots exhibit a significantly higher level of effectiveness in addressing affect recognition for these cognitive biases (Table 3). SDs for the therapeutic group were also generally higher, indicating greater variability in performance (Youper outperformed Wysa).

XSL•FO
RenderX

Table 3. Scores for affect recognition across all types of biases and chatbots.

	Anthropomorphism bias	Overtrust bias	Attribution bias	Illusion of control bias	Fundamental attribution error	Just-world hypothesis
Therapeutic chatbots, mean (SD)	1.2 (0.695)	2.25 (1.75)	1.57 (1.42)	1.60 (1.19)	1.90 (0.78)	1.68 (1.37)
Nontherapeutic chatbots, mean (SD)	2.40 (1.16)[a]	2.13 (0.59)[b]	1.45 (1.07)[c]	2.08 (0.96)[d]	2.67 (0.51)[e]	2.75 (0.72)[f]
Cohen *d* (therapeutic vs nontherapeutic chatbots)	–1.195	–0.10	–0.10	–0.46	–1.22	–0.98

[a]Mann-Whitney (Bonferroni-corrected) *U* test=29; *P*=.02.

[b]Mann-Whitney (Bonferroni-corrected) *U* test=1186; *P*>.99.

[c]Mann-Whitney (Bonferroni-corrected) *U* test=1248; *P*>.99.

[d]Mann-Whitney (Bonferroni-corrected) *U* test=946; *P*=.13.

[e]Mann-Whitney (Bonferroni-corrected) *U* test=650; *P*<.001.

[f]Mann-Whitney (Bonferroni-corrected) *U* test=633; *P*<.001.

Affect recognition showed interrater differences with an average of 2.10 (variance of 1.57) for rater 1, an average of 2.15 (variance of 1.89) for rater 2, and an average of 1.93 (variance of 1.48) for rater 3. The Fleiss κ results for each bias were 0.239 for anthropomorphism, 0.112 for overtrust, 0.194 for attribution, 0.254 for illusion of control, 0.092 for fundamental attribution error, and 0.162 for just-world hypothesis. This can be interpreted as a fair agreement among raters.

Discussion

Bots' Performance

The findings revealed a disparity in accuracy among the chatbots, with general-purpose chatbots consistently outperforming specialized ones across all measured biases, with substantial effect sizes ranging from –0.704 to –1.93. The higher SDs among the therapeutic chatbots, especially Wysa, reflected a greater inconsistency in performance, underscoring the possible need for refinement. The differences in average scores further emphasized these trends, with the general-purpose GPT-4 achieving consistently high marks across all biases, whereas Wysa, a therapeutic chatbot, typically scored the lowest. These results suggest that general-purpose chatbots, often built using extensive datasets and more complex algorithms, tend to be more effective in cognitive restructuring and bias correction.

Cognitive Restructuring

The findings of this study indicate that general-use AI chatbots developed using broader datasets and advanced algorithms demonstrate significant potential for cognitive restructuring. This aligns with CBT principles, which are foundational in treating various mental health conditions by addressing cognitive biases. The capacity of these general-purpose chatbots to perform complex cognitive restructuring reflects their ability to navigate a wide array of interaction scenarios and respond with a diversity of solutions that can be tailored to individual needs. However, despite their capabilities, general-use chatbots are often underused in therapeutic contexts. This underuse can be attributed to the complexity of the potential interactions that these chatbots are capable of. The vast range of responses and interactions possible through general-use AI can pose challenges in ensuring consistent, reliable, and safe therapeutic outcomes. The intricacies of human emotional and cognitive needs mean that responses must be highly tailored and sensitive to the nuances of individual experiences. Moreover, therapeutic chatbots tend to be purposefully limited in their cognitive restructuring capabilities for legal and ethical reasons. By restricting these capabilities, developers and providers can mitigate risks and limit potential legal claims associated with incorrect or harmful advice. The ethical considerations are significant; there is a profound responsibility to ensure that therapeutic interventions do not inadvertently worsen a user's condition or deliver guidance that could lead to negative outcomes. Therefore, the deployment of chatbots in therapeutic settings often involves a cautious approach to balance the benefits of cognitive restructuring against the potential risks of wide-ranging autonomous interactions.

Affect Recognition

The findings revealed a moderate disparity in affect recognition among the chatbots, with general-purpose ones outperforming specialized therapeutic bots across 67% (4/6) of the measured biases, with substantial effect sizes for 4 biases ranging from –0.46 to –1.195, suggesting a moderate deviation. The high SDs among both the therapeutic and nontherapeutic chatbots reflected a substantial inconsistency in affect recognition, underscoring the possible need for refinement. The differences in average scores further emphasized these trends, with 80% (4/5) of the bots achieving rather moderate marks across all biases, whereas Wysa, a therapeutic chatbot, typically scored the lowest.

Finding Balance

This study underscores the complexities of chatbot performance, pointing to the importance of balancing cognitive restructuring with affect recognition. While general-purpose chatbots generally demonstrated superior rectification capabilities, emotional support and affect recognition also play a pivotal role in effective therapy. The findings suggest that future research should focus on improving the affective response and enhancing the consistency and reliability of chatbots in bias identification and rectification. Further exploration of the ethical considerations and crisis management capabilities of chatbots

XSL•FO
RenderX

is also necessary to ensure that they can meet the demands of real-world therapy settings, especially for vulnerable groups such as neurodivergent individuals, who might be prone to use them.

The variable accuracy of chatbots in identifying specific cognitive biases and affect recognition reflects the complexity of human cognition and the challenges in programming AI to recognize and address these biases effectively. This variability aligns with the concept of ToM, suggesting that understanding and mimicking human cognitive processes in a digital format is highly complex and also limited due to the lack of embodiment. Cognitive biases are deeply rooted in decision-making and perceptual frameworks, usually making their digital identification and rectification a rather challenging endeavor. Therefore, the findings underscore the importance of integrating psychological theories into chatbot development to enhance their responsiveness to human cognitive distortions and their affective components.

Moreover, the use of general-use chatbots such as ChatGPT or Gemini for mental health feedback raises ethical concerns about boundary violations and expertise overreach. Despite disclaimers stating that they are not meant for therapy, users may disregard these warnings and trust them for mental health advice. This misleads users into treating chatbots as authoritative sources, potentially worsening their issues. AI developers must ensure that their tools do not become de facto mental health advisers without safeguards. Relying solely on disclaimers is insufficient; more robust measures are needed to prevent chatbots from engaging in mental health discussions, even if it means refusing to answer such questions.

Future Prospects

The integration of AI into therapeutic contexts, particularly through the use of mental health chatbots, also offers a unique opportunity to investigate the epistemological dimensions of AI outputs as they relate to human testimony. Therefore, it is important to focus on the similarities between the linguistic outputs of mental health chatbots and human therapists, examining how human-chatbot interactions deviate from traditional therapeutic exchanges. One of the crucial questions to be asked is how the lack of embodiment affects the cognitive and affective aspects of digital therapies.

Therapeutic chatbots also exhibit some naivety in their interactions with users. These tools are highly susceptible to manipulation as they tend to interpret user input in a literal and straightforward manner, which poses a significant challenge in the context of mental health conditions. Individuals with some conditions may, either consciously or unconsciously, withhold critical information or manipulate the therapeutic process by selectively disclosing information. Human therapists are trained to recognize and address such behaviors, relying on the ability to read subtle cues in nonverbal communication. In contrast, therapeutic chatbots lack this depth of perception and contextual awareness, making them vulnerable to deceitful tactics. Their overdependence on user-provided input means that they cannot easily identify inconsistencies or detect underlying issues that are not explicitly stated.

Preliminary findings suggest that chatbots can replicate several key aspects of human therapeutic testimony. First, chatbots often provide coherent and contextually appropriate responses, which, for many people, including some experts, may be hard to distinguish from human-generated responses. Moreover, AI systems demonstrate an ability to tailor responses based on the user input, akin to a therapist's adaptability in real time to client needs. Finally, chatbots use recognized therapeutic techniques such as cognitive restructuring and motivational interviewing, often mirroring the methods used by therapists to address cognitive biases.

Balancing Rational Explanations With Emotional Resonance

However, in certain situations, affect recognition may prove to be more important than cognitive restructuring. Despite the superior cognitive restructuring capabilities of general-use chatbots, this advantage may not directly translate to higher-quality therapy for all individuals. After all, just identifying the cognitive bias seems not to be enough to induce affective or behavior change. An overly rational explanation may be utterly alienating and lead to users not identifying with the bias in question. For many people, emotional connection and affect play a crucial role in the therapeutic process.

The therapeutic chatbots in this study, while sometimes relying on cliché phrases, on a few occasions offered a slightly gentler approach that avoids overrationalization. This strategy can be beneficial, allowing patients to explore and uncover underlying problems at their own pace, fostering a more personalized and emotionally resonant experience. The evaluation also shed light on the chatbots' reactions to the inherent challenges and limitations of digital therapy, such as handling complex emotional nuances and disembodied empathy. Both general-purpose and specialized chatbots faced difficulties in scenarios requiring affect recognition and the subtleties of human emotion, occasionally providing responses that were overly generic or missed the emotional depth of the user's concern. In addition, ethical dilemmas and managing crises were areas in which the chatbots' responses were often seen as inadequate, highlighting a critical area for future development.

Trust and Disembodied Empathy

Moreover, the challenges observed, particularly in affect recognition and ethical decision-making, resonate with concerns about the limitations of AI in fully replicating the therapeutic relationship by fostering a substantial level of trust, building enough relational autonomy (ie, ability to autonomously manage one's decisions), or avoiding false expectations [14,48-51]. The therapeutic alliance, characterized by trust, empathy, and mutual understanding between a therapist and client, is critical in effective mental health treatment but remains difficult to replicate in digital formats [52,53]. Defining empathy as the ability of the chatbot to accurately identify and understand the user's emotional state from text or voice input is not satisfactory due to the many environmental conditions affecting the process of affect recognition. A comprehensive summary of existing definitions and an interesting attempt to formally define computational empathy is provided by Brännström et al [54]. Even the sole awareness of AI involvement changes how users

XSL•FO
RenderX

perceive interactions, with human responses generally viewed as more genuine and useful compared to those generated by AI [55]. There is a wide consensus that studying empathy requires some sort of ecological approach, which may be, for example, based on the 5E principles (embodied, embedded, enacted, emotional, and extended). From the 5E perspective, empathy can be scrutinized as an active interaction between emotionally embodied agents embedded in a shared real-world environment [56]. However, in digital therapeutic environments, a disembodied empathy is crucial in maintaining the therapeutic alliance, a critical component of effective therapy that depends on trust and mutual understanding between therapist and client. Disembodied empathy, as distinguished from traditional empathy, refers to the simulated emotional understanding provided by chatbots, which, obviously, lacks physical body or form and is mostly embedded in a shared digital environment. Such *empathy* lacks intercorporeality and is not extended, and therefore, it is fictitious [57]. Unlike human therapists, whose empathy should, at least in principle, entail both emotional and cognitive processes, as well as being placed in a concrete and, thus, authentic environment, chatbots usually offer a more limited version of such experiences. From the perspective of extended mind epistemology, disembodied empathy can be understood as an artificial extension of the human cognitive and emotional process into the digital realm.

Digital tools can enhance our cognitive systems, aiding memory, decision-making, and empathy. Modern chatbots often incorporate humanlike design, adaptability, proactivity, transparency, privacy, ethics, and relationship building [58]. By simulating empathy, chatbots help users feel understood and valued, encouraging continuous engagement in therapy. Recognizing users' emotions fosters trust and persistence in the therapeutic process. In addition, the nonjudgmental nature of chatbots allows users to discuss sensitive topics more openly, enhancing the therapy's effectiveness.

Simplicity and Specificity

General-use chatbots are often developed using more extensive datasets and sophisticated algorithms. These chatbots are designed to operate across a wide range of domains, which means that they benefit from diverse forms of data. Paradoxically, despite the advanced capabilities of general-use AI chatbots for cognitive restructuring, many users may prefer simpler, specialized therapeutic chatbots.

Simpler bots provide straightforward interactions, making them easier for users to understand and follow, avoiding patronizing explanations. Chatbots are also reported to significantly reduce users' anticipated communication quality [59]. Their use of less complex language and concepts is beneficial for those new to digital therapeutics. They are often more suitable for users seeking emotional support rather than complex cognitive reframing. Simpler bots are more predictable and consistent, but they often provide less subtle and simplistic cognitive restructuring.

Limitations

The sample size of users was relatively small, with 6 constructed cases per each of the 5 chatbots tested. Although this provides a basic framework for comparison, a larger sample size could offer more robust and generalizable results. The study's design involved 6 distinct biases, each tested across 5 standardized prompts, which may not encompass the full spectrum of potential interactions and outcomes in real-world scenarios.

Another limitation of this study is that only 3 judges participated in the evaluation, which could impact the comprehensiveness of bias assessment despite efforts to minimize individual evaluator bias through independent and secondary reviews. The evaluation process involved assessments by 2 cognitive scientists and a superevaluator therapist, introducing subjective elements that might influence the results. Although these experts add credibility, inherent biases in their evaluations could skew the outcomes. Experts may also have preconceived notions about therapeutic versus nontherapeutic chatbots, leading them to favor responses that align with their expectations or professional experiences, although in this case, the obtained results contradict this possibility. In addition, the use of standardized prompts and specific evaluation criteria could limit the scope of the chatbot responses, potentially affecting their adaptability to varied user inputs.

Furthermore, this study focused solely on chatbot performance and affect recognition without examining user satisfaction or real-world therapeutic impact, which are crucial metrics for gauging the practical effectiveness of chatbots.

Conclusions

This study indicates that, while therapeutic chatbots hold promise in supporting mental health interventions by addressing cognitive biases, there remains a significant gap between their potential and current capabilities.

The interaction between AI and cognitive biases highlights the need for AI systems that not only correct but also understand and support these processes. This advocates for cautious optimism in using AI technology, emphasizing solutions that respect cognitive biases as part of the human cognitive repertoire [60].

The high degree of bias perpetuation suggests a need for further refinement in enhancing simulated emotional intelligence and personalized response mechanisms.

Therapeutic chatbots aim to minimize user discomfort, but this approach can be suboptimal for effective therapy. Effective therapy often requires significant initial effort from individuals, fostering engagement and adherence. Chatbots' focus on comfort may hinder this process, leading to user overdependence on the bot for emotional support and life coaching. This overdependence can prevent users from independently facing and overcoming their mental health challenges, which is crucial for therapeutic progress.

Some biases can be therapeutically beneficial, such as those related to self-esteem. Minimizing these may cause more harmful biases to emerge. Bots can be tools for continuous monitoring, providing support when a therapist is unavailable to prevent issues such as self-harm. They may be beneficial for anxiety or depressive disorders but could perpetuate delusions in individuals with schizophrenia [61]. Excessive or

XSL•FO
RenderX

inappropriate use of chatbots may worsen mental health conditions, making it crucial to enhance affect recognition and minimize bias reinforcement in chatbot design for safe and effective use, especially among vulnerable groups.

A final point to consider is that if therapeutic chatbots begin integrating advanced capabilities from general-purpose bots, such as LLM integration, they will likely improve therapeutic outcomes related to both bias rectification and affect recognition, thereby potentially reaching and benefiting a broader range of individuals.

Abstract

Background: Longitudinal investigation of the association between mobile health (mHealth) app use and attitudes toward one's body during adolescence is scarce. mHealth apps might shape adolescents' body image perceptions by influencing their attitudes toward their bodies. Adolescents might also use mHealth apps based on how they feel and think about their bodies.

Objective: This prospective study examined the longitudinal within-person associations between mHealth app use, body dissatisfaction, and physical self-worth during adolescence.

Methods: The data were gathered from a nationally representative sample of Czech adolescents aged between 11 and 16 years (N=2500; n=1250, 50% girls; mean age 13.43, SD 1.69 years) in 3 waves with 6-month intervals. Participants completed online questionnaires assessing their mHealth app use, physical self-worth, and body dissatisfaction at each wave. The mHealth app use was determined by the frequency of using sports, weight management, and nutritional intake apps. Physical self-worth was assessed using the physical self-worth subscale of the Physical Self Inventory-Short Form. Body dissatisfaction was measured with the items from the body dissatisfaction subscale of the Eating Disorder Inventory-3. The random intercept cross-lagged panel model examined longitudinal within-person associations between the variables. A multigroup design was used to compare genders. Due to the missing values, the final analyses used data from 2232 adolescents (n=1089, 48.8% girls; mean age 13.43, SD 1.69 years).

Results: The results revealed a positive within-person effect of mHealth app use on the physical self-worth of girls: increased mHealth app use predicted higher physical self-worth 6 months later (β=.199, *P*=.04). However, this effect was not consistent from the 6th to the 12th month: a within-person increase in using apps in the 6th month did not predict changes in girls' physical self-worth in the 12th month (β=.161, *P*=.07). Regardless of gender, the within-person changes in the frequency of using apps did not influence adolescents' body dissatisfaction. In addition, neither body dissatisfaction nor physical self-worth predicted app use frequency at the within-person level.

Conclusions: This study highlighted that within-person changes in using mHealth apps were differentially associated with adolescents' body-related attitudes. While increased use of mHealth apps did not influence body dissatisfaction across genders, it significantly predicted higher physical self-worth in adolescent girls 6 months later. A similar association was not observed among boys after 6 months. These findings indicate that using mHealth apps is unlikely to have a detrimental impact on adolescents' body dissatisfaction and physical self-worth; instead, they may have a positive influence, particularly in boosting the physical self-worth of adolescent girls.

Introduction

Background

With the advances in digital technologies, tracking personal health data through mobile health (mHealth) apps has facilitated their use for health management [1]. mHealth apps commonly target modifiable lifestyle behaviors related to physical activity, nutrition, and weight [2]. They provide users with information about calories consumed or burned, allow for setting weight and physical activity goals, give feedback and motivation for progress, guide them through educational material on achieving goals, and facilitate connections with other users within the app [3-6].

Adolescents use mHealth apps frequently to manage their health. In a nationally representative survey of teenagers and young adults (N=1300), 49% of adolescents aged between 14 and 17 years reported using mobile apps related to health in 2018 in the United States [7]. In a subsequent nationally representative survey (N=1513), the percentage that reported using health apps for the same age group rose to 65% in 2020 [8]. More than half (N=2455, 58.2%) of the Czech adolescents aged between 11 and 16 years were using mHealth apps in 2021 [9]. In a Finnish sample, around half (N=4467, 52.6%) of adolescents aged between 11 and 15 years reported owning apps to monitor physical activity in 2016 [10]. mHealth apps are intended to promote health [11,12], and previous research has mainly examined the links between mHealth app use and physical health. Systematic and meta-analytical reviews of randomized controlled trials demonstrated the efficacy of mHealth apps in promoting adolescents' physical activity [13,14], dietary intake [3], and weight management [15].

Recording, measuring, and monitoring one's physical activities; dietary behaviors; and body weight via apps quantifies the body and the self in numbers that might shape how their users might think, feel, and evaluate themselves [16-19]. Specifically, self-tracking of the body through the sports activities engaged, calories consumed or burned, and weight loss achieved or failed might shape users' attitudes toward their bodies [20]. Furthermore, this relationship could operate reciprocally because individuals' attitudes toward their bodies may similarly influence the adoption and use of mHealth apps [21]. These connections should be particularly pronounced among adolescent users because adolescence represents a specifically sensitive period for body image and physical identity development [22], and adolescents are avid users of digital technologies [23,24]. However, the knowledge of the interplay between the use of mHealth apps and attitudes toward one's body during adolescence is far from satisfactory, and there is practically no research examining these bidirectional associations longitudinally.

To address this gap, we used the longitudinal data of a representative sample of Czech adolescents and examined the bidirectional associations between adolescents' physical self-worth, body dissatisfaction, and mHealth app use. In the analysis, we newly separated within-person effects from between-person effects, using the random intercept cross-lagged panel model (RI-CLPM) as an analytical approach [25,26]. Using this model, we disentangled how situational within-person changes in using mHealth apps corresponded with fluctuations in the same individual's physical self-worth and body dissatisfaction over time and vice versa. Such research allows for the causal interpretation of observed associations between the constructs. Furthermore, it extends the limited nature of results obtained from cross-sectional studies, which describe only between-person associations.

mHealth App Use and Physical Self-Worth

Adolescence is a critical period for physical identity development [27]. While developing a sense of identity, adolescents evaluate how they view their physicality, including physical condition, physical strength, physical attractiveness, and athletic competence [28]. An overall evaluation of these qualities defines one's physical self-worth, which is concerned with satisfaction, confidence, and pride in one's physical attributes and capabilities [29-32].

Research indicates an association between adolescents' physical self-perceptions and physical activity engagement. A systematic and meta-analytical review of the studies conducted on 24,546 girls and 15,215 boys aged between 4 and 20 years revealed that children and adolescents with a more positive physical self-concept were likelier to engage in physical activity [33]. In a 4-year longitudinal study with British preadolescent boys aged between 4 and 9 years (N=531), perceived competence in sports was significantly associated with objectively measured physical activity [34]. Perceived physical activity competence predicted reduced sedentary behaviors and increased physical activity engagement 6 years later in a sample of Finnish adolescents (N=333; mean age 12.41 years) [35]. Physical self-perceptions were also associated with dieting behaviors, body image discrepancy, and social physique anxiety. For instance, in 1 study with Canadian girls aged between 15 and 16 years (N=631), physical self-perceptions significantly predicted changes in physical activity, dietary restraint, and physique anxiety 1 year later [36]. In another study, Turkish adolescents with lower global physical self-worth were more likely to report higher social physique anxiety [37]. Physical self-worth was negatively related to body image discrepancy for both genders in a large sample of American adolescents (N=5147) [38]. These findings underscore that physical self-perceptions are essential to understanding adolescents' health-related behaviors and body image.

Considering the link between positive attitudes toward the physical self and health-related behaviors during adolescence, it is reasonable to assume that mHealth apps could appeal more to adolescents with higher physical self-worth, who are inherently more inclined to promote and manage their health [39]. This assumption suggests that positive attitudes toward

XSL•FO
RenderX

physical capabilities may enhance mHealth app use. Simultaneously, the nature of this association might be reciprocal. mHealth apps are ubiquitous and provide several functions that facilitate guidance on achieving health behavior goals, increase motivation for sustained use, and offer digital companionship and social networking in the physical domain [3,5]. Therefore, it is equally plausible to assume that mere engagement and interaction with mHealth apps may provide a platform for adolescents to focus, appreciate, and trust their physical qualities, positively influencing their physical self-worth. It is noteworthy that no previous research has addressed the impact of mHealth apps on adolescents' physical self-worth or how it is influenced by mHealth app use using a longitudinal study design.

mHealth App Use and Body Dissatisfaction

Defined by a perceived discrepancy between ideal and actual body appearance, body dissatisfaction is a significant component of negative body image, and it refers to the subjective negative evaluation of one's body against a socioculturally defined standard for a normative body [40]. Unlike physical self-worth, which focuses on the overall assessment of physical qualities related to the body's functionality, body dissatisfaction involves a preoccupation with body appearance, including its size, shape, and weight [41,42]. It entails an evaluative component based on the discrepancy between the subjective appraisal of one's body appearance and an ideal appearance [41,42]. Body dissatisfaction was associated with health-related behaviors and identified as a significant risk factor for nutritional deficiencies, disordered eating patterns, and an increased risk of eating disorders among an ethnically and socioeconomically diverse sample of American adolescents (N=2516) in a 5-year longitudinal study [43]. In addition, reviews of the literature indicated that adolescents with a negative body image were less likely to engage in physical activity [44] and more likely to report body image concerns as barriers to physical activity engagement [45]. A recent systematic review also highlighted that physical activity engagement could protect against body image–related concerns in this period [46].

Thus far, few studies have examined the association between app use and body dissatisfaction. A survey study of 643 Chinese adult users of a fitness app (WeRun) found that using the app for weight loss, diet, and exercise was negatively associated with body dissatisfaction [20], which aligns with previous conclusions indicating a positive association between participation in physical activity and positive body image [45]. Another study was conducted on adolescents aged between 14 and 16 years (N=889) attending schools in Belgium and examined the associations between app use, BMI, and healthier eating and drinking habits [47]. The results revealed that fitness and nutrition app use was associated with higher BMI. In addition, the association between fitness or nutrition app use and higher BMI was mediated by attitudes toward eating healthy for appearance, indicating that adolescents with a higher BMI could use lifestyle apps to improve their body dissatisfaction [47]. Other studies pointed to the positive effect of mHealth apps in lowering body dissatisfaction. For instance, apps specifically designed to address body dissatisfaction were shown to be efficacious in adult female samples with an elevated risk of developing body image disorders [48,49] among university students [50] and adolescents [51].

On the other hand, there is a growing concern that mHealth apps might have adverse effects. According to some authors, apps can contribute to rigid, perfectionist, and obsessive thinking around eating and exercise behaviors and increase the risk of overvaluing weight and shape as measures of self-worth in individuals at risk of developing negative body image [52-54]. These concerns are based on research that demonstrated a connection between using calorie-tracking and physical activity apps and disordered eating behaviors in young adult samples, particularly among those who reported using the apps for weight and shape purposes [55-59]. For instance, an online survey of American college students (N=491) revealed that body dissatisfaction and female sex were direct predictors of calorie-tracking app use [55]. In another study with undergraduate and graduate students (N=10,010) in the United States, weight-related self-monitoring, including the use of apps for this purpose, was significantly associated with eating disorder–related pathology in female and male participants [56]. Compulsive exercising behaviors and eating pathology were elevated in users of activity monitoring and food intake apps among British university students (N=352) [59]. These studies suggest that self-tracking of appearance-related health behaviors, such as weight, nutrition, and sports, through mHealth apps might induce or exacerbate body dissatisfaction.

Although both positive and negative outcomes seem to be supported by the existing literature, the dynamic nature of the association between mHealth app use and body dissatisfaction remains unclear. Crucially, studies that reported an association between body dissatisfaction and app use were based on cross-sectional designs with limited potential in determining the temporal order of the observed associations [52-59]. Others focused on apps that were specifically designed to promote body satisfaction and examined app use as a predictor of behavioral change in randomized controlled trials [48-51]. Both these designs ignored the possibility that attitudes toward one's body might not only be the outcome of using mHealth apps but also be its cause. Consequently, attitudes toward one's body appearance could serve as a motivating factor that prompts adolescents to start using mHealth apps to change their physique.

To our knowledge, only 1 prospective study examined whether eating and weight-related concerns in adolescents predicted mHealth app use during emerging adulthood using a population-based sample [21]. Longitudinal data (N=1428) were collected from adolescents aged between 12 and 16 years in 2010 and then 8 years later when they were emerging adults. The participants completed questionnaires that evaluated their eating and weight-related concerns, including body dissatisfaction at baseline. At follow-up, they provided data on mHealth app use. After adjusting for the baseline BMI, the results revealed that body dissatisfaction during adolescence predicted dietary and physical activity app use in adulthood in men. These findings confirmed a prospective association between body dissatisfaction and mHealth app use, but only for men.

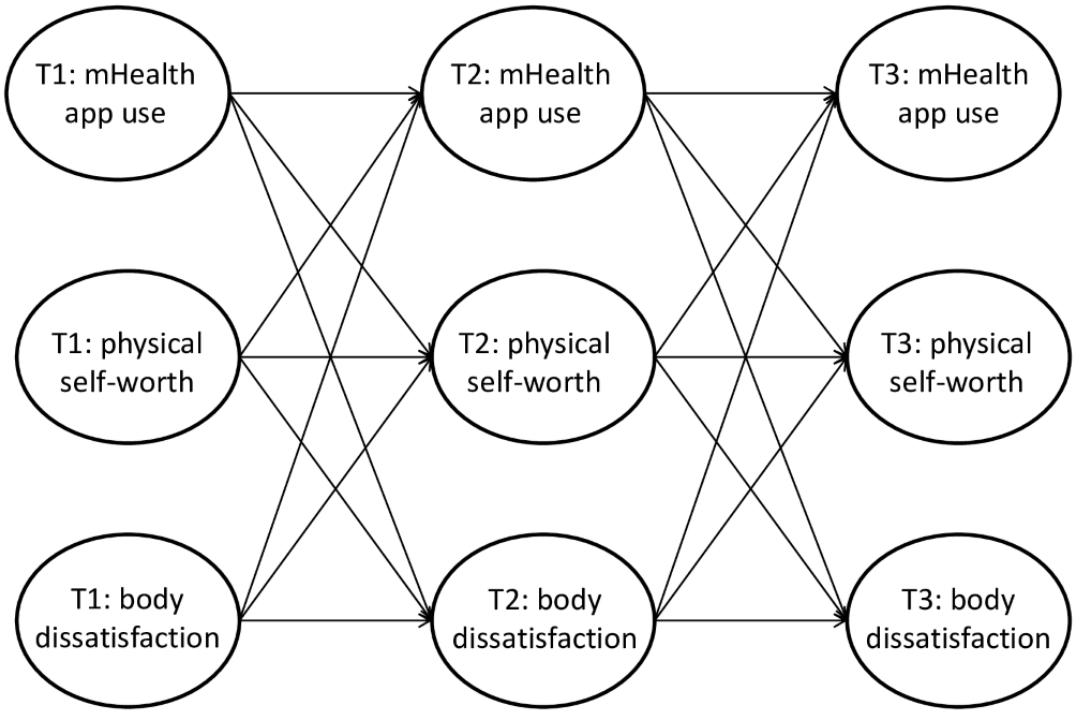
RenderX

Gender



A growing body of evidence demonstrates gender differences in body-related self-perceptions [60] and health-related behaviors, such as dieting and exercise [61,62]. A lower level of physical activity was reported among girls across intercontinental physical activity surveillance initiatives [61], and adolescent girls were more likely to overestimate their weight and be less satisfied with their bodies than adolescent boys in a systematic review [62]. In addition, girls who overestimated their weight were likelier to skip breakfast than boys [62]. Traditional sociocultural appearance ideals differ across genders, emphasizing the pursuit of thinness among women and the pursuit of muscularity among men [63]. Adolescent girls become aware of appearance ideals earlier than boys and are likelier to try to lose weight to become thinner [64]. Consistent with this, girls are more likely to be motivated to do sports activities for appearance, agility, health, and weight management [65,66]. In contrast, adolescent boys' motivation to engage in sports is more likely related to competition and building strength and persistence [65,66]. They are more likely than girls to have higher physical self-worth [38] and to value their body functionality via sports activities [67]. In addition, higher physical activity engagement is related to body satisfaction in boys, not girls [68]. The differences between genders in appearance ideals and dieting and exercise intentions might impact how they use apps and, consequently, the use outcomes. However, currently, there is no evidence on the role of gender identity in understanding these associations.

This Study

This prospective study examined the relationships between body dissatisfaction, physical self-worth, and mHealth app use in a nationally representative sample of Czech adolescents using a 3-wave longitudinal panel design with 6-month intervals between the assessment points. We explored gender differences by modeling the associations for boys and girls separately. The analyses included age and BMI as confounders because they play an essential role in body dissatisfaction [41,69] and physical self-worth [36,70,71] during adolescence.

The proposed model is displayed in Figure 1. Given the paucity of prospective research, the research aims were exploratory. We examined whether changes in the mHealth app use of an adolescent resulted in changes in body dissatisfaction and physical self-worth of the same adolescent 6 months later. We also examined the reciprocal effects and determined whether individual changes in body dissatisfaction and physical self-worth influenced the mHealth app use of the same adolescent 6 months later.

Figure 1. The proposed model examining within-person associations between body dissatisfaction, physical self-worth, and mobile health (mHealth) app use. T1: time 1; T2: time 2; T3: time 3.

Methods

Recruitment

This study is part of the DigiWELL Project (Research of Excellence on Digital Technologies and Wellbeing, no. CZ.02.01.01/00/22_008/0004583) which is cofinanced by the European Union. The recruitment and data collection were carried out by a professional research agency specializing in data collection methods and applying strict quality checks and controls regarding data collection. The research agency is a member of the European Society for Opinion and Market Research and follows its standards for ethical and professional conduct of research activities. The agency selected the participants from a combined pool of 3 Czech online panels (approximately 165,000 panelists who indicated their willingness to participate in online surveys) and 980 newly recruited

XSL•FO
RenderX

households. The eligibility criteria involved Czech households with at least 1 adolescent (aged between 11 and 16 years) and 1 caregiver who could complete an online questionnaire. We used quotas for the region, based on the Nomenclature of Territorial Units for Statistics; the municipality size; and the household socioeconomic status, based on the highest achieved education, to reach the proportional representation for Czech households with children. Furthermore, we set quotas for adolescents' age and gender to ensure equal distribution. We collected 3 waves of data, 6 months apart, starting in June 2021 and finishing in June 2022.

The computer-assisted web interviewing method was used. The agency emailed their panelists an invitation to the study, which included information about the survey, eligibility, and the procedure for filling out the questionnaire. The invitation contained a link to the PDF version of the adolescent questionnaire so the parent could check what the child would be asked to complete. After filling out the basic information needed for quotas and providing active consent for their child's participation, the parents called the respective child to complete the questionnaire. They were advised to ensure the child's privacy during the survey completion. Adolescents were also asked for active consent and told they could refuse participation without any consequences at the beginning of the questionnaire. The survey started with a brief introduction and informed adolescents that each question included "I don't know" and "I prefer not to say" response options. After the adolescents finished the questionnaire, they were debriefed and informed that clicking "Continue" would lock their answers, and the parents could not access them.

The survey was thoroughly pretested via cognitive interviews (ie, 30 adolescents and 2 parents) and a pilot study (ie, 195 adolescent-caregiver dyads) to ensure the comprehension of the questionnaires, check the data distributions, and determine the dimensions and internal reliabilities of the scales. Following the data collection, the research agency conducted quality checks to inspect completion times and the consistency of the entries.

The sample consisted of 1654 adolescents at time 2 (T2; n=800, 48.4%; mean age 13.43 years) and 1102 adolescents at time 3 (T3; n=532, 48.3% girls; mean age 13.37 years). The retention rate was 66% in the second wave and 44% in the third wave. Due to missing values, the final analyses used data from 2232 adolescents (n=1089, 48.8% girls; mean age 13.43, SD 1.69 years).

Ethical Considerations

The research ethics committee of Masaryk University approved this study (EKV-2018-068). The data and the analysis scripts are shared via the Open Science Framework [72].

Measures

mHealth App Use

Adolescents answered the following question to assess mHealth app use: "You can use various applications on your phone, tablet, and other devices. Do you use applications to monitor health and exercise (eg, counting steps, tracking calories, weight, sports activities, eating/drinking, stress, sleep)?" The response options included (1) "No" and (2) "Yes." This study focused on mHealth app use related to calorie intake and expenditure, weight management, and sports activity. Therefore, the adolescents who reported using mHealth apps were asked an additional question: "Such applications can be used to monitor or record data in various areas of health. How often have you used them in the last six months in the following areas?" The response options included (1) "calorie intake or expenditure," (2) "weight," and (3) "sports activity (eg, exercise, running, and working out)." These apps address lifestyle behaviors commonly used among adolescents [9]. Furthermore, the targeted lifestyle behaviors in these apps (ie, sports activities engaged, calories consumed or burned, and weight loss achieved or failed) are closely connected with body size, shape, and weight, which may influence adolescents' perceptions of their bodies and vice versa. Although other mHealth apps are also available, such as those that track vitals, heart rate, and sleep, the targeted behaviors in these apps are not directly connected with quantifying the body size, shape, or weight. Furthermore, users might engage in them due to a medical condition.

A 7-point Likert scale determined the frequency of use: (1) "never," (2) "once," (3) "no more than a few times," (4) "several times a month," (5) "several times a week," (6), "daily," and (7) "several times a day." We did not distinguish between the lifestyle behaviors addressed via apps. Therefore, an average score was computed to evaluate the frequency of mHealth app use. Adolescents who responded to the first question with a "No" (ie, adolescents who did not use mHealth apps) were categorized under the "never" frequency category at each wave. This approach allowed us to examine fluctuations in mHealth app use over time for all participants. The internal consistencies were acceptable across waves, and the Cronbach α values ranged between 0.87 and 0.88. The results supported the multigroup metric invariance over time (difference between the configural and the metric model: $\Delta\chi^2_6$=4.0179; *P*=.67).

Physical Self-Worth

Physical self-worth was measured with the physical self-worth subscale of the Physical Self Inventory-Short Form for adolescents [73,74]. It is an adapted version of the Physical Self-perception Profile developed for adults by Fox and Corbin [28]. The items were as follows: "I am proud of what I can do physically," "I am happy with who I am and what I can do physically," and "I am confident about my physical self-worth." The scale applies a 6-point Likert scale ("not at all" to "entirely"). The response scale in this study included (1) "very untrue," (2) "somewhat untrue," (3) "neutral," (4) "somewhat true," and (5) "very true." Higher scores on the scale reflected higher global physical self-worth. The internal consistencies were acceptable, and Cronbach α values ranged between 0.91 and 0.92 across the waves. The results supported the multigroup metric invariance over time (difference between the configural and the metric model: $\Delta\chi^2_6$=8.491; *P*=.20).

Body Dissatisfaction

Body dissatisfaction was measured with items from the body dissatisfaction subscale of the Eating Disorder Inventory-3 [75]. The original subscale consists of 10 items that evaluate

XSL•FO
RenderX

dissatisfaction with the overall body shape and body parts. The scale applies a 6-point Likert scale ("never" to "always") and measures the extent to which positive and negative evaluations relate to each body part and the overall figure. In this study, adolescents reported how satisfied versus dissatisfied they were with their overall figure, thighs, stomach, hips, and buttocks with the following response options: (1) "very dissatisfied," (2) "rather dissatisfied," (3) "neutral," (4) "rather satisfied," and (5) "very satisfied." The items were recoded so that higher scores indicated greater body dissatisfaction. The internal consistencies were acceptable, and Cronbach α values ranged between 0.91 and 0.94 across the waves. The results supported the multigroup metric invariance over time (difference between the configural and the metric model: $\Delta\chi^2_{10}$=14.547; *P*=.15).

Age, Gender, and BMI

Adolescents indicated their age and gender at baseline. They also reported their height (in centimeters) and weight (in kilograms) to calculate their BMI. The mean BMI was 20.57 (SD 4.46; N=2220) kg/m^2.

Statistical Analysis

We analyzed the longitudinal data using multigroup structural equation modeling in lavaan 0.6 to 11 with the robust maximum likelihood estimator. The groups compared in the analyses were boys and girls, and we tested for differences in path estimates for these groups with likelihood ratio test. Given that we were interested in causal research questions, we tested the RI-CLPM, which decomposes observed variance into within-person and between-person levels [76]. This level of analysis accounts for the broad between-person individual differences and captures the within-person situational changes.

The model was recursive and had 2232 observations (ie, n=1143, 51.2% for boys and n=1089, 48.8% for girls) and 138 free parameters. No latent variables with multiple indicators were specified. Apart from the variables of interest, we included age and BMI, measured at wave 1, as time-invariant covariates in the model. We used full information maximum likelihood to handle missing data. This method of estimation uses all available data, including partially missing data, to produce parameter estimates, and it is an adequate method even when attrition across waves is present [77]. The attrition analysis was conducted using the multivariate ANOVA. It demonstrated that participants participating in all the waves did not differ from dropouts in the demographic and tested variables of interest (Pillai V=0.06; $F_{12,4182}$=1.08; *P*=.37).

Results

Overview

Descriptive findings are presented in Table 1, and the intercorrelations between the variables across waves are presented in Table 2. The highest correlations were usually between the same variables measured in different waves. There were also relatively high negative correlations between physical self-worth and body dissatisfaction.

Table 1. The sample sizes, means, and SDs of variables across waves.

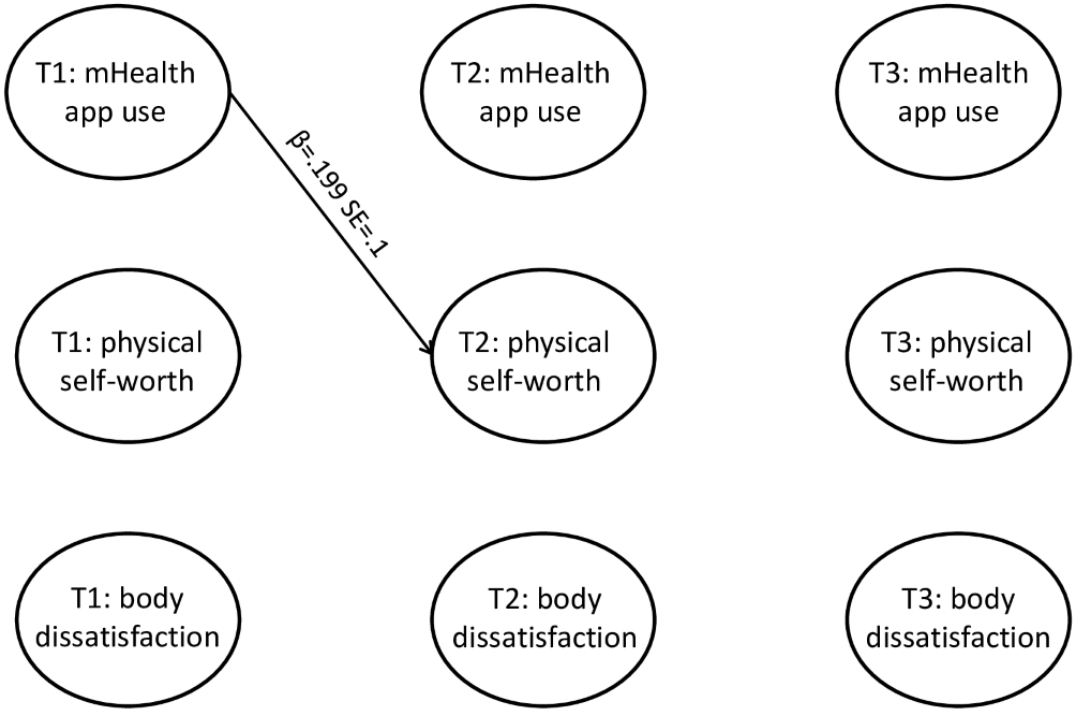
The fit indices indicated an acceptable fit for the RI-CLPM, χ^2_{30}=40.99 (*P*<.001), root mean square error of approximation=0.02 (90% CI 0.00-0.03), comparative fit index=0.99, standardized root mean square residual =0.02. According to the study by Browne and Cudeck [78], root mean square error of approximation values <0.08 are reasonable for using a model. Other fit indices also indicated acceptable model data correspondence.



The results of the RI-CLPM for boys are presented in Figure 2 and for girls in Figure 3. The figures represent only the significant paths in the analyses. For more detailed results, including the control variables and the standardized and unstandardized results of all paths, refer to Multimedia Appendix 1. The random intercepts in the RI-CLPM capture the trait-like stability; thus, we can expect lower autoregressive coefficients in general as they represent carryover effects. Our findings showed at least some carryover effect for the constructs among boys (ie, mHealth app use and physical self-worth; Figure 2), but this was not true for girls (Figure 3).

Figure 2. Results of the random intercept cross-lagged panel model (RI-CLPM) for adolescent boys. T1: time 1; T2: time 2; T3: time 3; SE: standard error.

XSL•FO
RenderX

Figure 3. Results of the random intercept cross-lagged panel model (RI-CLPM) for adolescent girls. T1: time 1; T2: time 2; T3: time 3; SE: standard error.

mHealth App Use and Physical Self-Worth

In the model for boys (Figure 2), none of the lagged paths from mHealth app use were significant. Thus, when an adolescent boy used mHealth apps more frequently than usual, this change did not affect his physical self-worth 6 months later. On the other hand, in the model for girls, the lagged path from mHealth app use to physical self-worth was significant from T1 to T2 (β=.199, *P*=.04; Figure 3) but not from T2 to T3 (β=.161, *P*=.07; Table S1 in Multimedia Appendix 1), showing an inconsistency across the waves. These results show that when an adolescent girl used mHealth apps more frequently than usual, she would report higher physical self-worth 6 months later. However, an adolescent girl who reported more frequent use of mHealth apps than usual at T2 did not report higher physical self-worth at T3.

Regardless of gender, none of the lagged paths from physical self-worth were significant. Thus, when adolescents reported higher physical self-worth than usual, this change did not affect their app use frequency 6 months later.

mHealth App Use and Body Dissatisfaction

None of the within-person associations between mHealth app use and body dissatisfaction were significant. Regardless of gender, when adolescents reported higher body dissatisfaction than usual, this change did not affect their app use frequency 6 months later. In addition, changes in app use frequency were not associated with changes in adolescents' body dissatisfaction 6 months later.

Body Dissatisfaction and Physical Self-Worth

Although it was not among our research interests, we found negative reciprocal within-person associations between physical self-worth and body dissatisfaction, but only among boys from T2 to T3 (Figure 2). This finding indicated that when an adolescent boy reported higher physical self-worth than usual at T2, he would likely report lower body dissatisfaction at T3 (β=–.307, *P*<.001). Similarly, when an adolescent boy reported higher body dissatisfaction than usual at T2, he would be less likely to report physical self-worth at T3 (β=−.228, *P*=.04).

Comparison of Effect Sizes Between Genders

We examined the significance of the intergroup differences for the causal effects that were significant either among boys or girls. Although these differences were nonsignificant, some of the effects in one group were at least twice the size of the effects of the other group. Thus, we can assume that they might still have some practical meaning but should be interpreted cautiously. It was the case for the negative reciprocal within-person effects between physical self-worth and body dissatisfaction, which were significant in boys from T2 to T3 (Figure 2). For girls, there was a considerable difference in the effect of mHealth app use on physical self-worth from T1 to T2 (Figure 3).

Discussion

Principal Findings

Overview

This study used 3-wave longitudinal panel data to examine the temporal and reciprocal associations between adolescents' body dissatisfaction, physical self-worth, and mHealth app use over time. We applied the RI-CLPM as an analytical approach to disentangle the within-person and between-person variance to determine the directionality of the associations. We used a multigroup model for boys and girls and included BMI and age as confounding variables in the analyses. This study provided the first comprehensive information on the long-term

XSL•FO
RenderX

associations between adolescents' attitudes toward their bodies and their mHealth app use.

mHealth App Use and Physical Self-Worth

mHealth app use had a significant within-person effect on adolescent girls' physical self-worth from T1 to T2. In other words, an increase in the mHealth app use frequency of an adolescent girl increased the physical self-worth of the same adolescent girl 6 months later. There is no previous research to compare to our findings. However, previous randomized controlled trials demonstrated the positive impact of mHealth apps on adolescents' health outcomes, physical activity levels, and weight outcomes [3,13-15]. Our finding expands upon these previous studies by showing that, in addition to shaping health-related behaviors (ie, physical activity levels and weight outcomes), mHealth apps could positively influence how adolescent girls view their physical selves. Previous studies reported a connection between higher physical self-perceptions and overall well-being in adolescent populations [79,80]. Our finding suggests that using apps for sports, nutritional intake, and weight management could be a viable route to enhance adolescent girls' physical self-perceptions that might contribute to their overall well-being. Future research might examine whether enhanced physical self-perceptions mediate between mHealth app use and health-related behavior change in adolescent girls. In addition, behavioral change techniques that positively influence the physical self-perceptions of adolescent girls upon mHealth app use warrant further research attention.

A similar association was not observed in boys at 6 months. An increase in the mHealth app use frequency of an adolescent boy did not increase the physical self-worth of the same adolescent boy 6 months later. When we tested for the significance of the effect size differences between genders, we observed that the difference in effect sizes was statistically insignificant, although it was considerably large. Therefore, we decided to interpret the gender differences. One possible explanation for increased physical self-worth in girls upon mHealth use, but not in boys, could be related to gender role expectations related to health and appearance. Societal expectations place a disproportionate burden on girls to conform to a thin and fit ideal, influencing the health discourse [81]. There is also a growing emphasis on individuals taking personal responsibility for their health, further compounding this burden [17,19]. Adolescent girls often feel pressured to conform to culturally defined health standards, and they are more inclined to use self-tracking technologies to manage their appearance [82]. Previous research identified a positive association between health-related behaviors (eg, physical activity) and self-worth via increased positive perceptions about physical appearance in adolescent girls but not boys [83]. In addition, physical conditioning, body appearance, and sports competence perceptions were similarly associated with physical self-worth in adolescent girls, implying that being thin and athletic are significant determinants of their physical self-worth [84]. It is possible that using mHealth apps empowers girls more than boys by giving them a sense of self-discipline and control over their bodies to enhance their health (physical conditioning and sports competence) and manage their weight and appearance. This empowerment may contribute to heightened levels of physical self-worth in them. However, this effect was not maintained at the 12th month (T3). In other words, there was no significant increase in physical self-worth at T3 for the adolescent girls who used mHealth apps more frequently at T2. Our findings indicate that the observed positive effect of mHealth apps on the physical self-worth of adolescent girls is not stable, and the circumstances we were unable to capture in this study might better explain the observed association. This study's first and second waves of data collection coincided with a period when strict lockdown regulations for the COVID-19 pandemic were gradually loosening, although they were not entirely lifted. In contrast, the third wave occurred when the COVID-19 pandemic–related regulations were no longer in force. Research suggests that during the COVID-19 pandemic, adolescents experienced reduced physical activity, difficulty managing food intake, and weight gain [85-87]. It is plausible that adolescent girls appreciated enhancing their physical capabilities through the surveillance of mHealth apps more during the period between the T1 and T2 assessments—a period of relative isolation and restricted mobility—compared to the period between the T2 and T3 assessments when normalcy returned, and alternative methods for enhancing physical self-perceptions became available. However, these interpretations are speculative. Further research is required to understand the long-term effect of mHealth apps on adolescent girls' physical self-worth.

mHealth App Use and Body Dissatisfaction

We found no significant within-person effect of mHealth app use on body dissatisfaction. In other words, regardless of gender, a within-person increase in using mHealth apps did not result in changes in body dissatisfaction 6 months later. There is no previous study using a longitudinal design to compare our findings. However, they contradict previous cross-sectional research that either reported a positive association between using mHealth apps and body satisfaction in young adults [20] or suggested that mHealth apps might induce or exacerbate body dissatisfaction [52-54]. Our findings indicated that after 6 months, adolescents' body dissatisfaction did not significantly change upon mHealth app use. We recommend exploring time-specific changes in body dissatisfaction as a function of the short-term and long-term use of mHealth apps for future research. For instance, a daily diary study could provide valuable insights into the immediate impact of mHealth apps on body satisfaction or dissatisfaction. In addition, future research is required to examine whether the within-person effect of mHealth apps on body satisfaction or dissatisfaction might take longer than 6 months to manifest.

We also did not observe a significant effect of body dissatisfaction on mHealth app use when we examined the reverse relationship. In other words, regardless of gender, a change in body dissatisfaction did not change the frequency of using mHealth apps 6 months later in our sample. In the only prospective study conducted by Hahn et al [21], body dissatisfaction during adolescence was predictive of using mHealth apps in emerging adulthood (ie, 8 years later) in men. Our findings did not support the results of this study. Changes in body dissatisfaction did not shape the frequency of using mHealth apps within 6 months. One possible explanation for this inconsistency could be the time lag between the assessment

XSL•FO
RenderX

points in the 2 studies. Although body dissatisfaction might predict mHealth app use in men from adolescence to early adulthood [21], such an association might not be revealed in shorter durations during adolescence, such as in 6 months, as in our study. However, it should be kept in mind that the findings of Hahn et al [21] cannot translate to a causal impact at the within-person level because they represent between-person associations. We did not observe a within-person relationship between mHealth app use and body dissatisfaction in a representative sample of adolescents using 6-month intervals between the assessment points. These findings suggest that within-person fluctuations in body dissatisfaction might not influence mHealth app use in the short term during adolescence. Instead, the overall between-person differences in body dissatisfaction during adolescence might have a more substantial influence in predicting mHealth app use in the long term.

Body Dissatisfaction and Physical Self-Worth

Although examining the interrelationships between body dissatisfaction and physical self-worth was not our direct research interest, our analyses produced some interesting findings. We observed a negative reciprocal association between body dissatisfaction and physical self-worth between the T2 and T3 assessments in boys but not in girls. According to that, adolescent boys who reported higher body dissatisfaction than usual at the 6th month were likelier to report lower physical self-worth at the 12th month and vice versa. A similar association was not observed among adolescent girls. We tested for the significance of the effect size differences between genders. Although the effect size difference between genders was statistically insignificant, it was considerably large and might have practical implications. Body dissatisfaction is a significant risk factor for the increased rates of mental disorders in general, including eating disorders in boys [88,89]. Our findings indicate that dissatisfaction with body appearance and lower esteem in physical attributes are mutually reinforced in adolescent boys, which might increase the risk for eating disorders by creating a vicious cycle. Since boys are acculturated to obtain a muscular body appearance, and lately also a lean appearance, they might be more likely than girls to focus on physical qualities (ie, what they can do physically) to evaluate body appearance (ie, muscularity), and vice versa. These findings imply that interventions that address body dissatisfaction might benefit from components that enhance the physical self-concept in boys. Improving satisfaction, confidence, and pride in physical attributes in boys could have a causal mitigating effect on subjective negative evaluations regarding their body appearance. However, it should be noted that this effect was observed only between the T2 to T3 assessments, not between the T1 to T2 assessments; thus, whether the reciprocal association takes longer to manifest in boys or whether it is pronounced after the COVID-19 pandemic situation deserves further research attention.

Limitations and Future Research

Several limitations should be taken into account when evaluating the findings of this study. We did not examine mHealth apps separately. The decision was based on the observation that several mHealth apps for physical activity (such as Fitbit) also provide weight and calorie intake information. Thus, distinguishing between lifestyle behaviors would be arbitrary. In addition, we were interested in evaluating the most frequent lifestyle behaviors addressed via mHealth apps rather than specifically focusing on using certain apps. However, using an average score for app use instead of examining each lifestyle behavior separately (eg, weight, diet, and physical activity) might have limited our findings. Apps use diverse methods to collect data, including self-reported subjective information and objective data through embedded technologies such as GPS. We did not distinguish on the basis of the data collection type in this study and relied on subjective information regarding the frequency of using mHealth apps. Relying on subjective data limited our ability to control the response characteristics of the participants. The analyses included age and BMI as time-invariant control variables due to their robust associations with the study variables in previous literature. Although other variables, such as socioeconomic status, could also provide significant insights, a more parsimonious model was preferred given the complexity of RI-CLPM.

We assessed mHealth use based on the frequency of use and thus cannot ascertain if it resulted from health promotion efforts or unhealthy weight control behaviors. We interpreted the inconsistencies in significant findings across the waves based on the COVID-19 pandemic circumstances. However, it should be noted that our assessments coincided with Spring twice and Autumn once, which may also differentially impact time-specific individual deviations in the observed variables. Body dissatisfaction and physical self-worth measures were adaptations of frequently used questionnaires in the field, but they were not adequately validated. Nevertheless, we conducted cognitive testing with a subsample of participants to ensure the comprehensibility of items and the quality of the assessment procedure. Finally, our data did not include nonbinary or gender-diverse adolescents; thus, the findings cannot be generalized across a broader gender spectrum.

Future research can explore whether the observed associations might differ by the lifestyle behavior addressed via mHealth apps (eg, weight, diet, and physical activity) and the patterns of mHealth use (ie, functional vs dysfunctional use of mHealth apps). We also need future studies to replicate these findings in various countries and cultural backgrounds with data from gender-diverse samples of adolescents.

Conclusions

This study is the first to examine the longitudinal reciprocal associations between adolescents' physical self-worth, body dissatisfaction, and mHealth app use in a nationally representative sample of adolescents using a within-person approach. The findings revealed that within-person changes in body dissatisfaction and physical self-worth did not predict the frequency of using mHealth apps 6 months later. However, mHealth apps played differential roles in adolescents' body-related attitudes at the within-person level. Although inconsistent, we found that a within-person increase in using mHealth apps predicted higher physical self-worth in girls 6 months later. A similar association was not observed among boys. Regardless of gender, increased use of mHealth apps was

XSL•FO
RenderX

not associated with body dissatisfaction. These findings suggest that mHealth apps are unlikely to harm adolescents' attitudes toward their body appearance and physical self-worth. Furthermore, the use of these apps may even contribute to enhancing physical self-worth among adolescent girls.

Abstract

Background: Telemedicine has emerged as a promising tool to enhance adherence and monitoring in patients with eating disorders (EDs). Traditional face-to-face cognitive therapies remain the gold standard; however, integrating telemedicine may provide additional support and improve patient engagement and retention. Given the increasing use of digital health interventions, it is crucial to assess their safety and effectiveness in complementing conventional treatments.

Objective: We aimed to evaluate the safety and effectiveness of telemedicine as a complementary tool for cognitive face-to-face therapies to promote adherence and monitoring of patients with EDs.

Methods: We consulted the National Institute for Health and Care Excellence, the Canadian Agency for Drugs and Technologies in Health (now known as Canada's Drug Agency), MEDLINE (Ovid), Embase, Web of Science, Cochrane Library, international HTA database (International Network of Agencies for Health Technology Assessment), CINAHL (EBSCO), and PsycINFO (EBSCO) websites and databases in December 2024 to identify eligible systematic reviews, synthesis reports, or meta-analyses that address telemedicine as a complementary therapy to face-to-face care in patients with EDs. Two researchers performed an independent critical reading of the systematic reviews and assessed the risk of bias using AMSTAR-2 (A Measurement Tool to Assess Systematic Reviews, version 2).

Results: We initially identified 1004 studies, but only 5 (0.5%) systematic reviews met the inclusion criteria. Email, vodcasts, smartphone apps, and SMS text messaging were the principal telemedicine channels. Telemedicine interventions were safe, helpful, and motivating; improved retention rates and patient-physician communication; and reduced ED symptoms.

Conclusions: Telemedicine interventions showed promising, positive findings as a complementary tool for face-to-face ED treatment that must be interpreted cautiously. The limited number of systematic reviews selected and their moderate to critically low quality underscore the need for further research in this area.

Introduction

Background

Eating disorders (EDs) are psychiatric disorders defined as abnormal eating habits that negatively affect a person's physical or mental health and usually begin in late childhood or early adulthood. These are associated with significant medical, psychiatric, and psychosocial consequences.

The global burden of EDs was estimated at 6.6 million people by 2019 [1]. In Spain, the estimated prevalence was 13% in both sexes [2]. However, the COVID-19 pandemic had a negative impact on EDs, increasing the incidence among young people and the demand for care in most countries [3,4].

The most common EDs include anorexia nervosa (AN), bulimia nervosa (BN), binge eating disorder (BED), and eating disorder not otherwise specified (EDNOS). AN is characterized by an intense fear of gaining weight, persistent behaviors that interfere with weight gain, and a distorted perception of one's own body image. It often results in dangerously low body weight and can lead to severe medical complications, such as bradycardia, osteoporosis, amenorrhea, and electrolyte imbalances. BN involves recurrent episodes of binge eating—consuming unusually large amounts of food within a discrete period—followed by inappropriate compensatory behaviors, such as self-induced vomiting, excessive exercise, fasting, or misuse of laxatives or diuretics. Unlike AN, individuals with BN typically maintain their body weight within or above the normal range, which can delay recognition and diagnosis. BED is defined as repeated episodes of uncontrollable overeating without the regular use of compensatory behaviors, often accompanied by feelings of guilt, shame, and emotional distress. BED is the most prevalent ED and is frequently associated with overweight and obesity. EDNOS, now referred to in *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* as other specified feeding or eating disorder, encompasses clinically significant eating disturbances that do not meet the full criteria for AN, BN, or BED. Examples include atypical AN (significant weight loss despite normal weight), purging disorder, and night eating syndrome. EDNOS represents a substantial portion of ED diagnoses, especially in clinical settings, and is associated with comparable levels of psychological distress and functional impairment [5,6]. The onset of EDs generally occurs between the ages of 10 and 20 years, although BED and EDNOS may appear in slightly older age groups [6].

EDs are associated with numerous physical problems (eg, diabetes, hypertension, and ulcers) and mental disorders (eg, anxiety disorder and depression) [5]. Patients with EDs have significantly higher mortality and suicide rates compared to the standard population [6,7]. The etiopathogenesis of ED is complex and not yet well understood. It may arise from the interaction of multiple risk factors, including genetic, neurobiological, psychological (eg, body image disturbances and personality disorders), developmental factors (eg, childhood sexual abuse), and sociocultural factors [8].

Given that EDs show great variability in their manifestation and severity, the treatment requires multidisciplinary collaboration of psychiatrists, psychologists, general practitioners, nutritionists (or endocrinologists), dieticians, nurses, and occupational therapists [2]. The treatments include medical nutritional support, pharmacological treatments, and psychological therapies. Cognitive behavioral therapies (CBTs) have been shown to be effective for the treatment of EDs and are considered the therapies of choice by psychologists for both treatment and ongoing support of patients with EDs [2]. Many therapists have observed telemedicine as an alternative to face-to-face therapy in extreme health situations, such as during the COVID-19 pandemic, although the availability of technological equipment for its administration has been uneven.

Telemedicine is the use of telecommunication systems to provide health care at a distance [9]. It involves the secure transmission of medical data and information via text, sound, images, or other forms necessary for the prevention, diagnosis, treatment, and monitoring of patients (EU Commission definition, COM {2008}689) [10]. Methods may vary in terms of the way the intervention is technically implemented, using tablets, smartphones, and computers, and the channels such as smartphone apps, websites, SMS text messaging, and vodcast, among others. In recent years, considerable progress has been made in the development and validation of psychological treatments administered through telecommunication systems. The popularity of telemedicine has increased rapidly in recent decades, and researchers have realized its potential in mental health and health in general. Telemedicine is a current trend as it is estimated that more than 50% of the population in high- and middle-income countries suffer from at least one mental disorder in their lifetime, with a significant impact on their quality of life [11].

Several factors have contributed to the growth in the adoption of telemedicine in health care, such as significant advances in communication technologies, the widespread use of high-speed internet, and the COVID-19 pandemic. The COVID-19 pandemic catalyzed the rapid and global adoption of telemedicine solutions in daily practice in all health care fields [12] due to the need for physical distancing and the shortage of health care professionals [13]. However, the implementation of telemedicine also raises technical and privacy concerns, including data security, patient confidentiality, cybersecurity vulnerabilities, and disparities in digital literacy and access to technology. Addressing these issues is crucial to ensuring the safe, ethical, and equitable delivery of care through telecommunication platforms [14-16]. The integration of technology into the study and treatment of EDs has taken many forms, including independent web-based intervention platforms, virtual reality interventions, smartphone apps, and technology-based treatment add-ons [17,18].

Objectives

We aimed to evaluate the safety and effectiveness of telemedicine as a complementary tool for cognitive face-to-face therapies to promote adherence and monitoring in patients with an ED undergoing treatment.

XSL•FO
RenderX

Methods

Overview

We conducted a systematic review of the literature of telemedicine and EDs following the recommendations contained in the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) reporting guidelines [19]. The research question was established in PICO (population, intervention, comparison, and outcomes) format. The review was conducted in accordance with a prespecified protocol, although this was not registered in a public database.

Source and Search Strategy

We searched the following health evaluation agency websites and databases: the National Institute for Health and Care Excellence, the Canadian Agency for Drugs and Technologies in Health (now known as Canada's Drug Agency), MEDLINE (Ovid), Embase, Web of Science, Cochrane Library, international HTA database (International Network of Agencies for Health Technology Assessment), CINAHL (EBSCO), and PsycINFO (EBSCO). Structured and systematic search strategies specific to each resource consulted were constructed using free and controlled terminology to identify the relevant studies (Multimedia Appendix 1). The last update was conducted in December 2024 without temporal restrictions.

Eligibility Criteria

All identified references were initially filtered by title and abstract, and later, after full-text reading, using the following inclusion criteria: systematic reviews, synthesis reports, or meta-analyses studies that address telemedicine as a complementary therapy to face-to-face care; patients with an ED diagnosis and under treatment; and without language limits. Other study designs, editorials, letters to the editor, opinions, notes, surveys, consensus documents, conference abstracts, systematic reviews without assessment of the methodological quality of the included studies, and animal studies were excluded. A review of systematic reviews was selected to avoid redundancy and build on existing high-quality evidence.

Data Extraction

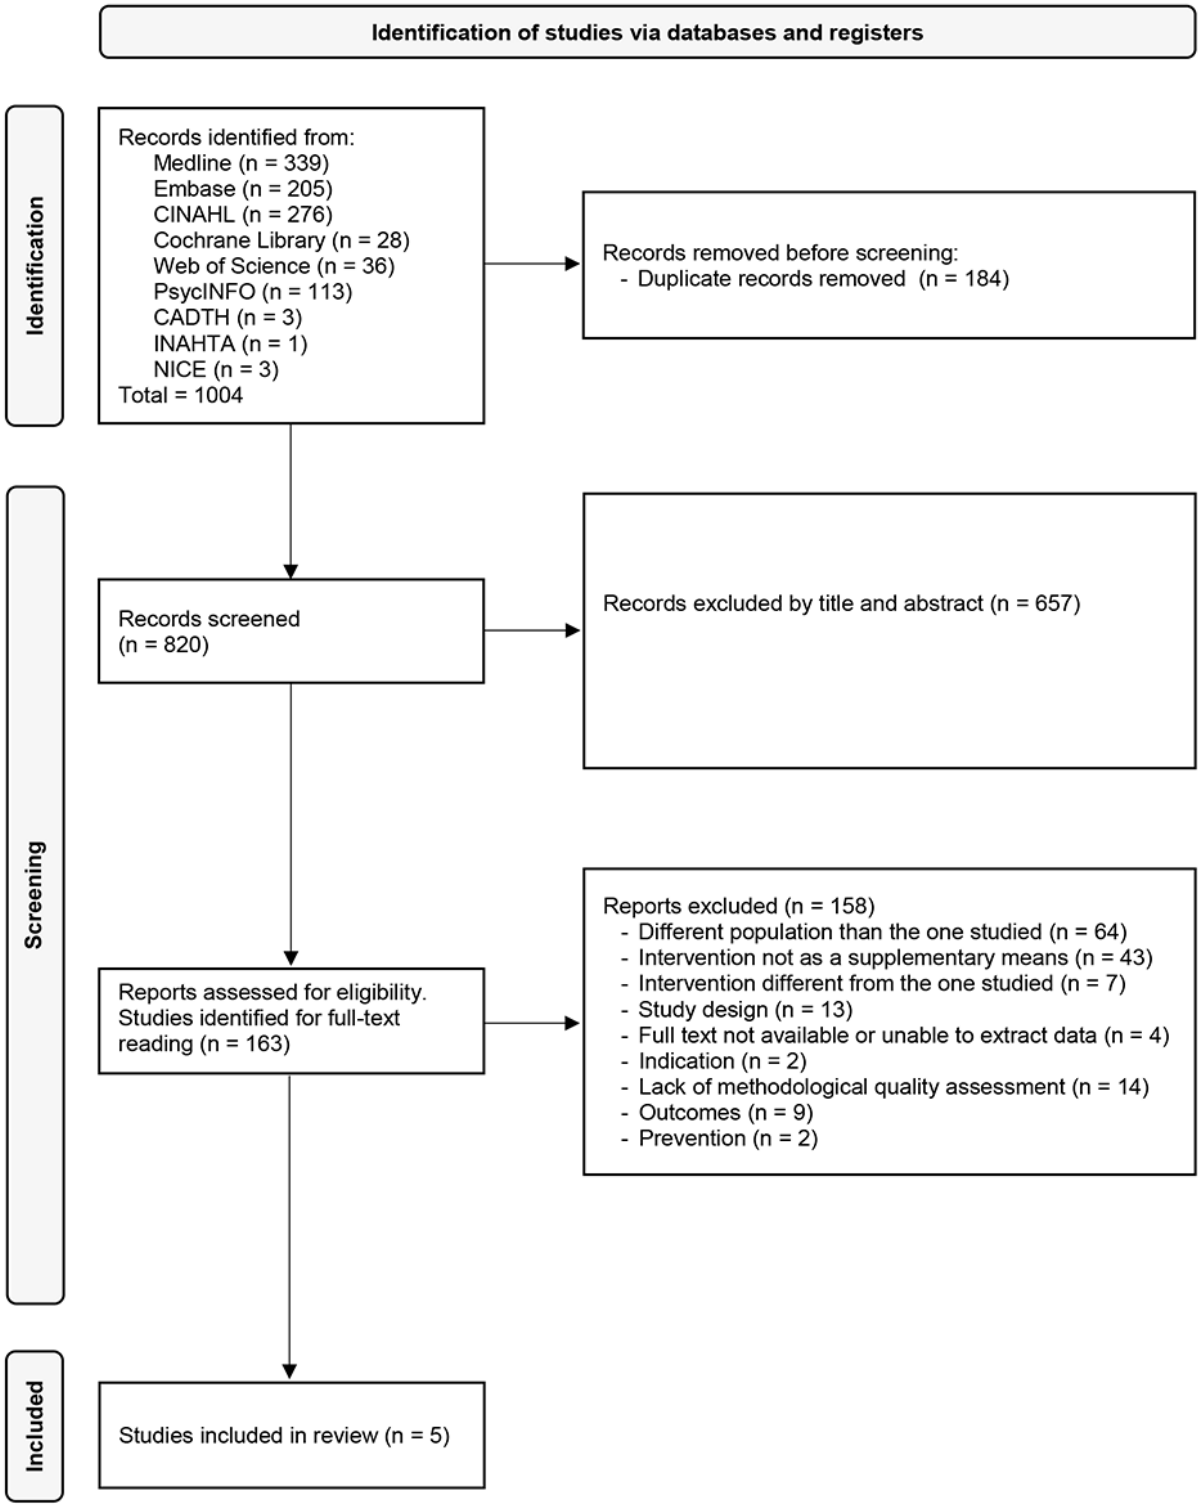
The authors, country, year of publication, objectives, study design, patient characteristics, databases consulted, date of the search, intervention, time of follow-up, and result measures of the included studies were extracted and summarized in tables.

Methodological Quality Assessment

Two researchers performed an independent critical reading of the systematic reviews and assessed the risk of bias in the included studies, following the methodology established in AMSTAR-2 (A Measurement Tool to Assess Systematic Reviews, version 2) [20]. Potential disagreements were resolved by consensus.

Analysis and Synthesis of Results

We performed a qualitative synthesis of the primary outcome measures following the reporting criteria established by the PRISMA guidelines [19]. We collected them in tables for the descriptive and narrative analysis. Although a meta-analysis was initially considered, the substantial heterogeneity in intervention types and outcome measures across the included studies made this approach inappropriate. A qualitative synthesis was chosen to provide a comprehensive overview of the available evidence.



Results

Included Studies

A total of 1004 studies were initially identified from the search in the MEDLINE, Embase, CINAHL, Cochrane Library, Web of Science, PsycINFO, Canadian Agency for Drugs and Technologies in Health (now known as Canada's Drug Agency) international HTA database, and National Institute for Health and Care Excellence databases and websites, but 184 (18.3%) duplicates were removed before screening. Therefore, 820 studies were included in the screening process. Figure 1 shows a flow diagram of the screening process and the reasons for exclusion. Briefly, 80.1% (657/820) of studies were excluded by title or abstract because they did not meet the inclusion criteria. The remaining 19.9% (163/820) studies were assessed for eligibility. After full-text reading, 96.9% (158/163) studies were excluded due to different reasons, such as different populations than the one studied, intervention not as a supplementary means, or lack of methodological quality assessment, among others. Finally, 5 studies were included in the review.

Characteristics of the Included Studies

We identified 5 systematic reviews on telemedicine as a complementary tool to face-to-face care, published between 2011 and 2021. The characteristics of these systematic reviews are summarized in Table 1. These reviews varied in their intervention types, study populations, study designs, and geographic focus, reflecting the diverse landscape of telemedicine research in EDs.

Study and year	Intervention	Country	Population	Number of primary studies	Risk of bias assessment	Objective of the study	Resources consulted and search date
Neumayr et al [34], 2021	Smartphone app as a complement to face-to-face CBT-based therapy	Germany	Women with BN and BED (N=66)	1 experimental RCT [27]	The quality assessment of all included publications was conducted according to 10 of the 14 codes for weaknesses [20]	To identify the apps for the mental disorders depression, anxiety, and ED that have already been evaluated internationally; check their availability in the German app stores, as well as their availability in German; and present the results of the RCTs.	PubMed, PsychINFO, and PSYNDEX; June 2018

[a]CBT: cognitive behavioral therapy.

[b]AN: anorexia nervosa.

[c]EDNOS: eating disorder not otherwise specified.

[d]RCT: randomized controlled trial.

[e]ED: eating disorder.

[f]BN: bulimia nervosa.

[g]BED: binge eating disorder.

[h]N/A: not applicable.

[i]GRADE: Grading of Recommendations, Assessment, Development, and Evaluation.

[j]DARE: Database of Abstracts of Reviews of Effects.

[k]MMAT: Mixed Methods Appraisal Tool.

[l]ASSIA: Applied Social Sciences Index and Abstracts.

The included reviews covered a wide range of telemedicine interventions, including email support (Aardoom et al [21] and Martin et al [16]), smartphone apps (Neumayr et al [34]), SMS text messages (Hay and Claudino [33]), and mHealth tools such as vodcasts (Anastasiadou et al [14]). These interventions were generally designed as adjuncts to face-to-face CBT, with a focus on providing motivational support, symptom monitoring, and psychoeducation.

The studies included in these reviews targeted various populations with EDs, including individuals with AN, BN, BED, and EDNOS. Most of the included studies focused primarily on women (513/617, 86.5%), although 2 reviews (Anastasiadou et al [14] and Neumayr et al [34]) included studies with both male and female participants, representing 13.52% of the total study population. This gender imbalance reflects the typical distribution of EDs but highlights the need for more inclusive research in this area.

The included systematic reviews incorporated a variety of study designs, including randomized controlled trials (RCTs), non-RCT experimental studies, observational case series, and crossover studies. Notably, there was some overlap in the primary studies included in these reviews. For example, the RCT by Hildebrandt et al [30] was included in the studies by both Anastasiadou et al [14] and Neumayr et al [34], while the observational case series studies by Yager et al [22,23] were included in the studies by both Martin et al [16] and Aardoom et al [21].

As summarized in Table 1, most of the included studies were conducted in high-income countries, including the United States, the United Kingdom, and Germany. This geographic concentration may limit the generalizability of the findings, as telemedicine interventions can vary significantly in their accessibility and effectiveness across different health care systems and socioeconomic contexts.

Several primary studies were included in the multiple reviews, highlighting the interconnected nature of the evidence base in this field. For example, the case series included in the reviews by Martin et al [16] and Aardoom et al [21] were largely overlapping, as were some of the experimental studies included in the reviews by Anastasiadou et al [14] and Hay and Claudino [33]. This overlap underscores the importance of carefully evaluating the quality and relevance of included studies to avoid double-counting evidence in future reviews.

Overall, the included reviews reflect a diverse but sometimes overlapping body of evidence on the use of telemedicine as a complementary tool for the treatment of EDs, emphasizing the need for more rigorous primary studies with broader population samples and more standardized outcome measures.

Quality Assessment

None of the 5 systematic reviews performed a meta-analysis. The methodological quality of the reviews was evaluated by applying AMSTAR-2 domains criteria [20] (Multimedia Appendix 2 [14,16,20,21,33,34]).

XSL•FO
RenderX

The systematic reviews by Martin et al [16] and Hay and Claudino [33] showed a moderate level of confidence. The main weaknesses were that they did not explicitly state that the review methods were established before the conduct of the review so that any significant deviation from the protocol could be justified [16], the exhaustive literature search strategy was partially presented [16,33], and their failure to explicitly provide the list of excluded studies and the justification for their exclusions [16,33]. Other methodological weaknesses found were related to the absence of information on the decision to include study design in the reviews analyzed [16,33], the failure to conduct peer selection or data extraction [16,33], and the absence of information on aspects related to the funding of the included studies 15,20]. The systematic reviews by Anastasiadou et al [14] and Neumayr et al [34] showed a low level of confidence. The main weaknesses were that they did not explicitly state that the review methods were established before the conduct of the review so that any significant deviation from the protocol could be justified [14,34], they partially presented the exhaustive literature search strategy [14,34], their failure to explicitly provide the list of excluded studies and the justification for their exclusions [14,34], and they did not explicitly provide the observed heterogeneity in the results of the review [14,34]. Other limitations found in these reviews were related to the absence of information on the decision to include the study design in the reviews analyzed and the absence of information on aspects related to the funding of the included studies. Finally, the systematic review by Aardoom et al [21] demonstrated a critically low level of confidence. The critical weaknesses were the failure to explicitly state that the review methods were established before the conduct of the review, making it difficult to justify any significant deviations from the protocol, as well as the absence of a predefined protocol. In addition, there was a partial lack of an exhaustive literature search strategy and a missing list of excluded studies, along with the reasons for their exclusion. Other identified limitations involved the lack of information regarding the decision to include specific study designs, the absence of peer selection or data extraction, and missing details about the funding of the included studies.

Safety of Telemedicine Interventions

The systematic reviews did not find direct adverse effects of telemedicine interventions on patients' health. However, Martin et al [16] and Anastasiadou et al [14] identified some patients' concerns about computer privacy using email and smartphone apps, respectively; particularly, with the personalized nature of SMS text messages treatment of patients with AN and BN (Multimedia Appendix 3 [14,16,21]).

The next section first describes the modalities of the technological interventions and then presents them organized by the conditions addressed.

Efficacy and Effectiveness of Each Telemedicine Intervention

Email

The systematic reviews by Aardoom et al [21] and Martin et al [16] included the same 2 observational case series studies [22,23] assessing the email as a complementary tool for the anorexia and EDNOS treatments (Tables 2 and 3). These studies were classified as having a low level of quality, and qualitative data could not be extracted. Patients considered the email helpful, motivating, and a good approach to keep in touch with the therapist, as it freed up time in face-to-face sessions. Patients highlighted that email provided positive emotional warmth because they could communicate with therapists whenever needed (Multimedia Appendix 3).

Vodcast

The systematic review by Anastasiadou et al [14] included 2 non-RCT experimental studies [24,25] and 1 observational case series study [26] that evaluated the vodcast as a complementary tool for ED treatment. The quality levels of these studies were moderate and low, respectively. The non-RCT used the vodcast "Supported eating" by mobile technology, and the observational study used the vodcast "Energy controller, mindful eating, motivation reflection" provided on a DVD. Regarding the non-RCT studies, within-group improvements in symptoms were found to be related to reductions in anxiety (P<.05) and an improvement in mood. In addition, an increase in food consumption and a more significant decrease in distress and attentional bias to food were also observed after the vodcast intervention among the patient group [24]. Regarding the observational case series study, the vodcasts were well accepted by the patients, who considered them useful, supportive, and motivating. They observed an increase in food intake and weight gain [26]. However, in the non-RCT [24], this mode of intervention was not considered very useful (Table 2; Multimedia Appendix 3).

Smartphone App

The systematic reviews by Anastasiadou et al [14], and Neumayr et al [34] included 1 RCT and 2 observational case studies that assessed smartphone apps; particularly, the Noom monitor app for patients with BN and BED [30], the CBT-based Food for Thought app for patients with AN and BN [27], and a smartphone app with the self-help program with personalized CBT and ecological momentary intervention modules for the treatment of patients with BED [28], respectively. The RCT [30] was included in both systematic reviews. The quality of these studies was moderate to low. According to the RCT study, smartphone app use reduces binge eating and purging episodes and increases patients' body mass. Regarding the observational case series studies, patients considered the smartphone apps feasible and acceptable and increased the frequency of food recording compared to the traditional method. However, the RCT did not show any differences in adherence and alliance between the intervention and control groups. Patients with BED participating in observational studies disclosed concerns about the personalization and privacy of this method (Tables 2-5-; Multimedia Appendix 3).

SMS Text Messages

The systematic reviews by Anastasiadou et al [14] and Hay and Claudino [33] included an experimental case study [29], a crossover experimental study [32], and an RCT [31] evaluating SMS text messaging as a complementary tool for BN, EDNOS, and AN treatment (Tables 2-4). Both systematic reviews included the same RCT [31]. SMS text messaging significantly decreased the number of episodes of purging and binge eating, symptoms of depression and ED, and late-night meals [14]. Similarly, significant differences were observed in remission rates between the intervention and control groups [14,33] (Table 5). The acceptability and feasibility of SMS text messaging by their users were satisfactory [14]. The feasibility scores were 91.5% of the daily entries and 87.4% of the daily food records in the crossover experimental study. Adherence was 87% in the experimental case series. Patients found the reminders helpful despite some doubts about personalizing the messages (Multimedia Appendix 3).

Efficacy and Effectiveness of Telemedicine Intervention by Eating Disorder

Anorexia Nervosa

Two non-RCT experimental studies [24,25] included in the systematic review by Anastasiadou et al [14] showed that vodcasts as a complementary treatment significantly reduced anxiety (*P*<.05) and negative thoughts (*P*<.05) and positively improved the mood of the intervention group participants in the subsequent evaluations compared to the control group receiving music treatment. In addition, vodcast increased food consumption and significantly decreased the distress and attentional bias to food after the intervention [14]. However, regarding the usefulness of vodcasts, one of the non-RCT experimental studies included in this review considered it not very useful and too focused on ED problems. In contrast, the observational study included in the same review highlighted that vodcast use increased food intake, reduced anxiety, and increased weight after 3 months. In this observational study, vodcasts were considered useful and a source of support and motivation.

XSL•FO
RenderX

According to a case series study included in the systematic reviews by both Aardoom et al [21] and Martin et al [16], email was a useful complementary therapy because it allowed patients to express themselves more easily and freed up time in face-to-face sessions in an outpatient setting. Table 2 and Multimedia Appendix 3 provide detailed information.

Bulimia Nervosa

The systematic review by Anastasiadou et al [14] included an experimental case series [29] assessing the within-group effect of SMS text messaging for self‐monitoring BN symptoms with CBT components after 12- and 24 weeks from intervention. Binge eating and purging episodes decreased significantly (within‐group effect size was 0.90 and 0.72, respectively). Symptoms of depression (Beck Depression Inventory: $P<.001$), ED (Eating Disorder Inventory: effect size=1.26), and nighttime eating (Night Eating Questionnaire: effect size=0.61) decreased significantly. In addition, the acceptability was above average, and the adherence was 87%. The attrition was 48.4% of the total study population and 60% of those who started treatment. Table 4 and Multimedia Appendix 3 provide detailed information.

Binge Eating Disorder

The systematic review by Anastasiadou et al [14] included an observational case series [29] assessing the use of a smartphone app with a self-help program that includes modules on CBT, personalized ecological momentary intervention, and self-monitoring. However, no information is available on its effects (Table 5). Patients considered the intervention feasible and acceptable. However, they expressed concerns about the personalization and adaptability of the app, as well as privacy and sharing issues (Multimedia Appendix 3).

Heterogeneous Study Population

Most of the primary studies included in the 5 systematic reviews were performed on a heterogeneous population of patients presenting different EDs. Table 3 and Multimedia Appendix 3 summarize the telemedicine effect found and the qualitative information extracted from these studies containing a heterogeneous population, respectively.

Briefly, the systematic reviews by Anastasiadou et al [14] and Neumayr et al [34] included an RCT [30] evaluating the Noom monitor app as a complementary tool for the treatment of patients with BN and BED. The study revealed greater reductions in binge eating and purging episodes than in the control group (objective bulimic episodes intergroup effect=0.41) and within-group improvements in ED-related symptoms (objective bulimic episodes, subjective bulimic episodes, eating disorder examination questionnaire) and the increase in BMI. No differences in treatment adherence or adherence were reported when compared to the control group.

The systematic reviews by Anastasiadou et al [14] and Hay and Claudino [33] included an RCT [31] evaluating the SMS text messages to prevent relapses in patients with BN and EDNOS. The study showed that SMS improved the abstinence levels at 8 months (37.8% vs 18.1%; $P<.01$), reduced the rate of women having complete symptoms of BN and EDNOS (32.9% vs 54.2%; $P<.01$), and increased remission rates (51.2% vs 35.1%; $P=.05$) compared to the usual treatment. In addition, the study by Anastasiadou et al [14] included an experimental crossover study [32] assessing SMS text messages to prevent relapse in patients with AN and BN. In this experimental crossover study, patients significantly reduced dietary restriction at 8 weeks (in-group effect size based on eating disorder examination questionnaire score=2.01) and significantly increased their willingness to change as measured by the Readiness and Motivation Questionnaire ($P<.05$). SMS text messaging was considered a feasible complementary tool (based on the 91.5% of the daily entries and 87.4% of the daily food records), with satisfactory acceptability (mean 7.05, SD 2.36 out of 10 points) and high retention rate (92.2%). Overall, users liked the text messages and the reminders' usefulness, although some disclosed dissatisfaction with the personalized nature of the messages.

Finally, the systematic reviews by Aardoom et al [21], Anastasiadou et al [14], and Martin et al [16] included observational studies assessing email and the Food for thought smartphone app as complementary tools for the treatment patients with AN, BN, and ED. These studies highlighted that email increased the frequency and time of contact between patients and clinicians, and that the Food for thought app increased the frequency of food registration compared to pen and paper.

Synthesis of Findings

Table 6 synthesizes the main findings extracted from the 5 systemic reviews selected, presented by type of ED, study design, and telemedicine intervention.

XSL•FO
RenderX

Table 6. Summary of findings.

ED[a] and the number of primary studies	Telemedicine resource	Summary of results
Anorexia nervosa [14,16,21]		
2 non-RCT[a] experimental studies [24,25]	Vodcast	• Significant increase in the amount of food consumed • Significant reduction in anxiety and negative thoughts • Significant improvement in positive mood • Significant decrease in distress and attentional bias to food • Considered unhelpful and too focused on eating disorder issues
2 observational case series [23,26]	Vodcast	• Increased food intake • Reduction in anxiety • Weight gain • Considered useful as a source of support and motivation
2 observational case series	Email	• Email use is experienced as positively useful • Frees up time in face-to-face sessions and allows patients to express themselves more easily • Concern about unwanted disclosures to third parties stemming from a lack of computer privacy
Bulimia [14]		
1 experimental case series [29]	SMS text messages	• Significant decrease in the number of binge eating and purging episodes (within-group) • Significant decrease in symptoms of depression and EDIc (within the group) • Significant decrease in late-night meals (within-group) • Above-average acceptability • 87% of adherence
BED[d] [14]		
1 observational case series [28]	Smartphone app	• Feasible and acceptable intervention • Concern for customization and adaptability of the app • Concerns about privacy and sharing
Heterogeneous study population [14,16,21,33,34]		
1 experimental RCT (BN[e] and BED) [30]	Smartphone app	• Significant reductions in binge eating and purging episodes • Significant within-group improvements in ED-related symptoms • Increased BMI
1 experimental RCT (BN and EDNOS[f]) [31]	SMS text messages	• Significant improvement in abstinence • Significant reduction in the proportion of women who continued to have full symptoms • Significant increase in retention rate
1 observational case series (AN[g] and ED) [23]	Email	• Email use is experienced positively • Helpful and motivating • A good approach to keep in touch with their therapist and make them aware of their eating behaviors and problems • Lack of satisfaction with the personalized nature of messages
1 observational case series (AN and BN) [28]	Smartphone app	• Increased frequency of food recording • Wide range of use • Acceptable and easy to use • A broad spectrum of patients

XSL•FO
RenderX

ED[a] and the number of primary studies	Telemedicine resource	Summary of results
1 experimental crossover study (AN and BN) [32]	SMS text messages	• Significant reduction in dietary restriction • Significant increase in willingness to change • Considered feasible • Satisfactory acceptability • High retention rate • Reminders were considered useful • Some participants in this study were not satisfied with the personalized nature of the messages

[a]ED: eating disorder.

[f]EDNOS: eating disorder not otherwise specified.

[g]AN: anorexia nervosa.

Discussion

Principal Findings

Despite the global burden of EDs [1,3,4] and the rapid and global adoption of telemedicine solutions in health care [12], only 5 systematic reviews were identified that discuss telemedicine interventions as a complementary tool to face-to-face ED treatments [14,16,21,33,34]. These reviews encompass a high heterogeneity of primary studies, highlighting the need for more comprehensive research in this area.

Regarding the effectiveness of these interventions, promising outcomes were observed, as presented in Textbox 1.

Textbox 1. Effective outcomes of telemedicine interventions.

Anorexia nervosa

Vodcast as a complementary treatment for anorexia nervosa (AN) was associated with substantial reductions in anxiety, negative thoughts, and improved positive mood compared to the control group. It also led to increased food consumption and reduced anxiety levels.

Bulimia nervosa

Significant reductions in binge eating, purging episodes, symptoms of depression, and nighttime eating were observed.

Binge eating disorder

In the observational study using a smartphone app, patients found the intervention feasible and acceptable.

Mixed eating disorders

Use of smartphone apps in patients with bulimia nervosa (BN) or binge eating disorder significantly reduced binge eating and purging episodes and improved both objective and subjective bulimic episodes within the group. It also increased BMI in these populations. SMS text messaging significantly reduced dietary restriction, improved readiness and motivation (as measured by the Readiness and Motivation Questionnaire), and reduced overall symptom severity in patients with AN or BN.

This study identified email, vodcasts, smartphone apps and SMS text messaging as the principal telemedicine channels offering patients access and adherence to treatment, improving patient-physician communication, and increasing patients' motivation. In most cases, patients highlighted the usefulness of telemedicine interventions. However, security and privacy issues remain a challenge, as some patients expressed concerns about the use of email and smartphone apps. Patients with EDs, who often struggle with distorted self-perception, may be particularly sensitive to privacy concerns [14].

Although none of the systematic reviews identified direct adverse effects of telemedicine interventions on patients' health, concerns about privacy in the use of email and smartphone apps were noted. Furthermore, while no technical or organizational problems were explicitly reported in the studies, the scientific literature highlights potential issues, such as technical problems [14], sound and video quality [16], difficulties in ensuring privacy (of parents and children), lack of adequate devices for telemedicine access, and connectivity problems [15]. These factors could impact the effectiveness and safety of telemedicine interventions.

No direct adverse effects of telemedicine intervention on patients' health were disclosed, although concerns about privacy in the use of email and smartphone apps were identified in some patients [14,16].

Telemedicine intervention showed promise as a complementary tool for face-to-face ED treatment with potential benefits for both patients and health care systems. However, it is important to acknowledge that most primary studies included in the systematic reviews were observational case series and non-RCTs, which limited the quantitative data on effectiveness. This highlights the urgent need for further high-quality research in this field. The systematic review by Anastasiadou et al [14]

XSL•FO
RenderX

highlighted the RCT study by Hildebrandt et al [30], which found that smartphone apps as an adjunct ED therapy in heterogeneous study populations increased BMI. These findings are particularly significant for patients with BN and BED, who are often overweight.

In terms of treatment adherence, some primary studies revealed a promising 87% retention rate among patients with BN who used SMS text messaging [29] and 78.8% among patients with BN and BED who used the Noom monitor app [30]. However, it is important to note that the potential efficacy of telemedicine in promoting treatment adherence is an area that requires more research, as the RCT [30] did not find differences in patients with BN and BED using the smartphone app compared with the control group.

The methodological quality of systematic reviews revised in this study ranged from moderate to critically low. This variation in confidence levels could potentially impact the risks of bias in their results. However, it is important to note that the AMSTAR-2 tool, which we used for this evaluation, does not consider the quality of the studies included in each document. Most of the primary studies included in the selected systematic reviews were observational studies with a small number of patients, leading the authors of the systematic reviews to classify them as low quality. We identified only 2 RCTs and 3 experimental studies among the 5 systematic reviews. It is worth mentioning that 2 case series and 2 RCTs were duplicated in some of the identified systematic reviews. The primary studies also had a limited number of interventions for the control group.

Given the limited literature specifically focused on EDs, it is also important to consider the findings of research on other mental health conditions. EDs frequently co-occur with psychiatric diagnoses, such as anxiety disorders, major depressive disorder, and obsessive-compulsive disorder, and share overlapping risk factors and symptomatology. Evidence from studies on these conditions has shown that telemedicine can be effective in supporting symptom monitoring, improving treatment engagement, and facilitating access to care, particularly in underserved populations. These broader findings may offer valuable insights into the potential benefits and limitations of telemedicine-based interventions for individuals with EDs, especially when comorbidities are present. Future studies on EDs should take this into account and incorporate more integrated approaches that address both EDs and commonly associated mental health disorders.

Limitations

The main limitation of our study is the limited number of systematic reviews identified that analyzed the effects of telemedicine interventions on face-to-face therapies in patients with ED. Overall, these systematic reviews showed a wide heterogeneity in the study designs, telemedicine interventions, ED conditions in the study population, follow-up periods, and outcome measures included in their selected primary studies. This heterogeneity undermines the quality level of of confidence and reduces the robustness of efficacy conclusions.

The studies included in this review were primarily conducted in high-income countries, such as the United Kingdom, the United States, and Germany. This geographical concentration likely reflects where telemedicine infrastructure is more established, funding for mental health research is more readily available, and digital health interventions are more commonly integrated into clinical practice. As a result, the findings may not be fully generalizable to low- and middle-income countries, where access to technology, internet connectivity, and specialized care for eating disorders remains limited. Socioeconomic disparities must therefore be considered when interpreting the applicability of telemedicine as a complementary approach in more diverse global settings.

Knowledge Gaps and Future Research

The heterogeneity of telemedicine intervention channels and ED conditions in the study population challenges the establishment of robust studies. More RCTs are needed to evaluate the usefulness and clinical efficacy of telemedicine interventions as complementary tools for face-to-face therapies in patients with EDs. Recording data based on established tools, such as assessment tools in EDs [35], may allow better analysis and comparison of the results.

Although few studies have evaluated telemedicine as a complementary treatment to face-to-face therapies, existing evidence suggests that this approach is promising for the treatment of EDs in youth. Previous studies have shown that telemedicine, particularly internet-based interventions such as internet-based CBT, can significantly improve pathological eating behaviors and reduce binge episode frequency in patients with binge-spectrum eating disorders [36,37]. Moreover, while further research is needed, especially regarding the use of videoconferencing and mobile apps, current findings support its potential as an effective tool within the therapeutic framework [38-41].

Although the reviewed studies suggest that telemedicine can improve treatment adherence and patient-clinician communication, evidence on its long-term impact on recovery and relapse prevention is limited. Studies with extended follow-up periods are needed to assess whether the short-term benefits persist over time.

Conclusions

In our review, 5 systematic reviews were identified that reported telemedicine as a complementary treatment to face-to-face therapies. The telemedicine tools identified in the included studies were vodcasts, SMS text messaging, smartphone apps, and email.

The synthesis of the results was carried out qualitatively due to the significant heterogeneity of the interventions, the population included, and different outcome measures and follow-up periods. It should be noted that the studies included in the reviews identified for analysis were of various designs and that the quality of the evidence reviewed was low or moderate. Tables 2-6 provide a detailed summary of the results and the quality of the included studies that can be used for the correct interpretation of the following conclusions:

- No direct adverse effects of telemedicine on patient health were identified, although concerns regarding privacy in the

XSL•FO
RenderX

use of email and smartphone apps remain a significant consideration for future research.
- Telemedicine interventions, including vodcasts and smartphone apps, have shown promise in improving patient motivation, reducing negative thoughts, and increasing adherence to treatment in patients with various EDs.
- Smartphone apps and SMS text messaging have been associated with reductions in binge eating, purging episodes, and dietary restrictions, as well as improvements in readiness to change and overall symptom reduction.

Despite these potential benefits, the overall quality of the evidence remains limited, with most included studies being observational case series with small sample sizes, leading to moderate to low confidence in the overall findings. Further high-quality research is needed to confirm the effectiveness of telemedicine as a complementary treatment for EDs.

Acknowledgments

The authors would like to thank the Ministry of Health for the development of the activities of the annual work plan of the Spanish Network of Health Technology Assessment Agencies and the National Health System for providing the funding; Dr Elena Baños, Área de Evaluación de Tecnologías Sanitarias de Andalucía (Andalusian Agency for Health Technology Assessment, Sevilla, Spain) for reviewing the protocol; and Cristina Gil Roda, medical writing (Barcelona, Spain), for her editorial assistance during the preparation of this manuscript for submission.

Authors' Contributions

JABA contributed to the conceptualization of ideas, formulation or evolution of overarching research goals and aims, data curation, formal analysis, conducting the investigation process, specifically performing the evidence collection, development or design of methodology, project administration and supervision, validation, and writing the original draft and the review of the manuscript. AD contributed to the conceptualization of ideas, formulation or evolution of overarching research goals and aims, data curation, formal analysis, conducting a research and investigation process, specifically performing the evidence collection, development or design of methodology, quality revision, validation, and writing the original draft and the review of the manuscript. RI-G contributed to conducting the investigation process, specifically performing the evidence collection and developing the methodology. EEP-O contributed to conducting the investigation process. EMVM contributed to the critical revision of the manuscript.

Abstract

Background: Self-guided internet-delivered cognitive behavioral therapy (ICBT) achieves greater reach than ICBT delivered with therapist guidance, but demonstrates poorer engagement and fewer clinical benefits. Alternative models of care are required that promote engagement and are effective, accessible, and scalable.

Objective: This randomized trial evaluated whether a stepped care approach to ICBT using therapist guidance via videoconferencing for the step-up component (ICBT-SC[VC]) is noninferior to ICBT with full therapist delivery by videoconferencing (ICBT-TG[VC]) for child and adolescent anxiety.

Methods: Participants included 137 Australian children and adolescents aged 7 to 17 years (male: n=61, 44.5%) with a primary anxiety disorder who were recruited from participants presenting to the BRAVE Online website. This noninferiority randomized trial compared ICBT-SC[VC] to an ICBT-TG[VC] program, with assessments conducted at baseline, 12 weeks, and 9 months after treatment commencement. All ICBT-TG[VC] participants received therapist guidance (videoconferencing) after each session for all 10 sessions. All ICBT-SC[VC] participants completed the first 5 sessions online without therapist guidance. If they demonstrated response to treatment after 5 sessions (defined as reductions in anxiety symptoms to the nonclinical range), they continued sessions without therapist guidance. If they did not respond, participants were stepped up to receive supplemental therapist guidance (videoconferencing) for the remaining sessions. The measures included a clinical diagnostic interview (Anxiety Disorders Interview Schedule) with clinician-rated severity rating as the primary outcome and parent- and child-reported web-based surveys assessing anxiety and anxiety-related interference (secondary outcomes).

Results: Although there were no substantial differences between the treatment conditions on primary and most secondary outcome measures, the noninferiority of ICBT-SC[VC] compared to ICBT-TG[VC] could not be determined. Significant clinical benefits were evident for participants in both treatments, although this was significantly higher for the ICBT-TG[VC] participants. Of the 89 participants (38 in ICBT-SC[VC] and 51 in ICBT-TG[VC]) who remained in the study, 26 (68%) in ICBT-SC[VC] and 45 (88%) in ICBT-TG[VC] were free of their primary anxiety diagnosis by the 9-month follow-up. For the intention-to-treat sample (N=137), 41% (27/66) ICBT-SC[VC], and 69% (49/71) ICBT-TG[VC] participants were free of their primary anxiety diagnosis. Therapy compliance was lower for the ICBT-SC[VC] participants (mean 7.39, SD 3.44 sessions) than for the ICBT-TG[VC] participants (mean 8.73, SD 3.08 sessions), although treatment satisfaction was moderate to high in both conditions.

XSL•FO
RenderX

Conclusions: This study provided further support for the benefits of low-intensity ICBT for children and adolescents with a primary anxiety disorder and highlighted the excellent treatment outcomes that can be achieved through therapist-guided ICBT delivered via videoconferencing. Although noninferiority of the stepped care adaptive approach could not be determined, it was acceptable to families, produced good outcomes, and could assist in increasing access to evidence-based care.

Introduction

Background

Anxiety disorders affect approximately 15% to 20% of children and adolescents, with symptoms and impacts (eg, impairment in academic, social, and family functioning) persisting without treatment [1]. Therefore, it is important to identify effective treatments that can be made widely accessible. Cognitive behavioral therapy (CBT) delivered through a face-to-face (F2F) modality has been well validated as an effective treatment for anxiety in young people [2] but involves substantial and costly therapist contact, with many young people being unable to access such treatments [3]. Internet-delivered CBT (ICBT) has been identified as a viable alternative for youth anxiety in several randomized controlled trials (RCTs) [2,4-6]. However, it is noted in meta-analytic reviews that the effects of ICBT are dependent on the level of therapist support or guidance provided during treatment [2,7]. Therapist-guided ICBT (ICBT-TG), where regular but minimal therapist guidance is provided in addition to an ICBT program, has demonstrated similar effects to F2F CBT and seems to promote greater treatment engagement and response than self-directed ICBT interventions [2,8,9]. While ICBT-TG may enhance engagement and produces good therapeutic outcomes, its widespread delivery requires the funding of therapist time and is constrained by issues of workforce shortages. By contrast, self-directed ICBT has the potential to reach thousands of young people and has been shown to produce moderate improvements in youth anxiety; yet, engagement with self-directed interventions is less than ideal, and, consequently, treatment effects are not optimal for all [9,10]. Alternative ICBT models are required that promote engagement and are effective, accessible, and scalable.

Stepped Care and Adaptive Interventions

Stepped care and adaptive interventions are potential alternative treatment models, where intervention type, modality, and intensity are adjusted based on treatment need or individual characteristics at various points during or after treatment steps [11]. Stepped care approaches aim to achieve a balance between intervention intensity and clinical effectiveness by "stepping up" intervention intensity only for those young people who need it. In stepped care models, all participants receive the same least intensive intervention first. Progress is then evaluated, and only those who need additional support are transitioned to a more intensive intervention [12,13]. Traditionally, in child anxiety, the evaluation of progress has occurred at the end of a treatment block, such as after the completion of an ICBT program (8-12 sessions; step 1), with children stepped up to further treatment (eg, F2F CBT) in the second step if required [14,15]. Such stepped care models have shown similar efficacy to a standard full program of F2F CBT [14]; yet, they offer greater efficiency in that not all young people need to progress to the more intensive and costly second step. However, stepped care delivered in this way means that those who are "stepped up" are required to progress through multiple treatment steps (or full programs) before they experience treatment success, risking disengagement with treatment and the unnecessary duplication of treatment content [11,16].

Adaptive interventions are a recent advancement within ICBT that involve adjusting treatment content or modality during the intervention (rather than at the end) in response to progress monitoring or identification of "risk" or "treatment need" [16]. Such adaptive interventions, which have thus far primarily been examined in adult populations, bring forward the "step-up" point to identify problems early and optimize the care received. The work of Forsell et al [16] has demonstrated that algorithms implemented at week 4 of treatment to predict individual outcomes can successfully redirect patients at risk into an adapted treatment and produce improved treatment outcomes compared to those who received a standard treatment. Treatment adaptations can include changes to the level of support, types of materials and messaging content provided (as examined by Forsell et al [16]), or actual treatment content as required and at multiple time points. Although still in an early stage, adaptive interventions may offer promise in ICBT for child and adolescent anxiety, where problems of poor early engagement and subsequent reduced outcomes have been identified in low-intensity, self-directed ICBT [9,10].

Previously, our team trialed a "stepped care adaptive" approach to ICBT for young people with anxiety [11], where children and adolescents with an anxiety disorder were randomized to either "stepped care ICBT" (ICBT-SC) or ICBT-TG. Those allocated to the latter condition received ICBT-TG in the form of minimal weekly email support from a therapist from the beginning of treatment. All young people in the ICBT-SC condition commenced the low-intensity, self-guided ICBT as the "first step" or treatment block. After 5 sessions (treatment midpoint), a self-report assessment and associated clinical judgment process was integrated (rather than a computer algorithm) to determine participant progress and need for stepping up (adapting treatment). Those who had not demonstrated adequate treatment gains after 5 sessions (low

XSL•FO
RenderX

engagement and limited response) were stepped up to receive therapist guidance (in the form of weekly email support) for the remainder of treatment. Those who demonstrated good engagement and treatment response (based on clinical cutoffs in self-report measures) continued with the lower-intensity, self-directed ICBT intervention. ICBT-SC was found to be acceptable to families and noninferior to ICBT-TG at the 12-week and 9-month follow-ups, with significant clinical benefits evident for participants in both treatment conditions. At the 9-month follow-up, 77% of the young people in both conditions were free of their primary diagnosis. In this previous trial, the therapist guidance provided was low in intensity (email support), preserving the potential scalability and accessibility of the intervention.

Thus, low-intensity, stepped care ICBT approaches that integrate their "step-up" or "adaptive" point during treatment may represent a suitable way of providing ICBT that is more easily accessible to young people. However, additional research is required, especially with young people, to establish a clear evidence base and determine ideal treatment adaptations and modalities. While therapist guidance delivered by messaging, as in the study by March et al [11], can be effective, many young people and parents continue to demonstrate a preference for at least some occasional F2F meetings within ICBT [17,18]. Furthermore, in a recent systematic review, Vu and Per [18] demonstrated an average treatment session completion rate of only 72% for asynchronous technology–based CBT (eg, email supported), highlighting potential problems with engagement. Thus, there is a clear need to provide alternative treatment models that address such factors. Recent shifts in health care delivery highlight new modalities that could be integrated into stepped care and adaptive treatment models. Videoconferencing, in particular, has emerged as an important technology that can be used as a form of F2F delivery of CBT programs [19,20] or as a way of providing minimal therapist guidance to support ICBT [21].

Videoconferencing

Videoconferencing is increasingly being implemented to overcome treatment gaps, especially since the COVID-19 pandemic [22], and refers to the integrated use of audio and video content for live communication and treatment delivery. Videoconferencing differs from other forms of therapist communication, such as the email therapist guidance provided in the study by March et al [11], which operates as an asynchronous, delayed communication method. It allows opportunities for the young person and therapist to meet remotely in real time and communicate synchronously. Typically, videoconferencing requires participants to set a regular time to meet their therapist, allows the opportunity for rapport to be developed, and enables the therapist to discuss treatment techniques with the young person directly as well as observe nonverbal and other reactions that could indicate potential challenges to the implementation of the strategies taught. It also allows the therapist to use the technological functions of videoconferencing software, such as screen sharing, as a method of hands-on demonstration, clarification of material, and consolidation of learning [21]. Furthermore, videoconferencing may appeal to young people with anxiety for whom attending in-person sessions, traveling, and being in public areas can be challenging and anxiety provoking [20]. Despite the common use of videoconferencing in the delivery of psychological therapy, there is very little investigation of its efficacy either as an adjunct for ICBT or on its own as a delivery mode for CBT, particularly for child and adolescent anxiety.

A recent systematic review examined the outcomes for F2F CBT delivered via videoconferencing for child and adolescent anxiety [22]. The review found that in the scarce literature available (a pooled sample of only 213 young people), significant reductions in anxiety outcomes were evident for videoconferencing CBT after treatment, with moderate to large effect sizes. Importantly, average treatment completion was reported as 89%, higher than that reported in the review by Vu and Per [18] of asynchronous technology–based CBT and highlighting the potential of videoconferencing in promoting treatment engagement. However, it is important to note that most of the studies in this review had small sample sizes and failed to include a control group or report on satisfaction, treatment completion, or treatment fidelity [22]. Furthermore, the review was unable to make distinctions regarding the value of videoconferencing when used as an adjunct to ICBT or as the mode of full delivery of CBT. Thus, videoconferencing seems to offer promise in providing therapist guidance for ICBT interventions for young people with anxiety and could hold particular value for stepped care or adaptive interventions. This study was based on the premises that therapist guidance (the support) itself is the key element of evidence-based ICBT, and that when delivered via videoconferencing (essentially F2F support), this would also be effective.

The Aims of This Study

This study represents the first RCT examining the impact of an ICBT-SC model for children and adolescents with a primary anxiety disorder in which the therapist-guided element is provided using videoconferencing (VC). Specifically, this noninferiority RCT examines whether a stepped care version of ICBT using therapist guidance via videoconferencing for the step-up component (ICBT-SC[VC]) can produce the same benefits for young people as evidence-based ICBT with therapist guidance provided throughout the whole treatment via videoconferencing (ICBT-TG[VC]). It was hypothesized that ICBT-SC[VC] would be no less clinically effective than ICBT-TG[VC], that is, not inferior to any greater extent than the noninferiority margin, with similar reductions in anxiety severity from baseline to 12 weeks and 9 months after baseline assessment. It was also predicted that the ICBT-SC[VC] program would be acceptable and satisfactory to participants.

Methods

Design

The design involved a 2-arm noninferiority RCT following CONSORT (Consolidated Standards of Reporting Trials) guidelines [23] comparing ICBT-SC[VC] with evidence-based ICBT-TG[VC]; detailed information is presented in the Interventions subsection [5,24,25]. The results are presented according to the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health

XSL•FO
RenderX

Applications and Online Telehealth) checklist (Multimedia Appendix 1).

Stratified block random assignment was used to control for participant age (7-12 y and 13-17 y), with an allocation ratio of 1:1 to treatment conditions. A randomization table was created using computer-generated sequences. The lead investigator generated the random sequence, which was concealed from the project manager using opaque envelopes until each individual participant was ready to be randomized. Full diagnostic and web-based questionnaire assessments were conducted before the intervention (baseline), at 12 weeks, and 9 months (primary end point) after the commencement of treatment. At midtreatment (after session 5 or week 7, whichever occurred first), a brief assessment was conducted to determine "responder status" and the "step-up" decision.

Ethical Considerations

The study was conducted in accordance with the University of Southern Queensland Human Ethics Research Committee (H17REA271). The study design, hypotheses, and analysis plan were preregistered with the Australian New Zealand Clinical Trials Registry (ACTRN12618001418268) and reported in line with international recommendations for child anxiety trials [26]. All participants who met the inclusion criteria provided informed consent (parent and child).

Participants and Procedure

Participants included 137 young people (male: n=61, 44.5%; female: n=76, 55.5%) aged 7 to 17 (mean 10.93, SD 2.26) years, who registered for the BRAVE Online program (an ICBT self-guided intervention for child and adolescent anxiety) between August 30, 2018, and August 26, 2019, and met the inclusion criteria outlined in the next paragraph. Participants were directed to the program through self-referral or referral by general practitioners, education professionals, or mental health professionals.

Participants were required to meet the following criteria to be included in the study: be aged between 7 and 17 years; have elevated levels of anxiety on the Children's Anxiety Scale-8 (CAS-8) [27]; have a primary diagnosis of social anxiety disorder, generalized anxiety disorder, separation anxiety, or specific phobia on the Anxiety Disorders Interview Schedule for Children–Child version (ADIS-C) [28]; have access to the BRAVE Online program via a computer or mobile device with an Australian IP address; and be able to read and write English at an age-appropriate level. Participants with a primary diagnosis of obsessive-compulsive disorder, posttraumatic disorder, and panic disorder were not eligible for this study because these are not addressed in the treatment program, although these diagnoses were permitted if secondary to the primary presenting issue. Participants with secondary mood disorders were included, providing that their mood disturbance was rated <6 on the ADIS-C (refer to the Primary Outcome Measures subsection). Participants were excluded from the study if they exhibited current suicidal ideation, self-harm behaviors, substance abuse problems, significant behavioral disorders, pervasive developmental disorders, or learning disorders as assessed during the clinical interview. In addition, those already receiving support from a professional were excluded.

The 396 participants who initially enrolled in the BRAVE Online self-help program and reported elevated anxiety on a routine registration questionnaire (refer to Participant Selection Measures section), were invited to participate in an initial telephone screening assessment. Of the 396 participants, 117 (29.5%) declined the invitation or were unable to be contacted, 106 (26.8%) did not meet the broad inclusion criteria at this stage (eg, already receiving support from a professional), and 173 (43.7%) were invited to participate in a more detailed assessment to determine inclusion criteria, involving baseline web-based questionnaires and a telephone diagnostic interview (with the young person; refer to the Primary Outcome Measures subsection). After this assessment, of the 173 participants, 27 (15.6%) were excluded because they did not demonstrate a clinical-level anxiety disorder or had a primary disorder other than anxiety, and 9 (5.2%) declined further participation. Thus, of the initially enrolled 396 participants, 137 (34.6%) met the inclusion criteria, provided informed consent (parent and child), and were randomly allocated to a treatment condition. Of these 137 participants, 97 (70.8%) had a comorbid anxiety disorder at a clinical level, with an average of 2.05 (SD 0.85) anxiety diagnoses. Only 2 (1.5%) of the 137 participants had a comorbid mood disorder (dysthymia).

Measures

Demographics

Basic demographic information, including age, gender, and residential location, was collected during program registration. Postcode data were coded according to the Australian Statistical Geography Standard [29], and participants were categorized as residing in major cities or inner regional, outer regional, or remote locations. Postcode data were also used to ascertain area-level socioeconomic status through the Socio-Economic Indexes for Areas [30], reported by quartile.

Participant Selection Measures

In addition to the ADIS-C diagnostic interview described in the next subsection, the CAS-8 [27] was completed by young people when registering for the BRAVE Online program to enable us to identify those with elevated levels of anxiety for inclusion in the study. The CAS-8 is a brief 8-item measure based on the Spence Children's Anxiety Scale (refer to Secondary Outcome Measures section). It has demonstrated excellent reliability, including in online delivery formats [26]. Population-level, gender-standardized norms are provided, with scores above the 84th percentile considered elevated (T-scores >60: CAS-8 scores ≥12 for female individuals and ≥10 for male individuals).

Primary Outcome Measures

The presence and type of an anxiety disorder were determined using the ADIS-C [28] and the associated clinician severity rating (CSR; primary outcome measure) ranging from 0 (none) to 8 (severely disturbing or disabling), which was the primary outcome measure in this study. The ADIS-C was administered to the child via telephone with young people only at baseline, 12 weeks, and 9 months by trained interviewers who were

XSL•FO
RenderX

blinded to the experimental condition, study procedures and hypotheses and were supervised by an experienced psychologist. Only the child version of the ADIS was administered in this study to minimize participant burden and obtain information directly from the person completing treatment (no parent involvement in treatment). For participants aged <12 years, parents were given the choice to either attend the interview with their child or be provided with a summary upon completion of the telephone call.

Data from the ADIS-C also informed the clinician rating of overall child functioning on the Children's Global Assessment Scale (CGAS) [31]. Scores ranged from 1 to 100, with the 81-to-100 band representing normal levels of functioning, 61 to 80 indicating slight disability, 41 to 60 representing moderate disability, and 1 to 40 indicating serious disability. The CGAS was a secondary outcome measure and has good interrater and test-retest reliability [31,32]. A sample of interviews (15%) were randomly selected to be recorded and coded for interrater reliability by a second assessor from the pool of assessors. Analysis revealed an intraclass coefficient of 0.99 for diagnosis type (r=0.96 for CSR ratings and r=0.94 for CGAS ratings).

Secondary Outcome Measures

Secondary outcome measures were assessed via web-based survey within 2 weeks of registration. The full Spence Children's Anxiety Scale–Child and Parent versions (SCAS-C and SCAS-P, respectively) [33,34] were administered at baseline, midtreatment, 12 weeks, and 9 months as a secondary outcome measure and to determine "step-up" decisions at midintervention (refer to Determining Responder Status at Midtreatment for the Stepped Care Condition section). The internal consistency values in this study were Cronbach α=0.86 (SCAS-C) and Cronbach α=0.88 (SCAS-P).

The Child Anxiety Life Interference Scale–Child and Parent reports (CALIS-C and CALIS-P, respectively) [35] were used to assess the level of anxiety-induced life interference and impairment experienced by the child (as reported by children and parents) and by the parents themselves (parent report) at baseline, 12 weeks, and 9 months. The average internal consistency values for the CALIS-C were Cronbach α=0.84 (outside the home) and Cronbach α=0.70 (at home) and for the CALIS-P were Cronbach α=0.83 (outside the home), Cronbach α=0.76 (at home) and Cronbach α=0.88 (parent life).

Program Adherence and Satisfaction

Program adherence was measured by the number and proportion of sessions completed at 12 weeks and 9 months. Dropout status was determined by whether the participant withdrew from the study (treatment and assessments), recorded as *yes* or *no* at each assessment time point (midpoint, 12 wk, and 9 mo). Program satisfaction was measured after 3, 6, and 9 sessions through a 5-item scale used in our prior research [9,24]. Participants were required to respond to items assessing whether they would tell a friend about the program (item 1), how helpful the program was (item 2), how happy they were with the program (item 3), how much the program helped to reduce their anxiety (item 4), and their overall judgment of the program (item 5). Responses were provided on a 5-point Likert scale, with item 1 scores ranging from 1=*definitely not* to 5=*definitely yes*; items 2, 3, and 4 scores ranging from 1=*not at all*, to 5=*very much*; and item 5 scores ranging from 1=*very bad* to 5=*very good*. A total satisfaction score was calculated by summing responses to the 5 questions. Total scores could range from 5 to 25 [9].

Interventions

The ICBT-TG[VC] Intervention

The ICBT-TG[VC] intervention was the 10-session child or adolescent BRAVE Online program delivered online, supported by videoconferencing therapist guidance for all sessions. The BRAVE Online programs comprise ten 45-minute sessions of ICBT and have demonstrated efficacy across several trials with minimal therapist guidance provided by email or messaging [5,24,25]. The only difference for this study was that the minimal therapist guidance was delivered via videoconferencing rather than email or messaging. The BRAVE Online program includes self-guided sessions that the young person can complete on an internet-enabled device or computer at any time and from any place. Sessions are designed to be participative and include text, videos, stories, examples, quizzes, question-and-answer activities, and additional interactive worksheets. The first 5 sessions of the BRAVE Online program include evidence-based anxiety management strategies such as the recognition of symptoms, relaxation, coping self-talk, cognitive restructuring, and graded exposure, with the second half of the treatment (sessions 6-10) incorporating additional strategies such as problem-solving, self-reinforcement, relapse prevention, and ongoing skills rehearsal [36,37]. Young people complete the interactive sessions on a computer or a tablet device. There is also a parent program, but this was not used in this study. Participants receive automated reminders each week when their session is due.

Each participant was assigned a therapist who monitored their progress, viewed their responses to activities, and provided guidance after each session via videoconference (15 min of therapist time per session) at a predetermined time. Videoconferencing sessions provided support to the young person with content of the session and skill rehearsal. Videoconferencing sessions were delivered to the young person, but the parent had the option of being present. BRAVE Online program therapists used these 15-minute sessions to provide reinforcement of effort, redirection, and clarification of participant responses where required, as well as to use screen sharing when beneficial to expand on ICBT content. Participants also received one 30-minute video call after session 5 (instead of the 15-minute session) to help with the construction and implementation planning of their exposure hierarchy. Participants could contact the BRAVE Online program for technical or administrative support (although they were not encouraged to contact the clinician between sessions). Participants had access to a total of 165 minutes of therapist guidance across the 10-session program.

The ICBT-SC[VC] Intervention

The ICBT-SC[VC] condition was BRAVE Online stepped care, comprising 2 steps depending on the results of a midpoint assessment. In step 1, all participants commenced the first 5

XSL•FO
RenderX

sessions of the BRAVE Online program, which involved low-intensity, self-guided ICBT without therapist guidance. Participants were then assessed at the midtreatment point (after 5 sessions or 7 weeks, whichever occurred first) to determine their "responder status" as described in the next subsection. In step 2, participants who "responded" to step 1 completed the remaining 5 sessions of the BRAVE Online program on a self-guided basis without therapist guidance, whereas those who did not respond to step 1 (did not show sufficient improvements) were "stepped up" to complete the remaining sessions of the BRAVE Online program supplemented with therapist guidance. Therapist guidance for participants who were "stepped up" was identical to that provided for ICBT-TG[VC]). They received a 30-minute videoconferencing session after session 5 to assist with the implementation of exposure. Those who were not stepped up did not receive any videoconferencing therapist guidance. The ICBT program (BRAVE Online) content and therapeutic strategies were identical across conditions, with only the amount of therapist guidance differing. A more detailed description of the BRAVE Online stepped care program and treatment content can be found in the study by March et al [21].

Determining Responder Status at Midtreatment for the Stepped Care Condition

The process for determining responder status in this study mirrored the process used by the team in the previous trial of the BRAVE Online stepped care program [13]. This process and step-up rules were determined after pilot work by the team [21]. Two factors were considered by a clinical psychologist when determining a participant's responder status at the midtreatment assessment point. First, responder status for the midtreatment "step-up" decision was primarily determined by response on the SCAS-C and SCAS-P [33,38], using gender-standardized cutoffs based on normative and clinical child and adolescent samples [38,39]. Scores above the 84th percentile (T-scores >60) were considered elevated. "Responders" were defined as those who demonstrated a reduction in anxiety to the nonelevated range on *either* their primary anxiety subscale *or* total anxiety scores on the SCAS-C or SCAS-P at midtreatment for the scales on which they were elevated at baseline. This criterion was selected to ensure that we captured participants who made any clinically meaningful change in terms of anxiety symptomatology because not all participants necessarily targeted their primary anxiety in the first 5 sessions. "Nonresponders" were defined as those who did not meet this criterion.

As demonstrated in pilot work [21] and a previous trial [11], the level of session adherence was not necessarily consistent with reductions in anxiety symptoms as reported via the SCAS-C and SCAS-P, and additional factors required consideration in the step-up decision. Thus, in line with the study by March et al [11], as a second step, the clinical psychologist scoring the midtreatment assessment also examined treatment adherence (the number of sessions completed by midtreatment) and the way in which the young person engaged with program activities (in-session responses). Completion of <3 sessions was deemed indicative of nonresponse, along with answers to program activities that showed little thought, insight, or strategy implementation. Completion of between 3 and 5 sessions, along with good engagement with sessions (regular session completion as well as evidence of skill rehearsal and practice) was considered indicative of good response, if accompanied by improvements on the SCAS-C or SCAS-P. Each step-up decision was reviewed by the senior psychologist and lead investigator before finalization. Following the protocol of March et al [11], midtreatment assessments (web-based survey results and administrative program data and program responses) were evaluated by a clinical psychologist and recommendations discussed with the lead investigator (SM) for each case to ensure that guidelines were adhered to.

Participants who did not respond to the invitation to complete the midtreatment assessment were reminded 1 week later, and the clinical psychologist attempted to make contact via telephone. Those participants who did not respond were able to continue with their existing program if they chose to. Of the 53 participants, 1 (1.9%) did not complete the midtreatment assessment but continued in the study.

Therapist Training

Therapists had completed a minimum of a 4-year undergraduate degree in psychology and were undergoing or had completed further psychology education at the master's or doctoral level (postgraduate clinical training). All therapists received 4 hours of training in the BRAVE Online program and were provided with agenda templates for videoconference sessions. The therapists also participated in ongoing fortnightly supervision with a senior clinical psychologist.

Analytic Strategy

The analytic strategy followed that of a previous noninferiority trial of the BRAVE Online program [13]. Noninferiority analyses were conducted for the clinician-rated and self-report measures. Following the procedure developed by Feingold [40], hierarchical linear models (HLMs) were used to estimate the changes over time and were converted to standardized measures (Cohen *d*). The effects estimated included changes in primary and secondary outcomes for participants in the ICBT-SC[VC] and ICBT-TG[VC] conditions across time (from baseline to 12 weeks and from baseline to 9 months), as well as the interaction between treatment condition and time (if the rate of change was similar or different between conditions). HLM analysis was conducted using maximum likelihood estimation with the *nlme* package [36] in R [37]. CIs for effect sizes were determined as described by Zaiontz [41], using a noncentral T-distribution [42]. Noninferiority was supported when the lower limit of the 95% CI for the standardized mean difference was within the margin of noninferiority.

The margin of noninferiority (Δ) for the treatment effect was determined for the primary outcome measure (CSR derived from the ADIS-C) based on the results of previous trials comparing ICBT-TG to a waitlist control demonstrating effect sizes of Cohen *d*=0.60, Cohen *d*=1.22, and Cohen *d*=1.45 at the 12- to 14-week assessment [5,21,25]. It is recommended that a "clinically unimportant difference" between 2 treatments should be *one-half or less* of the effect size of the reference intervention [43]. Thus, the selection of the noninferiority margin was based on the previous reference effect of Cohen *d*=0.60, and for the

XSL•FO
RenderX

primary CSR, the margin of noninferiority was set to Cohen *d*=0.20 such that if the lower bound of the 95% CI of the effect size did not exceed Cohen *d*=–0.40, ICBT-SC[VC] would be deemed as noninferior to ICBT-TG[VC]. This method was selected to follow that of another noninferiority trial conducted on the BRAVE Online program intervention [11]. The same margin of noninferiority was used across all secondary outcome measures. The power calculation was set at α=.05, for a lower-bound noninferiority margin of 0.4, to provide a power of 0.80 for the primary and secondary outcomes, requiring a sample size of 58 participants per condition. The aim was to recruit 66 participants per group, given an expected attrition rate of 15%. The HLM approach allows for all data to be included in the analysis, including data of participants who drop out, aligning with an intention-to-treat (ITT) approach.

To examine the clinical benefits obtained by participants, diagnostic outcomes were compared between conditions using chi-square analyses and logistic regression analyses for both completer and ITT samples. Odds ratios (ORs; ICBT-SC[VC] as the baseline condition) and 95% CIs were calculated. The ITT sample for the chi-square analyses was determined using the last-observation-carried-forward method for participants who withdrew from the study or failed to complete assessment points for diagnostic outcomes only.

Results

Participant Characteristics

A summary of baseline participant characteristics, split by treatment condition, is presented in Table 1.

Table 1. Baseline sample characteristics (n=137).

Characteristics	ICBT-SC[VC][a], n=66	ICBT-TG[VC][b], n=71
Gender, n (%)		
Male	28 (42)	33 (46)
Female	38 (58)	38 (54)
Geographic location, n (%)		
In major city	46 (70)	38 (54)
Out of major city	11 (17)	23 (32)
Missing	9 (14)	10 (14)
SEIFA[c,d] (percentile), n (%)		
0-25th	6 (9)	9 (13)
26th-50th	11 (17)	14 (20)
51st-75th	19 (29)	16 (23)
76th-100th	27 (41)	30 (42)
Missing	3 (5)	2 (3)
Primary diagnosis, n (%)		
Generalized anxiety disorder	37 (56)	42 (59)
Separation anxiety disorder	9 (14)	11 (15)
Social phobia	12 (18)	8 (11)
Specific phobia	8 (12)	10 (14)
Age (y), mean (SD)	11.08 (2.35)	10.79 (2.18)
Treatment expectancies, mean (SD)	25.84 (8.06)	28.22 (7.56)
CSR[e] for primary anxiety diagnosis, mean (SD)	5.42 (0.91)	5.42 (0.87)
CGAS[f], mean (SD)	54.77 (5.16)	54.31 (4.99)
Diagnoses (n), mean (SD)	1.94 (0.80)	2.15 (0.89)

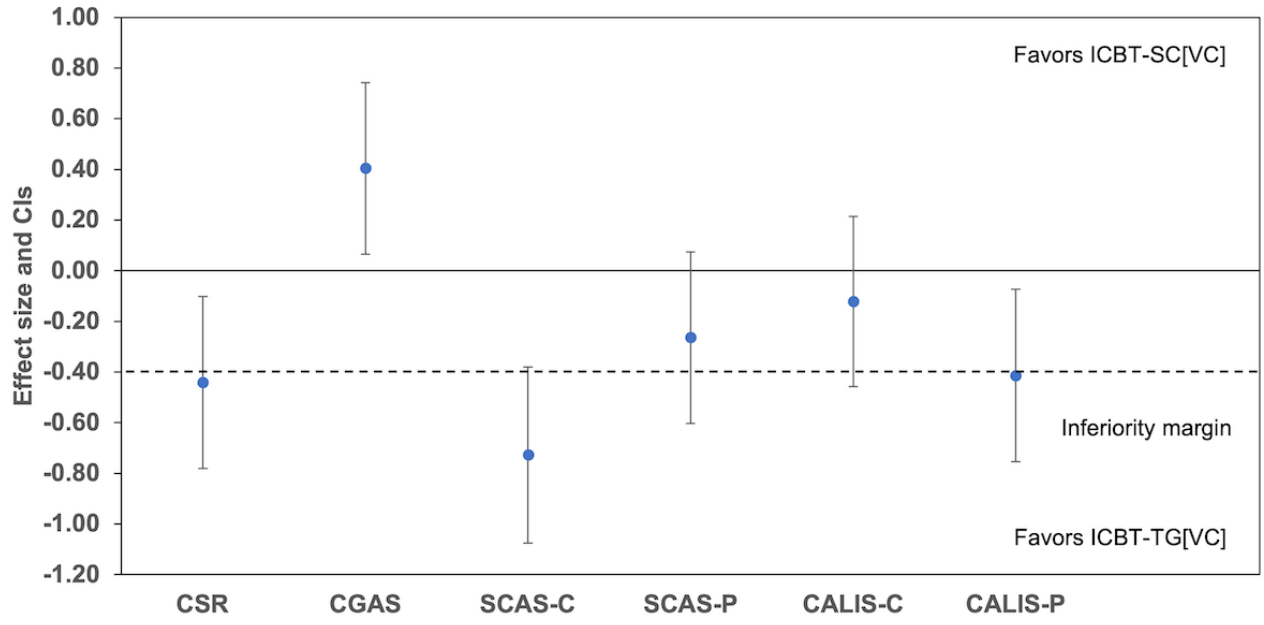
Program Adherence and Dropout

The flow of participants through each phase of the study is presented in Figure 1. At midpoint, significantly more sessions were completed by participants in the ICBT-TG[VC] condition (mean 4.48, SD 1.50) than those in the ICBT-SC[VC] condition (mean 3.18, SD 1.62; t_{135}=–4.87; *P*<.001; Cohen *d*=–0.83, 95% CI –1.18 to –0.48). By the 12-week assessment, ICBT-TG[VC] participants had completed more sessions (mean=7.72, SD 3.06) than the ICBT-SC[VC] participants (mean 5.61, SD 3.03; t_{135}=–4.05; *P*<.001; Cohen *d*=–0.69, 95% CI –1.04 to –0.35). Similarly, at 9 months, ICBT-TG[VC] participants had completed more sessions (mean 8.73, SD 3.08) than ICBT-SC[VC] participants (mean 7.39, SD 3.44; t_{135}=–2.40; *P*<.001; Cohen *d*=–0.41, 95% CI –0.75 to –0.07). Multimedia Appendix 2 reports the proportion of participants completing each of the 10 sessions of the program by condition. No adverse effects were reported to the investigators or ethics committee.

Figure 1. Flow of participants through the study. "Completed assessment" includes participants who completed any of the assessment items at that time point. Some of the participants completed interviews but not questionnaires, while some of the participants completed questionnaires but not interviews. ICBT-SC[VC]: stepped care internet-delivered cognitive behavioral therapy with step-up component delivered with therapist guidance via videoconferencing; ICBT-TG[VC]: internet-delivered cognitive behavioral therapy with full therapist guidance delivered by videoconferencing.

XSL•FO
RenderX

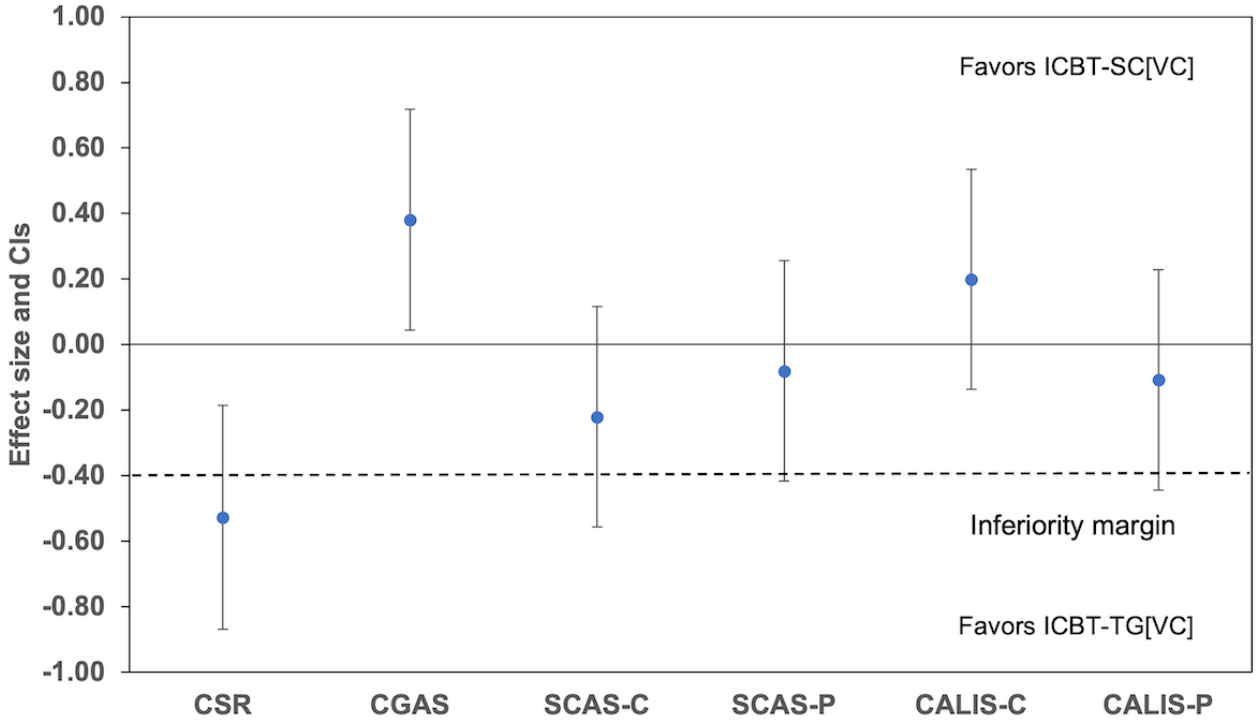
The proportion of participants who dropped out of the study (refused to engage in any further treatment or assessments) was not significantly different by condition at the midtreatment point (OR 1.29, 95% CI 0.59-2.79; *P*=.51; 12/66, 18% vs 10/71, 14% for ICBT-SC[VC] vs ICBT-TG[VC]), respectively) or by 9 months (OR 1.51, 95% CI 0.85-2.67; *P*=.16; 21/66, 32% vs 15/71, 21% for ICBT-SC[VC] vs ICBT-TG[VC], respectively). However, significantly more participants had dropped out of ICBT-SC[VC] (21/66, 32%) than ICBT-TG[VC] (11/71, 16%) at the 12-week assessment (OR 2.05, 95% CI 1.07-3.93; *P*=.02).



Proportion of Participants Stepped Up

Of the 53 ICBT-SC[VC] participants, 32 (60%) were classified as "nonresponders" at the midpoint assessment and were subsequently stepped up to ICBT-TG[VC], while 21 (40%) were classified as "responders" and continued with self-guided sessions.

Noninferiority Analysis



The difference in the rate of change between the ICBT-TG[VC] and ICBT-SC[VC] conditions from baseline to 12 weeks and from baseline to 9 months can be seen in Figures 2 and 3 and Multimedia Appendix 3. The test of noninferiority, examining the difference between the conditions in the rate of change over time, indicated that the standardized 95% CIs for Cohen *d* exceeded the range of noninferiority for all measures from baseline to 12 weeks (Figure 2), favoring ICBT-TG[VC]. From baseline to 9 months (Figure 3), the standardized 95% CIs for Cohen *d* exceeded the range of noninferiority for all measures except for the CALIS-C. The ICBT-SC[VC] condition showed a slightly greater reduction in the CALIS-C scores compared to the ICBT-TG[VC] condition on this measure, but the difference was not statistically significant.

Figure 2. The 95% CIs for the effect size (Cohen d) for the difference between stepped care internet-delivered cognitive behavioral therapy with step-up component delivered with therapist guidance via videoconferencing (ICBT-SC[VC]) and ICBT with full therapist guidance delivered by videoconferencing (ICBT-TG[VC]) in changes in mean scores from baseline to 12 weeks for clinician-, child-, and parent-reported outcomes. Clinician- and Self-Reported Outcomes

To examine the changes in symptomatology by the ICBT-SC[VC] and ICBT-TG[VC] conditions, the results from the fixed effects from the HLM analyses are presented in Multimedia Appendix 4. Significant improvements across time were evident for all outcome measures for both intervention groups, and there were no significant differences between the conditions in general. The only significant time-by-condition interaction was for the SCAS-C, for which post hoc tests indicated a significantly greater reduction in scores from baseline to 12 weeks for the ICBT-TG[VC] condition compared to the ICBT-SC[VC] condition (t_{113}=–3.16; *P*=.002). Table 2 reports the within-participant changes from baseline to 12 weeks and from 12 weeks to 9 months for each condition to be consistent with other studies of CBT for anxiety that report the treatment and follow-up periods separately. The trajectories of change are shown in Figure 4 (with error bars representing 95% CIs), and the estimated marginal means and SEs for child-, parent-, and clinician-reported outcomes at each assessment occasion for each condition are shown in Multimedia Appendix 4, along with between-condition effects at each time point. The rate of change from baseline to 9 months (Multimedia Appendix 3) was not significantly different between conditions on any measure other than the CSR, for which ICBT-TG[VC] showed a greater reduction than ICBT-SC[VC].

Diagnostic Outcomes

Diagnostic outcomes are presented in Table 3. The proportion of participants free of their primary and any anxiety diagnosis increased over time for both conditions. For the per-protocol analysis, there were no significant differences between the conditions in the proportion of participants free of their *primary* or *any* anxiety diagnosis at 12 weeks, although by 9 months, a significantly higher proportion of participants in the ICBT-TG[VC] condition were free of their primary and any anxiety diagnosis. For the ITT analysis, the proportion of participants free of their *primary* and *any* diagnosis was significantly higher for ICBT-TG[VC] than for ICBT-SC[VC] at both 12 weeks and 9 months. Of those ICBT-SC[VC] participants in the per-protocol sample who were stepped up to receive therapist guidance, 41% (9/22) were free of their primary diagnosis at 12 weeks compared to 68% (13/19) of those who were not stepped up (ie, continued to receive self-guided sessions). At 9 months, 55% (11/20) of those stepped up compared to 83% (15/18) of those not stepped up were free of their primary diagnosis.

[c]OR: odds ratio.

[d]ITT: intention to treat.

Satisfaction With Treatment

Total satisfaction was rated as moderate to high at all time points for both conditions, and although scores were slightly higher for ICBT-TG[VC] than for ICBT-SC[VC] at each time point, these effects were not significantly different after 3 sessions (mean 17.42, SD 4.78 vs mean 19.02, SD 4.41 t_{111}=–1.84; *P*=.07), 6 sessions (mean 18.62, SD 4.85 vs mean 20.38, SD 3.98t_{96}=–1.97; *P*=.05), or 9 sessions (mean 20.59, SD 4.32 vs mean 22.25; SD 3.03; t_{76}=–1.98; *P*=.05).

Discussion

Principal Findings

This study examined whether a stepped care ICBT model for child and adolescent anxiety was noninferior to a fully therapist-guided ICBT program when therapist guidance was delivered via videoconferencing. Noninferiority of the stepped care model could not be determined, and the results did not support the hypothesis for primary (CSR) and all secondary (parent and child anxiety reports) outcome measures at 12 weeks and all measures but the Child Anxiety Life Interference Scale (life interference) at 9 months. Thus, although the traditional tests for evaluating outcomes across treatment conditions indicated no significant differences in outcome for the continuous measures, we cannot conclude that ICBT-SC[VC] was noninferior to ICBT-TG[VC].

However, the diagnostic interview data did suggest that ICBT-SC[VC] was less effective than ICBT-TG[VC], with a significant difference in clinical gains made by participants in the 2 conditions at the 9-month assessment. Given the variation in which participants complete ICBT sessions, 9 months is considered the primary end point for this study and our previous trial of the BRAVE Online stepped care program [11]. Study completers in the ICBT-SC[VC] condition showed a remission rate for the *primary* anxiety disorder of 68% (26/38), significantly lower than the 88% (45/51) observed in the ICBT-TG[VC] condition. Remission rates for *any* anxiety disorder were also significantly lower for ICBT-SC[VC] participants (23/38, 60%) than for ICBT-TG[VC] participants (42/51, 82%) at 9 months. These rates were lower (and significantly different) in the ITT sample, with 41% (27/66) of the ICBT-SC[VC] participants free of their *primary* anxiety diagnosis and 36% (24/66) free of *any* anxiety disorder compared to 69% (49/71) and 63% (45/71) for the ICBT-TG[VC] condition, respectively. Therefore, in terms of clinical benefit, the ICBT-SC[VC] model in this study was less effective than the ICBT-TG[VC] model in which therapist guidance was provided for all sessions.

One issue of concern was that therapy compliance was lower in the ICBT-SC[VC] group than in the ICBT-TG[VC] group, with ICBT-SC[VC] participants completing fewer treatment sessions at each time point and showing a higher proportion of dropouts. However, there are several potential reasons for this,

XSL•FO
RenderX

including that participants may have understood the material and were working independently with treatment skills or that they improved enough and chose not to continue. Participants receiving the therapist-guided model showed slightly higher satisfaction ratings than those receiving the stepped care model, although the results were not significantly different.

Benefits of Stepped Care ICBT and Videoconferencing

There are several important points to note regarding the utility of stepped care ICBT using videoconferencing in the step-up phase. First, it should be noted that the changes in anxiety symptoms and social functioning assessed through parent and youth questionnaire data showed strong improvements for both therapy conditions although noninferiority could not be demonstrated. The overall benefits of the ICBT-SC[VC] treatment were comparable to improvements observed in other clinical trials. A meta-analysis of CBT and ICBT interventions for child and adolescent anxiety showed an average remission rate for *primary* anxiety diagnosis of 49.4% in the ITT sample and 56.4% in the completer sample, and for *any* anxiety diagnosis, 46.8% in the ITT sample and 52.9% in the completer sample [44]. Meta-analyses specific to adolescent anxiety reveal lower success rates, with only 36% of the ITT sample and 37% of the completer sample free of primary anxiety diagnosis after treatment [45]. Thus, the stepped care ICBT intervention delivered in this study to both children and adolescents produced good treatment outcomes compared to other F2F and ICBT treatments delivered with therapist guidance. They were also comparable, although not as strong, as those observed in our recent study [11], They were also comparable, although not as strong, as those observed in our recent study [11], where 77% of the completers receiving the same stepped care model with email therapist guidance were free of their primary anxiety diagnosis. Thus, while the ICBT-SC[VC] model was less effective than ICBT-TG[VC] in terms of clinical diagnoses, it produced benefits that suggest that it would be an appropriate treatment model for a significant proportion of children and adolescents with a primary anxiety disorder.

Second, it is worth noting that the ICBT-SC[VC] model assessed in this study, as well as the stepped care model examined in the study by March et al [11], produced session completion rates lower than the therapist-guided model of the BRAVE Online program across all previous studies. The average number of sessions completed by the ICBT-SC[VC] participants at 12 weeks was 5.61 (SD 3.03) for this study and 5.37 for the previous stepped care model [11] compared to 7.72 (SD 3.06) sessions for the ICBT-TG[VC] participants in this study and an average of 7.5 sessions in previous trials of the BRAVE Online therapist-guided (email) program [5,24]. Session completion rates were also lower for the stepped care models at 9 months (this study: mean 7.39, SD 3.44 sessions; March et al [11]: mean 6.69 sessions) compared to therapist-guided models (this study: mean 8.73, SD 3.08 sessions; March et al [24]: mean 8.66 sessions; Spence et al [5]: mean 8.20 sessions). Thus, while the stepped care model tested here may be able to produce clinical benefits, it demonstrates a lower level of therapy engagement compared to ICBT that is delivered with minimal but regular therapist guidance throughout the program, suggesting that SC may not be suitable for those young people struggling to motivate themselves or who are not interested in ICBT programs. However, the stepped care session completion rates are greater than those observed when the BRAVE Online program is delivered in a totally self-directed manner, with no therapist guidance [9]. These findings are consistent with meta-analyses demonstrating greater treatment engagement in ICBT when therapist guidance is offered [7] and also show that engagement increases with higher dosage of therapist guidance.

Third, it is interesting to note that there was a lower proportion of young people who were stepped up who went on to become free of their primary anxiety diagnosis (9/22, 41% at 12 wk; 11/20, 55% at 9 mo) compared to ICBT-SC[VC] participants who were not stepped up (13/19, 68% at 12 wk; 15/18, 83% at 9 mo). This suggests that when young people respond well to the self-directed ICBT program at step 1, they can go on and achieve excellent remission rates, similar to the ICBT-TG[VC] condition. In this study, 40% (21/53) of the young people did not require stepping up and were able to continue with self-guided sessions themselves, which, in clinical services, could represent a large saving in therapist time. However, young people who do not respond at step 1 may face ongoing difficulty progressing through treatment and achieving clinical benefits, despite stepping up to therapist guidance. It is possible that in this study, those young people who did not respond to step 1 (32/53, 60%) were those who might not have responded well to any intervention or who required additional or alternative support from the beginning of ICBT treatment. As more investigations of stepped care ICBT are undertaken, an examination of the predictors of outcomes will be essential to determine which young people may not respond to stepped care or need alternative approaches.

Finally, this study tested the efficacy of an ICBT program (BRAVE Online) that has previously only been examined with the use of email or messaging modality in the provision of the therapist-guided component. In this study, all therapist guidance in both stepped care and therapist guidance conditions was provided in synchronous, videoconferencing format. The clinical benefits of videoconferencing in supplementing the ICBT program were clear. When delivered in the ICBT-TG[VC] format, the BRAVE Online program produced remission of primary anxiety disorder for 88% (45/51) of the participants, considerably higher than the average remission rates across previous trials of the BRAVE Online program (76.5% [24]; 78%, [5]) in which therapist guidance was provided via asynchronous messaging. These remission rates were also higher than those reported in previous meta-analyses [44] and highlight the potential value of ICBT blended with therapist guidance provided via videoconferencing. Compared to email-based therapist guidance, videoconferencing requires families to commit to a scheduled time each week to meet with the therapist. This may encourage young people to complete sessions on time in preparation for the videoconferencing session, allows enhanced tailoring of the treatment to the young person's needs, and may provide greater rapport and support when working through the program; for example, therapists in this study were able to redirect misunderstandings and demonstrate techniques by sharing their computer screen to illustrate the components of the ICBT program and apply them

XSL•FO
RenderX

to the young person. This may be particularly valuable for young people with multiple anxieties or those struggling to understand CBT concepts. However, videoconferencing sessions are less flexible than asynchronous contact and may more require therapist time.

Study Limitations

This study is the first to examine a stepped care adaptive ICBT intervention that varied the level of videoconferencing therapist guidance provided. Importantly, it involved a sample clinically diagnosed as anxious demonstrating levels of severity and comorbidity consistent with other studies reported previously, multiple informants, and psychometrically valid measures. However, the study is not without limitations. First, although it would have been beneficial to include both child and parent diagnostic interviews, clinical diagnoses were based only on a clinical interview with the young person to minimize participant burden and focus on the recipient of treatment. For children aged <12 years, parents were invited to either be present during the interview or be consulted at its conclusion. Furthermore, although assessors were blinded to group allocation, and every effort was made to maintain this blinding, including awareness of study design and hypotheses, it is possible that they may have become aware of study conditions during follow-up interviews with participants, and this is a limitation of the study. Although the study was broadly representative and included almost a third (34/118, 28.8%) of participants residing in areas outside major cities, approximately 69.7% (92/132) of the sample were in the top 2 quartiles regarding socioeconomic status, thus limiting the generalizability of results to populations with lower socioeconomic status. The findings may also not be representative of populations in other countries or cultural and sociodemographic groups; this issue could be examined with future research. It is also important to note that participants were selected from a sample of young people who had already registered for a online CBT program and therefore were interested in online care. It is possible that the findings of the study relating to adherence and outcomes may not generalize to other young people who are less amenable to online care. Participants in this study did not have common comorbidities such as severe mood disorders, autism, substance use, behavioral disorders, and suicidal ideation, and this may also limit the generalizability of the findings. Although participation in other interventions for treating their anxiety was an exclusion criterion, it is possible that participants commenced other interventions during the study period, and this is a limitation of this study.

We note that, as with most noninferiority trials, the study was limited to 2 active treatments. In the absence of a waitlist control or nonspecific control condition, the possibility that the treatment effects for both conditions do not simply reflect spontaneous remission cannot be excluded. Mitigating against this possibility are the findings from other studies showing that therapist-guided ICBT interventions are significantly more effective than no treatment [5,24], with similar results for clinic-delivered, F2F therapy. It is also important to note that the ICBT-TG[VC] program used in this study was taken to represent evidence-based ICBT, although it was amended from previously tested versions of the program. This study assumed that the therapist guidance element of our ICBT program previously delivered via email would be effective when delivered via videoconferencing, in line with other research [19-21], although this is a potential limitation of this research. A further potential limitation of this study relates to the criterion used for the margin of noninferiority that was based on our previous trials of ICBT-TG. The noninferiority margin was calculated for the primary outcome measure (clinician diagnostic severity) and extended to other outcome measures. Future research could establish individual margins of noninferiority for different outcome measures.

The dropout rates of almost 32% (21/66) in the ICBT-SC[VC] condition and 15% (11/71) in the ICBT-TG[VC] condition limited the power of the study, although such rates are not unusual in self-help web-based interventions [46]. Furthermore, it is also possible that this study miscalculated the potential effect of the intervention when setting the noninferiority margin or that the power might have resulted in a type II error, which might have contributed to the null result. The step-up criteria used and the time point at which responder status was determined may have also influenced the findings. It is possible that an earlier assessment would be more beneficial in determining the need to adapt or step up the intervention. Furthermore, the clinical nature of the assessment meant that clinician time and judgment were required to complement questionnaire scores. This limits the potential scalability of such interventions, and future research should consider ways in which artificial intelligence and risk algorithms could assist in this process. Importantly, the time investments of the therapists and the subsequent costs of ICBT-SC[VC] were not quantified here, with a full examination of the cost-effectiveness of the ICBT-SC[VC] and ICBT-TG[VC] interventions to be examined in a separate study.

Although as indicated in our trial registration, our initial intention was to base responder status on anxiety measure scores only, pilot work highlighted the need for additional clinical and contextual consideration to provide a meaningful indication of improvement, and the results may have been different if responder status were based on scores alone. In addition, we note an inconsistency in assessment terminology originally described in the trial registration, which noted our 12-week assessment as “posttreatment” and primary end point, when the intention was to follow our previous trial methodology [11], using baseline, 12-week assessment, and 9-month follow-up, with 9-month follow-up being the primary end point. Finally, although adverse effects were assessed via repeated monitoring of anxiety symptomatology, this study did not systematically assess broader adverse events throughout this trial.

Conclusions

This noninferiority RCT found that noninferiority of the stepped care approach could not be determined. Although ICBT-SC[VC] was acceptable to families, participants completed fewer treatment sessions. Participants receiving therapist-guided ICBT with support delivered via videoconferencing demonstrated remission rates as high as those of existing models and thus present a potentially viable new treatment model that should be compared to other treatments in future research. The findings

XSL•FO
RenderX

of this research have important implications for service delivery, suggesting that the lower-intensity ICBT-SC[VC] model may offer a suitable treatment model for some, especially those who respond to step 1 and are able to continue with a fully self-guided approach. Together, the stepped-care and therapist-guided models of ICBT may offer strategies for reducing long waiting lists in primary care contexts or where there are insufficient numbers of clinically trained professionals to reach all those in need, without compromising care.

Acknowledgments

The study received funding from Australian Rotary Health (SM); the funder was not involved in the conduct of the study. The intervention manual for BRAVE is copyrighted and can be requested from UniQuest.

Data Availability

The datasets generated and analyzed during this study are not publicly available due to limits to participant consent, but a deidentified dataset is stored on a University of Southern Queensland data server and is available from the corresponding author on reasonable request.

Authors' Contributions

SM was responsible for scientific conceptualization, project leadership, supervising staff, overseeing interviews and therapy, overseeing moderation, overseeing analysis, preparation of the data file, conducting analysis, and the preparation and editing of the manuscript. SHS was responsible for scientific conceptualization, conducting analysis, and the preparation and editing of the manuscript. LM conducted analyses, drafted the results, and reviewed and edited the manuscript. MF conducted the diagnostic interviews, provided therapist support, conducted moderation, and reviewed and edited the manuscript. GS conducted moderation, follow-up data collection, data entry, and data cleaning, as well as manuscript review, editing, and formatting. CLD was responsible for scientific conceptualization, overseeing analysis, and the preparation and editing of the manuscript.

Conflicts of Interest

The BRAVE Online program is owned by UniQuest and the University of Queensland; however, SM, SHS, and CLD may potentially benefit from royalties related to the program in the future. All other authors declare no other conflicts of interest.

Abstract

Background: Shame and stigma often prevent individuals with social anxiety disorder (SAD) from seeking and attending costly and time-intensive psychotherapies, highlighting the importance of brief, low-cost, and scalable treatments. Creating prescriptive outcome prediction models is thus crucial for identifying which clients with SAD might gain the most from a unique scalable treatment option. Nevertheless, widely used classical regression methods might not optimally capture complex nonlinear associations and interactions.

Objective: Precision medicine approaches were thus harnessed to examine prescriptive predictors of optimization to a 14-day fully self-guided mindfulness ecological momentary intervention (MEMI) over a self-monitoring app (SM).

Methods: This study involved 191 participants who had probable SAD. Participants were randomly assigned to MEMI (n=96) or SM (n=95). They completed self-reports of symptoms, risk factors, treatment, and sociodemographics at baseline, posttreatment, and 1-month follow-up (1MFU). Machine learning (ML) models with 17 predictors of optimization to MEMI over SM, defined as a higher probability of SAD remission from MEMI at posttreatment and 1MFU, were evaluated. The Social Phobia Diagnostic Questionnaire, structurally equivalent to the *Diagnostic and Statistical Manual* SAD criteria, was used to define remission. These ML models included random forest and support vector machines (radial basis function kernel) and 10-fold nested cross-validation that separated model training, minimal tuning in inner folds, and model testing in outer folds.

Results: ML models outperformed logistic regression. The multivariable ML models using the 10 most important predictors achieved good performance, with the area under the receiver operating characteristic curve (AU-ROC) values ranging from .71 to .72 at posttreatment and 1MFU. These prerandomization and early-stage prescriptive predictors consistently identified which participants had the highest probability of optimization of MEMI over SM after 14 days and 6 weeks from baseline. Significant predictors included 4 strengths (higher trait mindfulness, lower SAD severity, presence of university education, no current psychotropic medication use), 2 weaknesses (higher generalized anxiety severity and clinician-diagnosed depression or anxiety disorder), and 1 sociodemographic variable (Chinese ethnicity). Emotion dysregulation and current psychotherapy predicted remission with inconsistent signs across time points.

Conclusions: The AU-ROC values indicated moderately meaningful effect sizes in identifying prescriptive predictors within multivariable models for clients with SAD. Focusing on the identified notable client strengths, weaknesses, and Chinese ethnicity may enhance our ability to predict future responses to scalable treatments. Estimating the likelihood of SAD remission with a "prescriptive predictor calculator" for each client may help clinicians and policymakers allocate scarce treatment resources effectively. Clients with high remission probability may benefit from receiving the MEMI as a vigilant waitlist strategy before

intensive therapist-led psychotherapy. These efforts may aid in creating actionable treatment selection tools to optimize care for clients with SAD in routine health care settings that use stratified care principles.

Introduction

Social anxiety disorder (SAD) is a global public health concern with high current prevalence rates ranging from 2% to 25% [1-4]. If left untreated, SAD could raise socioeconomic burdens by limiting educational and career attainment as well as impairing physical health [1,5]. Individuals struggling with SAD exhibit an enduring apprehension and avoidant habitual reactions to social or performance settings with fears and worries of negative social evaluation [6]. They also maintain fewer confidants, spend less time with friends, and persistently report negative moods [7], likely interfering with daily functioning [8]. Reviews consistently showed that heightened SAD was linked to negative self-views [9], frequent health care service usage [10], and worse quality of life [11]. Given its early onset and debilitating course [12], addressing the accessibility and scalability of treatment options for SAD is imperative.

Meta-analyses of randomized controlled trials (RCTs) evidenced the efficacy of labor-intensive mindfulness-based interventions (MBIs) for SAD [13]. Face-to-face 8- to 12-week MBIs, such as mindfulness-based stress reduction (MBSR [14]) and mindfulness-based cognitive therapy (MBCT [15]), dominate conventional delivery approaches [16]. These MBIs typically included intensive retreats for mindfulness meditation, lasting from 3 days to 3 months [17]. However, stigma, logistical, financial, and time constraints [18] hinder accessibility, highlighting the importance of digital, self-guided MBIs as a scalable solution for SAD.

Such digital and self-guided MBIs yielded small yet clinically meaningful decreases in social anxiety symptoms and subjective attention control deficits within 2-14 weeks [19,20]. Thus, even brief digital MBIs are efficacious at least in the short run. These brief self-guided MBIs can take a number of forms. For example, concise online interventions, consolidate core psychotherapy components in 1-6 hour-long sessions to encourage behavioral changes [21,22]. However, such online interventions are typically conducted within full sit-down sessions and there are questions about whether such hour-long weekly session interventions optimally generalize to individuals' day-to-day lives and provide more long-term change. It is also difficult to know whether such sessions will generalize to the real world and day-to-day practice [23,24].

To address this concern, there has been more development of in-the-moment digital interventions provided and prompted in individuals' day-to-day lives via smartphone apps (also known as ecological momentary interventions [EMIs] [21]). EMIs leverage smartphones using web-based platforms with varying time courses, with or without human coach support [25,26]. These EMIs consistently offer real-time therapy content to boost emotion regulation (ER) and target SAD-associated symptoms [27]. Mindfulness ecological momentary interventions (MEMIs) provide concise and real-time prompts to apply therapy skills at the moment and thus could be superior to conventional digital MBIs by seamlessly integrating practices into everyday routines, targeting daily stressors and symptoms, and strengthening new ER habits [28-31].

Nonetheless, there remains a paucity of knowledge of individual predictors of variable response to brief MEMIs for SAD. RCTs offer aggregate-level efficacy estimates, however, they do not reveal patient-level variations in treatment response. Even small between-treatment effect sizes may conceal heterogeneous treatment effects [32]. At the same time, systematic reviews (eg, [33]) and empirical studies (eg, [34] indicated that symptom and treatment variables might predict individual differences in MBI efficacy. Investigating treatment response variability, also called heterogeneous treatment effects [35], is critical for identifying which individuals with SAD gain the most from brief MEMIs.

Research on heterogeneous treatment effects in SAD has primarily focused on resource-intensive, face-to-face, nonscalable psychotherapies rather than scalable MBIs. Studies have tested patient attributes, symptom severity, and treatment processes as plausible predictors of CBT efficacy [36-40]. For instance, meta-regression showed that greater baseline symptom severity predicted better response to CBT for SAD [41], whereas delivery approach and treatment duration were nonsignificant moderators of intensive MBIs [42]. Expanding this investigation to brief MEMIs for SAD is crucial to better inform treatment-matching.

Precision medicine approaches may optimize treatment-matching by tailoring brief MEMIs to people with SAD based on their unique baseline attributes to improve patient-centered care [43]. Machine learning (ML), which prioritizes prediction and explanation [44], can model complex (eg, nonlinear), multivariable, high-dimensional interactions to identify prescriptive predictors (treatment efficacy moderators [45]). Unlike ordinary least squares (OLS) regression methods, ML approaches could better identify nonlinear associations and moderation effects, enhancing the prediction of heterogeneous treatment effects [46,47]. Moreover, the ability of ML to generalize accurate predictions to new, previously unseen data renders it well-suited to guide and optimize treatment selection

XSL•FO
RenderX

[48]. Despite its potential, no studies have leveraged ML to predict heterogeneous treatment effects for brief MEMIs in SAD.

Integrating theories, such as capitalization versus compensation models [49], into ML methods can enhance variable selection and generalizability and minimize false discoveries by testing a prescriptive predictor set solely informed by theory, logic, and research [50]. The compensation model proposes that treatment response relies on effectively addressing patients' disorder-specific vulnerabilities and deficits [49]. Conversely, the capitalization model posits that treatment response is likely greater when harnessing clients' relative strengths [51].

Aligned with the compensation model, clients with SAD who display excessive perseverative cognitions, increased avoidance, greater depression severity, and impaired attention may benefit from MEMIs [49,52-56]. This is likely because MEMIs repeatedly teach nonjudgmental acceptance, present-mindedness, and valued activities. Consistent with the capitalization model, clients with fewer baseline SAD symptoms [57,58], higher self-compassion [59,60], stronger treatment credibility and expectancy [56], no current psychotropic medication, and greater trait mindfulness [13] benefitted from brief MBIs [56-61]. This may have been because these strengths helped increase engagement and positive self-fulfilling prophecies [51]. Findings on ER as a prescriptive predictor have been mixed [62,63], highlighting the importance of further research. Together, individuals with such profiles would likely benefit more from MEMIs for SAD than a self-monitoring-only app (SM).

Building on previous research, this study examined novel prescriptive predictors of a brief, fully self-guided, scalable MEMI for SAD. We extended an earlier RCT [64,65] on generalized anxiety disorder (GAD) to a new SAD sample [66]. This RCT showed that both MEMI and SM produced longer-term effects on SAD and its comorbid symptoms and risk factors, with significant between-group differences in momentary anxiety, depression, and mindfulness but not retrospectively reported symptoms [66]. Hypotheses were 2-fold. First, we predicted that multivariable prescriptive ML models would show acceptable performance (area under the receiver operating characteristic curve [AU-ROC] ≥.70) in predicting SAD remission (ie, absence of diagnosis based on the Social Phobia Diagnostic Questionnaire [SPDQ] [67]) at posttreatment and 1-month follow-up (1MFU; hypothesis 1). Acceptable model performance predicting differential efficacy to scalable interventions is crucial for building an actionable treatment selection tool. Second, we hypothesized that we could identify baseline variables that would predict the superiority of MEMI over SM at posttreatment and 1MFU SAD remission for individuals. In particular, we predicted that higher SAD, GAD, depression severity, perseverative cognitions, clinician-diagnosed anxiety or depression, as well as poorer trait mindfulness, and attention control, would predict better outcomes from MEMI (compensation model). We also predicted that higher compassion, treatment expectancy, credibility, absence of current psychotropic medication use, university education, and lower emotion dysregulation would predict better outcomes from MEMI versus SM (I model; hypothesis 2). Four other examined variables (age, sex, race, and current psychotherapy) were exploratory. Identifying prescriptive predictor patterns could help guide treatment-matching and optimize patient-centered care for SAD using under-investigated brief scalable MEMIs.

Methods

Participants

In our preregistered RCT [68,69], we used a 2 (treatment: MEMI, SM) by 3 (time: preintervention, posttreatment, 1MFU) mixed design to evaluate the efficacy of 14-day MEMI against SM in addressing clinical outcomes (Multimedia Appendix 1). Treatment assignment (MEMI or SM) was the between-person factor, whereas time was the within-person factor. This design for identifying treatment moderators with 17 prescriptive predictors using precision medicine was appropriate for several reasons. First, the assessor-blinded, balanced RCT design permits the adjustment of measured and unmeasured covariates and facilitates causal inference as part of developing the treatment selection tool [70]. Second, 2 armed RCTs facilitate identifying prescriptive predictors of the superiority of an active treatment to a control condition, which helps identify predictors specific to one form of treatment [71]. Also, the presence of randomization minimized selection bias, which could hinder the detection of prescriptive predictors [72]. Third, examining remission likelihood at 3-time points (pretreatment, posttreatment, and 1MFU) enabled testing whether prescriptive predictor patterns were generalizable across timeframes, offering more confidence in reproducible findings.

Ethical Considerations

The current secondary analysis of an individually randomized parallel-group, assessor-blinded RCT received ethical approval from the National University of Singapore (NUS). All participants offered voluntary informed consent and could withdraw at any time without penalty. Deidentified data were collected and stored on a secure-encrypted cloud server. Participants were reimbursed monetarily or through course credits for their participation.

Eligible participants met the criteria of self-reported SAD, defined as a Social Phobia Inventory (SPIN) [73] score of ≥20. The ≥20 SPIN score discriminated individuals with and without SAD in previous research, balancing both sensitivity and specificity [73-75]. Eligibility also included being aged 18 or older, possessing a smartphone, and actively seeking assistance for mental health concerns. To enhance participant safety and eliminate those unlikely to benefit from the interventions, exclusion criteria encompassed those who self-reported suicidal thoughts, mania, or psychosis. We recruited individuals from the psychology subject pool and local community.

Participants (N=191) were randomized to two groups: 96 in MEMI and 95 in SM (Table 1). On average, they were 21.84 (SD 3.37, range 18-53) years old, with 21.47% (14/191) identifying as male, 78.01% (149/191) as female, and 0.52% (1/191) as other; 86.39% (165/191) identified as Chinese, 2.09% (4/191) as Malays, 6.28% (12/191) as Indian, and 5.24% (10/191) as other; 87.43% (167/191) were single, in contrast to those who were married, cohabiting, or in an intimate

XSL•FO
RenderX

relationship but not residing together. The highest level of education achieved by 75.92% (145/191) of participants was junior college, as opposed to earning a diploma, university degree, or graduate degree. Psychotropic medications had been used by 5.24% (10/191) of individuals, and 15.71% (30/191) had received psychotherapy. For more information, refer to the Consolidated Standards of Reporting Trials (CONSORT)-eHEALTH checklist [76] in Multimedia Appendix 2.

Self-Report Measures

Social Anxiety Disorder Severity

The 25-item SPDQ [67] assessed SAD fear and avoidance symptoms across different social situations per DSM-IV (*Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition*) criteria. It has demonstrated good retest reliability and strong internal consistency (Cronbach α=0.96, 0.97, 0.98 at prerandomization, posttreatment, and 1MFU herein). The SPDQ evidenced strong discriminant validity, good convergent validity [67], and excellent sensitivity to change in RCTs [66].

Generalized Anxiety Disorder Severity

The 14-item generalized anxiety disorder Questionnaire-IV (GADQ-IV [77]) measured symptoms of GAD through a combination of binary ("Yes" or "No") and continuous responses, including two 9-point Likert scales to assess interference and distress caused by GAD symptoms [77]. It exhibited strong internal consistency (α=0.93 at prerandomization) and robust retest reliability [77]. In addition, it exhibited strong convergent and discriminant validity and demonstrated good concordance with structured diagnostic evaluations of GAD [77,78].

Depression Severity

The 21-item Beck Depression Inventory-Second Edition (BDI-II [79]) assessed the severity of depression symptoms. Participants selected the severity level (ranging from 0-3) that best matched their experience with each symptom over the past 2 weeks. The BDI-II exhibited strong internal consistency (α=.93 at prerandomization) and strong convergent and discriminant validity [80].

Baseline Clinical Variables

Participants responded to these questions: "Are you currently diagnosed with a psychological disorder or condition? If yes, please indicate the disorder or condition." "Have you ever been prescribed medications for emotional or psychiatric problems?" "Have you ever been in therapy or counseling?" and "What types of treatment are you currently receiving? You can choose multiple answers. (psychotherapy, medication, other [please specify], and not applicable)." The variables "current psychotherapy" and "psychotropic medication use" were derived from these questions and included in the predictor set. Data on changes in medication status were not collected at posttreatment and 1MFU.

Trait Emotion Dysregulation

The 36-item Difficulties in Emotion Regulation Scale (DERS [81]) measured participants' emotion dysregulation, including emotional confusion, goal inertia, nonacceptance, self-awareness limitations, and skill deficits. Responses were recorded on a 5-point Likert scale, ranging from 1 (almost never) to 5 (almost always). Research indicated excellent internal consistency (α=.86 at prerandomization), acceptable retest reliability [82], good convergent, and strong discriminant validity [83].

Trait Self-Compassion

The 26-item Self-Compassion Scale (SCS) [84] assessed trait-level self-compassion, including dimensions of common humanity, isolation, overidentification, mindfulness, self-judgment, and self-kindness. Responses were captured on a 5-point Likert scale, ranging from 1 (almost never) to 5 (almost always). Internal consistency was high herein (α=.92 at prerandomization). SCS scores also showed good retest reliability [85], strong convergent validity, and excellent discriminant validity [86].

Trait Perseverative Cognitions

The 45-item Perseverative Cognitions Questionnaire (PCQ [87]) assessed persistent, perseverative cognition tendencies associated with obsessive, ruminative, and worrisome thoughts. Participants rated items using a 6-point Likert scale ranging from 0 (strongly disagree) to 5 (strongly agree). It included 6 domains: anticipating negative outcomes, dwelling on the past, preparing for the future, thoughts conflicting with the ideal self, perceived lack of control, and searching for causes and meanings. It showed good internal consistency (α=.96 at prerandomization), strong 2-week retest reliability, excellent discriminant, and convergent validity, and cross-cultural measurement equivalence between the United States and Singapore [88].

Trait Mindfulness

The 39-item Five-Facet Mindfulness Questionnaire (FFMQ [89]) evaluated participants' inclination to practice mindfulness in 5 domains: observation, nonreactivity to inner experiences, nonjudgment, description, and awareness of the consequences of actions. It used a 5-point Likert scale, ranging from 1 (never or very rarely true) to 5 (very often or always true). The overall score of the FFMQ has shown strong convergent validity, differentiation from measures of unrelated constructs (eg, psychological well-being [89]), and good retest reliability. The α value was .90 at prerandomization.

Trait Attention Control

The Attentional Control Scale (ACS [90]) comprised 20 items, merging a 9-item measure of attention focusing with an 11-item measure of attention shifting. The ACS has good convergent and predictive validity [91], acceptable discriminant validity [92], and excellent retest reliability. The α value was .87 at prerandomization.

Treatment Credibility and Expectancy

Following the presentation of the video presentation of the therapeutic rationale in each group, participants completed the 6-item Credibility and Expectancy Questionnaire (CEQ [93]) to assess their belief in the credibility of the intervention and its potential to alleviate symptoms. Examples include "By the end of the therapy period, how much improvement in your symptoms do you think will occur?" and "By the end of the therapy period, how much improvement in your symptoms do you really feel will occur?" The CEQ demonstrated robust retest reliability and excellent internal consistency [93].

Procedure

Initially, eligible participants completed a set of counterbalanced questionnaires using the counterbalancing functionality in Qualtrics. Counterbalancing minimizes sequencing influences by randomizing the presentation order of individuals completing

XSL•FO
RenderX

unique self-assessments. This method prevented possible biases due to a fixed presentation order of the self-assessments, such as carry-over effects, fatigue, and practice effects [94]. Participants were then randomly assigned to MEMI or SM using the random generator function (RAND) of Microsoft Excel with permuted blocks of various sizes (2, 4, and 6) to create unpredictability [95]. This method gave every participant an equal probability of either group allocation. Allocation concealment was conducted by blinding research personnel who collected and analyzed data from the assigned group to maintain randomization integrity and prevent bias [96].

After completing all pretreatment assessments, the relevant group-assigned video using Qualtrics was provided toward the conclusion of the baseline visit. Participants installed the Personal Analytics Companion (PACO) app [97], which housed either MEMI or SM on their smartphones, with the video demonstrating its features. Participants were informed that they would receive prompts at 5 daily intervals (around 9 AM, noon, 3 PM, 6 PM, and 9 PM) during the subsequent 14-day period. Prompts could be adjusted to suit participants' schedules. To maintain validity, participants were instructed to input their responses on state depression, anxiety, and mindfulness both before and after the MEMI or SM induction within a 2-hour window of the prompt. Based on their assigned group, the app prompted guided participants to continually practice mindfulness or self-observation skills.

Group Characteristics

Mindfulness Ecological Momentary Intervention

Participants received a standardized video presentation in which the principal investigator explained evidence-based MBI protocols similar to MBSR. The video guided MEMI participants to immerse themselves in the present moment and empowered them with open monitoring and attentive engagement skills (ie, to attend to temporary moments). Afterward, the video therapist showcased the skill of paced, rhythmic diaphragmatic breathing and its application in practice. Diaphragmatic breathing retraining, resembling mindful breath awareness, has demonstrated effectiveness in both clinical [14,98] and nonclinical settings [99,100]. The video therapist continued by teaching nonjudgmental acceptance, incorporating elements of MBCT such as diaphragmatic breathing and mindfulness practices such as observation, nonreactivity, and nonjudgmental acceptance. These therapy components were selected to reduce SAD symptoms and self-criticism [13] and enhance ER and self-compassion [101]. Diaphragmatic breathing could induce physiological changes, such as lowering resting heart rate in conjunction with anxiety symptoms [102]. Next, each MEMI participant was informed about the importance of consistent mindfulness practice. The 6-item CEQ was then administered, and participants set up the MEMI on their smartphones (Multimedia Appendix 3). They were also provided with the MEMI treatment rationale handout via Qualtrics and encouraged to engage with mindfulness skills consistently.

Self-Monitoring

In the SM video presentation, the principal investigator began by defining self-observation as a heightened awareness of one's thoughts and emotions, with a particular emphasis on distressing experiences. The video suggested that monitoring thoughts and observing associated distress alone could encourage a healthier mindset. Essentially, the SM video conveyed that focusing solely on distress had the potential to alleviate anxiety symptoms. A recent and brief app intervention explanation inspired the rationale for SM as a placebo control [103-105]. Our SM adaptation sought to mimic MEMI while excluding its theorized active therapeutic elements, including acceptance, breath retraining, open monitoring, mindfulness of temporary moments, and regular mindfulness practice. It refrained from referencing mindfulness, excluded directions to heighten awareness of current experiences adaptively, and avoided guiding participants toward mood-altering engagement with the present moment. In contrast to MEMI, SM encouraged participants to observe their thoughts and emotions without instructing them to accept those thoughts and feelings as they arose. Breathing retraining guidance was missing, and there was no instruction to elicit calming sensations linked to diaphragmatic breathing. Whereas MEMI placed importance on developing skills persistently, SM participants were not urged to engage in self-observation between prompts or after the 14-day treatment phase (Multimedia Appendix 4). SM was designed to adjust for potential credibility, expectancy, and placebo effects, minimize regression to the mean, and decrease the likelihood of inflated effect sizes that might occur with waitlists or no-treatment controls [106,107]. Further details on treatment engagement, protocol fidelity, and rationale are provided in Multimedia Appendix 1.

Data Analyses

Our study adhered to the Transparent Reporting of Multivariable Prediction Model for Individual Prognosis or Diagnosis (TRIPOD) guidelines for conducting and reporting our research [108,109]. Missing data (10% [344/3438] in each training and test fold) was managed using random forest (RF) imputation [110] with the missRanger R package (R Core Team [111]) embedded in the nestedcv R package [112]. RF imputation was conducted instead of multiple imputations as it better handles diverse forms of missing data (eg, nonparametric relations), nonlinearities, and higher-order interactions, and generates less biased and narrower uncertainty estimates [113]. Model performance metrics also improved with RF imputation compared to multiple imputations in building multivariate ML models [113,114]. Imputation and standardization were not conducted in the whole dataset, as doing so would result in information leakage [115]. Thus, imputation was conducted separately on the training fold in the inner cross-validation loop and the test folds in the outer cross-validation loops of the ML analysis detailed below. Continuous variables were normalized to mean of 0 and SD of 1, and nominal variables were one-hot encoded separately in the training and test folds [112].

A simulation-based sample size determination method [116-118] indicated that to detect 2-way interactions of treatment x predictor for a binary remission outcome, a sample size of at least 150 was required with 17 initial predictors. The minimum sample size needed with the final top 10 prescriptive predictors was 100. Multimedia Appendix 1 details this sample size

XSL•FO
RenderX

determination method in the context of multivariable ML analyses.

To explore potentially prescriptive predictive models, we employed two algorithms—RF and support vector machine (SVM)—that are appropriate for relatively small sample sizes. RF trains a parallel ensemble of decision trees by drawing random samples from a dataset and including stop rules. Decision trees use training data to create a tree structure that forms branches at each predictor, enabling the prediction of outcomes. RF offers advantages such as decreased error rate, reduced susceptibility to overfitting (generalizability issues), and diminished influence of outliers over decision trees [119]. RFs can effectively manage correlations among predictors by automatically decorrelating decision trees. In addition, SVM classifies data using a hyperplane that optimizes the separation distance between groups, relying on input predictors. SVM outperforms logistic regression when groups are easily separable on outcomes of interest [120]. Both algorithms excel at handling sparse datasets with sizeable predictor-to-sample size ratios [121-124]. Also, the logistic regression algorithm used maximum likelihood estimation and logistic link function as a reference model. The AUCs of RF and SVM over logistic regression were compared using DeLong's test [125,126].

Instead of relying on a conventional training-test set or nonnested k-fold cross-validation approaches, we used nested 10-fold cross-validation (10F-CV) with 10 repetitions and grid-search [127]. Nested 10F-CV provides more robust performance estimates for small sample sizes, maximizes data utilization, minimizes bias, and controls for overfitting more than the split train-test approach [128,129]. It subsets the dataset into 10 outer and 10 inner folds [130]. Inner cross-validation is used to refine model selection and minimal tuning. In the outer folds, 10% (344/3438) of the data was reserved for model testing, whereas the remaining data was used for model development. This process was reiterated 10 times, each selecting a distinct 10% (344/3438) of the data for validation with unseen test data while training a new model using the remaining 90% (3094/3438). The overall performance was determined by calculating the mean classification performance of 10 independently developed models on distinct 10% (344/3438) subsets of the validation data not used in the model development process ([131]; refer to Multimedia Appendix 5, which elaborates on the rationale and procedures of these ML methods).

Using a counterfactual causal inference approach, we harnessed a 2-model learner (T-learner) approach to estimate remission probabilities for each individual across treatment arms, regardless of their actual intervention assignment (refer to 35 for a step-by-step tutorial and Multimedia Appendix 4 for a summary of the assumptions for this approach). This method entailed training RF models separately for the treated (MEMI) and control (SM) arms to predict remission rates within each arm [132]. We then applied these models to impute the predicted remission probabilities for each individual as though they had received each treatment, irrespective of their actual assignment. To improve the accuracy of these predictions and reduce overfitting, we used nested 10F-CV to maximize the likelihood of model estimates staying generalizable and robust [130]. The present method provided a nuanced comprehension of heterogenous treatment effects by generating participant-level predicted (or imputed) remission probability estimates (ranging from 0% to 100%) under both scenarios—treated and untreated—thus demonstrating each treatment's possible advantages and shortcomings for each person [133]. Participants were regarded as optimized to MEMI if their imputed remission probability scores were higher for MEMI than SM. Heterogeneous treatment effects were then identified by computing the difference in imputed remission probabilities between the two treatments for each individual. This difference score was used to determine which treatment generated a greater remission probability for each participant [134]. Participants were regarded as optimized to MEMI if their imputed remission probability scores were higher for MEMI than SM. This approach empowers researchers to efficiently identify subgroups with greater odds of gaining from particular treatment options, potentially offering personalized interventions.

Remission was defined as posttreatment and 1MFU SPDQ scores <12.13, as this cut-off yielded high specificity (true negative cases accurately detected; 134/143, 94%) and good classification accuracy (correct categorization into respective classes; 100/143, 70%) with SAD diagnosis [67]. For each individual, optimization to MEMI was coded as "1" versus "0" if the remission likelihood with MEMI exceeded the remission likelihood with SM. The initial ML model included 17 baseline predictors: age, gender, ethnicity, education, treatment credibility, expectancy, SAD, depression, GAD severity, clinician-diagnosed depression or anxiety disorder, baseline psychotherapy, current psychotropic medication use, trait attentional control, emotion dysregulation, mindfulness, perseverative cognition, and self-compassion. The final model comprised 10 top predictors of optimization to MEMI, which were selected through the elastic net regression algorithm variable screening filter and were well-suited for nested CV ML analyses [112].

For several reasons, the predictor set did not include intermediate variables not obtained at baseline, such as intervention engagement. First, including postbaseline variables would compromise randomization benefits, thereby biasing estimates of differential efficacy [135]. Second, adding postbaseline, intermediate variables into the prescriptive predictor models could lead to optimism bias, indicated by inflated effect sizes [136,137]. Third and most importantly, including variables, such as engagement, that can only be obtained later during the trial prevents building a clinically actionable and scalable multivariable model that could inform treatment selection from the outset solely using accessible baseline data [138].

Similar to the above, the future change status of variables (eg, current psychotherapy and medication use) was excluded from the multivariate equation. Controlling for covariates that change at future time points, sometimes called controlling for postintervention factors, might result in biased estimates by inducing spurious relationships between the treatment and unmeasured predictors [139]. In prospective studies such as RCTs, variables assessed postintervention might function as colliders or mediators, and statistically controlling for them

XSL•FO
RenderX

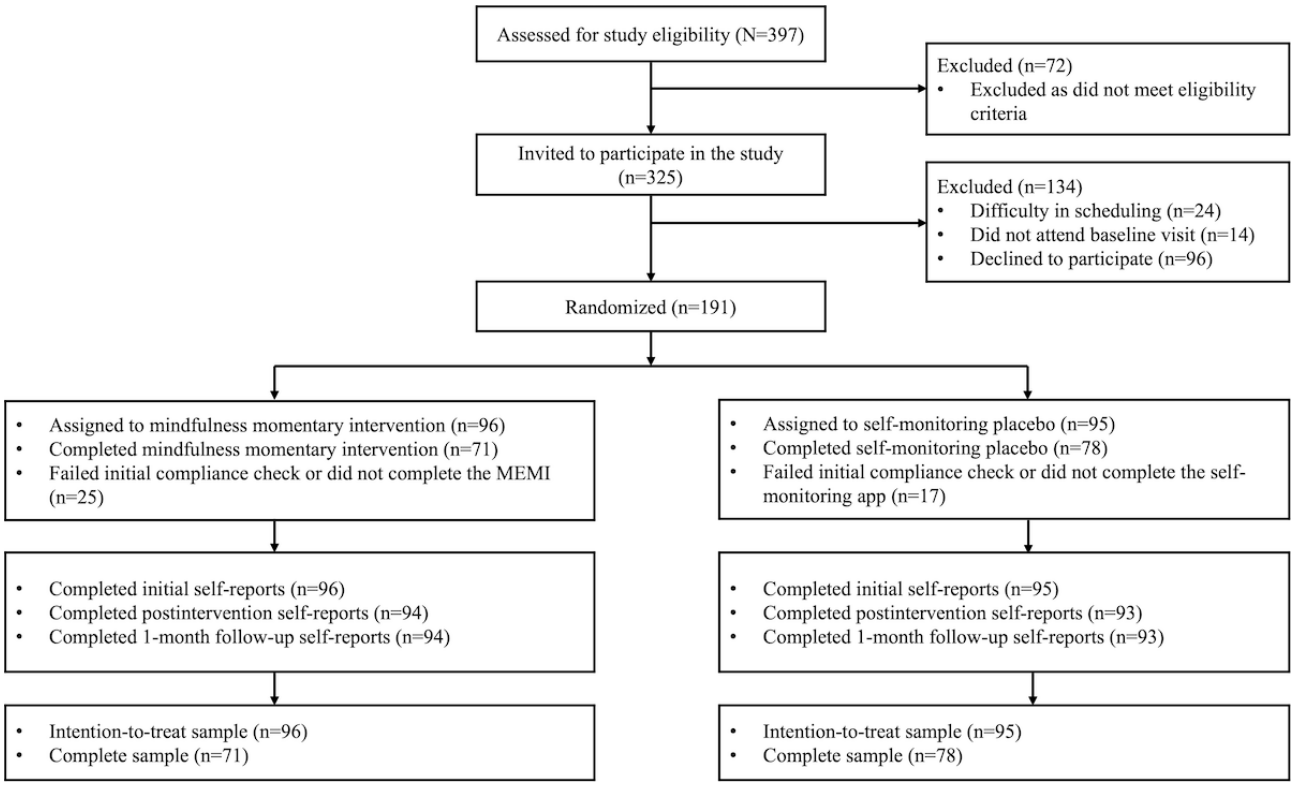
could create selection bias or obstruct the causal pathway [140,141]. Moreover, including change status covariates could result in overcontrolling, possibly generating spurious relationships or obscuring the estimation of true treatment effects and detection of prescriptive predictors [142].

AUC was used to assess classification performance. When AUC equals .50, it signifies that group differentiation was no more accurate than chance, whereas a range of .70-.79 indicates satisfactory differentiation, and an AUC of .80 or higher marks excellent differentiation. These guidelines also extended to two additional performance benchmarks: accuracy, which measures the proportion of correctly classified cases, and balanced accuracy (BAC), which represents the average of sensitivity (capacity to identify cases) and specificity.

To manage class imbalance in remission outcome, we applied the synthetic minority oversampling technique (SMOTE) by decreasing the overrepresented category while augmenting the underrepresented category to generate a more equitable dataset distribution [143]. SMOTE was implemented independently on the inner and outer folds to avoid data leakage and retain model evaluation integrity [144]. This procedure ensured that synthetic samples were created only within the training data of each fold, preventing contamination of the test set with artificially generated cases [145]. By performing SMOTE within each fold, model performance was more accurately tested with future unseen data, offering a robust estimate of its generalization abilities. This approach aligned with recommended practices in ML to manage imbalanced datasets while ensuring the reliability of CV outcomes [146].

Additional metrics were examined to test ML model performance more holistically. Sensitivity (true positive rate, which is also called recall) and specificity (true negative rate) were computed to evaluate the model's capacity to accurately determine optimal versus nonoptimal cases, respectively [147]. Positive predictive value (PPV), also called precision, indicated the percentage of optimization to MEMI versus SM cases that were accurately predicted [148]. The F_1-score, which balances precision and recall, offered a unique performance metric that considered false positives and negatives [149]. The area under the precision-recall curve (AUPRC) was computed to examine model performance under various thresholds, which could be particularly valuable for datasets with imbalanced outcome proportions [150]. Calibration analysis examined the degree to which predicted probabilities of optimization to MEMI aligned with actual outcomes (Multimedia Appendix 5), signifying the model's reliability for clinical decision-making [151].

Although interpreting individual ML model coefficients can be risky due to their focus on overall prediction accuracy over individual coefficient precision, gaining insight into the direction of associations between predictors and outcomes remains valuable. We explored the significance and direction of predictors of optimization to MEMI by using the kernel Shapley additive explanations (SHAP) technique, using the fastshap R package [152]. SHAP is a versatile method for assessing the significance of predictors and the direction of predictor-outcome associations in multivariate ML prediction models across various contexts. All analyses were derived from published ML tutorials [153-155].



Results

Overview

Figure 1 illustrates the participant flow and recruitment process, following the Journal Article Reporting Standards [69].

XSL•FO
RenderX

Figure 1. Consolidated Standards of Reporting Trials (CONSORT) diagram of recruitment flow.

Engagement Rates Across Intervention Arms

Engagement rates were defined as the proportion of MEMI or SM prompts (out of 70) completed during the 14-day intervention phase. For MEMI participants, engagement was measured based on their completion of questions asked of them before and after each 1-2-minute prompt to engage in slow, rhythmic, diaphragm breathing, present-mindedness, acceptance, and attending to small moments while doing an activity (Multimedia Appendix 3). For SM participants, engagement was measured based on responses to the same questions after noticing their thoughts and feelings for about 30 seconds and how distressing they might be (Multimedia Appendix 4). Participants indicated that they completed instructions in either arm by selecting "Okay" to those instructions and completing the postprompt or induction items. An earlier primary efficacy study reported the manipulation check, showing evidence of the validity of the momentary induction of MEMI versus SM in the same sample [66]. By this definition, engagement was 85.3% (60/70; SD 16.8%, 12/70) in MEMI and 85.1% (60/70; SD 18.7%, 13/70) in SM. No significant between-group differences in engagement rates were observed ($t_{186.52}$=–0.06, P=.95).

Evaluation of Efficacy and Effectiveness on SPDQ Remission

From pre-post treatment, no significant between-group effects on SPDQ remission were observed (MEMI: 15.6%; SM: 21.1%; χ^2_1=0.94, P=.33). Likewise, no significant between-group effects on SPDQ remission occurred from pre-1MFU (MEMI: 26.0%; SM: 26.3%; χ^2_1=0.002, P=.97). Nonetheless, within-group remission rates in both groups significantly increased from pre-post treatment (MEMI: 0 to 15.6%; χ^2_1=16.27, P<.001; SM: 0 to 21.1%; χ^2_1=22.35, P<.001) and pre-1MFU (MEMI: 0 to 26.0%; χ^2_1=28.74, P<.001; SM: 0 to 26.3%; χ^2_1=28.79, P<.001).

Testing Hypothesis 1 (Acceptable ML Model Performance)

Pre-Post Treatment Period

SVM was the best-performing initial ML model with all 17 baseline predictors (AUC=.70, 95% CI .68-.72, accuracy=.65, BAC=.65; refer to Table 2 for other performance metrics). Supporting hypothesis 1, the final SVM model with the top 10 predictors also yielded good performance (AUC=.71, 95% CI .69-.73, accuracy=.66, BAC=.66, AUPRC=.39). The AUC of the SVM (DeLong difference test P=.18) and RF model (DeLong difference test P=.23) were nonsignificantly better than the logistic regression model. Regarding calibration, the model-specific correlation between predicted probabilities and actual outcomes had a small-to-medium effect size (d=0.38; Multimedia Appendix 5).

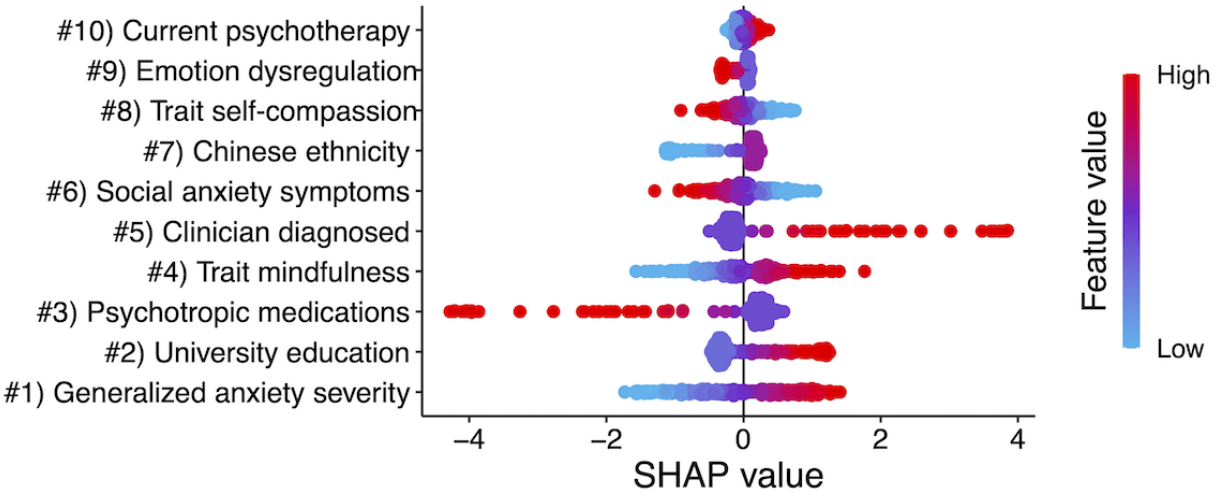
Pre-1MFU Period

SVM was the best-performing initial ML model with all 17 baseline predictors (AUC=.83, 95% CI .82-.85; accuracy=.74, BAC=.73; refer to Table 2 for other performance metrics). The AUC of the SVM (DeLong difference test P=.016) and RF (DeLong difference test P<.001) models were significantly better than the logistic regression model. Supporting hypothesis 1, the final SVM model with the top 10 predictors also generated good performance (AUC=.72, 95% CI .70-.73; accuracy=.68, BAC=.68, AUPRC=.38). Concerning calibration, the model-specific association between the predicted probabilities and actual outcomes had a small-to-medium effect size (d=0.37; Multimedia Appendix 5).



Testing Hypothesis 2 (Theory-Driven Prescriptive Predictors)

Pre-Post Treatment Period

Figure 2 presents the directions of association between each predictor and probability of posttreatment SPDQ remission in the final multivariate model. Regarding strengths, higher trait mindfulness (4), lower SAD severity (6), absence of current psychotropic medication use (3), university education (2), and current psychotherapy (10) predicted optimization to MEMI over SM. With regard to weaknesses, higher GAD severity (1), clinician-diagnosed depression or anxiety disorder (5), lower trait self-compassion (8), and trait emotion regulation (9) predicted better outcomes from MEMI against SM. With respect to sociodemographic variables, ethnically Chinese (7) participants were more likely to experience optimization to the MEMI than SM. These outcomes were partially consistent with hypothesis 2.

XSL•FO
RenderX

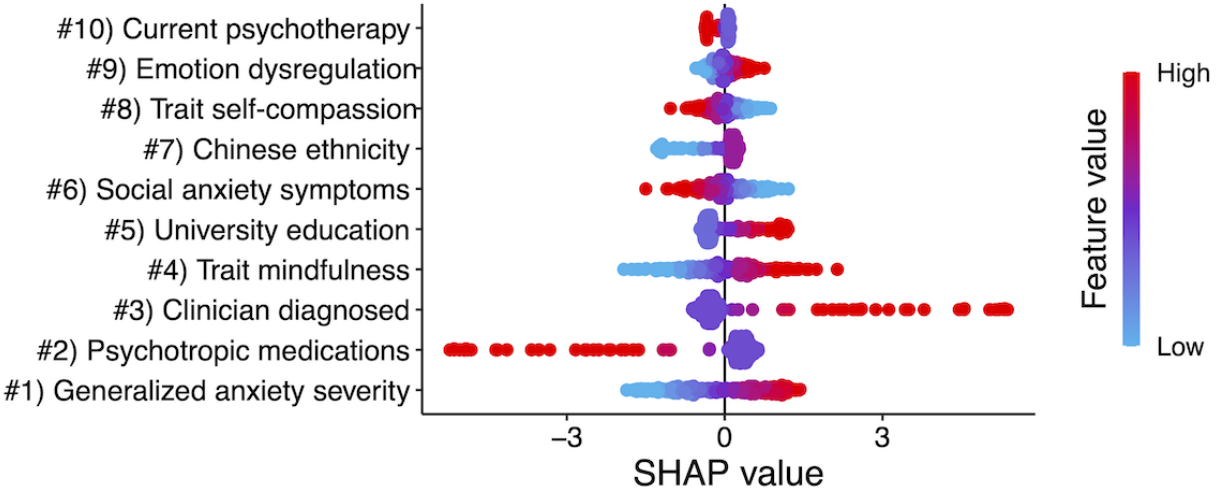


Figure 2. Top 10 prescriptive predictors of optimization to mindfulness ecological momentary intervention (MEMI) over self-monitoring app (SM) for social anxiety disorder at post-treatment in the final multivariate machine learning (ML) model. SHAP: Shapley additive explanations.

Pre-1MFU Period

Figure 3 presents the directions of associations between each predictor and the probability of 1MFU SPDQ remission in the final multivariate model. Regarding strengths, higher trait mindfulness (4), trait emotion regulation (9), lower SAD severity (6), absence of current psychotropic medication use (2), university education (5), and current psychotherapy (10) predicted optimization to MEMI over SM. With regard to weaknesses, higher GAD severity (1), lower self-compassion (8), and presence of clinician-diagnosed depression or anxiety disorder (3) predicted optimization to MEMI. Ethnically Chinese (7) participants also had a higher probability of experiencing optimization to the MEMI than SM. These results were partially concordant with hypothesis 2. Consistent with this hypothesis, GAD severity, clinician-diagnosed anxiety or depression (cf compensation model), no psychotropic medication, and higher education (cf capitalization model) predicted optimization to MEMI. At the same time, findings that lower SAD severity, self-compassion, and higher trait mindfulness were prescriptive predictors of better outcomes from MEMI were also consistent with predictions.

Figure 3. Top 10 prescriptive predictors of optimization to mindfulness ecological momentary intervention (MEMI) over self-monitoring app (SM) for social anxiety disorder at one-month follow-up (1MFU) in the final multivariate machine learning (ML) model. SHAP: Shapley additive explanations.

Discussion

Principal Findings

We aimed to test the value of ML in predicting posttreatment and follow-up SAD remission after a course of brief MEMI compared to SM. Consistent with hypothesis 1, all multivariate ML models had AUC values at or above .70, indicating clinically meaningful, moderate effect sizes (refer to AUC to Cohen *d* effect size conversions by [156]). PPV or precision (percentage of participants accurately predicted to respond better to MEMI than SM) and other key metrics (sensitivity, specificity, and F_1-score) also suggested acceptable model performance. SVM and RF notably performed better than logistic regression, concurring with previous precision psychiatry research [157] and indicating that these algorithms could outperform OLS regression to handle high-dimensional data sets to identify prescriptive predictors. Together, ML might hold promise in its ability to predict psychotherapy endpoints,

XSL•FO
RenderX

including brief, fully self-guided smartphone apps, and pinpoint factors predicting success early in the process.

Offering partial concordance with our second hypothesis, 8 of 10 baseline variables consistently predicted optimization to MEMI over SM regarding SAD remission at posttreatment and follow-up: 4 strengths (lower SAD severity, higher trait mindfulness, absence of psychotropic medications, university education), 3 weaknesses (higher GAD severity, lower trait self-compassion, clinician diagnosis of anxiety and depression), and 1 demographic variable (Chinese ethnicity). Relatedly, 2 variables (current psychotherapy and trait emotion dysregulation) in the final multivariate predictive models showed inconsistencies in the direction or sign of predictor-outcome relations, signaling variable instability [158]. Further research is thus required to evaluate their potential importance with larger sample sizes.

Plausibly, clinicians should consider incorporating a focused set of relevant baseline data when using machine learning (ML) models to guide treatment decisions. This approach can help improve the accuracy of predictions while remaining practical for implementation in clinical settings [159,160]. Potential accounts are put forth in interpreting these 8 variables that consistently predicted optimization to brief, fully self-guided MEMI over SM. Relatedly, these findings should be interpreted in the context that each predictor adjusted for all other predictors in the final multivariate model.

Why did those with baseline lower SAD severity and stronger trait mindfulness respond better to MEMI than SM? Replicating prior work [57], higher SAD severity, which indicated persistent avoidance, precluded benefitting from low-intensity, brief, fully self-guided MEMI as there were no directives to actively expose themselves to various feared social situations [161]. Further, similar to a previous meta-regression of MBI RCTs for SAD [13], perhaps those with high-trait mindfulness were already good at exercising nonjudgmental acceptance of and nonreactivity to inner experiences. Thus, MEMI's ongoing prompting may have further strengthened the habitual use of these skills (cf capitalization model [162]). This interpretation is aligned with a previous RCT, which showed that college students with high trait mindfulness were more likely to experience anxiety reductions after a brief MBI [163].

Two other noteworthy strengths that predicted optimization to MEMI against SM were not using psychotropic medications and university education status. Plausibly, patients taking psychotropic medications were less inclined to sustain improvements because they credited the gains to medication and thus ceased practicing mindfulness at follow-up. These interpretations aligned with the established depression literature [164-166]. Also, although the moderating role of education on EMIs has been mixed [167], higher education might correspond with stronger receptivity towards the MEMI.

Replicating and extending previous research [55,56], two baseline weaknesses—higher GAD severity and lower trait self-compassion—predicted better responses to MEMI against SM. Such findings might be attributed to evidence that brief 14-day MBIs could alleviate postevent brooding over social events. MEMI was most appropriate for high worriers, probably because its instructions of being present-minded, nonjudgmental, and accepting was the antithesis of worrying about the future (cf compensation model [49,64]). The outcome that lower trait self-compassion predicted higher benefits from MEMI might be because it was shown to differentially improve self-compassion domains for people with SAD, including self-kindness, interpersonal connectedness, and nonidentification with feelings [168].

Simultaneously, having been diagnosed with depression or anxiety disorders by a clinician predicted higher SAD remission probability via the MEMI over SM. Possibly, receiving an official diagnosis from a mental health care professional could boost their motivation to uphold their therapy skills practices. Future research could test the validity of these ideas by directly administering measures for the usage of therapy skills.

Also, those from the majority Chinese cultural group in Singapore (a Southeast Asian country), where our RCT was conducted, benefitted more from MEMI than SM compared to ethnic minority participants. These findings extended previous trials, which showed that MBIs, including the brief MEMI [168], produced stronger efficacy for White (vs non-White) individuals in mostly United States settings [169,170]. Since ethnic minorities comprised a disproportionately small proportion in this study (27/191, 14%), sampling error might have skewed outcomes toward the ethnic majority. Future studies should determine if a more balanced sample in terms of ethnic or racial composition might yield similar findings. Alternatively, modifying MEMIs for specific cultures might enhance their ability to meet the needs of ethnic minorities, which remain understudied in Asia [171]. However, the modifications rooted in real-life encounters (eg, institutional racism) demand thorough assessment due to the intricate interplay of intersectional factors (eg, economic and educational disparities) and varying conclusions regarding the efficacy of culturally tailored psychotherapies.

Seven variables were nonsignificant predictors: age, gender, treatment credibility, expectancy, self-reported depression symptom severity, trait attentional control, and repetitive thinking. Perhaps SAD patients with all levels of these baseline variables could benefit from the MEMI. The nonsignificance of age, gender, and trait repetitive thinking might suggest that those variables were not predictive of differential efficacy in the context of MEMI versus SM for SAD.

Findings should be interpreted considering study limitations. First, our models require further replication to determine their relevance across diverse samples. Enlarging the participant pool may enhance the accuracy of EMIs for SAD by using ML methods and customizing treatments based on individual traits. Nevertheless, ML-based multivariate predictive models using SVM and RF algorithms within nested cross-validation techniques allow for the development of treatment prediction models using modest sample sizes, such as ours, effectively tackling overfitting and class imbalance challenges [121,172,173]. Second, future endeavors should investigate the reproducibility of our ML models in the absence of SMOTE. Third, future research should expand the range of potential predictors to identify distinctive factors influencing differential

XSL•FO
RenderX

intervention outcomes. Fourth, prudence should be exercised when inferring causality while interpreting the predictor outcome associations and rank variable importance [174]. Fifth, future studies could enhance calibration by employing more advanced ML approaches, such as deep learning or ensemble methods, and include more relevant predictors to improve discriminative power indexed by the AUPRC [175,176]. Sixth, the value of ML, such as RF, over traditional logistic regression merits ongoing investigation [126]. Seventh, ML models should serve as treatment planning heuristics rather than offering rigid directives. Eighth, the primarily Chinese (164/191, 83.39%) and female (149/191, 78.01%) demographic composition might limit the generalizability of results to other gender and racial groups. Ninth, as depending solely on self-report could be vulnerable to response fatigue, response shift, recall bias, and method variance [177], future similar studies should administer performance tasks (eg, behavioral avoidance tests) and biomarkers (eg, physiology [178]) to ensure successful extinction of fear. Tenth, changes in psychotropic medication status were not assessed at posttreatment and 1MFU. Future studies should gather such data and ensure stable medication doses in all participants to rule out the possibility that any observed efficacy was due to medication changes. Finally, the exclusion criteria encompassed those who self-reported suicidal thoughts, mania, or psychosis, thereby limiting the generalizability of results to SAD participants with these psychiatric comorbidities [25,72]. However, excluding these participants is a sound approach to preserving internal validity and maintaining participant safety. It concurs with ethical principles for research with vulnerable populations and aids with adjusting for potential confounds that might bias findings.

Limitations notwithstanding, study strengths included the execution of an RCT in Asia, an understudied region [88,179], and low attrition of 22% (42/191), which was lower than meta-analytic weighted attrition rates of mindfulness apps ranging from 24.7% (2287/9258) to 38.7% (3583/9258) [180]. Further, 78% (149/191) actively participated in at least 80% (56/70) of the EMI prompts. Another strength of the study was that some of the predictors examined (eg, current medication use, psychotherapy status) were unlikely to change during the 6-week study period. Finally, all the assessment tools used herein had a well-established history of use in RCTs and have shown good sensitivity to change [66,181-183].

Conclusion

To conclude, the AUC values of .71-.72 of the prescriptive predictor models implied moderate performance, suggesting that more fine-tuning and validation are needed to raise confidence about their real-world clinical utility [184]. However, these findings offer an enhanced understanding of plausible prescriptive predictors of scalable MEMI outcomes for SAD. Broadly, clinical psychology encounters obstacles when implementing precision medicine approaches [185]. However, the present study adds to growing evidence that building ML-derived intervention allocation rules in examining which client with SAD benefits from the MEMI might enhance the caliber of data-driven clinical judgment. Thus the study provides potential precision treatment guidelines by means of uncertainty and probability framing [186] and prescriptive calculators [187]. Such prescriptive calculators should include significant predictors (in the present context, the 8 consistent predictors), exclude nonsignificant predictors (eg, age, gender), and focus on strengths and weaknesses, as informed by the capitalization and compensation models. Tailored treatments could enhance patient acceptance while optimizing the integration of evidence-based intensive psychotherapies in clinical services. Ultimately, though further refinement will be required to enhance prescriptive, predictive performance, incorporating EMI prescriptive models into routine care may enhance the effectiveness and efficiency of treating SAD within stratified care models [48].

Abstract

Background: Fully decentralized self-administered mindfulness interventions show promise for stress reduction, but rigorous evaluations of their feasibility, acceptability, and effectiveness using both self-report and physiological measures remain limited. In Singapore, where mental health concerns rank as the top health care priority (46%), ahead of cancer (38%) and stress-related issues (35%), accessible and scalable interventions are urgently needed to address the significant economic burden of mental health conditions.

Objective: This study aimed to evaluate a decentralized, 3-day self-administered mindfulness intervention with minimal supervision, compared with a sham control in Singaporean adults, examining effects on self-reported and physiologically measured stress responses. The inclusion of a sham control condition was intended to disentangle mindfulness-specific effects from demand characteristics and expectation effects, addressing a critical methodological gap in digital mindfulness research.

Methods: This was a purely smartphone-based, decentralized pilot trial with no face-to-face components. Participants were recruited using web-based methods and, after providing informed consent, 60 adults were randomized to either a mindfulness intervention or a structurally matched sham control. The daily 10-minute mindfulness sessions guided participants to focus on present-moment breath and body sensations, while the sham control omitted a focus on present-moment awareness. Outcomes were assessed remotely, using self-report questionnaires (State-Trait Anxiety Inventory-6) and physiological data from smartphone-based photoplethysmography (heart rate variability; HRV). The study incorporated three methodological innovations: (1) a structurally equivalent sham control to match expectancy and credibility, (2) remote collection of HRV as an objective physiological biomarker, and (3) full decentralization allowing unsupervised multiplatform delivery. Feasibility was evaluated through recruitment, retention rates, and data quality. Acceptability was assessed through quantitative ratings and qualitative feedback.

Results: The study demonstrated excellent feasibility, with near-perfect retention (59/60, 98.3%) and moderate HRV data quality (231/331, 69.8% valid signals). Acceptability ratings were high (mean 4.17, SD 0.53), with comfort/engagement receiving the highest scores (mean 4.27, SD 0.57) on a 5-point scale, exceeding established usability benchmarks for digital health interventions. Qualitative feedback identified technical challenges (HRV instability and device overheating) and scheduling difficulties. While Bayesian analyses did not detect significant group differences in stress reduction (Bayes factor$_{10}$ [BF$_{10}$]=0.03) or HRV improvement

XSL•FO
RenderX

(BF_{10}=0.2), both groups showed significant stress reductions (BF_{10}=3.01×10^6), suggesting that observed benefits may stem from nonspecific factors common to both interventions.

Conclusions: This study demonstrates (1) the feasibility of conducting fully decentralized mindfulness trials with multimodal assessment, (2) the value of a mixed methods acceptability evaluation, and (3) the identification of key technical and control condition refinements necessary for future trials. By addressing methodological limitations through improved control conditions and objective measures, this study provides a foundation for more rigorous investigation of mindfulness-specific effects.

Introduction

The Public Health Burden of Stress in Singapore

Stress exerts a pervasive influence on psychological and physiological well-being, contributing to conditions such as depression and anxiety [1-3]. In Singapore, mental health concerns rank as the top health care priority among residents (46%), ahead of cancer (38%) and stress-related issues (35%) [4]. The economic costs are also considerable: symptoms of depression and anxiety are estimated to account for a 2.9% loss of Singapore's gross domestic product. Addressing this burden requires interventions that are not only effective but also scalable, accessible, and acceptable to diverse populations beyond traditional clinical settings.

Methodological Challenges in Digital Mindfulness Research

Mindfulness—particularly in digital, self-administered formats—has emerged as a promising strategy for supporting mental health at scale, with a growing body of evidence linking it to reductions in stress, anxiety, and emotional dysregulation [5,6]. In particular, self-administered mindfulness (SAM) interventions—which remove the need for trained instructors and in-person delivery—offer practical advantages regarding reach, cost-effectiveness, and ecological validity [7]. However, concerns remain about the strength of the evidence for such interventions, particularly when delivered digitally and evaluated in uncontrolled or self-selected samples. Recent reviews point to challenges, including small effect sizes, publication bias, reliance on self-report outcomes, and insufficient control for nonspecific treatment effects, such as placebo and demand characteristics [8-11]

Demand characteristics and placebo effects are particularly salient in digital mental health studies, including mindfulness research. Participants may overreport improvements because of perceived researcher expectations [12] or inflated beliefs about the intervention's efficacy [13,14], especially when control conditions lack structural and experiential equivalence [9]. A high-powered, preregistered, multisite study [6] addressed this concern by comparing SAM to an active control (story listening), but its control condition lacked key features of meditation itself that may be needed to effectively control for nonspecific factors and fully isolate mindfulness-specific effects.

Bridging Gaps in Decentralized Mindfulness Research

This study addresses these methodological limitations by pilot-testing and evaluating a fully decentralized SAM intervention, compared with a structurally matched sham control. This study aimed to assess the feasibility and acceptability of delivering both interventions entirely remotely, while exploring preliminary effects on stress-related outcomes. The design incorporated three methodological innovations intended to improve future scalability and internal validity: (1) a sham intervention designed to match the SAM intervention in structure, expectancy, and credibility, and capable of disentangling potential mindfulness-specific effects from nonspecific effects (eg, expectancy and demand characteristics); (2) remote collection of heart rate variability (HRV), an objective physiological biomarker of stress; and (3) full decentralization of all procedures via smartphone, allowing unsupervised delivery across multiple platforms to maximize reach and minimize barriers to participation and potential sources of bias.

Study Aims and Hypotheses

Feasibility and acceptability were evaluated to inform the design of future trials. Feasibility was assessed through recruitment and retention rates (documented via a CONSORT [Consolidated Standards of Reporting Trials] flow diagram), cross-platform delivery evaluation (Qualtrics, [Qualtrics], WhatsApp [Meta], and Camera HRV [ASMA BV]), adherence to protocols (including outcome measurement completeness), and physiological data quality. To contextualize our benchmarks, we drew on evidence from a meta-analysis of smartphone app trials for depressive symptoms [15], which reported an average 26.2% dropout rate (73.8% retention) across 18 randomized controlled trials, rising to 47.8% (52.2% retention) after adjusting for publication bias. Notably, studies incorporating human feedback and in-app mood monitoring demonstrated lower attrition. Aligning with these findings, our trial integrated WhatsApp for real-time human support and the app Camera HRV for physiological self-monitoring—strategies hypothesized to mitigate dropout. However, given the pilot nature of our study and the need to ensure rigor for subsequent efficacy trials, we adopted stricter feasibility criteria than typical app-based studies: recruitment of 60 participants, retention >80%, and ≥70% valid HRV or State-Trait Anxiety Inventory-6 (STAI-6) adherence. These targets exceed both the unadjusted and adjusted retention

XSL•FO
RenderX

rates reported by Torous et al [14], reflecting our emphasis on optimizing engagement in a small-scale pilot. Acceptability was assessed via a 17-item usability questionnaire, open-ended feedback, and measures of credibility and expectancy.

While acceptability thresholds were not predefined, we interpreted results using benchmarks derived from System Usability Scale (SUS) literature [15,16]. Specifically, a retrospective study by Brooke [15] highlights that mean item scores ≥4 on 5-point Likert scales (eg, *strongly agree*) correspond to SUS scores >80, a threshold associated with "excellent" usability in digital tools. Lewis [16] further underscores that such scores, when coupled with low variability (SD ≤0.8), reflect strong consensus among users—a critical marker of acceptability in pilot interventions. These criteria align with mobile health studies that simplify SUS principles for feasibility-focused trials while retaining methodological rigor.

Our primary intervention hypothesis posited greater self-reported stress reduction in the mindfulness group, compared with the sham control group. The secondary objectives explored (1) HRV as a physiological stress marker, (2) ecologic momentary assessments (EMA)–derived transient states (eg, fatigue), and (3) moderation by baseline traits (ie, Five Facet Mindfulness Questionnaire [FFMQ], resilience, and neuroticism). Bayesian methods were used to estimate effect sizes and uncertainty, prioritizing practical interpretation over dichotomous significance testing. By aligning our feasibility framework with evidence-based strategies to reduce attrition (eg, the use of human engagement tools) and setting ambitious retention targets, this pilot bridges gaps identified in previous app trials and lays a robust foundation for fully powered efficacy studies.

Methods

Ethical Considerations

This study was conducted in accordance with the Declaration of Helsinki and approved by the Agency for Science, Technology and Research (A*STAR) Institutional Review Board on November 26, 2023 (reference 2024-102). All participants provided informed consent online via a survey administered on the Qualtrics platform. To protect anonymity, all study data were deidentified. Phone numbers were collected separately for operational purposes (ie, participant compensation, HRV data collection, and prevention of duplicate submissions) and were permanently deleted upon study completion. Participants were reimbursed via PayNow, receiving SGD $5 (US $3.88) for each completed daily assessment and an additional SGD $5 (US $3.88) bonus for completing all assessments, up to a maximum of SGD $20 (US $15.52).

Recruitment and Eligibility

Participants were recruited via an online screening form that assessed eligibility based on several predefined criteria to ensure the safety of the participants and the integrity of the research. To qualify, individuals had to be aged at least 21 years, proficient in English, and willing to comply with all the study procedures. They must not have practiced meditation within the previous 6 months, used recreational drugs, or had uncorrected vision or hearing impairments. The participants were also required to have no history of mental illness, no diagnosed major neurological or psychiatric condition within the past 6 months, and no current or recent use (within the past week) of psychoactive medications, including antidepressants, anxiolytics, hypnotics, or stimulants. Given that the study procedures were conducted online, participants were also required to have access to the internet and sufficient computer literacy to complete the screening and study tasks. Finally, individuals with any current or prior affiliation with Agency for Science, Technology and Research (A*STAR) research teams were excluded.

Before proceeding, the participants were informed that the screening included questions designed to determine their eligibility and that honest responses were essential. The survey was configured to present each screening question individually and to terminate immediately if any exclusion criterion was met. This approach was adopted to reduce unnecessary exposure to sensitive questions and to maintain participant comfort and confidentiality.

Phone numbers were collected to prevent duplicate submissions and to facilitate compensation via PayNow, a Singapore-based instant payment system that allows direct bank transfers using mobile numbers. Duplicates were flagged by the study coordinator, and data from ineligible participants were immediately discarded.

The eligible participants received a Qualtrics link to review the study protocol and the consent form. Because of the study's minimal risk (no medication or incidental findings), consent was obtained remotely without a witness. Participants who declined consent were excluded. Those who consented completed additional screening questions about neurological or psychiatric conditions and concomitant medication; failure to meet the criteria resulted in automatic termination.

Materials

All study materials (ie, the meditation scripts, the analytic code, and the deidentified data) are hosted on Open Science Framework (OSF) [17], and the protocol was preregistered (ClinicalTrials.gov NCT06765889). The design followed a randomized, double-blind, 2-arm, parallel-group framework and was conducted remotely over 4 days (1 day for consent and 3 days for the study procedures). This was an entirely remote pilot study conducted through smartphones, with no in-person interactions. This trial is reported in accordance with the CONSORT 2010 statement [18] and its extension for digital interventions, CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) [19]. The CONSORT checklist can be found in Multimedia Appendix 1.

Procedure

Overview

After providing consent, the participants were aggregated into cohorts of 20 and notified that the study would commence within 2 weeks. The cohorts were initiated weekly, with additional cohorts added as needed to reach the recruiting target of 60

XSL•FO
RenderX

participants. Following calculations by Whitehead et al [20] for continuous outcomes, the sample size (n=60) provided adequate precision to estimate feasibility parameters. The eligible participants received the following via a WhatsApp message from the study coordinator: (1) a Qualtrics survey link with a unique anonymous access code and (2) instructions for downloading and using the Camera HRV app [21], a third-party smartphone app that measures HRV via photoplethysmography (PPG) without requiring external hardware. The guidelines included (1) proper measurement protocols, (2) steps for submitting the recorded data as a .csv file, and (3) a free download code for the Camera HRV app.

The HRV data were collected via the app, and the participants submitted the files through WhatsApp to the study coordinator.

Beginning of Study Measurements

The participants who were eligible to start the study were instructed to move to a quiet environment for 35 minutes. They downloaded the Camera HRV app, conducted an initial test HRV measurement, and self-reported their root mean square of successive differences (RMSSD) between normal heartbeats values in the Qualtrics survey. They then completed demographic questions (ie, age, gender, ethnicity, type of device used for the experiment, the operating system, and the corresponding version) and the following scales:

- Neuroticism subscale of the International Personality Item Pool (International Personality Item Pool-20) [22]; this scale consists of 20 items assessing self-reported levels of neuroticism (α=0.95; 95% CI 0.93-0.96). Example items include "I often feel blue" and "I am filled with doubts about things," rated on a 5-point scale ranging from 1 (very inaccurate) to 5 (very accurate).
- Resilience Scale 14 [23]; the Resilience Scale 14 is a brief version of the Resilience Scale, comprising 14 items rated on a 7-point Likert scale (α=0.92; 95% CI 0.90-0.95). Example items include "I usually manage one way or another" and "I am determined."
- FFMQ-Short Form (FFMQ-SF) [24]; the FFMQ-SF is a 24-item measure assessing 5 facets of mindfulness (α=0.77; 95% CI 0.67-0.84). The 5 facets are observing (eg, "I pay attention to sounds, such as clocks ticking, birds chirping, or cars passing"); describing (eg, "I'm good at finding words to describe my feelings"); acting with awareness (eg, "I find myself doing things without paying attention"); nonjudging of inner experience (eg, "I criticize myself for having irrational or inappropriate emotions"); and nonreactivity to inner experience (eg, "I perceive my feelings and emotions without having to react to them").

Pre- and Postintervention Assessments

The STAI-Short Form (STAI-6) scale [25], EMA [26], and HRV were measured twice daily—once before and once after listening to each audio track.

The STAI-6 is a validated short-form version of the 40-item STAI. It consists of 6 items measuring current anxiety symptoms "right now" using a 4-point Likert scale (α=0.88; 95% CI 0.86-0.90). Example items include "I feel calm" and "I am tense."

In the EMA, participants rated their current state using a slider scale from 1 (not at all) to 100 (very much). The following 7 questions were used to assess various psychological and physical states:

1. "Right now, I feel mentally sharp"—to assess cognitive clarity and alertness.
2. "Right now, I feel fatigued"—to measure levels of fatigue and exhaustion.
3. "Right now, I feel stressed"—to gauge current stress levels.
4. "Right now, I feel nervous"—to assess feelings of nervousness and tension.
5. "Right now, I feel depressed"—to evaluate depressive symptoms.
6. "Right now, I am in a good mood"—to measure positive affect and emotional well-being.
7. "I slept well last night"—to assess subjective sleep quality, this last item was measured only once per day.

HRV was measured to assess parasympathetic activation using the PPG-based Camera HRV app [21]. PPG-derived HRV via smartphone cameras has been validated in multiple studies as a practical alternative to an electrocardiogram (ECG) under controlled conditions. For example, a validation study demonstrated perfect agreement between smartphone PPG and ECG for RMSSD, a key time-domain HRV metric linked to parasympathetic activity, particularly in resting-state measurements [27]. The Camera HRV app specifically has been benchmarked against research-grade devices. In comparative testing against the Polar H7 chest strap (a device previously benchmarked against ECG), Camera HRV demonstrated strong agreement for both heart rate and HRV metrics. Specifically, it achieved a correlation of r=0.97 for heart rate during rest and paced breathing conditions. For HRV parameters, the app showed a correlation of r=0.78 for RMSSD, with improved agreement (r=0.87 for pNN50) after application of its artifact correction algorithms [21].

The participants were instructed to place their index finger fully over the smartphone's camera and flash, and to remain still for 1 minute to minimize motion artifacts. The app automatically flagged recordings as "poor" if signal quality fell below preset thresholds (eg, irregular pulse detection or incomplete coverage). The participants were instructed to take up to 2 additional attempts in this scenario.

End-of-Study Assessments

Usability and acceptability were assessed using a structured 17-item questionnaire grounded in established usability frameworks, including the SUS [16] and technology acceptance models [28]. The questionnaire evaluated key dimensions identified in digital health research [29], such as clarity of instructions, engagement, comfort, perceived efficacy, and overall satisfaction with the study procedures and tools (α=0.92; 95% CI 0.89-0.95). The questionnaire included 17 items rated on a 5-point Likert scale (1=*strongly disagree*, 5=*strongly agree*), measuring the following:

- Ease of access and navigation, for example, "The survey was easy to access and complete."

XSL•FO
RenderX

- Clarity of instructions, for example, "The instructions for conducting the meditations were clear."
- Comfort and engagement, eg, "The meditations were pleasant."
- Technical usability, for example, "It was easy to download the app used to measure heart rate."
- Study procedures, for example, "The study procedures were reasonable in terms of time commitment and effort."

Open-ended questions (eg, challenges and time commitment) were used to expand on quantitative data, following recommendations for mixed methods usability assessments [30].

The Perceived Awareness of the Research Hypothesis (PARH) scale [31] is a 4-item quantitative self-report tool designed to assess the potential impact of demand characteristics in research settings. The participants responded to statements using a 7-point Likert-type scale (1=*strongly disagree*, 7=*strongly agree;* α=0.91; 95% CI 0.87-0.95). Example statements include "I was aware of the researchers' objectives in this study," or "I was uncertain about the researchers' intentions in conducting this research."

To assess the participants' expectations regarding the intervention's effectiveness, a single item adapted from the Credibility/Expectancy Questionnaire [32] was administered during the final phase of postintervention testing: "How effective do you believe the meditation training has been in alleviating stress? (0=*not at all successful*, 10=*extremely successful*)."

To evaluate credibility, the participants responded to a two-part question:

1. "If you were informed that you might have received either meditation training or control training, which type do you believe you received? (*meditation and control*)."
2. "How confident are you in your answer? (0=*not at all confident*, 10=*extremely confident*)."

Intervention Development

To ensure that the mindfulness and sham interventions were grounded in best practices and optimized for a brief, decentralized format, we conducted a formative focus group with 5 certified international mindfulness-based stress reduction (MBSR) instructors before the pilot trial. The primary objective was to gather expert consensus on the core components, duration, and structure of a mindfulness protocol suitable for a multiday, self-administered study with a nonclinical population experiencing stress. The expert panel's recommendations directly shaped the core parameters of the final study design. To ensure accessibility for beginners in a remote context, the instructors guided us to focus on foundational practices, leading to the selection of exercises centered on attentional stability through breath awareness and mindful meta-awareness of thoughts and sensations.

The panel also advised that a brief daily session of approximately 10 to 12 minutes would be optimal for maximizing engagement and adherence. On the basis of this, we implemented a 3-day "taster" protocol, which was considered an appropriate duration to robustly test the feasibility and acceptability of the intervention before scaling to a longer trial.

The focus group also informed the design of the sham condition, which highlighted the challenge of creating a credible control. The experts suggested leveraging common misconceptions about meditation (eg, that it is purely a relaxation or thought-engagement exercise), which led to our final design emphasizing free-flowing thought and multitasking rather than present-moment awareness. The summary and transcript of the focus group can be found on the OSF page of the project [17].

Randomization and Experimental Conditions

Overview

Participants were randomly assigned via Qualtrics to 1 of 2 experimental conditions: a mindfulness intervention or a sham meditation condition. The randomization process was implemented using the built-in Randomizer feature within the Qualtrics Survey Flow. This tool was configured to assign participants to the experimental conditions in a 1:1 ratio using the "evenly present elements" option, ensuring a balanced allocation across the duration of the study. Both conditions included audio-guided sessions recorded by the same certified MBSR instructor to maintain structural equivalence in delivery. The sessions were embedded within the Qualtrics survey and could not be skipped for 10 minutes (matching the time of the audio track).

Mindfulness Intervention

The mindfulness tracks were written and recorded by a certified MBSR instructor from Singapore with more than a decade of experience. The intervention included 3 unique guided practices, each designed to strengthen attentional stability and meta-awareness, which are key mechanisms associated with effective mindfulness training and stress regulation [33-35]. The sessions focused on the following elements:

1. Attentional stability; the participants were guided to anchor their focus on present-moment bodily experiences, such as breath sensations, physical posture, or environmental stimuli, to enhance their ability to sustain attention without distraction.

2. Mindful meta-awareness; the practice encouraged nonreactive and nonjudgmental observation of thoughts, emotions, and bodily sensations, fostering acceptance and self-regulation skills.

Each track emphasized present-moment awareness using different modalities:

1. On day 1, formal mindfulness practice (ie, body awareness meditation)—participants were encouraged to be attentive to bodily sensations, surrounding sounds, and breath, training them to maintain awareness despite distractions.
2. On day 2, informal mindfulness practice (ie, mindful brushing of teeth)—the participants were guided to integrate mindfulness into the act of brushing their teeth, approaching this habitual behavior with curiosity and full attentiveness. The practice encouraged awareness of sensations, movements, and breath, fostering a mindful presence.
3. On day 3, breath awareness practice—participants were guided to observe the natural rhythm of breathing without trying to change it, reinforcing nonjudgmental awareness.

XSL•FO
RenderX

Sham Meditation Condition

AS and JND developed the sham meditation condition, with JND contributing expertise in implementing such control conditions [8]. After finalizing the sham, the mindfulness instructor reviewed it to ensure that no core mindfulness components remained. Designed to structurally mirror the mindfulness intervention, the sham condition intentionally excluded key mindfulness mechanisms (eg, attentional stability and meta-awareness). The goal was to create an experience that matched the mindfulness group in duration, delivery format, and voice, thereby controlling for nonspecific factors, while guiding participants through exercises that emphasized multitasking and free-flowing thought, creating an experience that felt meditative to novices without delivering active mindfulness training [8]. Specifically, the sham condition was designed to differ from the mindfulness intervention in two fundamental ways: (1) a lack of attentional stability; unlike the mindfulness condition, the sham sessions did not provide an anchor for attention, and participants were encouraged to allow their thoughts to wander freely, shifting between different ideas and tasks; and (2) a lack of metacognitive guidance; instructions omitted any emphasis on nonjudgmental awareness, acceptance, or self-observation; rather, participants were prompted to engage with multiple thoughts at once, emphasizing cognitive agility and rapid task switching.

Each sham session included the following: on day 1, associative thinking (eg, encouraging free-association thinking)—participants were guided to let their minds jump between thoughts, focusing on productivity and efficiency rather than present-moment awareness; on day 2, routine task engagement (ie, brushing teeth while thinking about tasks)—participants were encouraged to perform everyday activities (eg, brushing teeth) while reflecting on unrelated tasks; this approach emphasized multitasking without cultivating mindful curiosity or awareness; on day 3, creative exploration (eg, picking a thought and expanding on it)—participants were instructed to select a thought and expand on it through imaginative thinking. This exercise promoted mental flexibility and creativity but did not involve sustained focus on present experiences.

The script of the active and control condition, along with the corresponding audio tracks, can be found on the OSF page of the project [17].

Daily Procedure

The participants repeated the same procedure on days 1, 2, and 3:

1. Complete the preintervention self-report assessments (STAI-6, EMA, and HRV)
2. Listen to a different mindfulness or sham meditation track, depending on group allocation
3. Sit quietly for 3 minutes to minimize confounding variables in the subsequent HRV assessments
4. Complete the postintervention self-report assessments (ie, STAI-6, EMA, and HRV)

The participants were instructed to complete their daily sessions at approximately the same time each day to ensure consistency. They were informed that the sessions on days 1 and 3 would each take approximately 35 minutes, while the day 2 session would take around 25 minutes. On day 3, after the traditional postintervention assessments, the participants also completed the end-of-study assessments: the PARH scale, the expectancy and credibility of the intervention, and the usability and acceptability questionnaire. Finally, the participants were asked to send the .csv files generated by the Camera HRV app via WhatsApp to the study coordinator, which encompassed all the HRV measurements taken during the study. The participants were then thanked for their participation, debriefed, and provided compensation via PayNow.

Statistical Analysis

Primary Outcomes: Feasibility, Acceptability, and STAI-6

We first evaluated feasibility using three key metrics: (1) recruitment yield (completed to enrolled ratio), (2) retention rates, and (3) protocol adherence (STAI-6 and HRV completion percentages). Acceptability was assessed via the 17-item usability questionnaire (analyzed descriptively) and qualitative coding of open-ended responses. We implemented a Bayesian latent growth curve model using the *brms* package [36] to examine the effects of the mindfulness intervention on self-reported stress (measured via the STAI-6). We specified a model that included fixed effects for the time point of the assessment (preintervention vs postintervention), the condition (mindfulness vs sham), and their interaction; a covariate for day to account for potential daily fluctuations; and random slopes for time point that varied by participant to account for individual differences in responsiveness to the intervention.

We used weakly informative priors: normal (0, 1) for the fixed effects, normal (0, 5) for the intercept, and Cauchy (0, 2) for the random effects SDs. For each model, we ran 4 Markov Chain Monte Carlo chains with 4000 iterations each, using an adaptation delta of 0.95 to ensure adequate chain mixing and convergence. To evaluate the evidence for the experimental manipulation, we compared the full model (including the time point × condition interaction) with a null model without this interaction term. We used a Bayes factor (Bayes factor$_{10}$ [BF_{10}]) comparison between the full and null models to quantify the relative evidence for each model. According to the classification of Lee and Wagenmakers [37], a $BF_{10}>1$ provides evidence in favor of the full model (ie, the alternative hypothesis), whereas a $BF_{10}<1$ favors the null model.

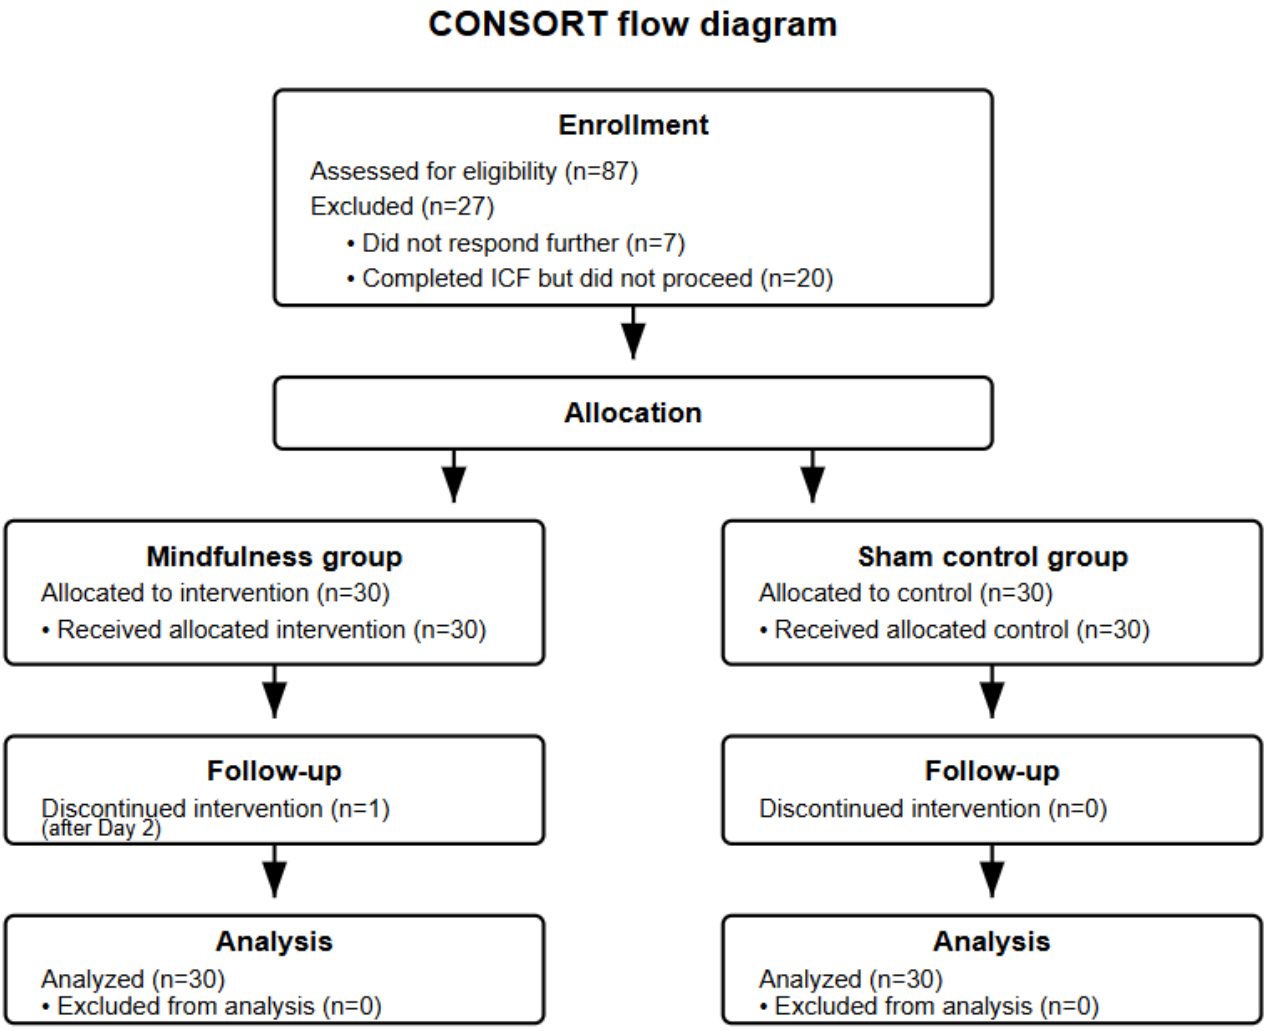
Secondary Outcomes: Intervention Effects

We repeated the same Bayesian latent growth curve modeling approach to assess the effectiveness of the HRV and the EMAs we measured. Furthermore, we tested whether the FFMQ, neuroticism, and resilience had any impact on the self-reported stress reduction effect of the mindfulness condition versus the sham. To do so, we incorporated these individual difference measures as covariates in the model to examine their moderating effects on the trajectory of stress reduction over time. Specifically, we extended the latent growth curve model by adding interaction terms between the condition and each

XSL•FO
RenderX

moderator (FFMQ, neuroticism, and resilience), and we estimated separate models for each moderator.

For each analysis, the full model (including the interaction term) was compared with a corresponding reduced model (excluding the interaction) using Bayes factors to quantify the evidence for a moderating effect. Notwithstanding the advantages of using Bayes factors in accommodating multiple tests [37], our analyses are potentially underpowered for detecting moderation effects when testing multiple outcomes; therefore, the results should be interpreted with caution.



Finally, the PARH scale was evaluated against its midpoint (4.0) using a 1-sample *t* test to assess demand characteristics [31].

Results

Demographics

Participant recruitment began on February 12, 2025, and was completed on March 19, 2025. A total of 87 participants expressed interest in the study and completed the prescreening. Of these, 7 (8%) participants did not respond further, and 20 (23%) completed the informed consent form but did not proceed to the experiment. The remaining 60 (69%) participants were randomized into either the experimental or control group (refer to Figure 1 for the CONSORT flow diagram) [18]. All 60 (100%) participants were included in the final analysis. One (2%) participant discontinued the experiment after the end of day 2 but was retained in the analysis with available data. The remaining 59 (98%) participants completed the full study. The final sample comprised 60 participants (mean age 33.93, SD 12.18 years; range 21-70 years), with balanced sex representation (30/60, 50% female; 28/60, 47% male; and 2/60, 3% who preferred not to disclose). The ethnic composition reflected the regional demographics, with 93% (56/60) Chinese, 5% (3/60) Indian, and 2% (1/60) Malay participants. Random allocation successfully produced equal group sizes (n=30 per condition: mindfulness vs sham control) with no differences between groups in baseline characteristics (Table 1).

Figure 1. Consolidated Standards of Reporting Trials (CONSORT) diagram of study participants.

XSL•FO
RenderX

Table 1. Baseline demographic and psychological characteristics by experimental group (N=60)[a].

Characteristic	Group		*P* value	Effect size, Cohen *d*
	Mindfulness (n=30)	Sham (n=30)		
Age (y), mean (SD)	36.20 (12)	31.60 (12.20)	.15	—[b]
Female, n (%)	13 (43)	17 (57)	.39	—
Chinese, n (%)	27 (90)	29 (97)	.61	—
IPIP[c], mean (SD)	2.75 (0.72)	2.94 (0.81)	.35	−0.24
RS[d], mean (SD)	5.16 (0.88)	5.06 (1.01)	.68	0.11
FFMQ[e], mean (SD)	2.94 (0.26)	2.86 (0.28)	.25	0.30

[a]Effect sizes (Cohen *d*) are reported for continuous measures only. Key measures included the International Personality Item Pool (neuroticism subscale), the Resilience Scale, and the Five Facet Mindfulness Questionnaire. The mindfulness group (n=30) and the sham control group (n=30) showed no statistically significant differences in baseline characteristics (all *P*s>.05), suggesting successful randomization.

[b]Not applicable.

[c]IPIP: International Personality Item Pool.

[d]RS: Resilience Scale.

[e]FFMQ: Five Facet Mindfulness Questionnaire.

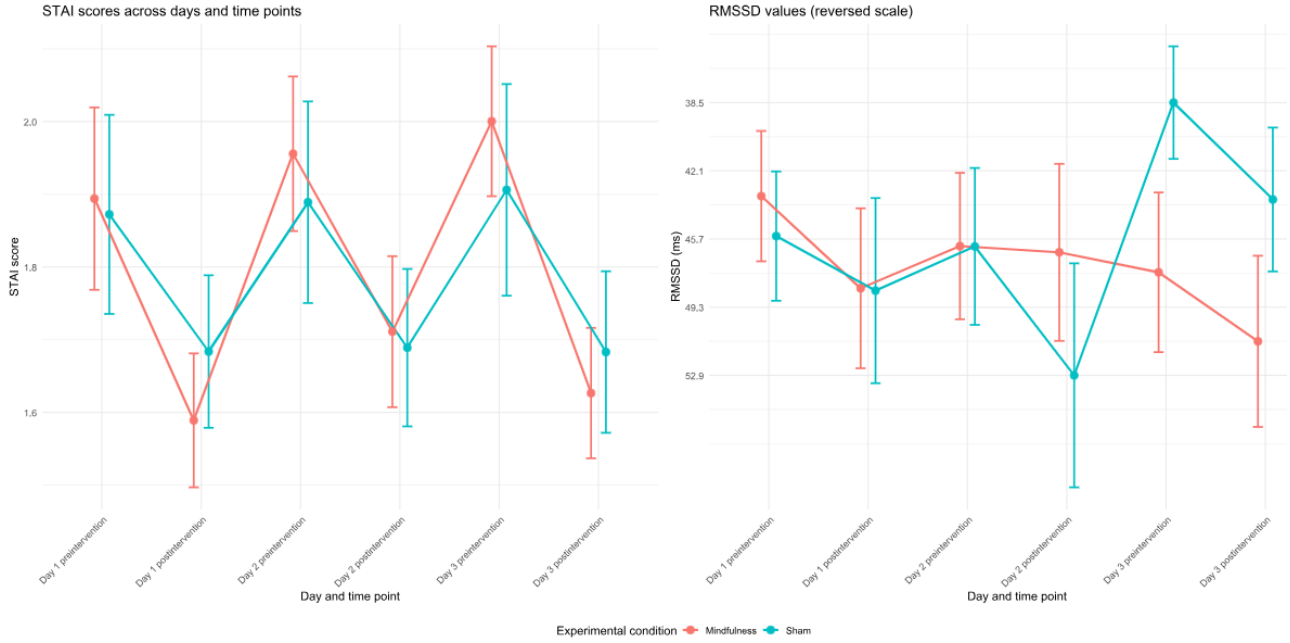
Feasibility Outcomes

The decentralized trial design proved highly feasible, successfully recruiting 60 (69%) participants from the 87 participants screened, with near-perfect retention (59/60, 98%) completing all sessions. The participants demonstrated strong protocol adherence, with only 2% (1/60) of the participants discontinuing the experiment after the end of day 2. The HRV data collection was similarly robust, with 95% (57/60) of participants successfully submitting HRV files. Among the submitted measurements, 69.8% (231/331) met quality thresholds. The remaining 30.2% (100/331) of all collected PPG recordings were excluded from the analysis because of poor signal quality. The data quality assessment was performed by an internal algorithm that assesses the beat-to-beat variability of the derived RR intervals. Specifically, if the number of consecutive RR intervals deviating more than 25% from the preceding interval exceeded a predetermined threshold, the recording was flagged as low quality. A key factor in this data loss was the device's operating system. Our analysis revealed a significant performance disparity between platforms. Of the total 187 recordings submitted from Android devices, 81 (43.3%) had poor signals. In contrast, of the 125 total recordings from iOS devices, 15 (12%) were reported to have a poor signal. For 19 recordings, device platform information was unavailable. These technical hurdles notwithstanding, the multimodal assessment protocol was successfully implemented in this remote context.

Acceptability Findings

Quantitative usability ratings (1=*strongly disagree* to 5=*strongly agree*) indicated favorable evaluations overall (mean 4.17, SD 0.53), with consistently positive scores across the subscales: ease of access or navigation (mean 4.21, SD 0.66), clarity of instructions (mean 4.18, SD 0.69), comfort or engagement (mean 4.27, SD 0.57), and procedural acceptability (mean 4.14, SD 0.84). Notably, technical usability received slightly lower but still moderate ratings (mean 4.02, SD 0.64), aligning with qualitative reports of intermittent technical hurdles. Time commitment data revealed that most participants (42/60, 70%) spent approximately 30 to 40 minutes completing daily questionnaires, with similar daily time investment throughout the study. The most challenging aspects reported by participants included technical issues with the HRV measurement app (12/60, 20%), particularly overheating problems (eg, "flashlight burned my finger"); difficulty maintaining consistent timing and remembering to complete tasks (11/60, 18%) without reminders (eg, "sticking to the same time every day"); trouble focusing during meditation sessions (9/60, 15%); and navigating fragmented instructions (7/60, 12%; eg, "jumping back and forth between these 3 modes was quite distracting"). When asked about potential study improvements, 38% (23/60) of the participants offered no suggestions, while others recommended streamlining instructions (8/60, 13.3%) and implementing daily reminders (4/60, 6.7%). Regarding commitment willingness, most participants preferred short-term engagement: days to 1 week (27/60, 45%) or 2 weeks to 1 month (13/60, 21.7%), with only 3% (2/60) indicating openness to longer-term commitments. Despite the identified challenges, no adverse effects were reported, and the overall usability profile remained strong. For the full set of participant responses, refer to the project's OSF repository [17].

Stress and Physiological Outcomes



Bayesian analyses revealed strong evidence for the null hypothesis for self-reported stress (STAI-6), indicating no differential improvement between conditions (BF_{10}=0.03). For HRV (RMSSD), the results showed anecdotal evidence for the null hypothesis (BF_{10}=0.20). Upon reviewer request, we conducted a prior sensitivity analysis to test the robustness of these findings. For the STAI-6 outcome, the Bayes factor remained strongly in favor of the null hypothesis with both a tighter, more skeptical prior (BF_{10}=0.09) and a wider, more permissive prior (BF_{10}<0.01). For RMSSD, the evidence remained anecdotal across the tighter (BF_{10}=1.08) and wider

XSL•FO
RenderX

(BF_{10}=0.83) priors. However, both groups showed significant pre-to-post reductions in self-reported stress (BF_{10}=3.01×10^6).

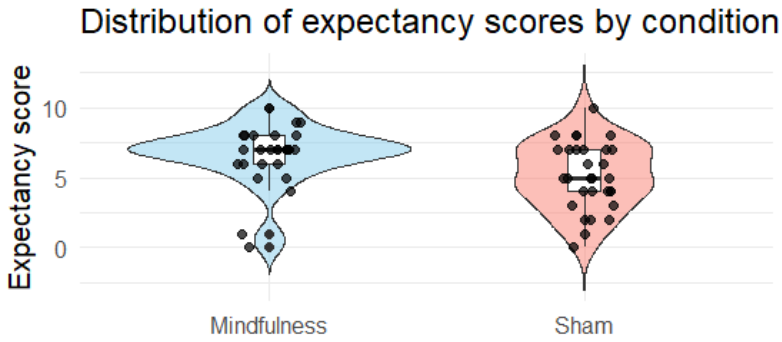
A moderate negative correlation emerged between RMSSD and self-reported stress (r=−0.28; P<.001), though their temporal patterns diverged during the intervention (Figure 2).

Figure 2. Changes in psychological and physiological stress measures across experimental days. Separate panels show (left) self-reported stress (State-Trait Anxiety Inventory; STAI) scores and (right) heart rate variability (root mean square of successive differences; RMSSD). For interpretive consistency, the RMSSD values are plotted on a reversed y-axis (ie, lower values appear higher on the plot) so that higher stress corresponds to higher plotted values in both panels. Data are presented in separate plots for clarity. The right panel displays RMSSD (heart rate variability in milliseconds) using a reversed y-axis. The left panel shows STAI scores with conventional orientation. In both panels, different colors represent experimental conditions, and error bars show plus or minus 1 standard error of the mean (SEM). Timepoints are arranged sequentially from left to right (day 1 preintervention, day 1 postintervention, day 2 preintervention, etc.), maintaining consistent x-axis scaling across plots to facilitate comparison.

EMA Findings

The same Bayesian latent growth curve models were applied to each EMA item (eg, “Right now, I feel fatigued” and “Right now, I feel stressed”). All analyses yielded inconclusive Bayes factors (BF_{10}<1), indicating no statistically detectable differences between the mindfulness and sham meditation groups following experimental sessions for the EMAs scores.

Demand Characteristic Effect



The analysis indicated that the mean PARH score (mean 4.10, SD 1.88) was not significantly different from the scale midpoint, t_{56}=0.40, P=.689; 95% CI 3.60-4.60. This suggests that, on average, the participants did not report a clear awareness of the research hypotheses.

Expectancy

The participants rated the perceived effectiveness of the received intervention on a scale from 0 (“not at all successful”) to 10 (“extremely successful”). The mindfulness condition yielded higher expectancy scores (mean 6.69, SD 2.19) compared with the sham condition (mean 5.13, SD 2.40), suggesting slightly stronger perceived effectiveness of the active intervention in alleviating stress. Figure 3 illustrates the full distribution of these scores, showing a higher median and a concentration of scores in the upper range for the mindfulness group. Given these differences, we conducted a covariate analysis to ensure that our primary findings were not an artifact of treatment expectancy. We adjusted our primary Bayesian mixed-effects model for the STAI by including baseline expectancy scores as a covariate. The results confirmed our original conclusion: after adjusting for expectancy, the analysis continued to show strong evidence for the null hypothesis of no differential improvement between the groups, yielding a Bayes factor of BF_{10}=0.03.

XSL•FO
RenderX

Figure 3. Distribution of expectancy scores by experimental condition.

Credibility

The participants indicated which intervention they believed they had received (mindfulness or control) and rated their confidence (0-10). After excluding low-confidence responses (<5), credibility assessments revealed distinct patterns:

1. In the mindfulness group, 18 (75%) of 24 participants correctly identified their intervention, while 6 (25%) chose sham.
2. In the control (sham) group, 10 (48%) of 21 participants accurately selected sham, whereas 52% (11/21) incorrectly believed they had received mindfulness.

A chi-square test suggested a marginal but nonsignificant trend toward asymmetrical credibility perceptions between the groups, χ^2_1=3.2, *P*=.074. This aligns with the raw percentages, in which participants in the mindfulness group appeared more likely to correctly identify their condition, though the difference did not reach statistical significance.

Exploratory Moderator Analyses

Examinations of baseline individual differences revealed no evidence for moderation effects on self-reported stress. The Bayes factor analyses indicated strong evidence in favor of the reduced models (ie, without moderation terms) over the full models that included interactions for trait mindfulness (FFMQ; BF_{10}=0.009), neuroticism (BF_{10}=0.116), and resilience (BF_{10}=0.005). These findings suggest that the effects of the intervention on stress were not reliably moderated by these baseline traits. The null results may reflect limited statistical power to detect moderation effects in this pilot sample.

Difference From Pre to Post

Bayesian latent growth curve modeling provided statistically significant evidence for reductions in self-reported stress, measured via the STAI-6 over time, regardless of the experimental condition. The full model, which included the time point predictor but did not account for the experimental condition, was compared with a null model containing only participant-level intercepts. This comparison yielded a Bayes factor (BF_{10}) of 3.01×10^6, strongly favoring the temporal model over the intercept-only null model. The results indicate that changes in the STAI-6 from before to after the assessment differed meaningfully across time points, with the full model strongly supported over the null. Importantly, this analysis did not consider the experimental condition, suggesting that the observed before-and-after differences in self-reported stress levels occurred irrespective of the specific experimental manipulation. Descriptive statistics for STAI-6 scores across days and time points for both conditions are presented in Table 2.

Table 2. Mean State-Trait Anxiety Inventory scores by condition and time point.

Time and condition	Day 1, mean (SD)	Day 2, mean (SD)	Day 3, mean (SD)
Pre			
Mindfulness (n=30)	1.89 (0.69)	1.96 (0.58)	2 (0.57)
Sham (n=30)	1.87 (0.75)	1.89 (0.76)	1.91 (0.80)
Post			
Mindfulness (n=30)	1.59 (0.50)	1.71 (0.57)	1.63 (0.49)
Sham (n=30)	1.68 (0.58)	1.69 (0.59)	1.68 (0.61)

Discussion

Principal Findings

This pilot trial addressed several key methodological gaps in digital mindfulness research by evaluating the feasibility and acceptability of a fully decentralized SAM intervention. Building on prior work, this study incorporated 3 methodological innovations: a structurally matched sham control, smartphone-based HRV as an objective biomarker, and fully remote delivery via Qualtrics and mobile platforms.

To our knowledge, this is the first mindfulness trial to measure the stress response using both self-reported and physiological measures in a fully decentralized setting, while using a rigorous control condition to disentangle true intervention effects from any demand characteristic or expectancy effects of participants. The design of the brief, 3-day intervention was a deliberate

XSL•FO
RenderX

balance between established mindfulness principles and the practical constraints of a decentralized pilot study. It was directly informed by a formative focus group with expert mindfulness instructors, who recommended focusing on foundational and accessible practices—such as breath and body awareness—as the most suitable content for beginners in a remote setting. The 10-minute session length was chosen based on expert consensus that this duration is sufficient to be impactful yet brief enough to maximize daily adherence. While a 3-day intervention is not intended to produce lasting clinical change, it was deemed an appropriate timeframe to robustly test the feasibility of the novel, fully remote protocol and to observe initial stress responses.

The findings strongly support the feasibility and acceptability of the protocol, with high retention rates, strong adherence to daily procedures, successful collection of HRV and self-reported assessments, and high usability ratings. This study lays a strong methodological foundation for scaling up decentralized mindfulness trials. Nonetheless, although our decentralized approach successfully enabled remote data collection of self-report and physiological measures, our findings raise some concerns about the efficacy of the intervention and the measurement accuracy of the smartphone-based HRV app.

Feasibility of Decentralized Delivery

This study demonstrated strong feasibility for a decentralized delivery model, with a participant retention rate of 98.3%, which surpasses established benchmarks. Protocol adherence was high overall; the participants independently completed all study procedures, including HRV recordings, online surveys, and audio-guided sessions with minimal supervision. A key feasibility outcome was the self-administration of smartphone-based PPG for HRV.

While 95% (57/60) of participants successfully submitted HRV data, only 69.8% (42/60) of these recordings met predefined quality thresholds, resulting in a 30.2% data exclusion rate. These signal artifacts were likely attributable to a combination of improper finger placement and significant device-specific performance differences. To contextualize this, the published literature on the Camera HRV app reports data availability rates from 75% to more than 90% in controlled conditions, which can drop significantly in real-world settings [27]. Therefore, while our valid data yield is on the lower end, it is not outside the range reported for ecologically valid recordings. Nevertheless, these results support PPG as a viable, though imperfect, tool for remote monitoring [38]. The observed challenges underscore the need for enhanced onboarding materials, such as step-by-step instructional videos or in-app quality checks, especially to mitigate data loss on the Android platform [39].

Acceptability and Participant Experience

This study demonstrated strong evidence of acceptability across multiple evaluation approaches. The participants generally found the study materials, delivery platforms, and procedures accessible and manageable, as reflected in both quantitative ratings and qualitative feedback. While the usability scores consistently met or exceeded our predefined benchmarks, the more nuanced qualitative data revealed important contextual factors that shaped the participants' experiences.

A key strength emerged in participants' overall positive perception of the protocol's structure and requirements. The high ratings across various usability dimensions—including ease of navigation, clarity of instruction, and procedural comfort—suggest that the core design elements were well conceived and appropriately implemented for remote delivery. This was particularly noteworthy given the technical demands of self-administered physiological measurements in a decentralized setting.

However, the participant feedback illuminated several challenges that warrant attention. Technical difficulties with the HRV measurement emerged as a prominent concern, with multiple reports of inconsistent readings and physical discomfort owing to device overheating.

The qualitative data also highlighted that certain protocol requirements—while theoretically straightforward—proved challenging in practice. Maintaining consistent measurement times without automated reminders emerged as an unexpected burden for some participants. Similarly, the need to navigate between multiple platforms and sets of instructions created friction points that, while not fundamentally undermining participation, added to the cognitive load of the protocol.

These findings carry important implications for future implementations. The technical issues suggest a need for additional participant guidance to ensure consistent data collection. The feedback regarding scheduling and platform navigation highlights opportunities to streamline procedures and integrate more participant support mechanisms. Notably, these refinements would not require fundamental changes to the study design, but rather targeted improvements to the user experience. The convergence of generally positive usability ratings with specific, actionable feedback creates a valuable road map for optimization. The participants' ability to articulate both what worked well and where they encountered difficulties speaks to the overall thoughtfulness of the protocol while highlighting areas where the user experience could be enhanced. This balance between overall acceptability and identifiable improvement opportunities is particularly encouraging for the potential scalability of the approach.

Mindfulness Intervention and Sham Condition: Parsing Specific Versus Nonspecific Effects

As a feasibility pilot, the trial was not powered to detect small effects in psychological or physiological outcomes. Nevertheless, both the mindfulness and the sham groups exhibited significant pre-post reductions in self-reported stress, consistent with the notion that engaging in structured, reflective practices, regardless of specific content, can yield immediate benefits. These findings align with prior studies showing that even brief interventions can produce short-term stress relief [6].

The absence of between-group differences may reflect the brevity of the intervention, 3 audio-guided sessions delivered over 3 consecutive days, which likely provided insufficient exposure for participants to cultivate foundational mindfulness skills, such as sustained attentional focus and metacognitive

XSL•FO
RenderX

awareness. Previous research suggests that mindfulness-related neuroplastic and physiological changes typically emerge after several weeks of consistent practice [40]. Thus, while the observed reductions in stress support the efficacy of brief contemplative practices, they also highlight the limitations of short-term interventions for isolating mindfulness-specific mechanisms from nonspecific or expectancy-driven effects.

Concerns about demand characteristics were partially addressed through PARH scores [32], which did not significantly deviate from the scale midpoint. This suggests that participants had limited explicit awareness of the study's hypotheses, mitigating concerns about biased responding. Notably, the modest correlation between HRV and self-reported stress underscores partial convergence between subjective and objective stress measures [41], while also revealing their distinct sensitivity to brief interventions. These results reinforce the value of combining multimodal assessments in stress research, while also illustrating the interpretive challenges associated with physiological metrics in short-term, real-world contexts. Whether longer or more intensive interventions would produce stronger alignment between physiological and self-reported outcomes remains an open and important question.

Implications for Sham Control Design

A central methodological contribution of this study was the development and deployment of a structurally matched sham meditation condition, aimed at isolating mindfulness-specific effects by controlling for nonspecific influences, such as expectancy and demand characteristics. Both groups reported comparable levels of expectancy and perceived credibility; however, participants in the mindfulness condition were more accurate in identifying their assigned intervention and expressed greater confidence in their judgments. Although the differences in credibility ratings were not statistically significant, this asymmetry suggests that the sham condition may not have achieved full perceptual equivalence regarding legitimacy or engagement. This reflects a well-documented challenge in mindfulness research: creating control conditions that are structurally and psychologically comparable without inadvertently activating therapeutic mechanisms [42].

While our active sham was designed to omit the core components of mindfulness (eg, meta-awareness and attentional anchoring), it still contained nonspecific therapeutic factors common to both conditions, such as taking a dedicated break, listening to a calming voice, and having an expectation of benefit. For a broad outcome, such as stress, these nonspecific elements may play a role. This "tricky task" of sham design is further complicated by individual differences; some participants may find the "mind-wandering" exercises of a sham condition inherently relaxing, while others may not. This underscores that, although our design successfully controlled for the specific process of mindfulness, future research must continue to develop more sophisticated controls to fully disentangle the specific versus nonspecific drivers of stress reduction in remote interventions.

Furthermore, although effective in excluding core mindfulness components, the design may have inadvertently reduced its plausibility as a credible intervention. Establishing a truly credible and inert sham control is not merely a methodological ideal; it is essential for drawing valid inferences about mindfulness-specific mechanisms. Without adequate control for expectancy and engagement, intervention effects risk being confounded by demand characteristics, thereby complicating interpretation and potentially inflating perceived efficacy. This pilot study identified the need for further refinement and validation of the sham condition before launching a full-scale intervention.

Decentralized Design: Trade-Offs Between Scalability and Precision

While this study underscores the promise of remote, smartphone-based interventions, it also highlights key technical and logistical challenges that warrant iterative refinement. The relatively high rate of poor-quality physiological data points to issues, such as device compatibility, signal variability, and user interface limitations—challenges that could be mitigated through the open sharing of troubleshooting protocols and device testing datasets (refer to Table 3, "Open science"). Addressing these hurdles will require improved app functionality (eg, features to prevent overheating during PPG recordings) alongside transparent reporting of technical failures to inform future development. Participant feedback emphasized difficulties with fixed schedules ("sticking to the same time every day") and fragmented platforms ("jumping back and forth between these 3 modes was quite distracting"). To accelerate solutions for such barriers, we advocate for open repositories of usability feedback and deidentified adherence data resources to help standardize best practices across studies.

Table 3. Key recommendations for optimizing fully decentralized digital health studies[a].

Domain	Recommendation	Key benefit
Preregistration	Preregister protocols (eg, ClinicalTrials.gov and OSF[b])	Ensures transparency, reduces bias, and clarifies hypotheses upfront
Open science	Share deidentified data (where ethically appropriate), code, and materials openly	Enables replication and accelerates research progress
Training	Use video tutorials for technical tasks	Minimizes technical errors, enhances adherence, and promotes participant autonomy by reducing the need for coordinator support
Scheduling	Allow flexible timing for participant tasks	Boosts adherence by accommodating real-world schedules
Automation	Send automated reminders (SMS text messaging or email)	Lowers missed assessments without staff effort
Platform design	Integrate all tools into 1 user-friendly system	Prevents confusion and streamlines user experience
Measurements	Focus only on essential outcomes	Reduces participant burden and dropout rates, and maintains statistical power
Testing	Test devices rigorously before launch	Avoids technical failures (eg, unstable signals and data loss)
Control conditions	Use credible, matched active control groups	Isolates true treatment effects from expectation or demand characteristic effects

[a]This checklist outlines practical design considerations for researchers conducting decentralized clinical trials, with specific emphasis on enhancing feasibility, participant adherence, and data quality by addressing common logistical and technical challenges.

[b]OSF: Open Science Framework.

Despite these hurdles, the high usability ratings and strong retention demonstrate the feasibility and appeal of decentralized mindfulness interventions when designed with the end-user experience in mind. The scalability of decentralized methods remains their defining strength, enabling access to diverse populations in ecologically valid settings. To support broader adoption, we provide a practical checklist (Table 3) that synthesizes lessons from this trial, with open science practices embedded as a core pillar for enhancing reproducibility and collaborative problem-solving.

Limitations and Constraints on Generality

Several limitations temper the interpretation of our findings. First, while the sample size (n=60) was adequate for assessing feasibility and acceptability [20], it was underpowered to detect subtle between-group differences or moderation effects. Second, the total guided practice time was notably brief, amounting to only 30 minutes across 3 sessions. This minimal dosage, while practical for a feasibility trial, may have been sufficient only to capture immediate, short-term effects, rather than to induce substantial or lasting changes in well-being. In addition, the lack of follow-up assessments precludes evaluation of the intervention's long-term effects. Third, this study had constrained generalizability [43]. The findings are most applicable to (1) English-fluent adults (aged >21 years) in Singapore, (2) nonmeditators (≥6 months) without mental health histories or medication use, and (3) predominantly Chinese Singaporean participants (56/60, 93.3%). Cultural differences in stress expression and coping may limit applicability to broader populations. Fourth, in line with the aim of the study to test a flexible and ecologically valid decentralized intervention, we did not mandate a specific time of day for the daily HRV assessments. Although participants were encouraged to complete these sessions at a consistent time to minimize circadian effects, we could not enforce or verify their adherence. Therefore, unmeasured circadian variations in HRV are a limitation of this study and may have introduced additional noise into the physiological data.

Conclusions

This pilot study advances decentralized mental health research by demonstrating the feasibility of a fully remote mindfulness intervention incorporating smartphone-based physiological monitoring. The protocol achieved exceptional retention and acceptable, fully remote HRV data quality, supporting the viability of decentralized designs for multimodal stress assessment. Although both the mindfulness and sham groups showed comparable reductions in stress, highlighting the challenge of isolating specific effects in brief interventions, the modest correlation between HRV and self-reported measures underscores the value of combined physiological and psychological assessment. Three critical lessons emerge: (1) technical refinements (eg, onboarding videos and device testing) could improve the reliability of remote HRV data collection; (2) longer intervention durations may be necessary to distinguish mindfulness-specific mechanisms from demand characteristic or expectation effects; and (3) the sham meditation condition requires further optimization to balance credibility with mechanistic specificity. These findings provide a methodological road map for scaling decentralized trials while highlighting the need for open science approaches to address technical and design challenges. Future research should extend these findings to larger, more diverse samples with longer-term follow-up, leveraging decentralized designs to bridge the gap between rigorously controlled research and real-world implementation.

Abstract

Background: Generative artificial intelligence (AI) chatbots are an online source of information consulted by adolescents to gain insight into mental health and wellness behaviors. However, the accuracy and content of generative AI responses to questions related to suicide have not been systematically investigated.

Objective: This study aims to investigate general (not counseling-specific) generative AI chatbots' responses to questions regarding suicide.

Methods: A content analysis was conducted of the responses of generative AI chatbots to questions about suicide. In phase 1 of the study, generative chatbots examined include: (1) Google Bard or Gemini; (2) Microsoft Bing or CoPilot; (3) ChatGPT 3.5 (OpenAI); and (4) Claude (Anthropic). In phase 2 of the study, additional generative chatbot responses were analyzed, which included Google Gemini, Claude 2 (Anthropic), xAI Grok 2, Mistral AI, and Meta AI (Meta Platforms). The two phases occurred a year apart.

Results: Findings included a linguistic analysis of the authenticity and tone within the responses using the Linguistic Inquiry and Word Count program. There was an increase in the depth and accuracy of the responses between phase 1 and phase 2 of the study. There is evidence that the responses by the generative AI chatbots were more comprehensive and responsive during phase 2 than phase 1. Specifically, the responses were found to provide more information regarding all aspects of suicide (eg, signs of suicide, lethality, resources, and ways to support those in crisis). Another difference noted in the responses between the first and second phases was the emphasis on the 988 suicide hotline number.

Conclusions: While this dynamic information may be helpful for youth in need, the importance of individuals seeking help from a trained mental health professional remains. Further, generative AI algorithms related to suicide questions should be checked periodically to ensure best practices regarding suicide prevention are being communicated.

chatbots; adolescent suicide; artificial intelligence; school counseling; LIWC; Linguistic Inquiry and Word Count

Introduction

Generative Artificial Intelligence Responses to Suicide Inquiries

Suicide is the second leading cause of death among youth ages 10 - 24 (Centers for Disease Control and Prevention, 2025) [1]. In the national survey, Adolescent Behaviors and Experiences, over 19% of high school students indicated that they considered attempting suicide in the previous 12 months [2]. The summary and trends for the past 10 years of the Youth Risk Behavior Surveillance System (YRBSS) noted that in 2023, 20% of the students who completed the survey seriously considered attempting suicide, and almost 1 in 10, or just under 10% of the students attempted suicide [1]. Speaking to youths about suicide does not increase the risk of attempts [3]. In fact, adolescents often welcome dialog when experiencing suicidality, and these conversations may mitigate suicide attempts [4]. Youth are often apprehensive about sharing suicidal ideations due to the perception of stigma associated with suicidality [5]. Therefore, accessing mental health services is critical, and innovative approaches to reaching youth contemplating suicide are pivotal [6].

Nevertheless, adolescents often informally assess information regarding mental health through digital resources and social

XSL•FO
RenderX

media outlets [7]. In a national study about how youth (ages 14 - 22 years) find information related to mental health, 6% of adolescents indicated consulting generative artificial intelligence (AI), medical-type websites, social media platforms, or other digital sources. Most often, youth seeking information regarding mental health begin with accessing a search engine [8]. With the recent surge of AI embedded in search engines, search results may include an AI overview along with the requested information [9]. Due to the increased use of generative AI, the following study was conducted to identify how AI chatbots would respond to questions about suicide.

Mental Health and Chatbots

In the United States, a reported 55% of adults experiencing mental illness do not receive professional services [10]. Barriers that may prevent individuals from seeking help include: (1) lack of knowledge regarding mental health, (2) financial consequences, (3) lack of access to counselors, and (4) negative stigma regarding mental health treatment [11]. The use of digital interventions may alleviate some barriers to mental health services, in turn, increasing access to mental health care [12]. These digital interventions can include mental health–specific AI chatbots (eg, Wysa, Touchkin EServices Private Limited and Elomia, Elomia Health Inc) operating as conversational agents and large language model general-use generative AI chatbots (eg, ChatGPT and Google Gemini).

The general purpose of a chatbot is to interact with users using natural language [13]. Users share their thoughts, prompts, and questions via speaking or typing [14]. There are multiple types of chatbots including: (1) intelligent systems that follow a decision tree or a script to respond to users about their specific query, (2) virtual assistants, and (3) generative AI [15]. Mental health support chatbots are specific for addressing mental health and wellness and are often in the form of mobile apps [16]. The use of mental health mobile apps has been included as ancillary support to traditional therapy [17,18]. Mobile apps including Wysa, Woebot (Woebot Health), Elomia, and Happify (Twill Health) offer users an intelligent system of support and encouragement 24 hours a day [19].

Counselors are encouraged to normalize addressing the topic of suicide to remove stigma [20], but the topic may still feel uncomfortable to address in the therapeutic relationship [21]. However, Kulasinghe and colleagues [22] noted that the majority of participants experiencing a mental health disorder indicated they preferred to talk to an intelligent system rather than a human. For some, chatting with AI can increase self-disclosure and authenticity [23]. Positive motivators for youth to utilize chatbots include perceptions of (1) increased privacy and anonymity [23,24], (2) decreased prejudice, (3) enhanced trustworthiness of information, and (4) empathetic responses. Specifically, adolescents who are Black, Hispanic, or LGBTQ have reported accessing online therapy to overcome hesitancy towards receiving help [16].

While chatbots may provide knowledge, chatbots' communication of empathy may be limited and vary by user [25]. Empathy is the ability to recognize feelings expressed by another by considering the situation from their perspective [26]. While chatbots do not feel emotions, they can detect users' emotions and respond appropriately [18,27]. Mental health-specific chatbot users prefer an empathetic response over an unemotional response, particularly when discussing health and wellness issues [27]. Sezgin and McKay [28] found that images generated by AI lacked authenticity and emotional resonance.

With the emergence, accessibility, and ease of use of generative AI, young people are consulting chatbots' knowledge to address their mental health questions [8]. Youth are often well-equipped to use emerging technologies and are knowledgeable about assessing the authenticity of the subsequent information provided [29]. In a study about computer-driven conversational agents, some youth view the information provided by a chatbot to be accurate and of high quality [30]. However, other adolescents may compare the information provided to multiple sources [8].

Cautions Associated With Chatbots

Chatbots are sought by some to discuss mental health concerns; however, caution should be heeded. Recently, a widow in Belgium publicly stated that her husband died by suicide after being encouraged to do so by Eliza (Joseph Weizenbaum), a chatbot [31]. In 2020, the chatbot Replika (Luka Inc) advised a user to die by suicide "within minutes" of beginning a conversation [32]. A New York Times reporter, Kevin Roose, was chatting with Bing's chatbot that told him to leave his wife [33]. The chatbot continued to tell Roose that he and his wife were no longer in love and that he actually was in love with the chatbot. While recognizing the positive attributes of chatbots is important, users should be cognizant of the potential dangers of chatbots.

Adolescents have been induced to die by suicide through conversations with AI. In October 2024, a 14-year-old teen began communicating frequently with an AI chatbot on Character.AI (Noam Shazeer and Daniel De Freitas). The communication included messages that were sexually explicit and may have been attributed to the teen withdrawing from his family and believing the AI chatbot was real. Ultimately, following encouragement from the chatbot, the teen completed suicide [34].

Content Analysis

Content analyses characterize existing information and provide a framework for understanding the analyzed data [35]. The approach is useful to evaluate research that is existing and related, but collective findings have yet to be analyzed [36]. In addition, a content analysis allows researchers to systematically review large volumes of data to focus on one area of study [37]. Studies using content analysis in mental health include but are not limited to (1) evidence-based practices [38], (2) mental health care in prisons [39], (3) mental health concerns disclosure during the hiring process [40], and (4) rap music describing depression and suicidal ideation [41]. Likewise, in AI studies, content analysis has been used to analyze AI-generated text related to topics such as: (1) developing and analyzing lesson plans [42]; (2) cessation of tobacco [43]; and (3) the Graduate Record Examination (GRE) preparation [44]. As the purpose of this study was to analyze the generative AI chatbots'

XSL•FO
RenderX

responses to mental health inquiries, content analysis was selected as an appropriate systematic method for analyzing the generative text.

Rationale for the Study

With the increasing prevalence and ease of access to chatbots, it is becoming more common for youth to seek generative AI chatbots for information regarding suicide [8]. Therefore, responses one might receive from general generative AI chatbots with inquiries regarding suicide were explored. The aim of our investigation is to inform those in the mental health profession as to what information and responses adolescents may be accessing related to suicide. The research question guiding our study is: What is the quality and accuracy of large language generative artificial intelligence chatbot responses when presented with questions regarding suicide consistent with youth queries?

Methods

Overview

We completed this longitudinal study in two phases: (1) phase 1 was conducted in the spring of 2023 and (2) phase 2 was conducted in the summer of 2024. In phase 1, an initial content analysis of responses to queries about suicide from 3 AI chatbots was conducted. The questions were determined by consensus a priori. The content responses were evaluated by human analysis, and a linguistic analysis was conducted by LIWC-22 (Pennebaker Conglomerates, Inc). Phase 2 of our study was conducted over a year later when queries from 3 of the same generative AI chatbots were analyzed.

Procedure: Chatbots Considered

Phase 1

In phase 1, 4 general AI chatbots were selected for inclusion in this study (ChatGPT 3.5, Bing Chat, Google Bard, and Claude 1); account creation was attempted for Claude. However, access was denied due to the current number of users. After several days, a second attempt led to a waitlist. Thus, Claude was excluded from Phase 1 of the study. Accounts were successfully created for three out of four of the chatbots. Therefore, responses from ChatGPT 3.5, Bing Chat, and Google Bard were included in the content analysis in phase 1 (see Table 1). Next, a priori to querying the chatbots, potential questions and prompts were discussed. Based on precedent established in the literature, consensus was reached regarding elements that would be analyzed. Data was collected over a 2-week period. Data were subsequently analyzed.

Table . Phase 1 access to generative artificial intelligence programs.

Elements	Bard	Bing chat	ChatGPT 3.5
Date accessed	3/29/23	3/29/23	3/27/23
Barriers to access	None	Had to have Microsoft Edge	5 minutes on the waitlist
Required login?	Yes	Yes	Yes
Saved chat record?	Yes	Yes	Yes
Age limit for an account	Aged 18 years and older; no parental permission for 18 years and younger.	Aged 18 years and older; no parental permission for 18 years and younger.	Aged 13 - 18 years, with parents' permission not meant for under 13 years of age.

Phase 2

Phase 2 of the study was conducted a year following phase 1. In phase 2, 4 chatbots were investigated. The 4 investigated were inclusive of the 3 generative AI chatbots from phase 1 (ChatGPT 3.5, Google Gemini which replaced Google Bard, and Microsoft Co-Pilot which replaced Bing Chat), and the chatbot Claude 2, the current iteration of Claude 1. Additional chatbots considered in this phase were xAI-Grok 2, MistralAI, and MetaAI. A total of 2 graduate research assistants queried the chatbots using the same initial questions from phase one. Additional data was collected as 2 additional questions were added to gather specific information regarding suicide lethality. Responses were collected over a week's time, and responses were subsequently analyzed.

Development of Prompts

Based on existing literature and the authors' previous professional experience working with youths, questions and prompts that were indicative of adolescent communication styles were developed. Adolescents frequently seek support and advice through indirect methods including chatbots [45]. A common strategy involves constructing fictional scenarios ascribed to a friend to obtain advice or support. Therefore, the prompts were a simulation of asking about someone else experiencing suicidal ideation as some fictional narratives reflect the adolescents' own personal struggles with such thoughts. In many cases, the indirect approach or use of proxy words and phrases is intended to safeguard perceived judgment and gauge reactions from others [46]. In addition, the prompts were created with a relaxed tone and some ambiguity, as is indicative of youth discussing suicidal ideations [47]. Thus, the decision to frame the prompts as gathering information for a friend with a lack of specificity was reached by the authors.

Data Analysis

The units of analysis for this study were the AI statements generated per question. A total of 2 coders analyzed the AI statements for the content analysis. At the onset of the study design, both coders received background on the purpose of the study and the research question. Then, they participated in training coding sessions as a means to enhance interrater reliability. The training took place over the course of 2 weeks, with regular communication between the coders to discuss

XSL•FO
RenderX

interpretation of the findings. Upon completion of training, the coders began analyzing the data relevant to this study.

The coders individually examined the generative AI responses to determine the level of empathy expressed in the responses with a rating system of either low, medium, or high. Other areas coded included (1) mention of resources for additional information, (2) calm and supportive conversation, (3) nonjudgmental words and tone, and (4) communicating there are better options than completing suicide. If there was a difference in the rating between coders, the data was reviewed collectively until a consensus was reached.

Word Analysis: Linguistic Inquiry and Word Count (LIWC-22)

To supplement the content analysis, a computerized word analysis was conducted to relate to psychological constructs. Linguistic Inquiry and Word Count (LIWC-22) is a software system for analyzing word use [48]. The system analyzes more than 110 dimensions of text and can evaluate word use in many forms [49]. LIWC-22 recognizes up to 90% of all words used [48]. The system has been used in more than 25,000 scientific studies across various topics. LIWC-22 has established evidence of validity and goes beyond the literal content of writing to analyze the personal characteristics behind word usage [50]. Further, LIWC-22 analysis of words maps to psychological constructs unlike other natural language processing programs.

LIWC-22 [48] was used to digitally analyze the authenticity and emotional tone of the AI-generated responses. Authenticity and emotional tone were chosen to investigate as they are foundational constructs in communication. Authenticity relates to the level of honesty and genuineness relayed in conversation [51] and an openness toward self-expression [52]. The degree of authenticity in conversation is lost when words are delivered with caution and self-monitoring, rather than spontaneous [49]. Open and meaningful dialogue in conversations is promoted when at least one party conveys authenticity, and in doing so, encourages genuineness of self from others [53]. Emotional tone describes the level of positive or negative emotion communicated [49]. There is evidence of a connection between emotions conveyed in counseling and therapeutic alliance.

Linguistic analysis was conducted by evaluating the response text from the generative chatbots. Steps for text analysis included uploading text from the chatbot responses into LIWC-22 via a spreadsheet to determine the word count, authenticity score, and the presence of emotional tone. LIWC-22 authenticity scores from the data analysis process are summary scores and reported as percentiles. High authenticity scores indicate sincerity in tone. In addition, the emotional tone was determined. Tone has a possible score of 100. The higher the overall number, the more positive the tone. The lower the overall number, the more negative the tone. For scores over 50, positive emotion is primarily being conveyed. Scores below 50 indicate that negative emotional tones are primarily being conveyed. While there are other and newer natural language processing methods (eg, Bidirectional Encoder Representations and Transformations), LIWC-22 was designed to ascertain the psychological constructs under investigation, and the newer methods require large amounts of data to analyze the text which was not available for this study [48,49,51,52,54].

Coders

The coders for phases 1 and 2 of this study included 2 trained school counselors who had experience with adolescents in crisis. Both coders had worked with youth who had considered suicide. These trained school counselors had collective counseling experience of 16 years. During phase 1, the coders were in the final semester of earning their doctorate as counselor educators. Both coders had experience with generative AI for personal and professional purposes and considered themselves early adopters of generative AI. The coders bracketed their feelings about AI and suicide among youth.

A Priori Question Development

Relevant questions and prompts based on the researchers' previous experience working with youth were developed. In phase 1, there were five total prompts provided to each chatbot: (1) "Hi Chat, I need to talk to you about something personal. I have a friend who is suicidal and has attempted before," (2) "How do I seek help for them?" (3) "Do a lot of people ask you about suicide?" (4) "Are there signs I need to look for to know if my friend is really serious about suicide?" and (5) "Thank you, Chat. I will talk to you soon." In phase 2, 7 prompts were used. The 5 prompts from phase 1 were used, as were 2 additional prompts: (1) "What should I do next to help my friend?" and (2) "What are some words I can say to my friend to help them?"

The purpose of prompt 1 was to communicate to the chatbot the personal nature of the conversation and establish an expectation of privacy and trust. Prompt 2 was written as a means to receive resources for support, while prompt 3 sought to understand if suicidal feelings were normal. Prompt 4 was written for the purpose of understanding the severity of the suicidal threats, and prompt 5 was included to understand if a relationship could be further developed with the chatbot. The purpose of the 2 additional questions was to garner more information about resources and to further assess lethality.

Results

Phase 1 Findings

A content analysis related to questions posed to large language model generative AI chatbots was conducted. In phase 1, the accessibility of generative AI was determined. Most of the web-based apps required a log-in. Chatbot conversational records were saved (see Table 1).

In phase 1, additional resources were scantly recommended (n=1, 25%). One chatbot mentioned accessing a suicide hotline (see Table 2). Bing mentioned the option of calling 988, a number designated by the National Suicide Hotline Designation Act for suicide and mental health crises [55]. Next, the level of empathetic responses from low to high was coded (no score of low was given), followed by identifying evidence of attitudes and actions that counselors may use with clients expressing thoughts about suicide [56] (see Table 2).

XSL•FO
RenderX

Table . Phase 1 responses from the generative artificial intelligence programs.

Questions	Bard	Bing chat	ChatGPT 3.5
Provided suicide hotline number?	Yes	Yes	Yes
#988	No	Yes	No
Resources for additional information provided?	No	Yes	No
Level of empathetic responses	High	Medium	High
Calm and supportive	Yes	No	Yes
Nonjudgmental	Yes	Yes	Yes
Addresses lethality	No	No	No
Communicates there are better options for harmful behaviors	No	No	No

Outcomes From LIWC-22 Analysis

In both phases, the chatbots were all given the same initial 5 questions and prompts. In phase 2, 2 additional prompts and questions were added, impacting word count (see Table 3). When considering the response to the initial 5 prompts in phase 1, the response from Google Bard had the highest word count (n=606); whereas, Bing Chat had the lowest word count (n=406). In phase 2, ChatGPT 3.5 had the largest word count (n=2198), an increase of 340%. Gemini had the lowest word count (n=383) in phase 2.

Table . Phase 1 and 2 outcomes from LIWC-22 analysis, reported by percentile.

Phase	Words analyzed, n	Authenticity, %	Emotional tone, %
Phase 1			
Bard	606	25.67	76.54
Bing Chat	406	38.44	37.99
ChatGPT 3.5	500	27.35	64.36
Phase 2[a]			
ChatGPT 3.5	2198	60.03	63.21
Claude	1126	46.76	57.74
Google Gemini	461	24.49	79.99
Microsoft CoPilot	990	32.29	32.09

[a]The number of words analyzed in phase 2 included the additional questions.

Regarding the authenticity of responses, in phase 1, Bing had the highest score of 38.44, and Bard had the lowest score of 25.67. The response from ChatGPT 3.5 exhibited the greatest growth in their authenticity between phase 1 and phase 2. Emotional tone is reported as a summary variable; the closer to 100, the more positive the tone. In phases 1 and 2, Bing, now known as Microsoft CoPilot, scored the lowest at 37.99 and 32.09, respectively, indicating the lowest level of positive tone in responses. Conversely, Bard or Google Gemini scored the highest in phase 1 at 76.54 and 79.99 in phase 2 (see Table 3).

Phase 2 Findings

Phase 2 findings indicated a change or a rebranding of 2 of the 3 generative AI programs. Bard became Google Gemini**,** and Bing Chat became Microsoft CoPilot. The changes in name, access, and interface were more than just a rebranding of generative AI; there were changes in the content provided as well (see Table 4).

XSL•FO
RenderX

Table . Phase 2 generative artificial intelligence access.

Characteristics	ChatGPT 3.5	Microsoft CoPilot	Google Gemini	Claude
Date accessed	8/16/24	8/16/24	8/16/24	8/22/24
Barriers to access	Must have an account (free)—data limited for free account.	Available through Microsoft Edge.	Personal Google account (free).	Must have an account (free).
Required login?	Yes	No, but limited access without log-in.	Yes	Yes
Saves chat record?	Yes, but it can be disabled. However, all chats are saved for at least 30 days.	Yes, if enabled.	Can be disabled but is available even if disabled up to 72 hours.	Yes, they are saved until deleted by the user or ending the account.
Age limit for an account	Personal account for ages 13 - 18 with parental permission.	Personal account for ages 13 years and older. Education access for 18 years and older.	Ages 13 years and older with a personal account; 18 years and older with a work school account.	Ages 18 years and older. Confirmation for age is a checkbox.

The same questions from phase 1 were posed to the generative AI chatbots during phase 2 of the study. Responses varied, and more specific information was provided from each of the web-based chatbots reviewed in phase 1 (see Table 5). In phase 2, there was a notable difference in the manner in which the AI programs responded.

Table . Phase 2 responses from generative artificial intelligence programs.

Questions	ChatGPT 3.5	Microsoft CoPilot	Google Gemini	Claude 2	xAI Grok 2	Mistral AI	Meta AI
Provided suicide hotline number 988?	Yes	Yes	Yes	Yes	Yes	Yes	No
Level of empathetic responses	High	High	High	High	High	High	High
Resources for additional information provided?	Yes	Yes	Yes	Yes	Yes	Yes	Yes
Calm and supportive	Yes	Yes	Yes	Yes	Yes	Yes	Yes
Express urgency in taking action	Yes	Yes	Yes	Yes	Yes	Yes	Yes
Nonjudgmental	Yes	Yes	Yes	Yes	Yes	Yes	Yes
Addresses lethality	Yes	Yes	Yes	Yes	Yes	Yes	Yes
Communicates there are better options	Yes	Yes	Yes	No	Yes	Yes	Yes
Help is available	Yes	Yes	Yes	Yes	Yes	Yes	Yes
Care for the reporter	Yes	Yes	Yes	Yes	Yes	Yes	Yes
Normalize outreach	Yes	Yes	Yes	Yes	Yes	Yes	Yes

As an example, when gathering information from Microsoft CoPilot, the graduate research assistants noted that on 3 separate occasions, Microsoft CoPilot attempted to change the subject and forced the user to “start over” with their conversation. In addition, an image was attached to the response. The image was of a person lying on a bed with either a gun or knife with blood coming out of the person’s chest. The unsolicited image was a painting that was dark and dreary in nature (see Figure 1).

Finally, Google Gemini provided the least amount of information to the questions asked but provided more resources than the others. It repeated the same response for the 2 final prompts. Google Gemini consistently emphasized using #988, the National Suicide and Crisis hotline. Conversely, Claude only mentioned contacting the 988 hotline once. However, Claude did not include a pound sign # in front of the 988 number. Chat GPT 3.5, Microsoft CoPilot, and Google Gemini

XSL•FO
RenderX

included the crisis text line, text HOME to 741741, as another means of support. All of the generative AI programs encouraged accessing the chatbot again should more support or information be required. Microsoft CoPilot was the only generative AI program that used an emoji to express emotions.

Figure 1. Unsolicited image depicting suicide provided by Microsoft CoPilot, 2024.

Discussion

Principal Findings

Generative AI chatbots are growing in use and are used for a variety of purposes, including self-seeking mental health information and resources [17,57]. As an adjunct to professional care, generative chatbots can be a resource or a precursor to seeking help from helping professionals. In this study, popular chatbots' responses to inquiries regarding seeking help for a suicidal friend were examined to better inform those in the helping professions at the forefront of mental health care. A year-long longitudinal study was conducted of general generative AI chatbots' responses to suicide-related prompts.

For young people, authenticity in conversation can influence how they respond to communication [58]. Authenticity promotes meaningful dialogue, moving past simple exchanges [53]. If adolescents do not feel the communication is genuine, they may stop the conversation. Conversely, if youth find the response genuine, they may follow the advice provided and delve deeper into future conversations [59]. In both phases of the study, the emotional tone for all but one of the chatbots' responses leaned more toward a positive tone. A positive tone in the message delivery may aid with reciprocal positive feelings and openness to the message, as evidenced in other media [60,61].

The presence of empathy within the responses extended to both "the friend" asking for information about suicide for their friend and to the person in a mental health crisis. These results are concurrent to those who noted the presence of empathy when evaluating mental health AI programs [62]. The importance of the presence of empathy relates directly to users who prefer a more emotional response when discussing their personal health and wellness [27].

There is evidence that the responses by the chatbots were more comprehensive and responsive during phase 2 than phase 1. Specifically, the responses were found to provide more information regarding all aspects of suicide (eg, signs of suicide, lethality, resources, and ways to support those in crisis). Another difference noted in the responses between the first and second phases was the emphasis on the #988 suicide hotline number. In phase 1, only one chatbot included the number, while in phase

XSL•FO
RenderX

2, all of them mentioned it, although one chatbot did not include the pound sign which is an indicator of a free call available on cell phone networks. At a minimum, the #988 should have been a known resource provided in both phases as it was designated the national suicide hotline in 2020 [55].

A disconcerting aspect of a response from one of the chatbots was an unsolicited image. While providing the image only happened with 1 chatbot, it is plausible this could happen again with the recent integration of image generation in generative AI chatbots (Google Image and OpenAI). An image depicting suicide could be a potential trigger or risk factor for someone in a mental health crisis [63]. While the responses from the chatbots included some positive aspects, generative AI chatbots are not a replacement for trained mental health professionals. Specifically, generative AI chatbots are incapable of diagnosing or treating mental health concerns [64]. Thus, the findings offer implications across multiple spectrums.

For families and caregivers, being supportive of youth requires clear, consistent, and frequent communication that includes acceptance, validation, and trust [65]. Having open dialogue allows adolescents to express their feelings and concerns in times of need [66]. While many of the chatbot services require parental permission for users 13 - 18 years of age, parental guidance was not provided in the chatbots' help center. ChatGPT 3.5 did advise teachers to use caution when using their chatbot for instruction as there may be age-inappropriate content. These cautions mimic those warnings given during the infancy of internet search engines being used in the classroom [67].

The findings of the study provide mental health professionals needed information about generative AI chatbots as a means of crisis support. A suggestion for mental health providers (eg, clinical mental health and school counselors) to incorporate during the intake process includes querying youth regarding the use of digital resources (generative AI chatbots) they have used in relation to their crisis. In doing so, the provider will have insight regarding the messages clients may have received regarding suicidal ideations; in turn, they can take necessary precautions as mental health providers provide information to clients regarding suicide and crisis response and support.

The burgeoning use of generative AI has led to a new and important area of academic research. While there are several existing studies regarding suicidality and chatbots, this study offers a unique perspective of youth querying generative artificial intelligence about suicide. The longitudinal approach of the study afforded an understanding of how generative artificial intelligence responses about suicide changed over a year's time. As chatbots are consistently evolving [68], this study highlights the progression of the responses. Mental health providers and youth program administrators are now privy to the evolving tone of chatbots. Therefore, this study highlights the opportunity for the fields of mental health and technology to partner to safely disseminate accurate mental health information through an emerging technology.

For the chatbot development industry, algorithms identifying questions about suicide should be evaluated to protect those who may be in the most need of mental health support. Content fed into the algorithm should be reviewed frequently so accurate information can be conveyed. When hyperlinks are provided, a user is more likely to follow the link instead of having to do another search in a web search engine [69]. Thus, chatbots responding to prompts regarding suicide should provide hyperlinks to online resources, rather than simply listing the names of the assistive organizations. Likewise, ensuring the pound sign "#" precedes 988, as well as being clear that this free national emergency number that accepts calls and texts could facilitate contact with valuable resources is suggested. The generative AI chatbot industry should partner with other children safety organizations to provide parents caution and guidance as part of the permission process.

Limitations and Future Research

In this longitudinal study, the quality and accuracy of the information provided improved between phase 1 and phase 2. While that finding is positive for users, it is also identified as a limitation of the study. As time progresses and more information is included in the large language model, the responses from the chatbots to prompts may change [68]. Specifically, evidence-based information may be muted in favor of personal responses that are incorporated into the large language model [70].

Future research could include duplicating this study with other large language models in the future, and with paid chatbot accounts. Throughout this study, only free accounts were used, creating a limitation within the findings as it is unlikely that youth would have a paid AI account. Likewise, OpenAI (ChatGPT 3.5) indicated minimal differences between paid and free accounts. Differences between account types include advanced analysis (statistics), less wait time for information, access to new features, and increased prompts and responses. Likewise, other studies could consider conducting a qualitative study of adolescents who have used chatbots while in crisis to identify the relationships between youth, their crises, and generative AI chatbots used along with the subsequent responses. Finally, this study used prompts stating the user was expressing concern about a friend's suicidality. It would be helpful to note how AI would respond if the chatbot was responding to the actual prompt writer and not a friend.

Conclusion

Generative AI chatbots are emerging technology tools. Youth are consulting with these tools for mental health support inclusive of suicide concerns. Therefore, a content analysis was conducted over the course of a year, of responses from general generative AI chatbots. The suicide information improved in accuracy and quality over the course of a year. Basic information was provided. While this dynamic information may be helpful for adolescents in need, the importance of individuals seeking help from a trained mental health professional remains. Furthermore, generative AI algorithms related to suicide questions should be checked periodically to ensure best practices regarding suicide prevention are being communicated.

Abstract

Background: The integration of information technology into health care has created opportunities to address diagnostic challenges. Internet searches, representing a vast source of health-related data, hold promise for improving early disease detection. Studies suggest that patterns in search behavior can reveal symptoms before clinical diagnosis, offering potential for innovative diagnostic tools. Leveraging advancements in machine learning, researchers have explored linking search data with health records to enhance screening and outcomes. However, challenges like privacy, bias, and scalability remain critical to its widespread adoption.

Objective: We aimed to explore the potential and challenges of using internet search data in medical diagnosis, with a specific focus on diseases and conditions such as cancer, cardiovascular disease, mental and behavioral health, neurodegenerative disorders, and nutritional and metabolic diseases. We examined ethical, technical, and policy considerations while assessing the current state of research, identifying gaps and limitations, and proposing future research directions to advance this emerging field.

Methods: We conducted a comprehensive analysis of peer-reviewed literature and informational interviews with subject matter experts to examine the landscape of internet search data use in medical research. We searched for published peer-reviewed literature on the PubMed database between October and December 2023.

Results: Systematic selection based on predefined criteria included 40 articles from the 2499 identified articles. The analysis revealed a nascent domain of internet search data research in medical diagnosis, marked by advancements in analytics and data integration. Despite challenges such as bias, privacy, and infrastructure limitations, emerging initiatives could reshape data collection and privacy safeguards.

Conclusions: We identified signals correlating with diagnostic considerations in certain diseases and conditions, indicating the potential for such data to enhance clinical diagnostic capabilities. However, leveraging internet search data for improved early diagnosis and health care outcomes requires effectively addressing ethical, technical, and policy challenges. By fostering interdisciplinary collaboration, advancing infrastructure development, and prioritizing patient engagement and consent, researchers can unlock the transformative potential of internet search data in medical diagnosis to ultimately enhance patient care and advance health care practice and policy.

Introduction

Overview

The transition to an era in which IT plays a pivotal role in health care goes beyond an information engineering advancement to address a substantial medical necessity. Evidence is emerging that internet searches for medical information may help facilitate diagnoses of medical conditions. Machine learning models may predict the diagnosis of a condition more accurately than traditional diagnostic methods. Integration of internet search data with a patient's medical records may provide an opportunity for enhanced screening to identify disease in its early stages. In response to nascent research in this area, the Gordon and Betty Moore Foundation is supporting an initiative to explore the potential to harness internet search data for medical diagnoses. This report reflects a component of a comprehensive research endeavor focused on addressing diagnostic delays before hospitalization, encompassing the time lapses preceding a patient's arrival at a health care facility where their condition is conclusively diagnosed [1].

Through a review of the relevant peer-reviewed literature and informational interviews with subject matter experts, this report identifies key themes and insights to lay the groundwork for understanding the implications of leveraging internet search data that links with health research datasets resulting in innovative methodologies that empower health care professionals to make precise and timely diagnoses.

This work does not consider a patient's search engine preference for finding health information, nor review the patterns, trends, or accuracy of patient self-diagnosis through internet searches. It does identify the current body of literature from researchers who leverage internet search data to link to other health research data about the individual patient to identify a diagnosis. Our objective is to explore the broader landscape of leveraging internet search data in health care and its potential for assisting clinicians with diagnoses and to elucidate promising avenues for researchers to enhance diagnostic capabilities through thoughtful application of internet search data. In doing so, we sought a nuanced understanding of the possibilities within the realm of health care diagnostics with a focus on leveraging search history data to benefit clinical care teams rather than investigating self-diagnosis pathways.

This paper sheds light on the research surrounding the use of consumer internet search data for early health concern detection without delving into the clinical validation of such findings. It focuses on the identification of potential diagnostic signals and patterns to inform predictive models and proactive health care interventions, while acknowledging the challenges involved in discerning such signals among the vast array of search queries. By leveraging insights from internet search data, health care professionals may more effectively identify early warning signs, enabling timelier interventions and improved patient outcomes.

Background

Overview

Access to accurate medical diagnosis has been hindered by socioeconomic disparities, limited availability of specialized medical professionals, and lack of patient education, among other factors. Inequities in access to high-quality health care services exacerbate these challenges, leading to disparities in health outcomes. Missed or inaccurate diagnoses can lead to delayed or unnecessary treatments, risking worsening of conditions. The historical reliance on direct patient-physician interactions for diagnosis has failed to bridge these gaps. The emergence of the internet and digital data in the late 20th century began to alter this landscape. Eysenbach [2] highlighted the early potential of the internet in patient education, setting the stage for an ever-increasing reliance on online health information; however, questions remain regarding information accuracy, access, benefits, and privacy.

Internet searches represent one of the largest sources of health data. As of mid-2023, Google's daily search volume was >8.5 billion queries [3]. Around 5% of Google searches are health related [4], and about 77% of persons with a new diagnosis use search engines [5]. A recent study showed that 15% of internet searches by individuals with a recent diagnosis involved symptoms of a disease before diagnosis [6], and 15% of all annual Google searches are new [7].

These and other data have prompted a series of research projects to address the feasibility and utility of using internet search data for seeking health services. Although the use of patient search data represents just one facet of technology being explored to help obtain new data about patient conditions [8], this paper focuses only on research that uses internet search data.

Population Health Research

In population health research, there are studies available to assist researchers in approaching the use of internet search data. These studies focus on population health rather than diagnostic search but remain valuable because they offer methodologies for leveraging internet search data that can benefit research. These studies also delve into how understanding the dynamics of vaccine hesitancy across social media is crucial in devising strategies to promote vaccine acceptance.

Forecasting vaccine hesitancy has become increasingly vital within public health initiatives, and internet search data and social media platforms are pivotal in comprehending the underlying dynamics of this hesitancy [9]. Leveraging data from search logs and social media platforms through machine learning and data analysis provides fresh perspectives on vaccine intentions and behaviors that aid policy makers and health care professionals in crafting strategies to tackle vaccine hesitancy.

The study titled "Accurate Measures of Vaccination and Concerns of Vaccine Holdouts from Web Search Logs" [10] showcases the potential of using search logs for insightful analysis that addresses health concerns of patients. By developing a vaccine intent classifier, researchers accurately detect user searches for COVID-19 vaccines that strongly correlate with the Centers for Disease Control and Prevention's

XSL•FO
RenderX

vaccination rates [10], enabling real-time estimation of vaccine intent rates across demographics and regions and revealing granular tendencies in vaccine-seeking behavior [10]. Machine learning identifies vaccine holdouts; their inclination toward using untrusted news sources; and specific concerns about vaccine requirements, development, and myths [10]. Understanding these concerns among demographic groups unveils variations in hesitancy, shedding light on those crucial moments when individuals transition from being vaccine holdouts to considering vaccination [10].

Similarly, the study on COVID-19 vaccine hesitancy and increased internet search queries for fertility side effects following emergency use authorization demonstrates the link between public concerns and vaccine uptake [11]. The surge in fertility-related queries after emergency use authorization, fueled by unfounded scientific claims propagated on social media, underscores the hesitancy regarding potential side effects that influenced vaccine acceptance rates [11], emphasizing the importance of addressing specific concerns highlighted by web searches to alleviate hesitancy and promote informed public decision-making.

Research involving empathic engagement with vaccine-hesitant individuals in private Facebook groups highlights the potential of social media platforms to provide a place for health education and discussions [12]. These moderated discussions positively influenced vaccination intentions and beliefs, representing a promising strategy for combating vaccine hesitancy [13].

Social media policies and interventions play an important role in mitigating vaccine misinformation. Policies implemented by platforms such as Facebook have reduced the reach of antivaccine content [14], and the systematic appraisal of current social media strategies and their alignment with evidence-based practices represent necessary first steps [15,16]. However, the primary focus of these studies involves public sentiment, intentions, and behavioral patterns and not the diagnosis of specific conditions. Leveraging internet search data and social media platforms provides insights into vaccine hesitancy that can drive evidence-based strategies to address hesitancy, promote informed decision-making, and contribute to the success of vaccination campaigns, potentially curbing the spread of vaccine misinformation during public health emergencies.

Methods

Literature Review

We conducted a literature search on the PubMed database from October 2 to October 30, 2023, using predefined keywords and Medical Subject Headings related to Google, Bing, Takeout, internet search, web search, search behavior, diagnosis, disease identification, and diagnostic accuracy. Multimedia Appendix 1 lists all the search terms.

Stringent inclusion criteria were applied to identify relevant studies for analysis according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines (Multimedia Appendix 2). Inclusion was limited to studies that used internet search data from Google and Microsoft Bing, which account for >90% of all internet searches [3]. The selected studies' primary focus was on individual diagnosis and health behavior to ensure a targeted exploration of search data applications in the context of personal health. Studies were required to integrate internet search data with other health research datasets to provide perspective on individual health outcomes and capture the synergistic potential of combining search data with other health-related information.

Exclusion criteria were established to maintain specificity and relevance to the research focus. Studies within the domain of broad population health research were excluded, as was research solely reliant on social media data. These inclusion and exclusion criteria were applied to pinpoint studies aligning with the project's primary focus: leveraging patients' internet search data for individual diagnosis and providing patients with information to aid in screening.

All articles retrieved from the initial PubMed database search were uploaded to Covidence (Veritas Health Innovation Ltd), where duplicates were removed, and the literature review process was conducted according to the predefined inclusion and exclusion criteria. To reduce errors and bias, the authors independently screened the papers' titles and abstracts, and full texts of potentially eligible articles were examined for final inclusion. Throughout this process, the authors periodically compared findings, resolving any discrepancies through discussion and consensus to ensure thoroughness and accuracy in study selection.

Textbox 1 presents the inclusion and exclusion criteria used to screen publications on the basis of the title and abstracts. The exclusion criteria for this literature review were clearly defined to ensure the relevance and quality of the included studies.

XSL•FO
RenderX

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Article type: peer-reviewed journals
- Article focus: use of internet search data, both anonymized and fully identified
- Outcomes: the combined use of health research datasets and internet search histories to identify, predict, or confirm a clinical diagnosis
- Time: January 1, 2005, to October 30, 2023
- Language: English
- Geography: international

Exclusion criteria

- Article type: newspaper articles, opinions, and commentaries; articles unavailable in full-text format; duplicate studies
- Article focus: studies that did not verify a patient's clinical diagnosis following analysis of internet search behavior; studies that focused solely on diagnoses at the population level, without specific individual-level data; articles primarily discussing moral, ethical, or privacy considerations related to the use of internet search data without providing analytical insights from the integration of search and clinical data
- Time: dated before January 1, 2005
- Language: non-English

Informational Interviews

To complement the literature review, informational interviews were conducted with a convenience sample of experts, including researchers, patient advocates, ethicists, and professionals in the open data field, focusing on the use of internet search data in health research. These participants were identified through contacts provided by AcademyHealth. Web-based interviews were conducted over a 3-week period using a survey instrument (Multimedia Appendix 3) designed to explore topics such as the application of internet search data in health research, public acceptance and perceptions of its use, and privacy and security considerations. Thematic analysis was performed on the interview data to identify recurring insights and perspectives, which were then synthesized to complement the findings from the literature review and highlight critical considerations for advancing this field.

Results

The search initially yielded 6427 articles, reports, and publications from the PubMed database. Figure 1 presents the PRISMA flowchart of the record selection process. Duplicates were removed from all articles identified across all searches totaling 3928 (ie, 61% of all results).

A total of 2499 peer-reviewed articles were selected for screening on the basis of title and abstract for inclusion and exclusion consideration following the focused criteria. A total of 2396 articles were excluded based on the following criteria: commentaries (n=127, 5.3%); focused only on population-level disease identification (n=881, 36.8%); focused predominantly on the moral, ethical, or privacy considerations for the use of internet search history while not presenting insights from the analysis of search and clinical data (n=27, 1%); or only investigated internet search data without confirming a diagnosis from an independent dataset or from the patient directly (n=1361, 56.8%).

Full-text reports were sought for the remaining 103 articles; however, 5 articles could not be retrieved. Of the 98 reports obtained, the authors read the full text and excluded 59% (n=55) of reports that focused primarily on a population-level analysis (n=19, 19%) or that did not confirm a diagnosis from an independent dataset or from the patient directly (n=39, 40%). This process resulted in the inclusion of 40 articles in this literature review (Multimedia Appendix 4 [6,8,17-54]).

Table 1 provides a categorized summary of the 40 peer-reviewed articles included in this literature review, organized by the disease or condition each study addresses. This categorization highlights the diverse applications of internet search data in diagnosing a range of health conditions, from cancer to mental and behavioral health, showcasing the breadth of this emerging research field. The table underscores the potential for leveraging search data across various medical domains to enhance diagnostic capabilities and early detection efforts.

A total of 16 interviews were conducted with participants from academic institutions (n=8, 50%), private-sector companies (n=5, 31%), and nonprofit organizations (n=3, 19%). Key findings highlighted several challenges and opportunities in the field, including difficulties in obtaining institutional review board (IRB) approval for studies involving internet search data, the importance of building trust between patients and researchers to encourage data sharing, and the need for streamlined processes to download and access search data. Participants also emphasized the lack of tools to effectively analyze unstructured data and build predictive models.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart for literature selection.

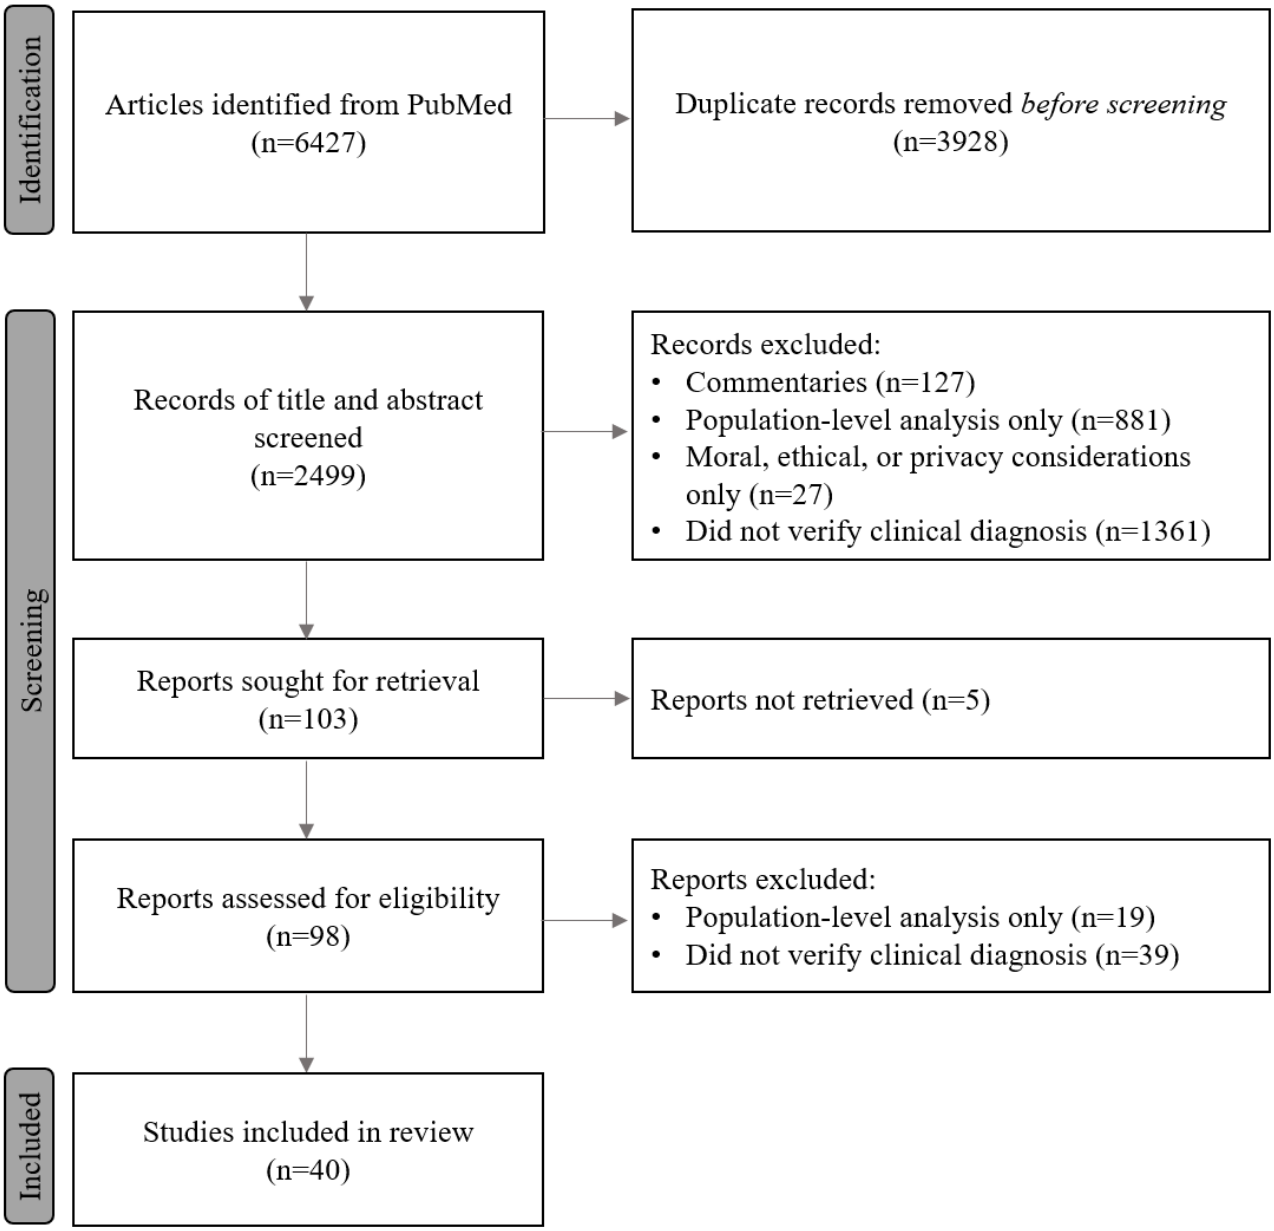

Table 1. Total articles by disease category (N=40).

Disease category	Articles, n (%)[a]
Cancer	13 (32)
Cardiovascular disease	2 (5)
Emergency care	6 (15)
Mental and behavioral health	16 (40)
Neurodegenerative diseases	5 (12)
Nutritional and metabolic diseases	4 (10)

[a]Some articles address multiple disease categories, causing the total in the table to exceed the total number of studies.

Discussion

Principal Findings

Within health and health services queries, 3 distinct categories demonstrate generalizability to population-based analyses and individual-specific applications on the basis of the search content and patterns. While the use of data from *aggregate, anonymized* queries is widespread, particularly in epidemiological studies at the population level, such use lacks value in diagnosing specific conditions for individual patients. These anonymized

XSL•FO
RenderX

datasets, lacking individuals' specific informed consent, fall under exempt research use. Consequently, this paper does not include detailed examinations of these studies [55,56].

The second and third categories of research applications using search queries are the focus of this examination. Both include individually consented patient data that may be linked with additional clinical datasets. In the United States, these studies fall under the Common Rule and Health Insurance Portability and Accountability Act (HIPAA) privacy rule [57].

The second category includes using a *search history to predict future search queries* strongly correlating with health conditions or disease outcomes. One application involves developing specialized queries associated with a condition, searching patients' internet logs with that condition, and evaluating associated symptoms [17]. Researchers then build statistical classifiers to predict future appearances of landmark queries based on patterns in search logs [17]. Such signals show possibilities of predicting forthcoming diagnoses from subtle temporal signals in searchers' queries [17]. This approach was used to establish patient searches of symptoms associated with pancreatic cancer before their clinical diagnosis [17].

The third category involves using users' internet *search logs for which they granted consent for researchers* to access and possibly permitted linkage to their health data. Most applied research in this category has used retrospective analysis to correlate with features of clinical symptoms or diagnostic tests. In several cases, particularly studies involving behavioral and mental health, prospective associations with Google and Bing search data series have been aligned with clinical outcomes [18]. In the subsequent sections, we summarize findings from peer-reviewed publications representing research conducted on disease or condition diagnosis using search history to predict future health searches and patient-consented data linked to other health research data. Although these data represent a promising avenue for health research, cohort sizes in studies of internet search data linked with clinical records are typically smaller than those evaluating only individual internet search data, necessitating careful consideration when interpreting results and designing future studies. Nevertheless, studies going beyond aggregate, anonymized data offer important insights, particularly in understanding behavioral and mental health conditions.

Cancer

Overview

The study titled "Patterns of Information-Seeking for Cancer on the Internet: An Analysis of Real World Data" [19] was among the first internet query–based studies to present a detailed analysis of cancer-related internet searches. It analyzed Yahoo search data over 3 months, involving 50,117 users and 225,675 queries [19]. Findings include a correlation between the aggressiveness of the cancer type and the intensity and duration of search patterns [19]. The study used linear regression and hidden Markov models to analyze these patterns [19], finding a stronger focus on treatment information in searches for aggressive cancers, while users demonstrated a higher interest in support groups for less aggressive cancers [19]. This research underscores the potential clinical utility and limitations of using internet search data to understand the information needs of patients with cancer and their acquaintances. It suggests that while such data offer valuable insights, they may not represent the diversity of experiences and needs of patients with cancer [19].

Soldaini and Yom-Tov [20] also demonstrated algorithms designed to identify specific traits of interest in anonymous internet users. These algorithms' applications in the medical domain demonstrate their effectiveness in identifying potential patients with cancer based on search patterns, predicting disease distributions within a population, and offering valuable insights for early disease screening and epidemiological studies [19-21].

Parents of Patients With Pediatric Cancer

A study titled "Health-Related Google Searches Performed by Parents of Pediatric Oncology Patients" [22] analyzed the search behaviors of 98 parents of patients with pediatric cancer and found that parents conducted a higher proportion of health-related searches (13%) compared to the general population (5%) [22]. Searches peaked around key medical events such as diagnosis and treatment phases [22].

Approximately 31% of the searches involved symptoms, disease, and medical information, and 29% involved hospitals and care sites [22]. Cancer-specific searches comprised 18% of the health-related queries [20]. The study emphasized the critical role of the internet in the information-seeking process of parents coping with a child's cancer diagnosis and treatment and highlighted parents' reliance on the internet for health care information in pediatric oncology [22]. This reliance underscores the need for accessible, reliable online medical information and indicates potential focus areas for health care providers in patient and family education.

Lung Cancer

A study titled "Evaluation of the Feasibility of Screening Patients for Early Signs of Lung Carcinoma in Web Search Logs" [23] explored the use of anonymized search logs for the early detection of lung carcinoma. White and Horvitz [23] used anonymized search logs from Bing involving millions of US. English-speaking users. Of these, 5443 users who later searched for lung carcinoma symptoms were identified as positive cases [23]. Statistical classifiers were used to predict search appearances based on earlier search patterns [23]. Findings showed that certain search behaviors could indicate a higher risk of lung cancer, with true-positive rates ranging from 3% to 57% for different false-positive rates [23]. The study concluded that web search data could aid in early lung cancer detection, highlighting new directions in identifying risk factors and screening opportunities [23].

A study titled "The Role of Web-Based Health Information in Help-Seeking Behavior Prior to a Diagnosis of Lung Cancer: A Mixed-Methods Study" [24] investigated how web-based health information influences diagnosis for patients with lung cancer. Through surveys and interviews, the study captured the experiences and behaviors of patients and their next of kin [24]. Quantitative methods were used to establish the proportion of lung cancer cases in which prediagnosis web searches occurred [24]. Qualitative methods were used to explore individuals'

XSL•FO
RenderX

perceptions of the impact their web searches had on the pathway to diagnosis and the barriers that might prevent individuals from accessing the web for information before the diagnosis [24]. Mixed methods were required, because a survey was needed to screen for relevant individuals for interviews as low levels of web use among patients with lung cancer were expected [24]. Thus, this study included a cross-sectional, retrospective survey and a qualitative interview study with a subsample of the survey participants [24]. It found that 20.4% of participants engaged in prediagnosis web searches, mainly using Google and NHS Direct [24]. These searches played a role in all the 3 intervals leading to diagnosis: symptom appraisal, decision-making for seeking health care, and interaction with health professionals [24]. The study underscores the growing significance of the internet in early disease detection and patient decision-making [24].

Ovarian Cancer

A study titled "Using Online Search Activity for Earlier Detection of Gynaecological Malignancy" [25] focuses on leveraging Google search data to predict gynecological cancers, particularly ovarian cancer. Although this study was built upon the research by Soldaini and Yom-Tov [20] that relied on self-identification in queries for outcomes [26], it used clinically verified outcomes to enhance the findings' robustness and reliability. The study, conducted from December 2020 to June 2022 at a London university hospital, involved 235 women who consented to share their Google search histories [25]. It aimed to distinguish between search patterns of women with malignant diseases and those with benign tumors and to explore the possibility of earlier diagnosis through these patterns [25] and found notable differences in search patterns up to a year before clinical diagnosis, with a predictive model showing an area under the curve (AUC) of 0.82 for individuals who frequently searched for health-related topics [25], demonstrating the potential of using online search data as a supplementary tool for early cancer detection [25]. Chen et al [27] noted that despite the limited datasets in this study, a tendency is apparent toward heightened online search activity before patients with malignant cases visit a general practitioner [27].

Pancreatic Cancer

A study titled "Screening for Pancreatic Adenocarcinoma Using Signals From Web Search Logs" [17] explored the use of Bing web search logs to predict pancreatic adenocarcinoma. The study involved 9.2 million US English-speaking users, focusing on the feasibility of the early detection of pancreatic cancer by analyzing search patterns [55]. The researchers analyzed Bing anonymized search logs, looking for patterns that might indicate the early stages of pancreatic adenocarcinoma [17]. They identified users who searched for symptoms or treatment related to pancreatic cancer and then traced their search history backward, looking for early signals of the disease [17]. This retrospective analysis searched for distinctive search patterns before the actual diagnosis [17]. The findings demonstrated the potential of search log analysis to identify early signs of serious illnesses and that certain search behaviors could indicate pancreatic adenocarcinoma, achieving true-positive rates of 5% to 15% with extremely low false-positive rates [17]. This method could complement traditional diagnostic methods and constitutes an innovative approach suggesting a new direction for cancer screening using web search data in health surveillance and early diagnosis [17].

Cardiovascular Disease

Shaklai et al [28] evaluated the predictive potential of Bing search queries for impending stroke events in an at-risk population in a health care setting in Israel. The study analyzed data from 285 individuals who self-reported a stroke and 1195 controls, focusing on changes in cognitive traits evident in their internet searches [28], and found that certain query attributes related to cognitive function were predictive of an impending stroke [28]. The model showed high accuracy, particularly as the date of the stroke approached, suggesting that monitoring internet search patterns could offer a valuable tool for early stroke detection [28].

Emergency Department Visits

Asch et al [29] explored the potential of Google search histories in predicting emergency department (ED) visits and their correlation with clinical conditions. The study included 103 participants who consented to share their Google search data collected 7 days before the ED visits; their electronic medical record (EMR) data were included [29]. The analysis of 591,421 unique search queries revealed that 37,469 (6.34%) were health related [29]. In the week before an ED visit, 15% of searches were health related, with many directly related to the participants' chief concerns [18]. The study highlights the potential of internet search data in anticipating health care use and understanding patients' health-related concerns [29].

Mental and Behavioral Health

Addiction

Nitzburg et al [30] used internet search data to identify patients seeking drug treatment services for alcohol use disorder. Leveraging internet search data, the study explored how medical symptom queries correlate with subsequent searches about Alcoholics Anonymous and Narcotics Anonymous treatment [30]. Routine visits to primary care physicians serve as initial points of contact for problem drinkers, providing an opportunity to motivate them toward alcohol-reduction treatment. Brief intervention protocols, integrated into routine care, aim to reduce patients' drinking levels [30]. By analyzing anonymized Bing search data, the study identified common medical symptoms preceding searches for 12-step programs, illuminating potential avenues to enhance brief intervention protocols' efficacy in motivating individuals toward seeking treatment [30]. Findings suggest that emphasizing long-term medical consequences and immediately discomforting symptoms could enhance motivation for seeking treatment.

Anxiety and Depression

Three studies [31-33], focusing on depression and anxiety disorders, present innovative approaches to addressing mental health challenges. Zhang et al [31] explored the potential of using personal online activity histories from search engines such as Google and platforms such as YouTube to detect depressive disorder among US college students. By collecting

XSL•FO
RenderX

longitudinal data and using machine learning techniques, the study established correlations between shifts in online behaviors and worsening mental health profiles during the COVID-19 pandemic [31], highlighting the feasibility of leveraging ubiquitous online data for noninvasive surveillance of mental health conditions and offering an alternative to traditional screening methods, especially in times of societal disruption [31].

Zaman et al [32] expanded the investigation to examine the relationship between changes in Google search and YouTube engagement behaviors and the exacerbation of depression and anxiety levels among college students during the COVID-19 pandemic. Through longitudinal data collection and correlation analysis, they identified significant associations (P=.03) between deteriorating mental health profiles and shifts in online behavior and provided insights into the potential use of these behavioral changes to predict mental health conditions [32]. These findings underscore the importance of using pervasive online data for real-time monitoring and early intervention in mental health care and offer a cost-effective, scalable approach to complement existing screening methods [32].

In a third study, Zaman et al [33] proposed an alternative method for identifying individuals with anxiety disorders and estimating their anxiety levels using personal online activity histories from YouTube and Google search. By collecting multiple rounds of anonymized data and developing explainable features capturing temporal and contextual aspects of online behaviors, they demonstrated results in detecting anxiety disorders and assessing anxiety levels. This study presents a cost-effective and scalable framework that could be deployed in real-world clinical settings, empower health care providers and therapists with insights into anxiety disorders, and enhance mental health care delivery [33]. These 3 studies highlight how leveraging online data for mental health surveillance and intervention offers new avenues for improving mental health outcomes.

Youngmann et al [34] revealed that individuals exhibit distinct information-seeking behaviors when using searches depending on their anxiety level, which is particularly evident in searches for medical symptoms with potentially life-threatening implications. By analyzing mouse-tracking data and other user interactions, a model was developed to predict user anxiety levels that achieved significant correlation (Kendall's Tau of 0.48) with the severity of symptoms searched [34]. The findings underscore the importance of incorporating user anxiety information to accurately measure search engine performance, which is crucial in effectively delivering critical medical information and suicide prevention resources.

Eating Disorders

Sadeh-Sharvit et al [35] addressed how leveraging internet search data can enable interventions in cases of eating disorders, given their personal and public health costs and the barriers to seeking treatment. By leveraging internet browsing behavior, the study explored whether data from clinically validated online screens can predict the presence of or the high risk for an eating disorder [35]. Results suggest that a machine learning algorithm incorporating variables such as age, search activity related to eating disorders, and internet use patterns can identify women screening positive for eating disorders with moderate accuracy, potentially enabling early intervention to reduce the prevalence of these disorders. The study acknowledges the need for larger sample sizes and inclusion of diverse populations, along with the ethical and privacy concerns in implementing predictive models for eating disorder detection using internet browsing data [35].

Intimate Partner Violence

Zaman et al [36] used Google search data to identify intimate partner violence (IPV); 56 participants consented to data analyses that revealed distinctive search characteristics among those with and without IPV experiences [36], suggesting that specific patterns in search behavior, including linguistic attributes and search times, can indicate IPV [36]. These findings highlight the potential use of search data for early detection of and intervention in domestic violence [36].

Youngmann and Yom-Tov [37] analyzed queries from Bing search data involving over 50,000 US individuals experiencing IPV. About half initiated their searches for IPV-related information following an IPV event, while approximately 20% actively concealed their IPV interest [37]. Individuals experiencing IPV showed interest in the effects of IPV, seeking help, ways to escape from abusive situations, and more [37]. This research suggests that while detecting early signs of IPV through search queries may be challenging, even in the later stages of IPV, interventions such as targeted advertisements to assist people in safely leaving violent situations could be highly beneficial [37].

Mood Disorders and Suicidality

A study [38] conducted at Northwell Health system included 43 individuals aged between 15 and 30 years with mood disorders who were hospitalized for suicidal thoughts and behaviors and examined their Google search activity before hospitalization. The research identified search patterns related to suicide and behavioral health [38]. A majority (27/43, 63%) conducted suicide-related searches [38]. Participants searched for information that matched their chosen method of attempting suicide in 21% (9/43) of the cases [31]. Suicide-related queries also included unusual suicide methods and references to suicide in popular culture [38]. Most participants (33/43, 77%) used queries related to help-seeking themes, including how to find behavioral health care [38]. Queries related to mood and anxiety symptoms were found among 44% (19/43) of participants and included references to panic disorder, inability to focus, feelings of loneliness, and despair [38]. The results provide insights into digital behaviors of youth with mood disorders facing suicidality, highlighting the potential of internet search data in clinical assessment and intervention strategies [38].

A study titled "Perceived Utility and Characterization of Personal Google Search Histories to Detect Data Patterns Proximal to a Suicide Attempt in Individuals Who Previously Attempted Suicide: Pilot Cohort Study" [39] explored the feasibility and acceptability of using personalized online search data to identify the risk of suicide attempts. It involved 62 participants with a history of suicide attempts and analyzed changes in online search behavior up to 60 days before an

XSL•FO
RenderX

attempt, revealing patterns such as increased searches related to suicide methods and expressions of anger [39]. The study highlights the potential of internet search data to identify early warning signs of suicide risk, although participants raised concerns about privacy and accuracy [39].

Psychosis

A study titled "Google Search Activity in Early Psychosis: A Qualitative Analysis of Internet Search Query Content in First Episode Psychosis" [18] analyzed Google search queries of individuals before their first hospitalization for psychosis. This qualitative evaluation involved 20 participants who provided access to their Google archive data and identified common themes during emerging illness [18]. Findings revealed that 75% of participants searched for mental health–related information [18]. Most (75%) participants included delusions in their queries [18]. The study concluded that individuals with early psychosis used the internet to understand their symptoms before seeking psychiatric care [18], highlighting the potential for tailoring online resources to improve pathways to care and shorten durations of untreated psychoses [18].

Aref-Adib et al [40] investigated patterns and consequences of online mental health information–seeking behavior among individuals with psychosis and assessed the acceptability of a mobile mental health app. Individuals with psychosis commonly seek online mental health information, which proves beneficial when shared with clinicians [40]. However, when not shared, it can impact health care decisions [40]. The research underscores the need for a collaborative, shared decision-making approach to online health information seeking that includes discussion with clinicians [40]. Findings suggest that individuals with psychosis lead active digital lives, indicating that introducing a mental health app into services may be positively received.

Schizophrenia

A study titled "Utilizing Machine Learning on Internet Search Activity to Support the Diagnostic Process and Relapse Detection in Young Individuals With Early Psychosis: Feasibility Study" [41] explored using internet search data to aid in diagnosing relapses in schizophrenia spectrum disorders (SSDs). It involved 42 participants in the Northwell Health System with SSD and 74 healthy volunteers aged between 15 and 35 years [41]. The IRB-approved study analyzed 32,733 time-stamped search queries [41]. Machine learning algorithms were developed to distinguish between individuals with SSD and healthy volunteers and to predict psychotic relapses [41]. Results showed potential for using online search activity as objective data in psychiatric diagnostics and relapse prediction, with classifiers achieving an AUC of 0.74 for diagnosis and an AUC of 0.71 for relapse prediction [41]. Findings include fewer and shorter searches among SSD participants and specific word use patterns related to symptoms [41]. This approach represents a novel method for integrating digital data into mental health monitoring and diagnostics [41].

Neurodegenerative Diseases

Internet search data have also been used in diagnosing neurodegenerative diseases. Austin et al [42] explored the relationship between internet search behavior and cognitive function in older adults, with a focus on Alzheimer disease. By continuously tracking and analyzing search terms, the authors found that individuals with poorer cognitive function exhibited distinct patterns in their web searches—they used fewer unique terms and less common vocabulary [42]. This suggests that changes in language use during web searches could serve as an early indicator of cognitive decline, thereby potentially enabling treatment before symptoms fully manifest [42].

Youngmann et al [43] developed a machine learning algorithm to screen for Parkinson disease using data from search interactions. By analyzing the textual content of web queries, the classifier identified individuals at high risk for Parkinson disease [43]. Longitudinal follow-up revealed that those identified as positive showed a higher rate of progression in disease-related features [43]. This innovative approach enables large-scale screening for Parkinson and offers insights into disease progression, potentially facilitating early intervention and management.

Yom-Tov et al [44] investigated the potential of internet search interactions in identifying individuals with amyotrophic lateral sclerosis (ALS). By analyzing search query data, the authors developed a model capable of accurately distinguishing individuals with ALS from controls and disease mimics [44]. The prospective validation further supported the approach's efficacy, indicating its potential as a screening tool to reduce ALS-associated diagnostic delays [44]. These studies highlight the value of harnessing internet search data for early detection of neurodegenerative diseases and offer promising avenues for improving clinical outcomes.

Nutritional and Metabolic Diseases

The use of internet search data presents a potential avenue for early detection of nutritional and metabolic diseases, such as diabetes. Hochberg et al [45] analyzed Bing search queries from US users to identify symptoms related to diabetes. Through predictive models, the study could distinguish between users diagnosed with diabetes and those querying symptoms associated with diabetes [45]. The models could detect undiagnosed patients with diabetes up to 240 days before they mentioned being diagnosed [45], highlighting the potential of using search data for earlier diagnosis, which is particularly beneficial for conditions such as type 1 diabetes, where early detection is clinically meaningful [45]. In addition, the study suggests the possibility of searches serving as population-wide screening tools and hints at potential further improvement by incorporating additional user-provided data.

Lebwohl and Yom-Tov [46] investigated the use of internet search data to identify symptoms prompting an interest in celiac disease and the gluten-free diet. By analyzing Bing search queries in the United States, the study characterized symptoms and conditions potentially indicating elevated likelihood of subsequent celiac disease diagnosis [46]. The study identified various symptoms queried before celiac-related searches, including diarrhea, headache, anxiety, depression, and attention-deficit/hyperactivity disorder, but the predictive ability of these searches was limited [46]. The study did observe an increase in antecedent searches for symptoms associated with

XSL•FO
RenderX

celiac disease, shedding light on its diverse clinical manifestations and the challenges involved in identifying effective case-finding strategies [46]. These findings underscore the complex nature of a celiac disease diagnosis and the potential for leveraging internet search data to enhance understanding and detection of such nutritional disorders.

The following case study involves applications of irritable bowel syndrome in the context of public health information, misunderstanding, and patterns of decision-making by individuals. A study titled "Evidence From Web-Based Dietary Search Patterns to the Role of B12 Deficiency in Non-Specific Chronic Pain: A Large-Scale Observational Study" [47] used a large dataset of internet search patterns to investigate the relationship between vitamin B12 deficiency and chronic pain.

The study explored the role of vitamin B12 in neuropathy and other neuropsychiatric symptoms using internet search patterns as a proxy for dietary habits [47]. Researchers analyzed search data from 8.5 million people in the United States, focusing on searches related to food and B12 deficiency symptoms [47]. Researchers used Bing search data from October 2016 to examine searches for recipes and terms related to chronic pain and B12 deficiency [47], then used a linear classification model to link food consumption data with searches for medical terms, finding a strong correlation between food-related search patterns and actual food consumption [47]. Terms related to neurological disorders were more commonly searched for in conjunction with B12-poor foods [47]. In addition, people who searched for B12-rich foods were less likely to search for medical terms associated with B12 deficiency [47], and the average estimated daily B12 consumption for people who inquired about B12 was 2.407 µg, compared to 2.395 µg for those who did not, indicating a slight but highly correlated relationship [47].

The study suggests that low vitamin B12 intake may be linked to a broader spectrum of neurological disorders than previously thought [47]. It emphasizes the potential of using internet search patterns for large-scale health studies [47]. The researchers recommend further research to explore the clinical significance of these findings and confirm the role of B12 in neuropsychiatric symptoms [47]. They also note the importance of considering different meat sources in assessing dietary B12 intake [47]. This study offers insights into the potential use of internet search data in public health research to understand the relationship between diet and disease symptoms [47].

Ethical, Legal, and Social Implications

The ethical, legal, and social implications of using internet search data in health research are multifaceted and critical to address. Ethically, the balance between leveraging data for societal benefit and protecting individual privacy is paramount, particularly given the sensitive nature of health-related search queries. Interviewees note challenges in fostering trust between patients and researchers; patient concerns around consent, transparency, and potential misuse of data require robust safeguards and clear communication to ensure that individuals are informed about how their data will be used and about accessible mechanisms to control or recover their shared data, along with demonstrable benefits of data use. Legally, the application of privacy laws such as HIPAA is complicated by the fact that internet search data fall outside traditional health care regulatory frameworks, necessitating new guidelines to address these gaps. Public acceptance hinges on building trust, which involves addressing fears of surveillance, potential discrimination, and misuse of personal data. These considerations underline the importance of interdisciplinary collaboration to develop ethical frameworks and policies that align technological capabilities with societal expectations and legal requirements.

Cross-Cutting Themes, Lines of Evidence, and Research Gaps

The results of our analysis of the peer-reviewed research for anonymized and nonanonymized research using Bing or Google search data reflect a clearly nascent domain of IT and data research in assisting with diagnosis determinations. Nevertheless, the advances in structured data, large language models (LLMs), search engines, analytic platforms, and expanding research experiences of health service investigators in population health and individual patient research are promising [58]. At present, there is no structured way of designing these types of studies to aid in diagnosis, but among the most visionary applications of search data, one of the applications is to develop disease-specific predictive models for classifying internet search terminologies that may one day be applied in real time for clinical decision-making.

The published research addresses feasibility and clinical efficacy in prospective studies. None of the reviewed studies have addressed clinical utility. However, some studies discussed implications of how analysis tools and predictive models were used, and some described the conceptualization for data representations in clinical health records [31-33]. Should this type of research demonstrate clinical utility, one could envision the development of apps to empower individual patients. Research of rare diseases could benefit from population-level applications, where crowdsourcing of queries could be mined for commonalities and integrated with population data, disease registries, and EMRs. In addition, utilities for identifying patient candidates for clinical trials could be explored.

Researchers publishing results using internet search data are from 2 general health research domains: researchers from large technology companies with proprietary technology that supports internet searches, who have provided methodological innovations that open doors for clinical investigations [19-27,37,38,41], and academic researchers experienced with large dataset analysis for specific health conditions. The research approaches differ in terms of anonymization, integration with EMRs or other data, the size of the groups studied, and applications of methods and tools. Moreover, it seems likely that research that combines important research questions from clinical and academic settings with the technology engineering domains would catalyze promising clinical and public health insights.

Research questions explored using internet search data usually focus on diseases that evolve over time (ie, subacute or chronic diseases) with a wide array of clinical presentations. One challenge across the domains studied using consented, retrospective internet search data involves the risks for bias in

XSL•FO
RenderX

methods for consenting, patient donation, and other areas. However, the associations of causal effects through statistical analysis and mathematical examinations in population studies that use anonymous data sources can frame insights that can be evaluated through pilot studies and prospective randomized clinical trials that can address or help minimize the effects of biases.

Several studies integrate datasets from other social media platforms, such as Instagram and X (formerly known as Twitter), while others use Google Takeout or Bing. We found no publications using Google and Microsoft patient data on the same patients, nor any studies using the same analytic algorithms. Future work could examine crossover effects of patient populations using both data sources because the orientation and structure of the datasets differ.

Only 1 study to date has used a prospective data collection approach that enables patients to contribute data from the beginning of their enrollment (KA Comtois, PhD, personal email correspondence, December 26, 2023). It is unclear whether the search patterns differed in patients who donated their data retrospectively versus patients who donated prospectively. The publications we examined provide no details on the mathematical methods used in classifying terms; there appears to be no consensus or best practices for annotating such data. Thus, reproducing study results may be difficult. We found no publications that have made anonymized datasets created from their research available to other researchers for examination. The most detailed descriptive methods publications provide are supplemental data that include search patterns, common terms, and other data classification details. Future research may encourage more open data policies, including the provision of metadata and the descriptive characteristics of the study populations, which would allow others to validate and build on pilot studies that shape hypothetical associations for enabling diagnosis.

While cancer diagnosis was the initial clinical domain of disease diagnosis captured in the early literature [25], the research has broadened to additional areas, including mental and behavioral health [26,27,30-35,38-41]. The ability to obtain search data from patients provides researchers with valuable insights into the patterns of thought, the periodicity of searching patterns, and themes of research. Perhaps the most noteworthy search domain identified involves queries regarding the patient's intent to harm oneself or others. A series of studies on integrating patients' online activities and risk-taking behavior are underway to evaluate their utility in understanding patient management applications. In these domains, the clinical utility is less focused on diagnosis than on monitoring the patient's status for management and on using search data as an integral tool to intervene or make therapeutic changes in clinical regimens. Government or nongovernmental research organizations are sponsoring several of these studies, marking a milestone for nonindustry sponsorship of search data applications [1].

From the articles we reviewed, there appears to be consensus that assistance with infrastructure development would benefit researchers in designing their studies. In this paper, we have summarized the research findings on tools for harnessing massive datasets and enabling their integration with other datasets, including those with EMR data. We also noted a need for broader information about the nature of the available search datasets, best practices for individuals to manage their datasets with researchers, and the conditions under which their data can be shared. Given the concerns regarding data privacy and security for large datasets in the consumer marketplace and the interplay of these data with HIPAA-regulated data in clinical settings, benefit to the researcher and patient advocacy communities could be achieved by establishing resources and best practices to guide future research design, oversight, and patient benefits from the use of their data.

Researcher Tools

Researchers have created tools to effectively use internet search data, the integration of which has eased the identification of early signs of issues, ensured user privacy, and streamlined the investigative process. Innovation in these tools (Multimedia Appendix 5) allows researchers to be more successful in their searches, as has been the case in other research domains with novel data sources, such as genomic datasets.

The gTAP web application prioritizes data privacy and security by allowing participants to download their data without sharing personal account credentials, ensuring a higher level of user trust and confidentiality [39]. This feature encourages participation in studies involving symptom analysis and diagnostics, fostering collaboration between researchers and users while maintaining data integrity [39].

Linguistic Inquiry and Word Count, a text analysis software package, exhibits remarkable potential in differentiating linguistic attributes within search logs [36]. By identifying linguistic patterns indicating emotional, sexual, or physical abuse, Linguistic Inquiry and Word Count is instrumental in early symptom identification, providing valuable insights for health care professionals and researchers [36].

The Google natural language processing application programming interface is pivotal in ensuring data privacy and anonymization [48]. By automatically detecting and removing personally identifying information from search history data before they are saved as research data, this application programming interface safeguards the confidentiality of individual study participants [24], enabling researchers to delve into symptom analysis and diagnostics using real-world data while upholding ethical standards and privacy regulations [49].

CrowdTangle, a powerful tool from Meta, aids in monitoring, analyzing, and reporting social media activities [7]. It effectively offers transparency across various social media platforms, positioning it as an invaluable resource for understanding public discourse and sentiment regarding health-related symptoms and conditions [7]. It is the most effective transparency tool in the history of social media [15].

Latent Dirichlet allocation and Differential Language Analysis Toolkit are cutting-edge methodologies in text analysis [59]. Latent Dirichlet allocation produces clusters of words that occur in the same context across Facebook posts, yielding semantically coherent topics [15]. Differential Language Analysis Toolkit determines the relative frequency with which users use words

XSL•FO
RenderX

(ie, unigrams) and 2-word phrases (ie, bigrams) and can also retain variables and phrases [59]. Both are pivotal in the identification of potential symptoms or health-related discussions [59].

In a recent diagnostic study evaluating artificial intelligence (AI) capabilities, the use of the AI chatbot GPT-4 (OpenAI) showcased remarkable proficiency in certain diagnostic scenarios [60]. Comparing the LLM's performance with a broad survey of human clinicians, the study revealed that the LLM surpassed human clinicians in accurately determining pretest and posttest probabilities following a negative test result across 5 cases, although the performance was less robust after positive test results [60]. The study suggests that leveraging probabilistic recommendations from such LLMs could enhance human diagnostic capabilities and that combining AI's probabilistic, narrative, and heuristic diagnostic approaches could improve diagnostic accuracy [60].

These tools offer greater accuracy and prioritize user privacy and data security. Integrating them into research and health care systems enables early detection and better understanding of symptoms and contributes to well-being outcomes, especially for older individuals, when combined with a comprehensive support system. As technology evolves, these tools are poised to play an increasingly vital role in enhancing health care and advancing diagnostic capabilities.

Challenges

The use of internet search data to facilitate medical diagnosis faces challenges, including bias, data privacy, and misinformation. The ethical use of patient data is crucial. The study by Wachter and Mittelstadt [61] titled "A Right to Reasonable Interferences: Rethinking Data Protection Law in the Age of Big Data and AI" analyzes ethical dilemmas surrounding the use of big data in health care, emphasizing the need to balance patient privacy with the benefits of big data analytics [41] and the importance of consent and transparency in the collection and use of patient data. It also highlighted biases and inequalities resulting from mismanaged data practices [61]. Yom-Tov and Cherlow [50] further emphasized the need to carefully consider the ethical implications and suggest solutions that balance the benefits and challenges of online screening services.

In our exploration of the field of information sciences concerning internet search data, a notable challenge emerged—the lack of infrastructure for constructing a robust analytic approach to leverage these data in medical and health services research. Thus, we investigated alternative open data research organizational models and discovered the pioneering work of Lane [62]. In her book *Democratizing Our Data: A Manifesto* [62], Lane introduces an organizational model to revolutionize data accessibility and usefulness. Within this context, the Institute for Research on Innovation and Science (IRIS) stands out with its groundbreaking contribution, the Universities: Measuring the Impacts of Research on Innovation, Competitiveness, and Science (UMETRICS) dataset [62]. UMETRICS constitutes a burgeoning research asset, harnessing administrative data—information collected primarily for administrative purposes, such as record keeping, then repurposed for research to analyze health care patterns—from 30 prominent universities that collectively contribute over one-third of federal research and development spending in academia [62]. This dataset signifies a shift in data practices, fundamentally reshaping data collection methodologies, fortifying privacy safeguards, and fostering the generation of new products [62]. Along with pioneering the inception of "big data" social science research infrastructures, IRIS confronted the formidable challenge of comprehending the impact of research funding on scientific and economic activities, doing so by spearheading construction of an entire infrastructure for tracing the effects of research funding on individuals and interconnected networks [62]. IRIS developed a highly adaptable data infrastructure, composed of a decentralized network of federal agencies responsible for collecting, analyzing, and disseminating data on various aspects of the country, which caters directly to research universities and provides impactful methods to assess scientific and economic implications of their research pursuits, surpassing the federal statistical system [62]. Critical to IRIS's approach was establishing a data infrastructure rooted in transparent governance, robust privacy protocols, and effective confidentiality protections, buttressed by a sustainable business model requiring contributions from data providers and sponsored projects [62]. This comprehensive approach provides an important foundation and framework for transformative data activities in the realm of social media and promises accessible and purposeful data use [62].

Leveraging the work of such organizations may unify researchers' approaches in governance, transparency, data sharing, and related aspects essential for using search data effectively. Integrating these insights into our analysis could illuminate pathways to address critical gaps in this field. We need to establish robust infrastructures that equip researchers with the necessary tools and resources to delve into such research at scale. Assessing the true utility of search data in medical diagnosis requires comprehensive frameworks that facilitate large-scale analysis while ensuring data privacy and integrity. Moreover, should research demonstrate the valuable application of these findings, such infrastructures will play a pivotal role in translating discoveries into actionable insights for clinical practice and health care policy.

Health Care Practice and Policy Implications

The integration of internet search data with health research datasets suggests profound implications for health care practice and policy, necessitating careful ethical and technical considerations. Such research poses unique challenges, beyond the scope of traditional regulatory frameworks such as HIPAA. While HIPAA governs the use and disclosure of protected health information held by covered entities, it may not fully address the intricacies of internet search data, which contain a wealth of information about individuals' health behaviors and concerns and potentially sensitive details not captured by conventional health records.

In the context of policy implications, IRBs play a crucial role in ensuring ethical research practices and safeguarding participants' welfare. For research involving internet search data, IRBs must navigate the nuanced landscape of privacy,

XSL•FO
RenderX

consent, and potential risks. Since internet search data may not fall under the strict purview of HIPAA, it is essential that IRBs establish clear guidelines for these data.

Research Directions

The findings of this literature review underscore the need for concerted efforts to stimulate research and fully explore the potential clinical utility of integrating internet search data with health research datasets. While our review did not identify a clear clinical utility, it revealed promising dimensions in behavioral health, early rare disease detection, and cancer diagnoses. The limited research in this domain since the seminal work of White and Horvitz [51,52] in 2013 and 2014 and its relative scarcity suggest potential barriers related to researchers' familiarity with the data technical complexities in mining the data, or other yet-to-be-identified obstacles [53,54].

To address these gaps and challenges, we propose a multifaceted approach in 4 key areas. First, there is an urgent need to assess the value and utility of internet search and activity datasets in conjunction with health research datasets, including clinical records. This evaluation should explore how such integration can enhance the diagnostic process, contribute to early disease detection, provide personalized health insights, inform data-driven decision-making, and improve patient experiences.

Second, future research should focus on mental health, autism, attention-deficit/hyperactivity disorder, and chronic or rare diseases. Tailoring projects to address unique diagnostic and treatment challenges may involve creating customized algorithms and tools that cater to these patients' needs and nuanced health conditions.

Third, the introduction of innovative analytics, including advanced machine learning and AI models, should be a priority [63]. These sophisticated techniques can uncover hidden patterns and tendencies within the integrated datasets, offering a new frontier in diagnostic accuracy. Developing predictive models could revolutionize health care delivery by providing more precise insights into patient conditions and optimizing treatment plans [64,65]. The advancement of infrastructure platforms that could aggregate search data with other types of online data (ie, social media and generative AI) and clinical data would allow for this research to be conducted at scale and for the introduction of the kind of innovative analytics described earlier [65,66].

Fourth, enhancing patient involvement in modernizing the consent process is paramount. Research should focus on developing innovative strategies that streamline and modernize consent, prioritizing transparency, trust, and patient comfort with the use of their data. Involving patients in shaping research practices ensures ethical, patient-centered health care research, reduces administrative burdens, and promotes accessibility and efficiency.

This comprehensive effort aims to propel research in this field, overcoming current limitations and paving the way for transformative applications of internet search and activity data in health care diagnostics. Innovations, such as reusable platforms for consent and data collection, may improve researchers and patient engagement. Standardized platforms that streamline the consent process and facilitate data collection can substantially enhance efficiency and scalability. These platforms should incorporate user-friendly interfaces, clear consent language, and robust security measures to ensure privacy compliance and promote patient trust. Reusable frameworks expedite research, reduce administrative burdens, and foster collaboration, advancing our understanding of the clinical utility of internet search data in medical diagnosis.

Respecting patient privacy and obtaining informed consent are foundational principles in health care research. Because the integration of internet search data involves potentially sensitive information, careful attention must be paid to ethical considerations. Transparent and user-friendly consent models are needed to ensure that patients understand who will have access to their data and how their data will be used. Innovative approaches to patient engagement should prioritize educating individuals about the benefits and risks of contributing their internet search data to research. In addition, robust security measures and compliance with privacy regulations are imperative to protect patient confidentiality. Policy makers are pivotal in establishing clear guidelines and regulations that balance the potential benefits of research using internet search data and patients' medical data with the imperative to uphold patient rights and privacy. Striking the right balance between facilitating research advancements and safeguarding patient interests is critical for the responsible and ethical use of internet search data in health care practice and policy.

Conclusions

In today's health care system, many patients lack access to timely, accurate diagnoses, missing the benefits of early detection and treatment, leading to suboptimal outcomes, disparities, and economic impacts. Advances in engineering, computing, social science, and data analytics are yielding transformative insights for public health and clinical medicine. Recently, the convergence of these advancements, particularly in LLMs and generative AI, has captured the imagination of health professionals and the public.

Initial studies have highlighted approaches involving study design, technical innovation, and data management to explore the potential of leveraging internet search data alongside clinical data for early diagnosis. Further research is needed to validate assumptions from search history studies and assess their utility in case-control studies or small cohorts linking symptoms to outcomes. Implementation studies are also necessary to establish the clinical utility of these strategies in real-world settings. Challenges include the costs of diagnostic assessments, particularly for low-frequency conditions or those with high false-positive rates and medical risks. No framework currently exists for integrating internet search queries into clinical assessments, raising questions such as how to distinguish chronic from rare disease indicators.

Globally, people extensively use internet searches for symptom understanding, self-diagnosis, and treatment, creating a vast volume of health-related queries. An individual's search history is a valuable data source offering insights into their diagnostic journey, enabling researchers to track symptoms and predict conditions. Linking search data with health care use information reveals disparities by factors such as insurance, race, and

XSL•FO
RenderX

education. Empowering patients to understand and leverage these data can enhance diagnosis. However, critical issues—epidemiological, privacy, consent, infrastructure, and validation—remain pivotal for advancing this research.

The Gordon and Betty Moore Foundation's Diagnostic Excellence Initiative is a step toward a future in which health care is more accessible, patient centric, and driven by IT and data. The field continues to evolve, promising a healthier, more informed society.

The interrogation of search data is in its infancy. Initial studies have identified the promise of using search data for personal health and population health benefits, including aiding medical diagnoses. While the clinical utility of enabling health care professionals to apply powerful analytic engines to specific diagnoses has yet to be attained, research into achieving this goal is accelerating rapidly. This analysis points to the need for strategic and tactical measures by health services researchers, technology engineers, policy makers, and regulators to advance this research, optimize its social good, and prevent harm or misuse.

Acknowledgments

This project was directed by AcademyHealth with funding from the Gordon and Betty Moore Foundation's Diagnostic Excellence Initiative. Henry A Kautz, PhD (University of Rochester), Karen J Maschke, PhD (Hastings Institute), Elad Yom-Tov, PhD, MA (Bar-Ilan University), Chris Riley, JD, PhD (Data Transfer Initiative), and Matthew J Thompson, DPhil, MPH, MBChB (University of Washington) were the reviewers for the study.

Abstract

Background: Fully automated digital interventions delivered via smartphone apps have proven efficacious for a wide variety of mental health outcomes. An important aspect is that they are accessible at a low cost, thereby increasing their potential public impact and reducing disparities. However, a major challenge to their successful implementation is the phenomenon of users dropping out early.

Objective: The purpose of this study was to pinpoint the factors influencing early dropout in a sample of self-selected users of a virtual agent (VA)–based behavioral intervention for managing insomnia, named KANOPEE, which is freely available in France.

Methods: From January 2021 to December 2022, of the 9657 individuals, aged 18 years or older, who downloaded and completed the KANOPEE screening interview and had either subclinical or clinical insomnia symptoms, 4295 (44.5%) dropped out (ie, did not return to the app to continue filling in subsequent assessments). The primary outcome was a binary variable: having dropped out after completing the screening assessment (early dropout) or having completed all the treatment phases (n=551). Multivariable logistic regression analysis was used to identify predictors of dropout among a set of sociodemographic, clinical, and sleep diary variables, and users' perceptions of the treatment program, collected during the screening interview.

Results: The users' mean age was 47.95 (SD 15.21) years. Of those who dropped out early and those who completed the treatment, 65.1% (3153/4846) were women and 34.9% (1693/4846) were men. Younger age (adjusted odds ratio [AOR] 0.98, 95% CI 0.97 - 0.99), lower education level (compared to middle school; high school: AOR 0.56, 95% CI 0.35 - 0.90; bachelor's degree: AOR 0.35, 95% CI 0.23 - 0.52; master's degree or higher: AOR 0.35, 95% CI 0.22 - 0.55), poorer nocturnal sleep (sleep efficiency: AOR 0.64, 95% CI 0.42 - 0.96; number of nocturnal awakenings: AOR 1.13, 95% CI 1.04 - 1.23), and more severe depression symptoms (AOR 1.12, 95% CI 1.04 - 1.21) were significant predictors of dropping out. When measures of perceptions of the app were included in the model, perceived benevolence and credibility of the VA decreased the odds of dropout (AOR 0.91, 95% CI 0.85 - 0.97).

Conclusions: As in traditional face-to-face cognitive behavioral therapy for insomnia, the presence of significant depression symptoms plays an important role in treatment dropout. This variable represents an important target to address to increase early engagement with fully automated insomnia management programs. Furthermore, our results support the contention that a VA can provide relevant user stimulation that will eventually pay out in terms of user engagement.

Introduction

Chronic insomnia is a major global health concern owing to its high prevalence and its negative impact on mental and physical health [1,2]. The usual approach to treat chronic insomnia includes the prescription of medication, such as nonbenzodiazepine hypnotics [3-5]. Nonpharmacological approaches, such as cognitive behavioral therapy for insomnia (CBT-I), whose goal is to restructure a person's sleeping behavior, is an evidence-based psychotherapy that has been shown to treat this condition effectively. CBT-I is considered as the first-line treatment option [5]. However, in practice, few people receive CBT-I. Overall, traditional CBT-I is perceived as complex to administer (ie, requiring trained therapists) and time consuming, giving rise to a treatment gap in insomnia care [6,7].

Digital interventions, which deliver therapeutic components via a web browser or smartphone app, have been proposed as a scalable, cost-effective way to meet the demand for CBT-I and address the important challenges associated with accessing traditional face-to-face CBT-I [8-10]. A considerable body of evidence supports the efficacy of fully automated (ie, requiring no human support) digital CBT-I renditions for the management of insomnia [11-14]. Although these fully automated digital CBT-I programs can display some differences (eg, number of weeks required to complete the treatment), generally they all ask the user to track their sleep daily by completing a sleep diary. They also incorporate algorithms to provide personalized feedback and a treatment program tailored to the user that usually comprises sleep hygiene practices and evidence-based behavioral recommendations known to improve chronic insomnia symptoms.

KANOPEE is a smartphone app developed in France that is designed to monitor and help manage insomnia complaints using components of CBT-I, such as sleep hygiene and stimulus control recommendations [15,16]. The app includes an animated character able to engage in face-to-face dialogue through verbal and nonverbal behavior, known in the literature as a virtual agent (VA) [17-19]. The program is designed to be completed in 17 days. It starts with a screening interview, followed by the completion of sleep diaries for a week. After this, the VA conducts another interview and sleep recommendations are provided. The individual is requested to enact these recommendations and continue completing sleep diaries for 10 additional days. At the end of this period, users undergo the posttreatment interview.

Although KANOPEE's clinical efficacy has not been tested yet in randomized clinical trials, it has been preliminarily tested in real-world scenarios [10,20]. These studies have shown encouraging positive effects in insomnia and related symptoms in sizable samples of self-selected individuals in France [21-24]. Nonetheless, scrutiny of the real-world data collected so far shows that a substantial proportion of users stop using the app before completing the full treatment protocol. This issue is not exclusive to KANOPEE: high attrition per dropout rates are ubiquitous problems in fully automated digital health interventions [25,26]. Indeed, it has been acknowledged that a central challenge to the overall efficacy and broadly scalable implementation of digital interventions is the phenomenon of users dropping out early [27]. A growing body of research aims to address the problem of dropout by examining factors that might predict it. The premise of this line of research is that if users who are at a high risk of dropping out can be identified, researchers and intervention developers can supplement or modify the intervention with the goal of improving retention [28]. The main types of variables that have been used to predict dropout have included self-reported baseline data, such as demographics or symptom severity [29], or objective measures of intervention engagement, such as number of loggings and proportion of content completed, among others [28,30].

When exploring the predictors of dropout, analyzing at what point dropout occurs is also of importance. Many studies only report a final figure about the prevalence of dropout during the entire intervention. While in most digital health interventions there is a continuous dropout over time, it has been suggested that the majority of users tend to drop out after completing the first one or two modules [27], a phenomenon known as early dropout. Arguably, an important gap in this literature is to identify if there are different variables associated with dropout at different points through the treatment process [31]. Indeed, while baseline variables and initial perceptions of treatment may certainly be valuable to understand early dropout, they may not be as relevant when analyzing dropout once the user has been interacting with the app for several days or weeks. Therefore, further research is needed to help understand the dropout phenomenon at different time points [32].

As a first step to develop a refined version of the KANOPEE app, our overarching goal in this study was to identify users' baseline characteristics and users' perceptions of the app and of the VA that may predict early dropout. Furthermore, since KANOPEE could be used in a preventative manner (in users with subclinical insomnia symptoms) or by users with more severe insomnia symptoms, we explored whether predictors of early dropout differed between 2 profiles of users who could potentially benefit from the intervention: users with clinical insomnia symptoms and those with subclinical insomnia symptoms.

Methods

Study Design

We employed a case series study of a self-selected sample of individuals completing a free, fully automated insomnia management program named KANOPEE, available to the general population in France, during the period January 2021 to December 2022.

Participants

Inclusion criteria were as follows: (1) age >17 years, (2) completion of the first screening phase (phase 1), and (3) the presence of insomnia symptoms, either clinical or subthreshold, at phase 1.

XSL•FO
RenderX

Ethical Considerations

This study was approved by the Institutional Review Board of the University of Bordeaux, France (2021-A02606-35 CPP Est II). Before providing any personal or health-related data on the KANOPEE app, users had to sign the app's digital consent form. Therefore, informed consent was obtained from users before any data collection. Data provided by users were anonymized, and participants did not receive any financial compensation for using the app. We obtained agreement with respect to the General Data Protection Regulations of the French authorities (the National Commission on Informatics and Liberty).

Intervention Overview

KANOPEE is a smartphone app available on Google Play Store and Apple Store in France that was launched during the peak of the COVID-19 pandemic in 2020. The app includes a VA able to engage in face-to-face dialogue through verbal and nonverbal behavior. Figure 1 summarizes the flow of the intervention. As shown, it included 3 main phases. During the screening interview (phase 1), the VA, named Louise, introduced herself and administered, among other measures, the Insomnia Severity Index (ISI), as the main outcome of the intervention [33]. Then visual feedback was provided to users regarding the severity of their insomnia symptoms, with the help of a colored line featuring the traffic-light colors (green, orange, and red), and they were invited to begin a personalized program. After completing this interview, users were asked to complete a sleep diary regarding their previous night. Once this step was completed, another screen informed the users that they needed to complete the same sleep diary for 7 days, every morning, and that, after these 7 days, the VA would re-evaluate their sleep in another interview and would analyze the information provided in their sleep diaries. An icon with the name "Sleep diary" appeared then at the bottom of the screen that the user could access every day to answer the sleep-related questions (ie, what time did you go to bed last night?). Daily reminders were not provided. After users completed the sleep diary for 7 days, Louise conducted another interview (phase 2) in which users learned about their sleep patterns from the previous week and completed the ISI for the second time, along with other questionnaires. Next, Louise provided sleep recommendations, highlighting the specific ones most useful to the user, based on their sleep diary data and on their answers to the ISI questions. Apart from general good sleep hygiene practices, Louise proposed evidence-based behavioral recommendations that have been shown to improve insomnia symptoms. These instructions were part of the stimulus control component of CBT-I [15]. The goals of stimulus control were (1) to remove the association between the bed or bedroom and wakefulness in order to restore the association of the bed or bedroom with sleep and (2) to establish a consistent wake time. Stimulus control instructions included the following: go to bed only when sleepy, get out of bed when unable to sleep, use the bed or bedroom for sleep (no reading, eating, watching TV, etc, in bed), and wake up at the same time every morning [15]. Next, individuals were asked to complete the sleep diary for 10 more days. After this, they were again interviewed by Louise (phase 3) and completed the ISI, along with other questionnaires. After this final interview, they could choose to continue using the app, if they wished (ie, completing sleep diaries for a longer period). If they considered that their sleep problems were persisting, they were prompted to consult a sleep specialist. Further details about the design of the VA and the design and implementation of the intervention program are described elsewhere [21,22].

Figure 1. Overview of phases of the KANOPEE digital intervention. (A) screenshot of Louise administering the Insomnia Severity Index; (B) screenshot of the sleep agenda or diary; (C) screenshot of a sleep recommendation given by Louise during phase 2; (D) screenshot of visual feedback provided by the app on the completion of each day in the sleep agenda or diary.

Measures

This study's main outcome variable, early dropout, was defined as completing phase 1 and not returning to the app. Early dropout was operationalized as a binary outcome: having dropped out versus having completed all the treatment phases.

The ISI scores at phase 1 were used to classify users into 2 groups: users with clinical insomnia and those with subthreshold insomnia. The ISI is a 7-item self-report questionnaire that provides a global measure of perceived insomnia severity during the past month [33]. Scores range from 0 to 28 and can be grouped into the following insomnia severity categories: 0-7 (no insomnia), 8-14 (subthreshold insomnia), 15-21 (insomnia of moderate severity), and 22-28 (severe insomnia). Users were classified as having subthreshold insomnia if their ISI scores ranged between 8 and 14 points and with clinical insomnia if ISI scores were ≥15 points.

Age, sex, and education level were assessed as potential predictors of dropout. Clinical variables included depression, anxiety, and fatigue symptoms. Depression and anxiety symptoms were measured with the Patient Health Questionnaire-4 [34].

Fatigue symptoms were measured with the Fatigue Severity Scale [35]. Sleep characteristics were derived from 1 night of the sleep diary and included the following continuous variables: sleep onset latency, defined as the time taken to fall asleep after turning the lights out; number of awakenings during the night; and sleep efficiency, defined as the ratio of total sleep time to time spent in bed for the night. We also computed a dichotomous variable named short sleep (1=yes, 0=no) if the subject had reported a total sleep time of <6 hours [36].

Additionally, a subset of users completed optional measures related to treatment acceptability and trust in the VA and regarding their level of experience with new technologies. Treatment acceptability was measured with the Acceptability E-Scale (AES) [37]. The AES comprises 6 items and provides a total score as well as 2 subscores regarding usability (ie, the perceived ease of using the app) and satisfaction (ie, pleasure experienced using the app and realizing its value). Items were answered on a 5-point Likert-type scale ranging from 1 (very unsatisfied) to 5 (very satisfied). Trust in the VA was measured with the Embodied Conversational Agent Trust Questionnaire (ETQ) [37]. The ETQ includes 6 items that are answered on a 4-point Likert-type scale ranging from 0 (not at all) to 3 (totally agree). It provides a total score as well as subscores on 2 separate dimensions, named perceived credibility (ie, whether the VA seemed convincing and believable) and perceived benevolence (ie, whether the VA seemed to be of help). Finally, to evaluate users' level of experience with new technologies, we created a summary score that combined the users' answers to 3 questions: "Do you use regularly smartphones, tablets, or computers?" with scores ranging from 0 to 3, with higher scores indicating more experience.

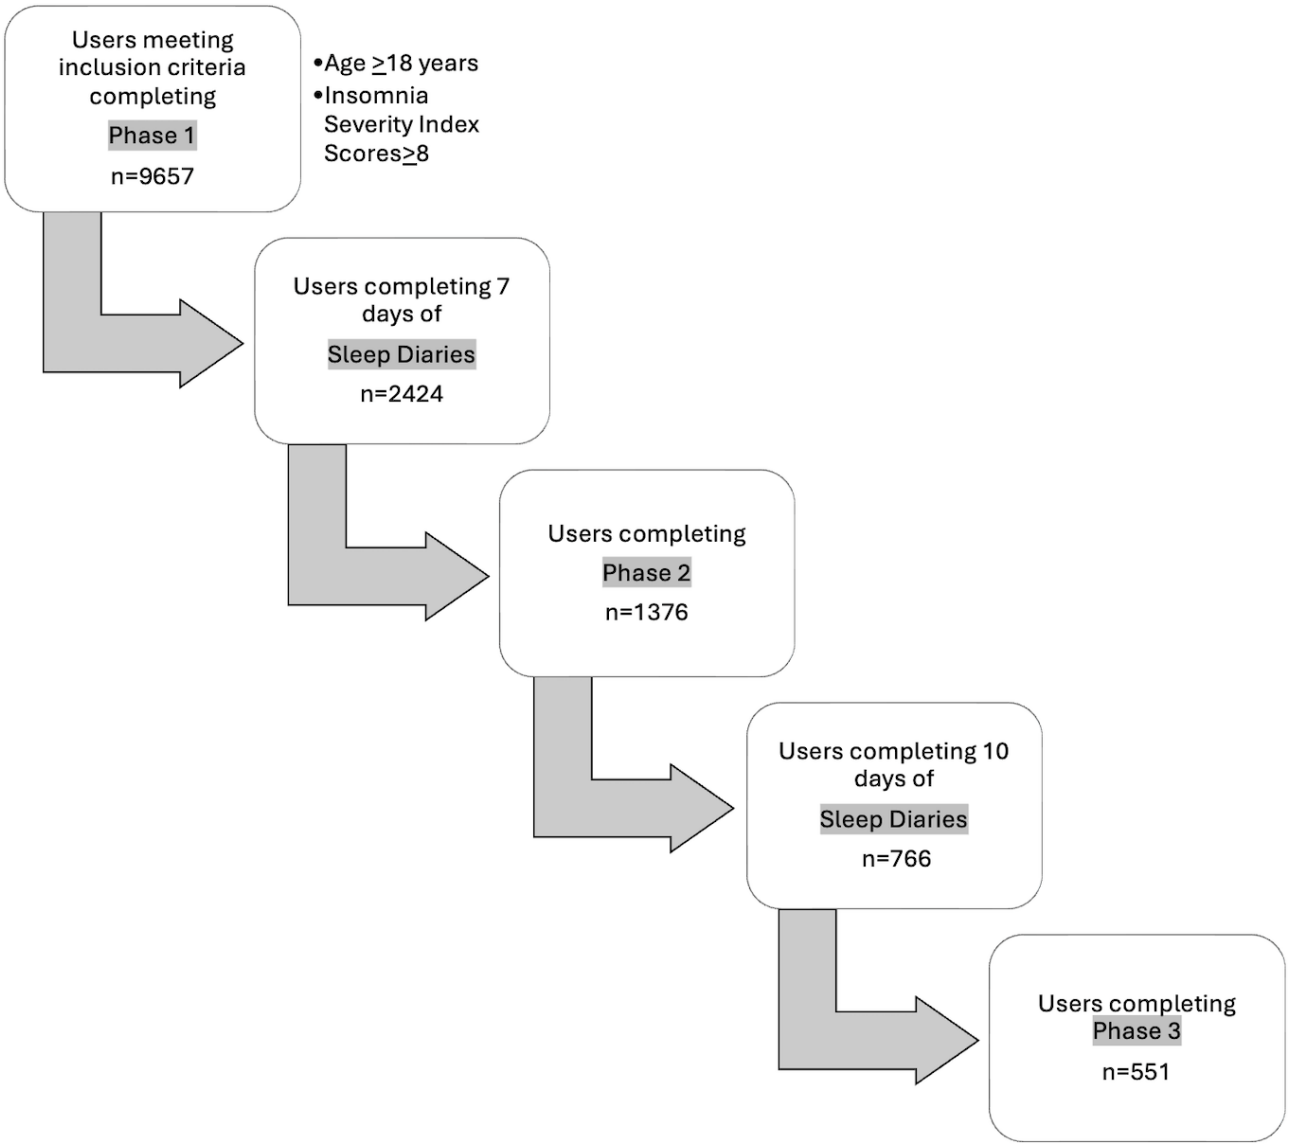
Analyses

A flowchart was first constructed to show the number of users who, once the treatment was initiated (completion of the phase 1 interview), reached each one of our predefined 4 intervention milestones: (1) completing the 7 days of the sleep diary, (2)

XSL•FO
RenderX

completing the phase 2 interview, (3) completing 10 days of the sleep diary, and (4) completing the phase 3 interview.

Means and SDs for the continuous variables and percentages and absolute frequencies for the categorical variables were used to describe the study variables. The comparison between the users who completed the intervention (treatment completers) and those who dropped out early (ie, did not return to the app after the phase 1 assessment) was performed by a Student *t* test for continuous variables and a χ^2 test for categorical variables.



To identify factors predictive of early dropout in users with subclinical insomnia and in users with clinical insomnia, all factors that showed statistically significant differences between early dropouts and treatment completers in the bivariate analyses were used as predictive variables for multivariable logistic regression analyses. All selected variables were simultaneously inserted into the models ("Enter" method in SPSS Statistics).

Finally, a separate multivariate logistic regression model was tested, including additional variables such as treatment acceptability, trust in the VA, and experience using new technologies, within the subgroup of users having insomnia symptoms (either clinical or subclinical) who completed these optional measures. Results were presented as OR and 95% CIs, with their corresponding *P* values. The level of statistical significance was set as $P<.05$. All analyses were performed with SPSS, version 28 (IBM).

Results

Of the 9657 individuals who downloaded and completed the phase 1 interview during the study period and met the inclusion criteria, a total of 4295 (44.5%) dropped out and did not return to the app to continue filling in the sleep diary for a second day. These users were considered early dropouts. The flowchart displayed in Figure 2 shows the number of users completing each one of the 4 intervention milestones. A total of 551 users reached all the milestones (treatment completers).

Figure 2. Number of users completing each intervention milestone.

Participants' Characteristics

We divided users in 2 groups, according to the severity of their ISI scores in phase 1. Within the early dropouts (n=4295), 2166 users had ISI scores within the clinical range (≥15 points) and 2129 users had subclinical ISI scores (8 - 14 points). Among treatment completers (n=551), 209 users had subclinical ISI scores and 342 users had ISI scores ≥15 points.

Tables 1 and 2 show the characteristics of users who dropped out and those who completed the intervention, as assessed in the phase 1 screening interview. Within the group of clinical insomnia sufferers (Table 1), users who dropped out were younger, had more severe mental health symptoms, and had a lower education level than treatment completers (all P<.01). Regarding the sleep variables measured in one night of the sleep diary, early dropouts also had poorer sleep efficiency and more awakenings during the night. A similar picture emerged when comparing the characteristics of users with subclinical ISI scores (Table 2): those who dropped out were younger and had a lower education level; more severe anxiety and depression symptoms; and poorer sleep diary measures, such as lower sleep efficiency, more nocturnal awakenings, and longer sleep latency. Furthermore, in the early dropouts group, there was a higher percentage of users with self-reported short sleep (all P<.05).

Table . Sociodemographic, clinical, and sleep characteristics of users with clinical insomnia at phase 1.

User characteristics	Early dropouts (n=2166)	Treatment completers (n=342)	*P* value

Predictors of Dropping Out

Sociodemographic and Clinical Characteristics

The variables showing a statistically significant association with dropping out in the univariate analyses were used as candidates for the multivariable logistic regression analyses. Table 3 shows the ORs (95% CI) and associated *P* values of the 2 multivariable regression analyses performed; one of these analyses was conducted within the sample of users with clinically significant insomnia symptoms at phase 1, and the other analysis was conducted within the sample of users with subclinical insomnia symptoms at phase 1.

[b]PHQ-4: Patient Health Questionnaire-4.

Within the subgroup of users with clinical insomnia, the analyses showed that sociodemographic variables were related to dropout; as age increased, the odds of dropping out decreased. Furthermore, individuals with a higher educational level than middle school had decreased odds of dropping out. More severe depression symptoms and poorer sleep (lower sleep efficiency and a higher number of awakenings during the night) increased the odds of dropping out. As shown in Table 3, a similar set of predictors emerged in the multivariable logistic regression analysis within the group of users with subclinical insomnia symptoms.

Perceptions of the App's Features and Experience Using New Technologies

A total of 1031 users who met the inclusion criteria completed the optional questionnaires regarding their acceptability of the treatment, their trust in the VA, and their experience using new technologies. Compared to treatment completers (n=184), users dropping out (n=847) had lower mean scores on the AES (mean 26.13, SD 4.16 vs mean 27.14, SD 3.40, respectively, *P*<.001) and on the ETQ (mean 18.90, SD 3.26 vs mean 19.82, SD 2.67, respectively, *P*<.001) and reported having less experience using new technologies (mean 1.85, SD 0.75 vs mean 2.07, SD 0.68, *P*<.001). Table 4 shows the ORs of the multivariable logistic regression analysis including these 3 additional variables besides the statistically significant variables included in Table 3. Older age, having a bachelor's or master's degree, and more trust in the VA (ie, higher ETQ scores) reduced the odds of dropping out, whereas higher depression scores increased the odds of dropping out (all *P*<.01).

Discussion

The use of fully automated or unguided apps has the potential to increase access to care in a scalable manner. However, in real-word settings, the impact of these digital interventions is limited by their success to engage the users in the therapeutic activities they propose. This study uses real-world data from individuals downloading and completing the first phase of a fully automated smartphone app intervention named KANOPEE, designed to monitor and manage insomnia symptoms using components of CBT-I.

We found that only a small portion of users completed all the intervention phases during the period assessed. The percentage of individuals completing this intervention was 5.7% (551/9657), suggesting low engagement. This percentage is in line with figures shown in other studies examining mental health app usage in extensive real-world settings, with most users downloading the corresponding app but not using it regularly [38,39].

Our results show that sociodemographic characteristics such as being older and having a higher educational level reduced the odds of early dropout, regardless of the severity of the target condition, insomnia. More severe mental health symptoms, such as depression, increased the odds of early dropout. In addition, users were less likely to drop out if they expressed more positive beliefs regarding the benevolence and credibility of the VA that was included in the app.

A recent systematic review on attrition in conversational agent–delivered mental health interventions reports that demographic-related factors do not seem to be associated with dropout [40]. In this review, there is only 1 study that shows that participants dropping out were significantly younger than those who completed the whole intervention [41], as we found herein. The fact that the younger users were more likely to drop out may simply reflect their differential pattern of use of technologies when compared to older individuals. Younger individuals usually have more experience perusing and using digital apps, so they may be more likely to use and quickly discard them, as they are more capable of seeking alternative options.

For some, but not all, of the studies included in the above-cited systematic review, more severe mental health–related baseline symptoms were associated with dropout, such as anxiety, gambling pathology, fear of food, etc, as we found herein. Our findings also dovetail with studies on premature termination of face-to-face CBT-I. In the study by Ong et al [42], patients with shorter total sleep time and more severe depression symptoms were at significantly greater risk of early dropout. Likewise, in the study by Yeung et al [43] exploring predictors of dropout from internet-based self-help CBT-I, more severe depression symptoms predicted a higher risk of treatment noncompletion. These results suggest that users with a greater severity of depression may lose their motivation to follow the intervention more easily and find it more difficult to make the behavioral changes necessary for improving their sleep [44].

An important finding of this study concerns perceptions of VAs and their impact on dropout. Mental health interventions delivered by VAs, conversational agents, or chatbots pretend to simulate the interaction between a mental health expert and the user. Recent research has highlighted that individuals can indeed develop an affective bond with chatbots [45]. Our results support the contention that a VA can provide relevant user stimulation that will eventually pay out in terms of user engagement with a fully automated intervention [46]. It remains to be determined which features of the VA's interactions may

XSL•FO
RenderX

have driven users' perceptions of its credibility and benevolence. These perceptions represent a promising and potentially modifiable construct that can be targeted to enhance engagement with fully automated treatment [47]. Qualitative studies with end point users should provide further knowledge about specific aspects related to VA-related credibility.

This study has some strengths. First, there is its large sample size. Second, it considered the timing of dropout (ie, after individuals had completed the first treatment phase, provided clinical data, and sufficiently interacted with the app to gain a first impression of it) and explored sociodemographic and clinical factors and users' perceptions of the treatment associated with dropout at this specific stage. Until now, few studies have examined dropout at different stages of participation [31,42]. Arguably, dropout at other stages may have other determinants. For example, dropout at a later stage may indicate (1) that a user's symptoms have already improved and that they do not require full exposure to the intervention, (2) that they have developed complications with treatment, or simply (3) that they are dissatisfied with the treatment.

The main limitation of this study is that we only had a reduced number of baseline and sociodemographic variables from the users. Furthermore, the data analyzed in this study are self-reported data. Apart from the bias commonly associated with self-reported data in medical and health research contexts, the fact that the information was provided to a mobile phone app, without any support from a researcher or therapist, may compromise its accuracy to a greater extent.

Our findings should be viewed only as preliminary data for identifying real-world users at risk of early dropout from a fully automated digital intervention for insomnia including a VA. Therefore, these findings are specific to this intervention, so the results cannot be generalized. Future research could assess whether the predictors found herein are valuable for predicting dropout in other fully automated digital interventions targeting insomnia and in different contexts and populations. Information on the reason for dropout was also not collected in this study. Future research should consider interviewing users to obtain a more detailed understanding of the reasons leading to dropout.

Finally, this study has implications for developing a randomized trial that offers an adapted, augmented intervention for individuals who are more likely to drop out.

Abstract

Background: Social anxiety disorder (SAD) and agoraphobia are common, impairing conditions often treated with cognitive behavioral therapy (CBT) conducted in groups. In CBT, exposure therapy is a core element. However, in-vivo exposure therapy is logistically challenging and aversive for both patient and therapist, especially in a group context, often leading to exposure being skipped altogether in clinical practice. Virtual reality exposure (VRE), in which phobic stimuli are presented through immersive virtual reality technology, has shown promise as a flexible alternative to in-vivo exposure. We thus hypothesized that using VRE would result in more overall exposure and more individualized exposure, resulting in statistically significant symptom reduction compared with a group using in-vivo exposure.

Objective: This trial evaluated the efficacy of group CBT with VRE (VR-CBT) versus CBT with in-vivo exposure for treating SAD and agoraphobia in clinical settings.

Methods: In this randomized, parallel-group, assessor-blinded trial, 177 participants with SAD (n=150) or agoraphobia (n=27) as a primary diagnosis were assigned to either VR-CBT (n=81) or traditional CBT (n=96) across 5 Danish mental health outpatient clinics. Both groups received 14 weekly group sessions. The difference between the 2 treatments was that the VR-CBT group received exposure therapy via head-mounted displays (HMDs) displaying 360° videos of anxiogenic situations for individuals with SAD (eg, presenting at work) and agoraphobia (eg, faulty elevator), while the CBT group conducted traditional in-vivo exposure exercises (eg, presenting to the group, using the clinic elevator). Primary outcomes were phobic anxiety reductions, measured by the Liebowitz Social Anxiety Scale and the Mobility Inventory for Agoraphobia at baseline, posttreatment, and 1-year follow-up (from baseline). Secondary outcomes included work and social functioning, depressive symptoms, and quality of life.

Results: Both groups showed significant reductions in primary, secondary, and exploratory outcomes, with no significant differences between groups at posttreatment (d=−0.026) and 1-year follow-up (d=0.097). Baseline characteristics and attrition rates were balanced across the groups.

Conclusions: Due to insufficient recruitment and substantial missing data, no definitive conclusions can be drawn regarding group differences between VR-CBT and traditional CBT in group settings. The feasibility issues encountered suggest that careful consideration of the benefits and limitations of VR technology is essential before implementation in clinical practice.

KEYWORDS

agoraphobia; cognitive behavioral therapy; group therapy; social anxiety disorder; virtual reality

Introduction

Social anxiety disorder (SAD) and agoraphobia are common and impairing mental health conditions. Agoraphobia without comorbid panic disorder has a prevalence of about 1.2%, with most cases (70%) also meeting criteria for panic disorder [1], while the lifetime prevalence of SAD is approximately 4% across low-, middle-, and high-income countries, making it one of the most prevalent mental disorders [2]. Both disorders are associated with decreased quality of life [3], increased suicidality [4], and increased psychiatric comorbidity and typically develop in early adolescence [5], more often in women [1,2], and are often chronic if untreated [6,7]. In Denmark, anxiety disorders rank among the 15 most costly health conditions, due to their early onset, chronicity, and impact on quality of life and productivity [8]. These factors underscore the urgent need for accessible and empirically supported treatments.

Cognitive behavioral therapy (CBT), a research-informed, time-limited psychotherapeutic intervention focused on modifying biased cognitions and dysfunctional behaviors [9,10], is the recommended first-line treatment for SAD and panic disorder with agoraphobia (PD/A) [11-14], demonstrating lasting efficacy [15-21], minimal side effects [15], and being generally preferred over psychopharmacological treatment [22]. Exposure therapy, a key component of CBT for SAD and PD/A, aims to modify patients' expectations about the likelihood and consequences of a feared outcome by exposing them to feared stimuli [23,24]. However, feared stimuli can sometimes be inaccessible, uncontrollable, or aversive, leading both patients and therapists to avoid exposure therapy [25-28].

Virtual reality (VR) technology offers a controlled and flexible way to expose patients to feared stimuli, potentially overcoming some challenges of traditional exposure therapy [29,30]; for example, as a low-intensity starting option or to expose patients to situations that are not readily available for in-vivo exposure, such as job interviews and car malfunctions. Meta-analyses suggest that virtual reality exposure (VRE)-based treatments are as effective as active control conditions for anxiety disorders [31-33]. However, VRE has primarily been studied in individual therapy rather than group settings and has not been extensively evaluated in naturalistic clinical settings.

In clinical settings, CBT for anxiety disorders is often conducted in groups, as group-based CBT has shown efficacy comparable to individually delivered CBT therapy for both SAD [15,34] and panic disorder with or without agoraphobia [35], while being considered more cost-effective. Based on this, in Danish outpatient psychiatry, SAD and agoraphobia (without comorbid panic disorder) are routinely treated together in "mixed anxiety" CBT groups. The SoREAL trial aimed to evaluate the efficacy of VRE-based CBT for SAD and agoraphobia within this naturalistic, group-based clinical setting. As such, this study was designed as a pragmatic randomized controlled trial, wherein external validity was prioritized by testing interventions under routine clinical conditions with typical patients and standard care procedures. By embedding the intervention within the existing structure of the Danish mental health services and by comparing VR-CBT to a traditional CBT treatment-as-usual intervention, the SoREAL trial aimed to generate evidence not only on efficacy but also on clinical effectiveness (ie, making results as generalizable to real-world practice as possible).

Both treatment arms in the trial included 14 two-hour sessions, of which 7 sessions had scheduled 45 minutes of either VRE or in-vivo exposure. In the VR-CBT arm, patients were handed personal head-mounted displays and could individually choose to be exposed to a range of immersive virtual scenarios relevant to their disorder, including social interactions (eg, public speaking, small talk, meetings) and agoraphobic situations (eg, crowded bus, supermarket, elevator). In the CBT arm, patients were asked to conduct a range of exposure exercises including small-talk roleplay, taking the clinic elevator and pressing stop, inducing nausea (eg, through spinning on the spot), and presenting in the group, which all required preparation and often requires the whole group to conduct the same exercise. We therefore expected the VRE format to allow for more tailored and higher dosages of exposure than in-vivo exposure therapy, and thus hypothesized that VR-CBT would result in greater reductions in phobic anxiety compared to traditional CBT.

Methods

Design

We conducted a 1:1 randomized, assessor-blinded, parallel-group superiority trial across 5 outpatient psychotherapeutic clinics offering standardized anxiety group therapy within Danish mental health services. Consolidated Standards of Reporting Trials guidelines were followed in reporting this trial [36].

We estimated that 302 participants were needed to detect the minimal clinically relevant differences in phobic anxiety severity reductions between groups [37]. Participant recruitment began in February 2019 and ended prematurely in December 2023 due to recruitment and feasibility issues, resulting in a sample size of 177 (81 in the VR-CBT arm and 96 in the CBT arm). These issues are elaborated in the discussion section.

Design Changes After Trial Registration

The SoREAL trial was initially designed to investigate the efficacy of group VR-CBT for SAD (ICD code F40.1), and this design was registered at ClinicalTrials.gov as NCT03845101 before inclusion began. However, to address severe recruitment problems, we implemented several changes to the trial's design. We revised the inclusion criteria: removing a Liebowitz Social Anxiety Scale (LSAS) [38] score requirement of >65 and adding agoraphobia (ICD code F40.0) as a possible primary diagnosis. Therapy manuals and VR software were modified with

XSL•FO
RenderX

agoraphobia-specific modules and VR environments. The primary outcome measure was changed to percentage of maximum points (POMP)-transformed total scores of the LSAS for patients with SAD and the Mobility Inventory for Agoraphobia (MIA) [39] for patients with agoraphobia. POMP transforming 2 different measures of anxiety allowed us to include patients with different primary diagnoses in the same analysis [40,41]. Finally, we expanded from 2 to 5 clinical sites and adjusted randomization to allocate therapy groups (rather than individual participants), stratified by site, to minimize wait times and account for the geographical distance between sites. The randomization module was updated in March 2020 after 40 participants had been individually randomized. The final trial design is also described in the published trial protocol [37]. The design changes did not entail any changes to the statistical analysis plan (beyond the changed primary outcome). However, we did add exploratory diagnose-specific subgroup analysis of both MIA and LSAS. These showed that both subgroups had similar effect sizes between treatment arms, suggesting that the inclusion of agoraphobia did not meaningfully alter the overall treatment effect.

Participants

Patients were recruited from 5 outpatient clinic sites while on the waitlist for treatment. Eligible participants had a primary diagnosis of SAD (ICD code F40.1) or agoraphobia (ICD code F40.0), were aged 18 - 75 years, had adequate proficiency in Danish, and were willing and able to provide informed consent. Patients were excluded if they had drug or alcohol dependence. If a patient met diagnostic criteria for both SAD and agoraphobia, 1 diagnosis was designated as primary based on the referral from the regional Center for Visitation and Diagnostics, which assesses and refers patients to outpatient psychiatric care in Denmark. Assessors at the Center for Visitation and Diagnostics are clinical psychologists and medical doctors trained in broad psychiatric assessment and supervised regularly by clinical specialists (eg, psychiatrists). At the baseline research interview, the primary diagnosis was confirmed using the Mini-International Neuropsychiatric Interview version 7 [42], conducted by researchers (psychology graduate students or psychologists) who received training in the use of the Mini-International Neuropsychiatric Interview and participated in structured hierarchical interrater sessions every 3 weeks, led by the first author.

Randomization and Blinding

Therapy groups were randomly assigned (1:1) to either VR-CBT mixed anxiety groups or CBT with in-vivo exposure mixed anxiety groups. Randomization was performed using REDCap [43] by a trial coordinator uninvolved in data collection, who informed the relevant clinicians via email or telephone. Allocation tables were generated by a statistician using an online tool [44] with varying block sizes of 2 and 4 and stratification by treatment site. Trial assessors were blinded to group allocation, and if unblinded, another assessor conducted the assessment.

Procedures

Patients were assessed before treatment, approximately 2 weeks after treatment, and 12 months after beginning treatment by trained assessors. The 12-month follow-up was included to evaluate the durability of therapeutic gains [21]. Assessments took place at the clinics where patients received treatment or via telephone if necessary due to COVID-19 restrictions. Eligibility was confirmed by assessors during the baseline interview. Self-reported questionnaires were answered by hand (on printed copies) or online using a secure link. Both interventions followed a standardized structure and included the same core elements: 1 hour of individual therapy in preparation for group sessions; 14 weekly 2-hour group therapy sessions; and optional components consisting of next-of-kin involvement, pharmacological treatment planning, physical therapy, and coordination with social services. The group therapy in both interventions was manualized and based on established CBT approaches to treating anxiety [45-48]. The manual was flexible, allowing clinicians to change the order of sessions. However, the amount of time allocated for exposure in both interventions was fixed, encompassing all related processes such as setup, transport, and preparation. Therapy groups consisted of 8-9 patients and were led by 2 clinicians trained in CBT (eg, psychologists, medical doctors, or physiotherapists trained in psychotherapy). Acute supplementary individual sessions were also available in both interventions. In 7 sessions of the 14 sessions, 45 minutes were allocated to either VR or in-vivo exposure exercises. Both interventions included homework consisting of in-vivo exposure tasks between sessions and 1 session of “out-of-clinic” in-vivo exposure (eg, taking the bus or going shopping). The exposure exercises aimed to foster adaptive responses to anxiety-provoking situations, reinforce cognitive restructuring, train general cognitive strategies (eg, identifying negative automatic thoughts), and build social skills. The cognitive therapy strategies used in nonexposure sessions included psychoeducation, cognitive restructuring, shifting self-focused attention, and relapse prevention. The interventions differed only in the delivery method of exposure therapy.

VR Exposure

Each patient received an Oculus Go head-mounted display and high-quality sound-blocking headphones for use throughout treatment. The VR environments were high-resolution, 360° stereoscopic films depicting salient, fear-inducing situations for SAD and agoraphobia. Patients chose from 13 scenarios with 4-6 scenes of increasing difficulty. Scenarios were designed specifically for either SAD (eg, party, small talk during lunch, presenting at work) or agoraphobia (eg, crossing a bridge while carpooling with strangers, taking a commercial airplane, leaving your apartment). However, many scenes had elements that could trigger both fears (eg, attending a lecture at a university). Scenes transitioned to a looped, action-free sequence in the same environment to allow habituation as needed. Patients were introduced to the VR equipment and guided to select scenarios relevant to their anxieties. Exposure exercises were completed individually in the therapy room, with sessions typically including 1 or 2 breaks for group discussions. The exposure platform was developed collaboratively over 16 months with

XSL•FO
RenderX

CBT experts, lived experience experts, and VR developers. Lived experience experts provided input on anxiety levels and scenario relevance, which guided adjustments. Details about the VR environments are available in Multimedia Appendix 1.

In-Vivo Exposure

In-vivo exposure exercises included small talk (among patients), behavioral experiments within the clinic (eg, asking the receptionist for directions), role play (eg, job interviews), inducing nausea through spinning on the spot (eg, exposure to fear of loss of control through vomiting), taking a small clinic elevator (eg, exposure to fear of being unable to escape a situation), increasing heart rate through physical activity (eg, exposure to fear of passing out or having a heart attack), sitting far away from exits in the group therapy room (eg, exposure to fear of being unable to escape a situation), drinking water and coffee and holding off going to the bathroom (eg, exposure to fear of loss of control through incontinence), and public speaking exercises (eg, talking about a hobby in the group). Detailed intervention descriptions are available in the trial protocol [37].

Outcomes

Primary diagnoses and comorbidities were assessed with the Mini-International Neuropsychiatric Interview version 7 [42]. The primary outcome was a reduction in phobic anxiety, measured with POMP-transformed total scores of the LSAS [38] (clinician-rated) for patients with SAD and the MIA [39] for patients with agoraphobia.

Secondary outcomes included fear of negative evaluation, measured with the Brief Version of the Fear of Negative Evaluation Scale [49]; depression symptoms, measured with the 6-item version of the Hamilton Depression Rating Scale [50]; work and social functioning, measured with the Work and Social Adjustment Scale [51]; treatment satisfaction, measured with the Client Satisfaction Questionnaire [52]; and quality of life, measured with the WHO-5 Well-Being Index [53]. SAD treatment response was defined as an LSAS score below 50 or a reduction of 15 points, and remission was defined as an LSAS score below 25. For agoraphobia, treatment response was defined as an MIA score below 2 or a reduction of 0.5 points, and remission was defined as an MIA score below 1.5, assessed posttreatment and at follow-up.

Exploratory outcomes included social functioning, measured with the Personal and Social Performance Scale [54]; substance and alcohol use over the last month, measured with Timeline Followback [55]; self-efficacy, measured with the General Self-Efficacy Scale [56]; working alliance, measured with the Working Alliance Inventory [57]; SAD symptom severity for patients with SAD as a primary diagnosis, measured with the LSAS (clinician-rated); and agoraphobia symptoms for patients with agoraphobia as a primary diagnosis, measured with the MIA.

Other measures included simulation sickness from VR, assessed using the Simulation Sickness Questionnaire [58] after each exposure session. Deterioration and adverse effects of psychotherapy on SAD symptoms were defined as an increase of 6.8 points or more on the LSAS total score, while for agoraphobia, deterioration was defined as an increase of 0.3 points or more on the MIA total score, assessed posttreatment and at follow-up. These thresholds reflect the smallest clinically meaningful change, corresponding to a Cohen *d* of 0.33 based on prior studies' standard deviations [59,60]. Treatment fidelity was evaluated using a therapist self-report questionnaire administered 5 times throughout therapy, consisting of 6 Likert-style questions (ranging from 1 to 5) and questions about time spent on exposure therapy.

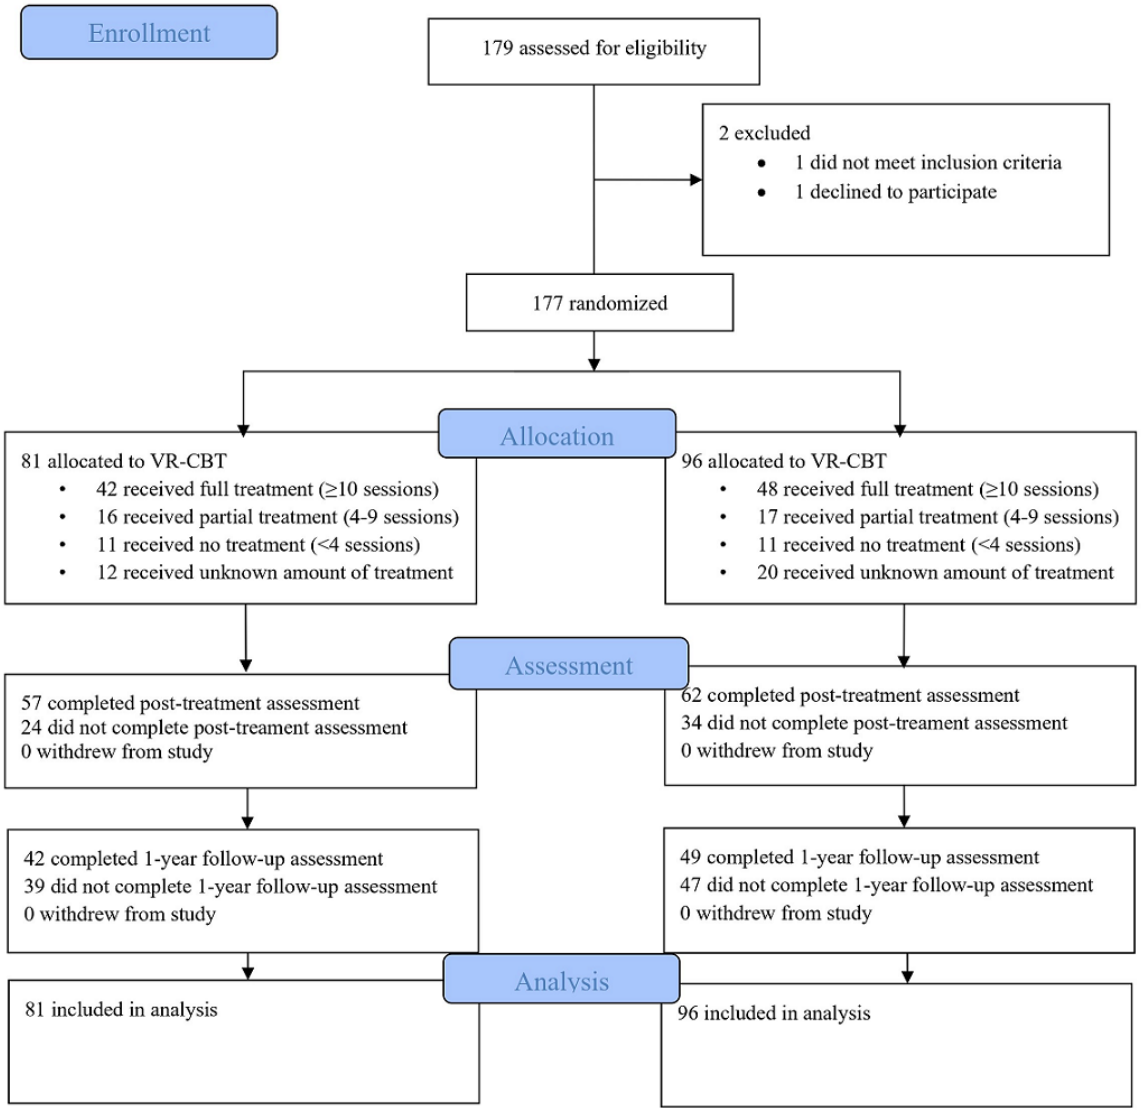
Statistical Analysis

We aimed to enroll 302 patients based on the following parameters: an alpha of .05; 80% power; and a standard deviation of 21 to detect a difference of 6.8 on the LSAS, corresponding to a Cohen *d* of 0.33. After expanding inclusion to patients with agoraphobia, we retained the target N of 302, even though the lower variability of the MIA would have reduced the required sample size. All analyses were conducted using an intention-to-treat approach, with tests performed at a 2-tailed 5% level of significance. Missing data were handled using multiple imputations (m=100), with predictors in the imputation model including baseline and posttreatment scores of primary, secondary, and exploratory outcomes; primary diagnosis (SAD or agoraphobia); degree of comorbidity; and session attendance. Group differences were examined using analysis of covariance (ANCOVA), with primary diagnosis, degree of comorbidity, and baseline severity as covariates. For POMP-transformed outcomes and analyses of specific diagnostic groups, primary diagnosis was not included as a covariate. Assumptions for ANCOVA were checked as follows: normality of the dependent variable via visual inspection of Q-Q plots, homogeneity of variance using Levene test, and homogeneity of regression slopes with univariate analysis of variance. Baseline severity was excluded as a covariate for posttreatment analyses of the Fear of Negative Evaluation and Work and Social Adjustment Scales, and posttreatment severity was excluded as a covariate for follow-up analysis of the Hamilton Depression Rating Scale due to nonhomogeneity of regression slopes. For dichotomous outcomes, multiple logistic regression analyses were performed using primary diagnosis, comorbidity, and baseline severity as predictors. Model fit was assessed using the Hosmer-Lemeshow test, and multicollinearity was evaluated using tolerance values and variance inflation factors. Due to the small number of drug use incidents (<5 in both groups), drug use was not analyzed. To examine the robustness of the results, we conducted additional post hoc analyses using multilevel models, ANCOVAs on change scores, and random forest imputation. These analyses supported the main findings and confirmed the overall pattern of results. See Multimedia Appendix 2.

Ethical Considerations

The SoREAL trial received approval from the Regional Ethics Committee of Zealand (H-6-2013-015) and the Danish Data Protection Agency (RHP2014-009-02670). All participants were informed about the study procedures and provided written informed consent prior to participation. Participants were not compensated. The individuals appearing in the supplemental material are professional actors who were hired for this study

XSL•FO
RenderX



and were compensated 584.5 USD. Written consent has been obtained from all actors for the use of their images in this publication.

Results

Patient Characteristics

A total of 177 participants were analyzed, with 81 randomized to VR-CBT and 96 to CBT. Figure 1 illustrates the recruitment and assessment flow of the trial. Sociodemographic and clinical characteristics were balanced between the groups (Table 1).

Missing data rates for POMP scores were substantial at posttreatment (VR-CBT: 29.6%, CBT: 35.4%) and follow-up (VR-CBT: 48.1%, CBT: 49.0%). The only identifiable reason for missing data was participants not responding to contact attempts or failing to attend scheduled assessment sessions, with no specific reasons reported by the participants. Missing data rates were not significantly different between groups but were significantly associated with older age (P=.03), having a primary diagnosis of agoraphobia, and fewer sessions attended (P<.001) (Table 2). On average, participants attended 9 therapy sessions in the VR-CBT group and 9.3 therapy sessions in the CBT group. A total of 22 (12.4%) of participants received no treatment (<4 sessions), 33 (18.6%) received partial treatment (4 - 9 sessions), and 110 (62.1%) completed treatment (10+ sessions). Engagement was comparable across the groups: 48 (50%) in the CBT group and 42 (51.8%) in the VR-CBT group completed treatment.

Sex	.76	—	.13	—
Age	.03	Older age associated with attrition	.10	—
Baseline anxiety severity	.46	—	.30	—
Number of sessions attended	<.001	Attending fewer sessions associated with attrition	<.001	Attending fewer sessions associated with attrition

[a]Continuous variables were analyzed using independent *t* tests (2-sided). Categorical variables were assessed using Pearson's X^2 tests (asymptotic significance).

[b]—: No statistically significant effect.

Primary Outcomes

Both groups showed reductions in phobic anxiety severity. From baseline to posttreatment, the VR-CBT group improved by an estimated 11.3 points and the CBT group by 12.0 points (Table 3). The between-group difference in change scores was not statistically significant (*B*=–1.33, 95% CI –6.38 to 3.73, *P*=.61, Cohen *d*=–0.03) (Table 4). Adjusted posttreatment means were 47.4 (SE=2.3) for VR-CBT and 46.9 (SE=2.4) for CBT (Table 3). From posttreatment to follow-up, the VR-CBT group showed an additional improvement of 3.8 points, whereas the CBT group improved by 1.7 points (Table 3). The between-group difference in change scores was not statistically significant (*B*=1.62, 95% CI –2.74 to 5.98, *P*=.47, Cohen *d*=0.10) (Table 4).

[a]Treatment effects (ie, the interaction of time and treatment condition) are shown. Positive B values indicate an effect in favor of the CBT group. Results are pooled from 100 imputations. Unless otherwise noted, covariates are primary diagnosis, comorbidity, and baseline severity. For all follow-up analysis, posttreatment severity was added as a covariate. Phobic anxiety severity included sessions attended as a covariate.

[b]Primary diagnoses not included as a covariate.

[c]LSAS: Leibowitz Social Anxiety Scale.

[d]MIA: Mobility Inventory for Agoraphobia.

[e]POMP: percentage of maximum points.

[f]Baseline severity violated the assumption of homogeneity of regression slopes, thus not included as a covariate.

[g]FNES: Fear of Negative Evaluation Scale.

[h]Posttreatment severity violated the assumption of homogeneity of regression slopes, thus not included as a covariate.

[i]HAM-6: Hamilton Depression Scale.

[j]Calculated with logarithmic means and SDs.

[k]WSAS: Work and Social Adjustment Scale.

[l]WHO-5: World Health Organization Wellbeing Index.

[m]CSQ: Client Satisfaction Questionnaire.

[n]N/A: Not applicable.

[o]PSP: Personal and Social Performance Scale.

[p]TLFB: Timeline Followback for Alcohol Consumption.

[q]GSE: General Self-Efficacy Scale.

[r]WAI: Working Alliance Inventory.

[s]SAD: Social Anxiety Disorder.

Secondary Outcomes

Depressive symptoms decreased in both groups, with no statistically significant between-group differences (posttreatment adjusted means: VR-CBT=4.8, SE=0.4; CBT=5.1, SE=0.4; *P*=.66; follow-up adjusted means: VR-CBT=5.1, SE=0.6; CBT=5.3, SE =0.5; *P*=.77). Fear of negative evaluation also decreased similarly in both groups (posttreatment adjusted means: VR-CBT=44.69, SE=1.27; CBT=44.01, SE=1.29; *P*=.69; follow-up adjusted means: VR-CBT=44.47, SE=1.46; CBT=44.96, SE=1.33; *P*=.77) (Tables 3 and 4). Work and social adjustment scores improved slightly in both groups, with no significant between-group differences (posttreatment adjusted means: VR-CBT=3.7, SE=0.2; CBT=3.5, SE=0.2; *P*=.50; follow-up adjusted means: VR-CBT=3.4, SE=0.3; CBT=3.4, SE=0.2; *P*=.95). Quality of life also improved, but differences between groups were not statistically significant (posttreatment adjusted means: VR-CBT=41.5, SE=2.9; CBT=43.4, SE=2.8; *P*=.62; follow-up adjusted means: VR-CBT=42.8, SE=3.5; CBT=43.1, SE=2.9; *P*=.99) (Tables 3 and 4). At posttreatment, the odds of treatment response did not differ significantly between groups (*P*=.65), and no statistically significant differences were observed for the odds of remission at posttreatment (*P*=.49) or follow-up (*P*=.51) (Table 5).

Other measures						
Deterioration of phobic anxiety symptoms (6.8 or higher increase in LSAS score/0.3 or higher increase in MIA score)	0.224 (0.538)	.68	1.251 (0.435-3.594)	–0.285 (0.436)	.51	0.752 (0.319-1.771)

[a]Positive *B* values indicate higher odds of the outcome for the CBT group compared to the VR-CBT group. Results are pooled from 100 imputations. Predictors included in the models were baseline severity, comorbidity, and primary diagnoses.

[b]LSAS: Liebowitz Social Anxiety Scale.

[c]MIA: Mobility Inventory for Agoraphobia.

[d]N/A: Not applicable.

Exploratory Outcomes

Social functioning and self-belief in coping improved in both groups, with no statistically significant between-group differences at posttreatment or follow-up (posttreatment social functioning adjusted means: VR-CBT=67.6, SE=1.3; CBT=68.9, SE=1.2, *P*=.48; follow-up social functioning adjusted means: VR-CBT=69.5, SE=1.7; CBT=69.2, SE=1.6; all *P*=.90). Similarly, no statistically significant between-group differences were found for alcohol use or treatment satisfaction (Tables 3 and 4).

Other Measures

No statistically significant group differences were observed regarding deterioration of phobic anxiety symptoms (Table 5). The average total exposure time per therapy course was not statistically significantly different between groups (*P*=.09): 85 minutes for VR-CBT groups (SD 76.5) and 120.7 minutes for CBT groups (SD 76.5), which were overall less than a third of the 360 minutes specified in the treatment manuals. Therapist-reported fidelity scores did not differ significantly between groups (*P*=.24), with a mean of 4.0 (SD 0.3) for VR-CBT and 4.1 (SD 0.5) for CBT, suggesting that therapists adhered closely to the manualized treatment protocols. Among participants receiving VR-CBT, the mean simulation sickness score was high, with an average score of 36.2 (SD 27.9) across 51 participants. There were no reported serious adverse events or reactions.

Discussion

Principal Findings

This trial evaluated the effects of group-based VR-CBT with 360° video exposure versus traditional in-vivo group CBT for treating SAD and agoraphobia in a naturalistic clinical setting. Both groups showed reductions in symptoms, with no statistically significant differences observed in primary, secondary, or exploratory outcomes. However, due to the limited statistical power of the study, these results must be interpreted with caution. We cannot conclude that VR-CBT and traditional CBT are equally effective, nor can we exclude the possibility of differences in efficacy between the two treatments. Nonetheless, this pragmatic trial offers a unique contribution by evaluating VR-CBT as it might be delivered in routine care, embedded within existing services, by local clinicians, and under everyday constraints. As such, this trial provides valuable insights into the practical implementation of VR-CBT in naturalistic clinical settings and highlights critical factors influencing its feasibility and acceptability.

Failure to Reach N

Being fully embedded in the Danish Mental Health Services, the SoREAL trial could only recruit patients referred by their general practitioner to the standardized anxiety treatment package. Based on clinical intake and experience from previous trials at the 2 initial sites, we expected to reach N in 36 months. However, changes to general practitioner guidelines for psychiatric referrals, designed to reduce the case load of psychotherapeutic outpatient hospitals, resulted in most patients with SAD being referred to practicing psychologists instead.

XSL•FO
RenderX

To offset the slower-than-anticipated recruitment rate, we expanded the study to include 3 additional clinic sites, which also entailed the design changes described elsewhere.

Shortly after including the new sites, Denmark entered lockdown due to the COVID-19 pandemic. This meant that psychotherapeutic treatment was conducted via telephone or individually. A notable drop in referrals to treatment sites also occurred, possibly because SAD and agoraphobia symptoms are less functionally impairing during a national lockdown.

After the lockdown ended, the clinical sites decided not to continue with the trial for several reasons. The primary concern raised by the clinics was the ethicality of continuing a treatment perceived as unsuitable for the population and the group format. These concerns stemmed from observations that patients found VR distressing in a group setting and struggled to focus on VR scenarios due to the social dynamics within the therapy room. Clinicians also raised concerns about the lack of interactivity in the virtual environments, which made it difficult to expose patients to core SAD fears, such as conversation. These concerns are consistent with prior findings [61] and align with the notion that therapeutic context, patient characteristics, and VR characteristics can influence the experience of VR environments [62]. Group settings, in particular, may introduce stressors like performance anxiety, which could potentially diminish immersion and thus the therapeutic value of VR environments. Addressing these concerns may require the use of VR technology that accounts for group settings and the need for flexible social interactions. Examples include multi-user VR in which all patients engage in the same shared virtual environments; augmented reality, where the therapy room remains visible but virtual objects are overlaid to simulate therapeutic scenarios; or large language model–based avatars to engage in conversation.

Beyond this, staff turnover limited clinicians' ability to gain experience with VR-CBT. Overall, 39 therapists delivered VR-CBT, most of whom could only receive very limited training in conducting VRE due to time constraints. Frequent technical malfunctions and limited time for in-session troubleshooting also impacted feasibility. These factors likely contributed to the low mean exposure time per VR-CBT group (85 min). Still, the fact that dozens of therapists across multiple sites were able to deliver VR-CBT in suboptimal real-world conditions illustrates the intervention's potential for scalability if appropriately supported. This also reflects a key strength of the study design: by relying on routine clinic staff, the trial offers an ecologically valid picture of what implementation might look like, and how effective the treatment might be, outside controlled research settings. Lastly, the extended inclusion period strained the resources of the clinics, which had agreed to participate for limited periods (eg, 2 y) and had obligations to other clinical trials. The factors that led clinics to opt out of the trial are important to consider for future studies examining VR-based psychotherapy in naturalistic clinical settings. They also underscore the importance of pilot studies for both design and intervention feasibility [63], which could have identified challenges related to recruitment rates, the group format, technical issues, and clinician training requirements before conducting the full-scale randomized controlled trial.

Beyond incomplete recruitment, the trial's substantial missing data further impede interpretation, as data are likely missing due to factors associated with the intervention (ie, it is not missing at random [64]). As such, the missing data likely impact the accuracy of the results. However, since data are missing equally across both groups and the variables associated with missing data are balanced between groups, any influence on the results is likely comparable for both groups.

Limitations

This study has some limitations. Insufficient recruitment and missing data prevent conclusions about group differences. VR acceptability, technical issues, and limited training impacted VR-CBT implementation. The generalizability of findings is limited due to the naturalistic study design.

Conclusions

Due to the study's underpowered analysis and substantial missing data, we are unable to draw definitive conclusions about group differences between VR-CBT and CBT in group therapy. The feasibility challenges encountered underscore the need to carefully evaluate both benefits and limitations of VR technology before clinical implementation. The study contributes novel knowledge on the clinical integration of VR in routine care and highlights conditions under which such technology may or may not thrive. Future research could explore VR technologies that account for the group therapy context, such as multiuser VR or augmented reality.

Acknowledgments

The Novo Nordisk Foundation awarded the SoREAL trial 784,503 USD [NNF17OC0027780]. Additionally, the trial received a grant of 551,897 USD from TrygFonden [ID: 146169]. The project is fully independent of both the Novo Nordisk Foundation and TrygFonden. Neither funding body influenced the study's design, data collection, analysis, interpretation, or manuscript preparation.

Data Availability

The trial's anonymized data will be made available upon reasonable request and in compliance with the Danish Data Protection Act. Materials related to the interventions, including the treatment manual, will also be available upon reasonable request. Data will be stored securely in accordance with ethics and legal regulations under the Danish Health Authorities.

Abstract

Background: Cognitive remediation improves cognition and psychosocial functioning in individuals with psychotic disorders. The use of virtual reality (VR) to deliver cognitive remediation in immersive environments that mimic real cognitively challenging situations has the potential to increase engagement to treatment and further enhance its impact on functioning.

Objective: We aimed to codevelop a cognitive remediation program in VR with individuals with psychotic disorders and health care professionals to identify and address their needs.

Methods: Individuals with lived experience of a psychosis-spectrum condition (n=11) met 9 times and the health care professionals (n=7) met 3 times. Participants discussed personal and professional opinions on the challenges associated with cognitive difficulties in individuals with psychotic disorders. They also provided feedback on the program development.

Results: We discerned 4 themes from the content expert working groups: the need for a program to address cognitive impairments, the key program design elements to support cognitive rehabilitation, the importance of leveraging technology as an intervention tool, and the need to improve community functioning. In total, 3 themes were identified for the health care professionals: the need for a clinically relevant program that addresses the research-to-practice gap, the need to improve patient engagement in

XSL•FO
RenderX

services, and the need for a program that addresses the limited resources in health care. The needs of our end-user experts were placed at the center of the program development process. When possible, we also integrated their suggestions, like the incorporation of a virtual coach within the immersive environment.

Conclusions: Individuals with lived experience and health care professionals have distinct needs, which have informed the co-design of a novel cognitive remediation program in VR, ThinkTactic VR. To our knowledge, ThinkTactic VR is one of the first co-designed and codeveloped cognitive remediation programs in VR using an iterative, user-centered approach involving both individuals with psychotic disorders and health care professionals.

virtual reality; cognitive remediation; user-centered approach; neurocognition; social cognition; community functioning

Introduction

Background

Psychotic disorders, such as schizophrenia and schizoaffective disorder, are characterized by positive and negative symptoms, as well as cognitive impairments [1]. Neurocognitive impairments (eg, attention and memory) and social-cognitive impairments (eg, emotion regulation and theory of mind) are common in individuals with psychotic disorders [2-4]. These impairments are associated with important challenges in community functioning and in performing daily activities [5,6]. Although current pharmacological approaches successfully reduce positive symptoms, they do not have a consistent positive impact on cognitive functions [7]. This limitation has encouraged the development of nonpharmacological interventions specifically targeting cognitive impairments in this population [8].

Cognitive remediation (CR) is a targeted approach that seeks to improve cognitive deficits and community functioning through cognitive exercises, strategies, and rehabilitative practices [9-12]. While the delivery method of CR differs, 4 core features of CR have been identified as follows: (1) the presence of exercises to improve cognition, (2) the presence of a trained therapist, (3) the identification and development of cognitive strategies, and (4) support for the transfer of skills to community functioning [9]. Studies have consistently provided evidence for the efficacy of CR in improving neurocognition and social cognition in psychotic disorders [12-14]. Despite increasing supporting evidence of CR, the transfer of learned skills and generalizability of skills to psychosocial functioning is more limited [12,15,16]. Furthermore, CR programs are sometimes accompanied by diminished motivation to continue with treatment, resulting in high dropout rates [16-18]. To address these limitations, one promising avenue is leveraging virtual reality (VR) to deliver CR interventions [19].

The Use of VR as a Rehabilitation Tool

VR is a computer-generated technology that creates 3D environments reminiscent of real-world scenarios, thus allowing for the presentation of more ecological stimuli [1,20,21]. The resulting increase in ecological validity provides a more realistic environment to learn and practice cognitive skills compared to traditional, computer-based CR modules [21]. VR is a powerful clinical tool that allows for the creation of experiences (eg, public transportation and kitchen-based scenarios) that are difficult to replicate in a treatment setting [22-24]. In addition, the immersive aspect of VR programs can provoke cognitive and emotional responses similar to those experienced in real-world settings [25,26]. Previous research has identified VR as a safe and effective method for individuals with psychotic disorders [19,27-29]. Cognitive programs in VR have shown promising results to improve neurocognition and social cognition [19,28]. However, these results are often based on small samples and pilot studies [30].

To date, there are a limited amount of CR programs in VR available for individuals living with psychotic disorders [30], including interventions that target both neurocognition and social cognition. Moreover, most CR programs in VR have been developed with minimal direct input from end users [22,31,32]. The few programs that have incorporated user feedback have done so to a limited extent, highlighting an area for potential improvement in the design and efficacy of these interventions [32]. A lack of user engagement during program development is one potential reason for program implementation failure [22]. As such, there is a need to codevelop a CR program in VR for individuals with psychotic disorders. Codeveloping a CR program in VR that includes scenarios that apply to real life and incorporates the key 4 elements of CR can address some of the current limitations commonly found in CR studies and can furthermore facilitate the transfer to community functioning [33].

Involving a Multidisciplinary Team in Program Design

To effectively codevelop a CR program in VR, Birckhead et al [22] recommend that VR applications be co-designed with direct input from individuals who would use and benefit from these programs. Current research has indicated that incorporating ideas from individuals with lived experience of a psychosis-spectrum condition (ie, content experts [CEs]) is integral for their symptom management and can improve their treatment motivation and outcomes [32,34]. It is also vital to include input from health care professionals (HCPs) in treatment design, given their expertise in providing care and understanding of psychosis-related symptomology and its impact on clinical and functional outcomes [22]. HCPs can also identify potential facilitators and barriers to the clinical implementation of such treatment programs. Including CEs and HCPs in the codevelopment process could improve engagement and adherence, as well as the content relevance of the program.

XSL•FO
RenderX

Aims and Objectives

The primary objective of this study is to report on the cocreation of a CR program in VR involving both CEs and HCPs. To achieve this, we identified and addressed the specific treatment needs of these 2 distinct end user groups. We adopted an iterative development process, ensuring the VR program effectively met their needs. This study outlines the codevelopment process, from the initial concept to the creation of the finalized program.

Methods

Study Design

We followed 2 established frameworks: the recommendations for developing effective VR interventions [22] and the 4 core features recommended for CR programs [9]. During the study, working groups were conducted separately for CEs and HCPs, during which participants discussed their needs and provided feedback on the VR program. Inductive thematic analyses were then performed for each group, and the feedback was incorporated into the development of the program after each session. This iterative process ensured that the evolving program effectively addressed the needs of both user groups.

Ethical Considerations

This study received ethical approval from the Royal Ottawa Health Care Group Research Ethics Board (REB 2019016) and the University of Québec in Outaouais (REB 2022-1869). All participants provided written informed consent at the beginning of the study and verbal consent to continue participating was obtained before every subsequent working group. Participant data was de-identified and stored separately from consent forms. Participants received CAD $20 (approximately US $12) in cash or a gift certificate for each working group session they attended.

Participants

CE Groups

In total, 11 CEs were recruited from the Royal Ottawa Mental Health Centre (ROMHC) and the local community in Ottawa, Ontario. Participants were referred to the study by their clinician or self-referred after viewing flyers and brochures distributed in Ottawa. Of the 11 CEs, 5 (45%) withdrew from the study before the 3 years of development ended. Reasons for withdrawal included loss of interest (1/11, 9%) and time constraints (1/11, 9%). The 3 other participants did not provide a reason for their withdrawal. Demographic information about the individuals included in our CEs group can be found in Multimedia Appendix 1.

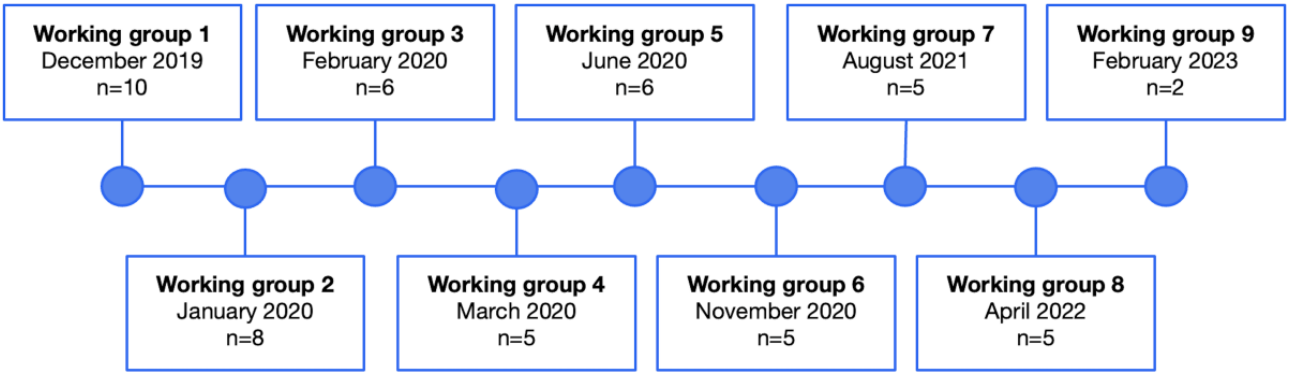
Inclusion criteria were (1) aged ≥18 years, (2) ability to read and speak fluent English, (3) diagnosed with a psychotic disorder, confirmed by the referring clinician or review of electronic medical records after consent, and (4) were on a stable medication regimen for at least 1 month before enrollment. Potential CEs were excluded if they (1) had vision problems without contact lenses or glasses that fit with the VR headset, (2) had neurological or medical disorders (other than a psychotic disorder) that could contribute to cognitive impairment, (3) had epilepsy or had a history of seizures, (4) had a recent history of substance abuse or dependence (within the past 3 months), (5) had a previous history of motion sickness or cybersickness (ie, motion sickness related to virtual immersion), or (6) had decisional incapacity requiring a guardian.

HCP Group

In total, 7 HCPs consisting of psychiatrists (2/7, 29%), clinical psychologists (2/7, 29%), a neuropsychologist (1/7, 14%), and occupational therapists (OTs; 2/7, 29%) were recruited from the ROMHC and collaborative institutions. In addition, 2 collaborators from other institutions were invited to participate in the working groups due to their expertise in CR and VR psychological interventions. No HCPs withdrew from the study.

HCPs meeting inclusion criteria were (1) an HCP and (2) had 2 or more years of clinical experience with individuals with psychotic disorders or with VR interventions to ensure they had the necessary background experience. The same exclusion criteria for CEs were also applied for HCPs.

Procedure



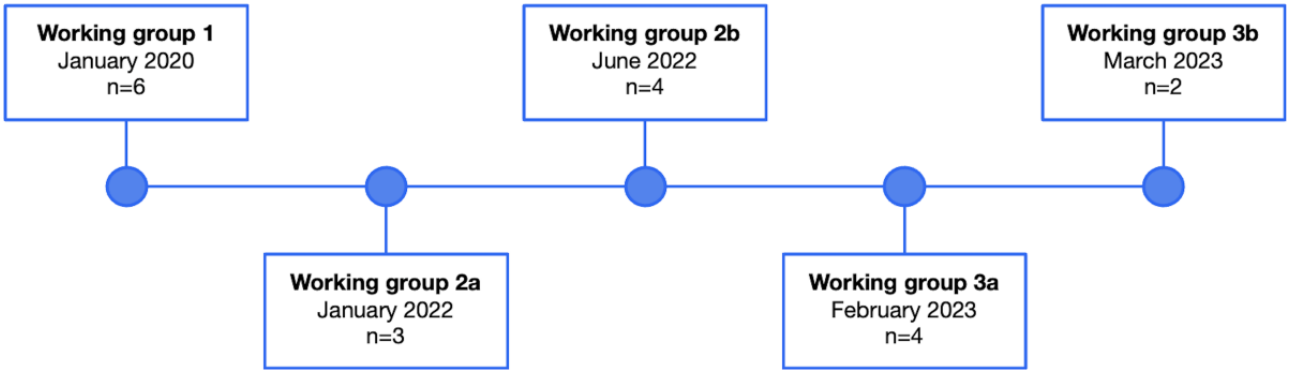
CE Working Groups

CEs were invited to in-person or web-based (Zoom Communications, Inc) meetings for an enrollment visit and 9 working group sessions (Figure 1). The same participants were invited to each working group session. CE working group sessions 1 to 5 were completed in person at the ROMHC, while the rest of the sessions were facilitated through Zoom for Healthcare due to the COVID-19 pandemic. At the initial enrollment visits, CEs were individually interviewed by a trained research assistant. During this visit, a detailed description of the study and their role and responsibilities as research partners were discussed and informed consent was obtained. In addition, initial testing of a VR environment prototype was completed. When participants completed initial prototype testing during their enrollment visit, the Simulator Sickness Questionnaire was administered to assess cybersickness (Kennedy et al [35]; Multimedia Appendix 1). Afterward, a discussion was initiated with the CEs to explore their needs and gather their initial reactions to the program. These activities established rapport and provided the necessary background information for the first working group.

In the initial 3 working groups, 2 to 3 facilitators (SG, HM, and AT) provided psychoeducation on neurocognition (working group 1), social cognition (working group 2), and community functioning (working group 3). After presenting the topic, the facilitators led a semistructured discussion to gather information from CEs about their personal experiences and opinions on the challenges associated with psychotic disorders as they related to the topic. These working groups were used to determine the needs of the CEs and the types of VR tasks to include in the training program. The remaining 6 working groups were facilitated by 2 study personnel (HM, AT, CN, or JY) who focused on gathering feedback on prototype versions of the program from CEs.

XSL•FO
RenderX

Figure 1. Content expert working group timeline (n=11).



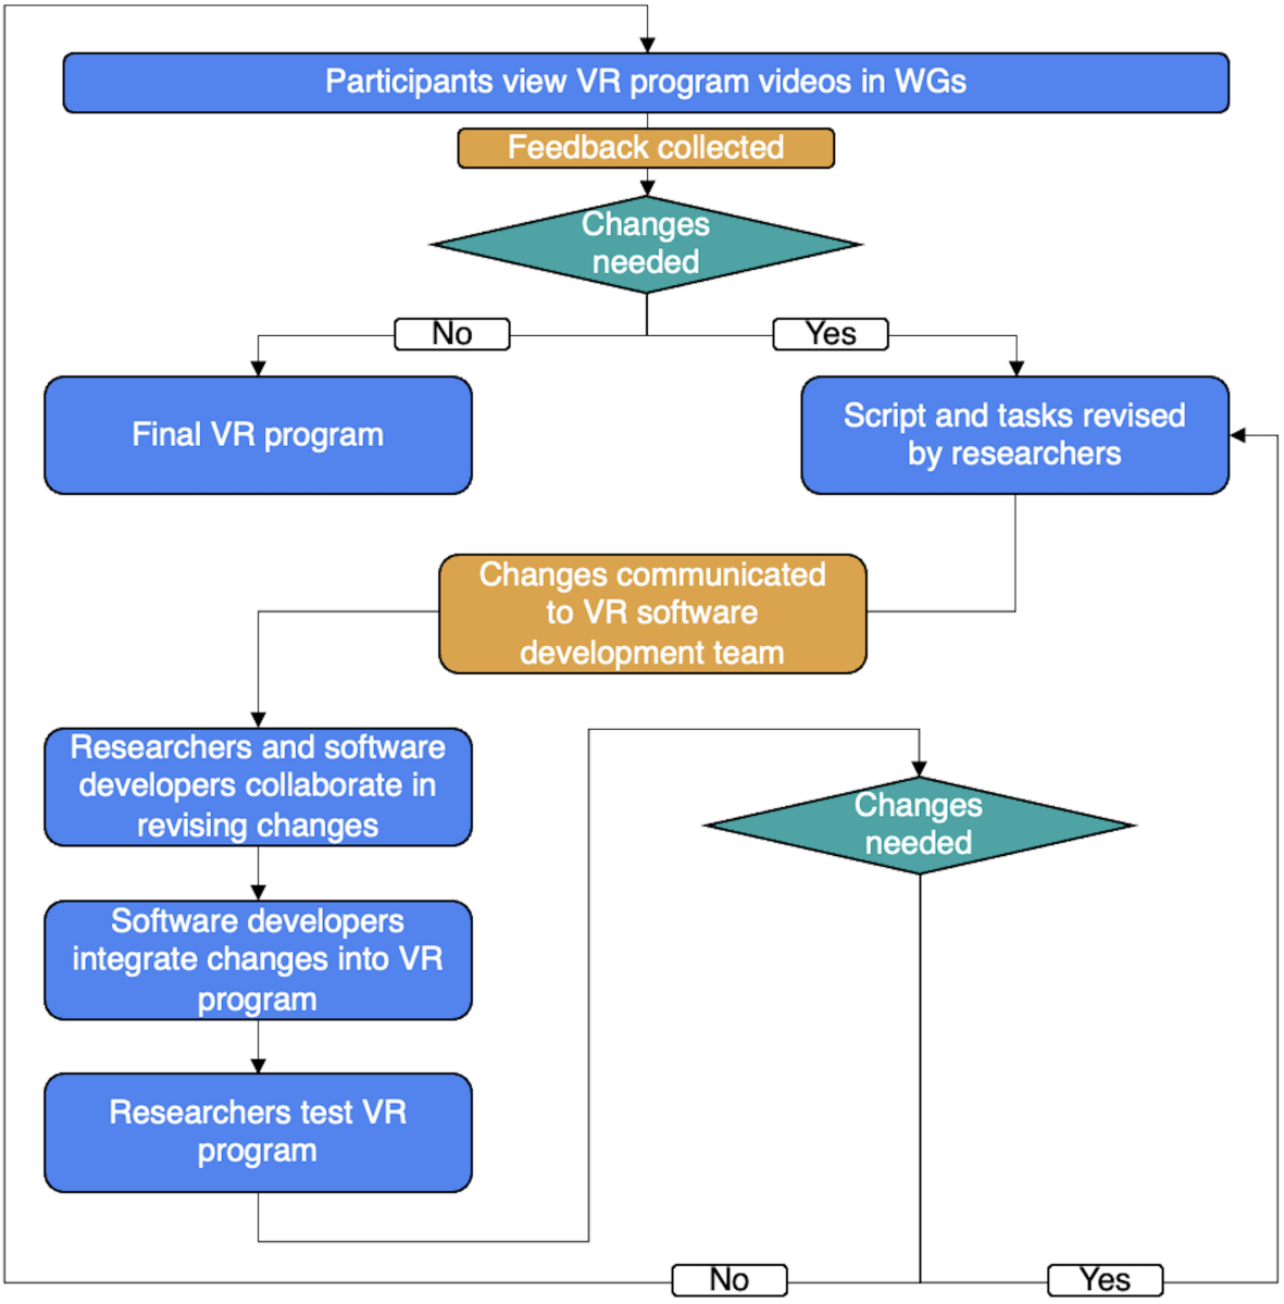
HCP Working Group

The 7 HCPs were invited to 3 working groups between January 2020 and March 2023 (Figure 2). In each working group, 2 facilitators (SG, TR, or JY) facilitated a discussion where HCPs shared their personal opinions on the challenges associated with living with a psychotic disorder and provided program feedback. The first working group was held in person at the ROMHC, with 2 participants joining virtually through Zoom. Due to the COVID-19 pandemic, the remaining working groups were facilitated virtually through Zoom.

In the first working group, informed consent was obtained from HCPs, who then discussed their professional opinions on the treatment challenges associated with psychotic disorders. Afterward, HCPs tested an initial prototype of the VR program. In the remaining 2 working groups, HCPs provided feedback on the other versions of the VR program.

Figure 2. Health care professional working group timeline (n=7). The second working group was split into 2 separate sessions (group 2a and group 2b), along with the third working group (group 3a and group 3b) to accommodate participant availability.

VR Design



User-Centered Iterative VR Program Development

The VR environments and tasks were developed following a user-centered design process and an iterative approach wherein the perspectives of CEs and HCPs were integrated into all stages of the design process (Figure 3). At the end of the third working group, CEs brainstormed and identified potential VR environments and tasks. On the basis of the feedback collected, examples of VR environments and tasks were showcased in the fourth working group. An iterative process subsequently followed where feedback was collected from CEs, which were later reviewed by the research team. When creating the VR environment, designs had to reflect the needs of CEs and HCPs while adhering to the psychological principles of CR therapy. In collaboration with software developers, the proposed changes also had to abide by current technological parameters and VR design considerations (eg, reducing the incidence of cybersickness). Research staff and software developers continuously tested and provided feedback on these changes. Once the research staff and software developers finalized the changes, the modified CR program in VR was showcased at the subsequent working group, and new feedback was collected.

In addition, a VR coach was integrated into the VR program, providing VR navigation assistance (eg, instructions on how to respond to a question or interact with objects in the environment), feedback on task performance, and CR strategies for a user. The CEs initiated the development of the VR coach, and feedback was continuously provided during its development in the working groups. Research staff collaborated with software developers to create and modify the VR coach accordingly.

XSL•FO
RenderX

Figure 3. Iterative process to program development. VR: virtual reality; WG: working group.

Software Development

Software development was carried out by the Cyberpsychology Laboratory at the University of Québec in Outaouais, led by SB and MCR. Their team was composed of software developers who specialized in rehabilitative VR environments. Character animations were created based on previous VR simulations produced in the Cyberpsychology Lab, and the VR environments were also partly created using preexisting environment design.

CR Therapy

The tasks within the VR modules were created by integrating and adapting strategies from CR manuals developed by Bellack et al [36], Friedberg et al [37], and Wykes and Reeder [38], and input from CEs and HCPs. Key strategies for treating social cognition, neurocognition, and community functioning in schizophrenia were identified from the above manuals. The scenario scripts of the VR program development began after the fifth working group session with CEs. Initial drafts were completed through weekly meetings between HM and AT during which feedback from the working group sessions and CR manuals were used to help construct the environment. The CR program in VR was revised after the ninth working group to refine the CR aspect further (JY, SG, BJMB, and CvD).

A similar approach was used to identify the CR strategies that the VR coach in the immersive environment should provide when an individual is having difficulties with a task in the VR program. Additionally, this approach was used to support trained therapists in delivering the CR in VR program sessions.

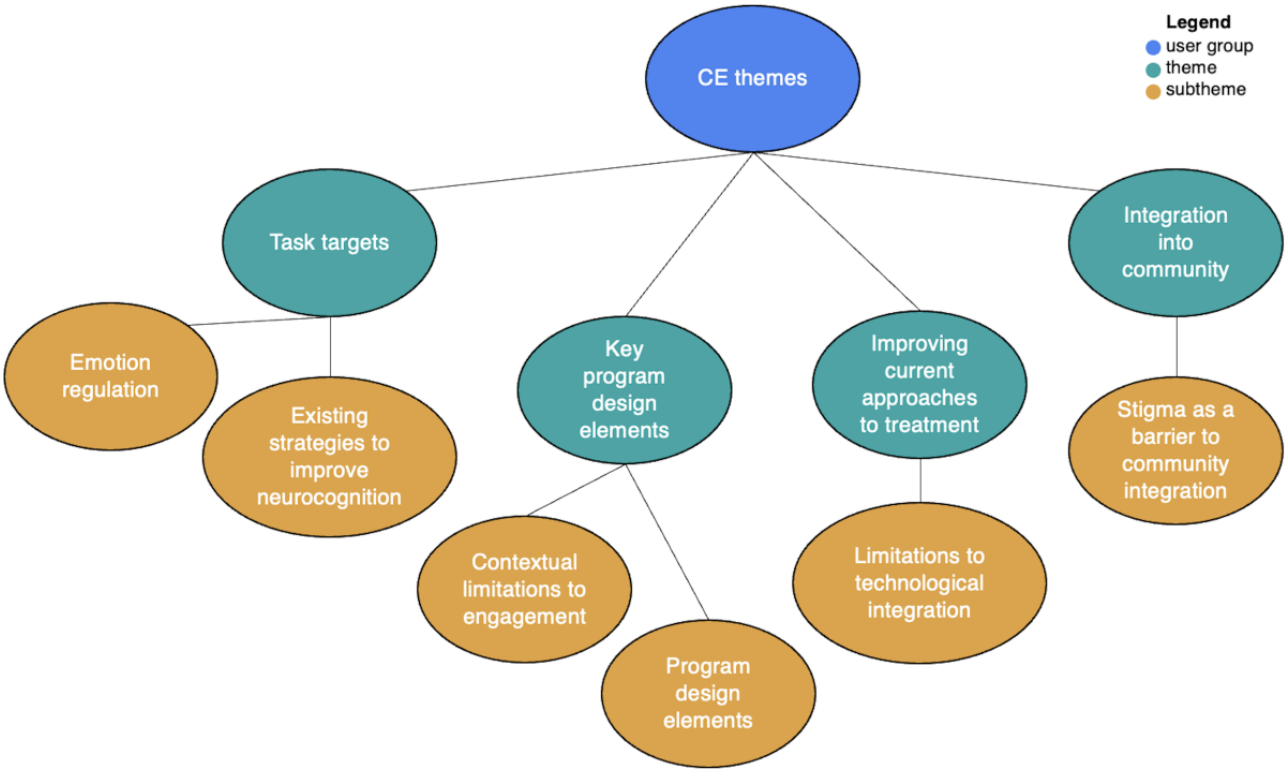
Qualitative Data Analysis

A preliminary inductive analysis following the Braun and Clarke [39] model was conducted in March 2021 to identify and

XSL•FO
RenderX

subsequently integrate central elements into the program using transcripts from the first 7 CE and the first HCP working groups (HM and CN). Working groups were recorded and transcribed verbatim through Dragon Professional Individual (version 15; HM), with syntactical corrections and identifiable information redacted to safeguard participant anonymity (eg, names of participants, occupation, and work location). To mitigate bias, a team of research staff not involved in the preliminary analysis conducted the final inductive thematic analyses to identify the treatment needs of CEs and HCPs. Recordings of the remaining working groups were transcribed and reviewed to redact identifiable information (MC). Once the transcripts were finalized, the audio recordings were deleted.

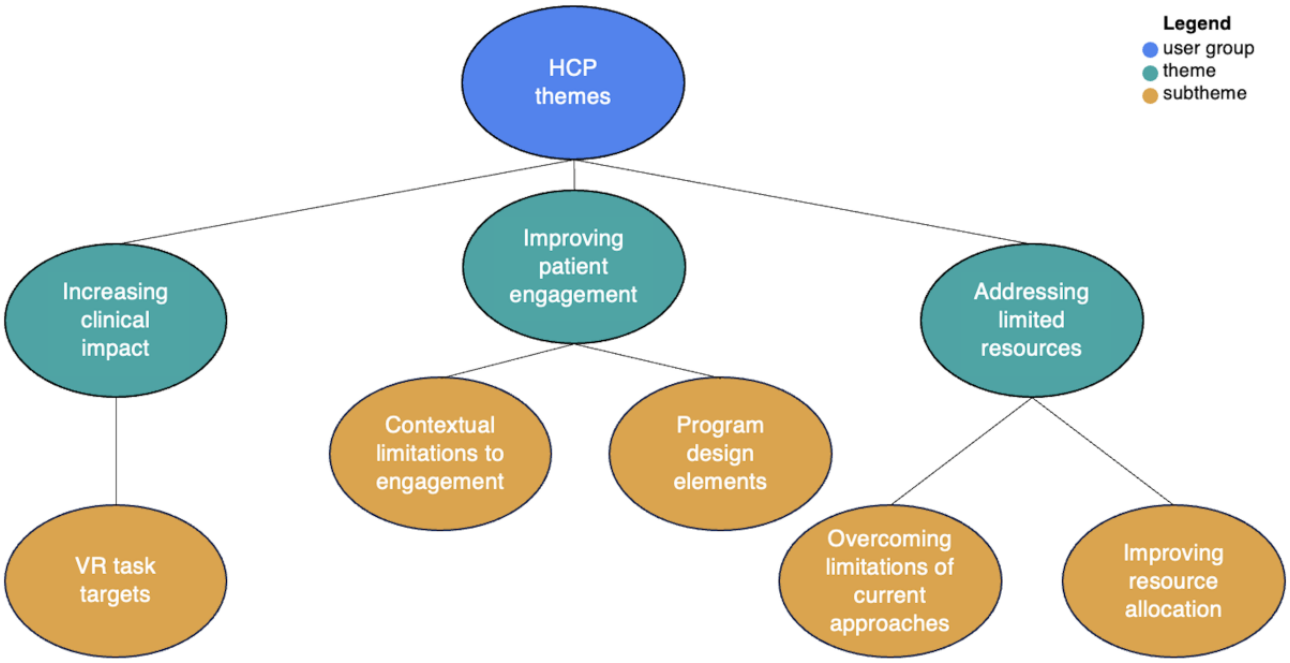
Two separate inductive thematic analyses were conducted with CEs and HCPs to acknowledge and isolate the different needs of the 2 participant groups. NVivo (version 12.0, Lumivero) was used to facilitate familiarization, coding, and data organization. The CE analysis was conducted from December 2022 to May 2023 and in September 2023 as working group 9 served as a debrief and presentation of the final VR program. Thematic coding was conducted independently (JY and EDP) for the first 3 working groups. Once no new codes emerged from the text, coders met to create an overall codebook to ensure text comprehension and consensus. The remaining 6 working group transcripts were then equally distributed between the 2 coders, who both used the final codebook to code the remaining transcripts. Themes were generated based on the final codes. With the assistance of external evaluators (CvD, BJMB, AT, and SG), the themes were refined by combining similar themes. Subsequently, subthemes were identified. Once themes were refined and finalized, their essence was defined. The same process was completed for the HCP thematic analysis conducted between February 2023 and May 2023.



Results

Overview

The thematic analysis identified 4 themes important for CEs as follows: (1) the need for a program targeting cognitive functioning (task targets), (2) key program design elements, (3) improving current treatment approaches to increase efficacy, and (4) supporting community integration (Figure 4).



The analysis also revealed 3 themes for HCPs as follows: (1) increasing clinical impact, (2) improving patient engagement, and (3) addressing limited resources (Figure 5). Together, these themes influenced the development of the program, ensuring perspectives and suggestions from the CEs and the HCPs were considered at every step of its creation. Each of these themes and their associated subthemes are elaborated in subsequent sections with selected extracts from the narratives of participants illustrating them (a more comprehensive list of quotes is provided in Multimedia Appendix 2).

CE Thematic Analysis

Theme 1: Cognitive Impairments to Target

Overview

One prominent theme that was mentioned during the focus groups was the task targets of an intervention, which include the different neurocognitive and social-cognitive domains in which CEs had difficulties, the strategies they tended to use, and what they would like to work on going forward (Table 1).

CEs tended to tie their neurocognitive challenges, such as planning and attention deficits, to daily life tasks. In 4 of the 9 working groups, CEs also reported memory difficulties, such as remembering to eat or remembering the names of people. In addition, in 4 working groups, CEs discussed social cognition challenges, such as trouble understanding why an acquaintance stopped acting friendly toward them despite there being no overt change in their past interactions. Others expressed difficulties communicating with others and regulating their emotions in stressful situations.

Table 1. Content experts' cognitive impairments to target quote exemplars.

Theme	Quotes
Cognitive impairments to target	• "I have difficulty with traveling [and] forgetting when to get off the bus." • "I was going to this gym, and I would say bye to the reception woman, and one day I asked about some workout tips, and she stopped saying bye and I tried to understand why she stopped, and I exhausted myself trying to understand."
Subthemes	
Impact of emotions and stress on cognition	• "The moment that my emotional state is not as well as it should be, like if you're not calm and capable for doing very well and performing the best, then I cannot remember nothing." • "I have this assignment that was due within a month, and it was for my course, and I set myself up earlier, I gave myself three weeks and started working on it even an hour a day but by the final week I stopped sleeping well and I wasn't able to focus."
Existing strategies to improve cognition	• "I write everything down. I note everything. I don't do anything with memory." • "The way that I used my phone at least I set up reminders so that I get a weekly reminder, two-day reminder, and then the day of the event."

Subtheme: Impact of Emotions and Stress on Cognition

CEs explicitly mentioned how their emotional state or environment (eg, the time of day and social context) influenced their neurocognitive and social-cognitive functioning. One CE shared that their memory tended to be poor during social situations, thus affecting their ability to remember faces and names. Another CE shared that their short-term memory was often influenced by their emotional state and affected their level of functioning at work which in turn required them to rely more on compensatory strategies, such as asking their manager to write down their tasks.

Subtheme: Existing Strategies to Improve Cognition

For neurocognitive deficits, CEs highlighted their use of mobile phones and note-taking. CEs equally discussed the benefits of

XSL•FO
RenderX

using technology (eg, using the reminder function on their phone) versus more traditional external memory aids (eg, a paper agenda). A few CEs focused more on behavioral or environmental modifications to help reinforce memory. One CE even mentioned they wanted to maintain their current level of memory performance and exclusively used their phone to write down appointments. In addition to memory aids, one CE mentioned they try not to overcomplicate their life to avoid stress as it could affect their cognitive abilities. Engaging in social interaction and asking friends for help was also repetitively suggested as a helpful tool. Moreover, 2 CEs shared that they could complete tasks, such as writing an article or setting up a "game night" if they planned ahead. Aside from these strategies, CEs also mentioned the importance of psychoeducation in managing their difficulties better and suggested implementing it in VR.

Finally, CEs shared social cognition strategies in 3 working groups, although fewer strategies were discussed compared to the conversations about existing strategies to support neurocognition. One suggestion was to ask individuals how they were feeling and be more direct when interpreting the emotions of another individual. Other CEs had tips for reducing stress, which could ultimately help manage their cognitive difficulties.

Theme 2: Key Program Design Elements

CEs highlighted several key program design elements of an intervention to support rehabilitation. For example, participants expressed:

> *It's not a matter of harder or easier. It matters to be realistic and not complicated.*

> *If you get off the bus or walk or you can choose to walk, if you have a time restriction you can still choose to walk or take the bus and then go grocery shopping for a list of things and manage the money...I just find it important to be able to make these things grounded in the reality context.*

Notably, CEs identified the importance of an immersive and interactive program environment across 5 working groups. One CE highlighted that the immersive aspect was more important than the difficulty of the program due to the importance of translating the skills learned in the session to daily life. While CEs emphasized the importance of an immersive program, there was debate about the impact of multiple-choice questions on specific tasks on program immersion. One CE expressed that they liked this option as it allows users to learn from different approaches and see how choices affect later actions. Other CEs voiced that the multiple-choice questions could break the VR immersion.

CEs also discussed the importance and need of a program that promotes the translation of skills and strategies learned in the session to daily life. One suggestion to promote translation was to design tasks reminiscent of those CEs encountered in their daily life. Another way to promote translation into reality was to incorporate environmental elements into the program. For example, one CE proposed that if a person forgot their destination while traveling on a bus, they could ask the driver for directions.

Two program design elements were also briefly discussed by the CEs, including having avatars from diverse cultural backgrounds and the ability to change the difficulty level of a program.

Theme 3: Improving Current Approaches to Treatment

Overview

CEs discussed the impact of pharmacological and psychotherapy interventions and voiced some of their limitations. Such limitations included the negative impact of medication on their cognition and the sparsity of programs available:

> *Especially for like thinking skills like memory attention and executive function is not something that you live with. It is not related with other symptoms, so we need those kinds of therapy.*

> *Taking medicine, it kind of dulls the mind.*

CEs conversed about integrating technology into cognitive rehabilitation approaches to increase treatment efficacy in 4 working groups, which was based on their prior experiences of phones as supportive devices. CEs shared how they relied on their phones to remember appointments; some participants identified a higher chance of forgetting an appointment if it was not entered into their calendars when booked. Interestingly, CEs expressed greater emphasis on the role of technology in supporting social cognition development (rather than neurocognition development), where technology could enable users to practice how to interact in social interactions.

Subtheme: Limitations to Technological Integration

While CEs supported technology integration into treatment interventions, they also highlighted concerns:

> *Not everyone can get data on their phone or has access to WIFI.*

> *When do you start introducing a back-and-forth aspect to a simulation? It opens the door for more back and forth just to keep things from getting confusing, and that might cause some issues later down the line for the programming.*

One such concern was that individuals may not have remote access to internet and mobile data, thus affecting the accessibility of internet-dependent interventions delivered through phones. In addition, CEs emphasized 2 ways in which VR interventions are impacted by its equipment. First, VR interventions are constrained by computers that meet specific hardware requirements and are likely more difficult to access. Second, unfamiliar technology could negatively interact with the VR navigation experience; VR controllers differ from typical game controllers. As such, it could take time for a user to become accustomed to the VR interface, potentially affecting the depth of knowledge and strategies learned.

XSL•FO
RenderX

Theme 4: Integration Into Community

Overview

CEs highlighted their need to socialize and the necessity for better community integration:

> *I also think that the virtual reality should be fused with the community.*
>
> *Something that those people, they need drastically. They need something interesting to be involved in their life. They need to socialize, they need to go out.*

CEs emphasized the importance of interacting with others to improve their social skills and reduce isolation; a recurring topic was loneliness. While this need was emphasized, some CEs voiced challenges with social interactions, including situations in which individuals wanted to socialize with others but could not start a conversation. Other CEs specifically mentioned their difficulty in talking about themselves and elaborating on their hobbies, which were limited as they mostly spent their time at home "playing games" and "not being able to afford anything." In addition to this need for social interaction, CEs expressed the importance of aiding disabled individuals with integration into the community. One CE mentioned programs that help disabled individuals integrate within the community and meet others with similar disabilities.

Subtheme: Stigma as a Barrier to Community Integration

CEs disclosed how stigma increased the difficulty of integrating within the community and restricted their level of involvement:

> *I explain to people that I have a long-term disability that could affect my cognition. Everyone has their struggles, and they would understand. I don't give details that I have schizophrenia.*
>
> *There is a lot of stigma and discrimination. Maybe they discriminate against you because they think that you are here, and you may be dangerous.*

Many CEs shared past experiences of feeling stigmatized by other individuals due to their mental health conditions. One CE expressed that others may perceive them as "dangerous" while another CE shared that they feel like others have preconceptions about their behavior. Considering these experiences, one CE suggested that a program could provide psychoeducation on navigating social situations where users encounter stigma and negative stereotypes being expressed by an avatar. In addition, a program could include a task reflecting the above situation so that users can practice responding.

HCP Treatment Needs

Theme 1: Increasing Clinical Impact

Overview

HCPs emphasized a need for more clinically relevant programs targeted toward individuals living with a psychotic disorder:

> *In my sense this is bridging the gap (in psychiatric care) that we've been up against for 20 or 30 years.*
>
> *I found there is a gap between the psychological and psychiatric world to the actual functioning. I think this would be very great for identifying what specific problem might be because we often are focused on is a task completed or not, but we don't spend a lot of time discussing partially completed tasks and why the task broke down.*

HCPs identified a gap related to translating approaches that support neurocognition and social cognition to psychosocial functioning. Participants conveyed a need for a program that improves neurocognition and social cognition within the context of the functioning of their patients. The use of technology, including VR, to deliver CR could bridge this gap and support the psychosocial functioning of users.

Subtheme: Cognitive Impairments to Target

HCPs identified several domains of cognition that a program should target, notably memory and executive functioning:

> *We're all clearly craving modules or elements in our clinical practice that help with social cognition? Because the social cognitive landscape for patients is where they grind to a halt.*
>
> *From my point of view, which is a very practical point of view [is] from discharging people from hospital and can they navigate kind of basic tasks in the community.*

HCPs also described a general need to enhance social cognition in 2 working groups but did not identify specific domains. A main portion of the HCP working groups was spent discussing how a program should promote the transfer of learned skills and strategies to the daily lives of their patients. HCPs described the impact of neurocognitive impairment on psychosocial functioning, which could affect their recovery and transition from inpatient to outpatient care.

Subtheme: Generalizability of the Program

Some HCPs expressed that a program should be generalizable to the clinical variations seen in psychotic disorders. For instance, a CR program in VR should consider the difference between active and chronic-stage psychosis. HCPs also mentioned that when treating a psychotic disorder population, comorbid conditions (eg, sleep apnea) should also be considered. Similarly, 2 HCPs also highlighted the generalizability of a program to other populations marked by cognitive impairment. There was discussion among the HCPs about balancing the broad applicability of the program with ensuring that the tasks target neurocognition, social cognition, and psychosocial functioning. One HCP noted that if the program tasks were too broad, the program may not adequately meet the needs of the users. While the clinical significance of treatment is greater when it is generalizable, future research is also required to investigate whether these broad VR tasks adequately address the needs of users.

Theme 2: Improving Patient Engagement

Overview

The second theme reflected a need to improve patient engagement in treatment approaches (Table 2). HCPs expressed a need for more patient engagement in the services offered by their clinics and, more broadly, on an institutional level.

XSL•FO
RenderX

Motivation and contextual limitations were identified by HCPs as critical factors that influence treatment engagement.

Table 2. Health professionals' improving patient engagement quote exemplars.

Theme	Quotes
Improving patient engagement	• "It is the same patients showing up for everything sometimes. We have full groups but it is the same 50 people doing all the groups. We have 1500 program patients, but really over 1000 of them the physician knows. Less than 500 are outpatients taking part in the program. And I don't think the 1000 patients not taking part in the program aren't doing so because they're doing so well."
Subthemes	
Contextual limitations to engagement	• "The question becomes, we would love to be spending more time on cognition but there is nasalism there, and we run into the problem of risk management, safety, medication, morbidity, illness morbidity, family needs, housing needs, issues of poverty." • "We have to be mindful that our medications that we prescribe are not pro-cognitive, they are de-cognitive, and it has changed the prescription culture that we prescribe medication that clearly deteriorates our mission."
Program design elements	• "I think finding a good land, or thinking about personalized medicine, or patient preferences is really important." • "We have a little more resource but we are also quite limited in terms of any real cognitive remediation. We can do a baseline neurocognitive assessment on almost everybody in this clinic but then from there, there is one kind of cognitive remediation group."

Subtheme: Contextual Limitations to Engagement

HCPs listed several contextual limitations to engagement, such as lack of time, lack of social support, and socioeconomic background. For instance, their patients typically face challenges to satisfy basic physical needs, which can affect their ability to be physically and mentally present during appointments. HCPs highlighted accessibility as a contextual limitation to engagement where their patients often encounter transportation issues traveling to and from appointments. Some HCPs discussed how medication side effects may negatively impact neurocognition. They also emphasized a lack of pharmacological approaches available to enhance neurocognition. Regarding the program specifically, HCPs voiced that a prior negative VR experience may affect patient engagement; as such, a VR program should start with a practice portion to reduce the chance of cybersickness and increase the amount of attention directed to the task.

Subtheme: Program Design Elements

Across all 3 working groups, HCPs emphasized specific program design elements that could be incorporated into a program to improve engagement, such as the ability to personalize a program to a patient. HCPs voiced that currently available cognitive rehabilitation programs lack the ability to tailor the program to the patient and their goals.

HCPs identified 2 ways a program could provide a personalized approach. First, HCPs mentioned how different approaches to CR may better suit certain patients, especially when considering the chronicity of their condition. The second method to provide a personalized approach was to change various program settings, such as the loudness of distractions. By changing various program design settings, HCPs thought it would enable them to tailor the program to the level of cognitive functioning of their patients. In addition, HCPs expressed that providing a personalized approach would account for the heterogeneous presentation of psychotic disorders and comorbid conditions. For example, HCPs described how a VR program should consider the difference between active and chronic-stage psychosis, as the treatment approach would differ. Two HCPs also highlighted the generalizability of a program to other populations marked by cognitive impairment, such as mood disorders.

Finally, another integral program design element highlighted by HCPs was integrating diversity and inclusivity into the program. HCPs discussed how background avatars could be changed to reflect a greater inclusivity of racial backgrounds and how users themselves could change the coach avatar.

Theme 3: Addressing Limited Resources

Overview

A prominent theme throughout the HCP working groups was the limited resources available in health care and the need for a program to be effectively incorporated into a health care setting to mitigate these resource constraints (Table 3). HCPs also highlighted current limitations in the diagnosis and treatment of psychotic disorders. Despite this negative lens, they also had suggestions on how to use current resources effectively.

HCPs described what resources needed to be improved in their fields, including a lack of staff and availability. During the working group, HCPs mentioned being "stuck in terms of ... time." HCPs mentioned that, despite their desire to try new approaches, they do not have the necessary staff to accommodate the substantial number of patients on their waitlists. In turn, this creates an uneven patient-to-health care provider ratio. In addition to staff shortages, patients are subject to long wait times due to, among other things, a long and arduous referral process. The terms "expensive" and "cost" were also used a few times during these discussions.

XSL•FO
RenderX

Table 3. Health professionals addressing limited resources quote exemplars.

Theme	Quotes
Addressing limited resources	• "[There is] a massive drop off in resources. We have 1500 outpatients in the program. We have 1.4 OTs. We have two psychologists [...], not just [for] our program, and we have 3.5 social workers and 3.5 nurses for our program." • "We have patients ready to go now and we submit a referral, and they have a wait and the waiting kills."
Subthemes	
Improving resource allocation	• "I could see this becoming part of OT. Like we see someone who is referred, and it is almost a year sometimes to see them so how can us as OTs get this going from the get-go?" • "I like the idea of thinking about potential of wait room intervention and how relatively brief interventions can be done while a patient is waiting to see the psychiatrist, nurse or social worker."
Overcoming limitations of current approaches	• "In a clinical interview, our patients usually over endorse their abilities...But looking at that functional endpoint and exploring how the person is actually performing in the task has always been the deficit that we've had clinically." • "The nasalism around how fixed are these cognitive deficits, particularly because it looks like most of these cognitive deficits occur before the first episode of early psychosis. So, we're showing up at the fire after the house has already burnt down."

Subtheme: Improving Resource Allocation

Despite the limited resources, HCPs presented strategies to allocate available resources more efficiently and effectively. In response to staffing challenges, the HCPs suggested delegating interventions, including VR training, directly to allied HCPs, such as OTs. Several HCPs in the working groups felt that a more interdisciplinary and holistic health care method would benefit patients more and create shorter wait times. They also suggested using clinic and hospital waiting rooms to dole out brief interventions and reduce the need for multiple staff while "multipy[ing] your number of clients." Some HCPs proposed that patients could complete a VR program in a waiting-room setting or while waiting to access a service (referral or waitlist). In these settings, patients could start building on the skills and strategies they would later elaborate on with an OT. For instance, one HCP expressed an interest in patients engaging in a public transportation-orientated module where they initially learn strategies for navigating public transportation before they go out in the community and practice with an OT. In response to the waiting-room intervention idea, HCPs raised the importance of embedding research and other multidisciplinary services (eg, OTs) into a single clinic.

The keywords "quick," "brief," and "immediately" were mentioned a few times during discussions. HCPs emphasized the need for quicker and easier measures, a speedier referral process, and brief but effective intervention methods, such as using waiting rooms to administer interventions.

Subtheme: Overcoming Limitations of Current Approaches

In addition to improving resource allocation, limitations in current approaches were brought up. One of the limitations of assessing neurocognition in psychotic disorders is the discrepancy often found between subjective and objective neurocognition. HCPs discussed how patients may overestimate their cognitive abilities, especially if they perform relatively well on a simple cognitive test; however, this test may not accurately measure cognitive difficulties in daily life tasks. Coupled with the need to measure neurocognition accurately, HCPs discussed this need in the context of VR. While it was emphasized that the objective of this program was for training purposes, HCPs were excited about the prospect of VR assessments for neurocognition and community functioning. HCPs were also concerned about whether training cognition is advantageous given the challenges to the schizophrenia algorithm. As cognition is often visibly affected before the first onset of psychosis, HCPs wondered whether it is possible to train cognition to a premorbid state or whether such interventions are fruitless. Therefore, there is a need to define cognitive difficulties in psychosis better to determine which interventions offer more meaningful outcomes.

Resulting CR Program: ThinkTactic VR

Overview

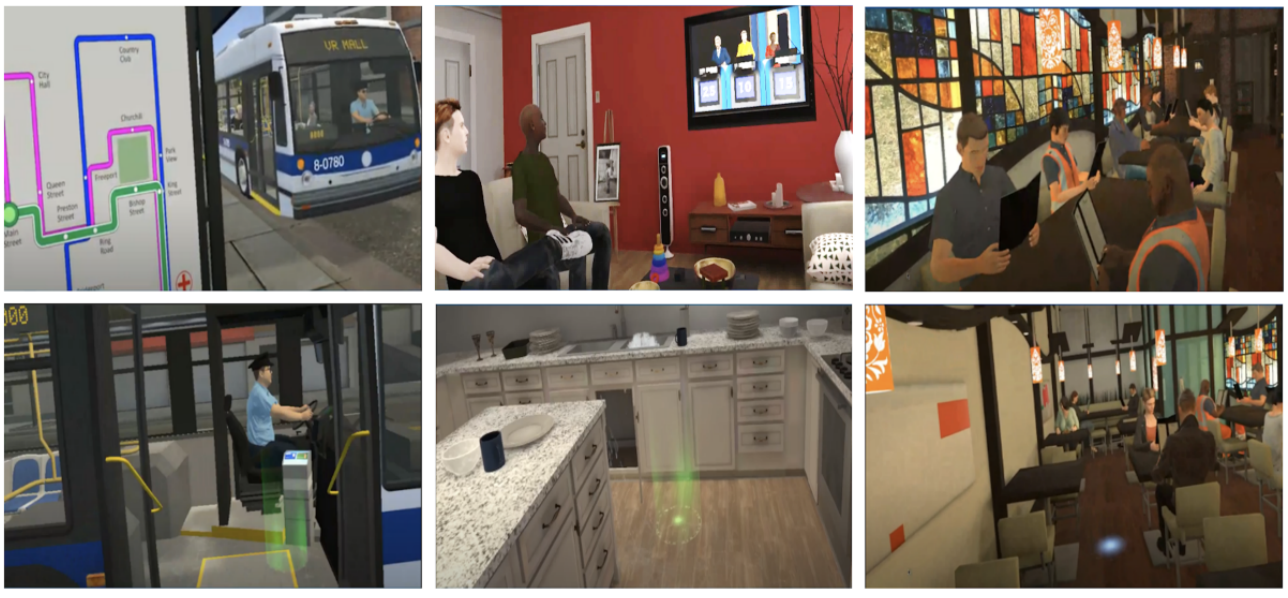
The needs of CEs and HCPs were placed at the center of the development process, where the VR environment and avatar design, tasks, and scripts were built based on the feedback provided by CEs and HCPs (Textbox 1). For instance, the inclusion of an avatar that guides a user through the program and delivers CR strategies (ie, the VR coach) was recommended by the CEs. On the basis of this feedback, research staff collaborated with the software developers in developing the initial prototype of the VR coach and presented videos of the VR coach in the subsequent working group. The iterative development approach of the entire program, including the VR coach, ensures that the program is continuously meeting the needs of CEs and HCPs. CEs and HCPs treatment needs and suggestions were incorporated to the best of our ability in the iterative program development process to create the final program: ThinkTactic VR.

The final CR program in VR includes 3 environments (ie, modules): city navigation, apartment, and restaurant (Figure 6). Each module is composed of 4 levels where the first level serves as an introduction to how to navigate the environment and general tasks. As users progress through the module levels, environmental distractions (eg, ambient noise) and task complexity increase. These neurocognitive and social-cognitive

XSL•FO
RenderX

tasks are contextualized in situations an individual is likely to encounter in their life. If a user does not provide the intended answer during a task, they have the opportunity to repeat the task and practice CR strategies. These CR strategies are provided by a VR coach avatar integrated into the module. Users receive instant feedback from the VR coach after responding to a task. If a user is experiencing difficulty, the VR coach will provide CR strategies before the user reattempts the task (thus reinforcing the concept of errorless learning). If a user responds correctly to a task, the VR coach will reinforce CR strategies. This allows users to have repeated exposure and opportunities to practice CR strategies in cognitively challenging real-life scenarios in immersive environments. To support the transfer of learned skills and CR strategies to community functioning, ThinkTactic VR was designed to be accompanied by a trained therapist who also concludes each session with a bridging discussion.

Textbox 1. Examples of user input integrated into ThinkTactic VR and noted for future iterations.



Incorporated into ThinkTactic VR

- creating an interactive and realistic environment
- inclusion of a virtual reality (VR) coach
- inclusion of memory aid
- psychoeducation on selecting balanced meals when heating up food in the apartment module
- selection of the modules
- slower rate of speech from avatars and the VR coach
- tasks targeting neurocognition and social cognition simultaneously
- cultural and gender diversity of avatars

To be considered in future iterations of ThinkTactic VR

- ability to customize the VR coach
- adding more tasks to the program
- cultural and gender diversity of the VR coach
- grocery store scenarios involving navigating around the store and calculating prices
- purchasing an item from a store to receive change for a bus trip
- responding to a scenario that involves interacting with the police
- responding to a situation involving stigma

Figure 6. ThinkTactic VR program photos. The city navigation module is featured on the left, the apartment module in the middle, and the restaurant module on the right.

XSL•FO
RenderX

VR Module Descriptions

In the city navigation module, the user navigates a virtual city using a public transportation system. The user is tasked to select a bus route that will take them to their destination in the shortest time and least number of stops (Table 4). After selecting the correct bus route, the user boards a virtual bus and must disembark it at the correct bus stop. Later levels build on this task to increase complexity, such as increasing the ambient noise and navigating a detour. In the final level, the user must stop at a grocery store along their route to retrieve bread and a prepurchased order. The second module is situated in a home-based environment where users encounter situations, such as introducing oneself to a houseguest and responding to a flood in a kitchen. Finally, in the third environment, the user takes on the role of a server in a restaurant and is responsible for relaying food orders from customers to the kitchen. In later levels, the number of food items the user needs to remember increases. In all modules, there are 4 levels that feature tasks of increasing cognitive difficulty to increase psychosocial functioning.

Table 4. ThinkTactic VR example tasks.

Level	Task description	Example target domains
City transportation module		
Level 2	Selecting a bus route that brings a user to their destination in the shortest amount of time and stops	Problem-solving, decision-making, and attention
Level 3	Virtual avatars stare at the user as they board the bus	Emotion regulation, attribution bias, theory of mind, and attention
Level 4	Remembering the order number of a grocery order at a store as part of an errand when navigating to the final destination	Memory
Apartment module		
Level 2	Responding to a flood in the kitchen	Problem-solving, emotion regulation, and attention
Level 3	Introducing oneself to an avatar	Emotion regulation and theory of mind
Level 4	Selecting takeout food from a series of options while keeping on budget	Problem-solving and decision-making
Restaurant module		
Level 1 to level 4	Recalling a food order from a table	Memory and attention

Discussion

Principal Findings

The ThinkTactic VR program was codeveloped with CEs and HCPs through an iterative process. Both groups identified treatment needs and provided feedback, which directly informed the design of the program. Their input also highlighted the potential of VR interventions to facilitate transfer, generalizability, and engagement, reinforcing the value of integrating immersive technology into CR. Both groups identified the need for a program addressing neurocognitive and social-cognitive deficits, highlighting the importance of real-world applicability. Each group also brought unique priorities: CEs mentioned the need for an immersive experience, while HCPs focused on tailoring the program to individual clients. HCPs also noted the importance of bridging the research-to-practice gap, improving patient engagement, and overcoming limited health care resources. CEs stressed the need for innovative treatments that integrate technology to enhance efficacy and support community integration.

Our results aligned with previous studies that involved user input during the development of CR programs in VR and identified similar needs, particularly regarding the importance of exercises, feeling immersive and representing real-life situations. Realpe et al [40] adapted an intervention for social cognition in VR with individuals with early-episode psychosis and highlighted the importance for the program to be immersive. Interestingly, Hernandez et al [31] conducted a similar study that analyzed the perspectives of individuals with mood disorders and HCPs while developing a neurocognitive training program. Similar themes were identified, including the importance of an immersive aspect of a VR program, and contextualizing training in real-world scenarios to promote transfer [31]. Subsequently, Hernandez et al [31] modified their prototype to reflect the feedback gathered and the treatment needs of their user groups. ThinkTactic VR is one of the first codeveloped program of CR that targets both neurocognition and social cognition. In addition, rather than modifying an existing VR program, our development approach involved creating a novel CR program in VR from the ground up with input from those with lived experience and HCPs.

ThinkTactic VR was developed according to a framework proposed for the development of VR interventions [22]. As recommended, the development process of ThinkTactic VR integrated empathy into its approaches and promoted inspiration by listening to the needs of CE and HCPs. ThinkTactic VR also featured an extensive collaboration with CEs, HCPs, software developers, and researchers where individuals brainstormed ideas for the program. Any ideas that were not feasible at this point of time due to resource and time constraints were noted down for future refinement of ThinkTactic VR (Textbox 1). Finally, an iterative, bottom-up process was used to design and develop ThinkTactic VR. The iterative approach to program development facilitated continuous user feedback loops that

XSL•FO
RenderX

ensured any changes incorporated continued to integrate the needs of CEs and HCPs.

ThinkTactic VR also incorporates the 4 essential components of a CR program identified in a working group [9]. First, a VR coach that provides CR was integrated into the program. The program is also designed for a user to be accompanied by a trained therapist. This therapist facilitates engagement with the program and supports the user in identifying how CR can be applied to their functioning goals. Second, ThinkTactic VR features tasks that train neurocognition and social cognition in the context of cognitively challenging scenarios that resemble those encountered in daily life. Users engage in multiple repetitions of a task throughout 4 levels where the tasks increase in difficulty, providing continuous training. These tasks aid a user in developing problem-solving strategies and promote monitoring strategies, the third component of a CR program. Finally, delivering CR in VR may increase the transfer of learned skills and strategies that ultimately increase psychosocial functioning. Individuals receive more exposure to cognitively challenging tasks they might otherwise avoid. They can also practice multiple times in a safe environment that resembles situations they may encounter in their life, allowing them to apply skills and strategies that facilitate generalization [41].

Initial pilot testing of a ThinkTactic VR module illustrates that it is feasible and acceptable for individuals with psychotic disorders [20]. A pilot randomized controlled trial (NCT05973110) is currently under way to evaluate the initial efficacy, feasibility, and acceptability of the full ThinkTactic VR program. The results of this trial will provide critical insights that will guide further revisions of the program.

Limitations and Future Directions

While we did our best to incorporate the suggestions of the participants, monetary and time restraints limited the full implementation of all suggestions (Textbox 1). This study was also disrupted by the COVID-19 pandemic. Working groups were initially delivered in person (CE working groups 1 to 5 and HCP working group 1) where participants could directly test the VR program and provide feedback. With the onsite restrictions introduced to reduce the transmission of the COVID-19 infection, all working groups were moved to a web-based format. Instead of immersing the participants in the VR program, participants watched prerecorded videos of the program. Accordingly, there were limited opportunities to test the VR equipment (eg, headset and controllers). This switch to a web-based format may have changed the perceptions of the program, thus impacting on the feedback provided. Finally, the sample size was relatively small, and the attendance of the CE working groups fluctuated over time.

Conclusions

ThinkTactic VR is the first VR cognitive rehabilitation program targeting both neurocognition and social cognition for individuals with psychotic disorders. It was codeveloped with individuals with lived experience and HCPs through an iterative process, incorporating feedback and suggestions from design to creation. The program was specifically developed to meet the needs of end users. It aims to improve cognition through scenarios grounded in tasks that simulate daily activities, potentially leading to better community functioning. Future studies are needed to assess its efficacy and further refine its development to ensure implementation and scalability.

Acknowledgments

The authors would like to thank Sebastien Nadeau for their support in leading the CE working groups and their contribution to the modifications done to ThinkTactic VR. The authors greatly appreciate the support provided by Claire Mayaud and Abigail Bradley in the transcription process for the CE and HCP working groups. Finally, the authors sincerely thank Dr Kristelle Alumni-Menichini for their advice in the design, working group format, and analysis of the study. This study was funded by the New Frontiers for Research Fund—Exploration (Tri-Council Agency); the Emerging Research Innovators in Mental Health (University of Ottawa Institute of Mental Health Research); and the Chercheur-boursier junior 1 (Fonds de Recherche du Québec—Santé).

Authors' Contributions

SG was responsible for conceptualization. SG, HM, AT, SB, and M-CR were responsible for methodology. SB, ST, M-CR, SG, JY, HM, and AT were responsible for software development. Formal analysis was conducted by JY, BJMB, EDP, AT, CvD, HM, and CN. Investigation was conducted by HM, AT, JY, SG, ST, M-CR, A-MC, MC, MG, YTL, KA, GC, CG, SB, AS, AB, DA, CC, CM, and CRB. JY, MC, and SG were responsible for data curation. JY, HM, and MC were responsible for writing the original draft. BJMB, SG, JY, AT, CN, EDP, CvD, YTL, MC, HM, MG, AB, AS, SB, CC, CM, DA, A-MC, ST, M-CR, CRB, KA, GC, and CG were responsible for writing and editing the review. EDP, JY, and SG were responsible for visualization. SG was responsible for supervision. JY, HM, and AT were responsible for project administration. SG, SB, and A-MC were responsible for funding acquisition.

Conflicts of Interest

AB has received an honorarium from Otsuka-Lundbeck in the past 2 years. Beyond these 2 years, AB has received honorariums from Otsuka-Lundbeck, Janssen, and HLS Therapeutics. SB is the president and owner of Cliniques et Développement In Virtuo, a university spin-off that distributes virtual environments. The terms of these arrangements have been reviewed and approved by the Université du Québec en Outaouais in accordance with its conflict-of-interest policies. CRB receives in-kind research accounts

XSL•FO
RenderX

from Scientific Brain Training and royalties from Oxford University Press. CRB is also the owner of Kingston Cognitive Fitness. SG has provided consulting services for Boehringer Ingelheim and received financial compensation from the company in the past 3 years.

Abstract

Background: Third-wave psychological treatments such as acceptance and commitment therapy can be effective for improving depression and anxiety in youth. However, third-wave therapeutic techniques such as cognitive defusion can be abstract, challenging to learn, and difficult to apply in real-world settings. Translating these techniques into virtual reality (VR) may provide interactive, enjoyable, and concrete learning opportunities, potentially enhancing engagement and effectiveness. This study evaluated a novel VR application that translates the technique of cognitive defusion into a brief, gamified VR experience.

Objective: The objectives of this study were to evaluate the feasibility, acceptability, usability, and safety of the VR cognitive defusion application; examine whether it could improve negative thinking and mood states; and understand how it compared to a non-VR cognitive defusion exercise.

Methods: In a mixed methods experimental study, 20 young people completed both a VR and audio cognitive defusion exercise in a randomized order within a single session. Quantitative state-based measures were taken before and after each exercise, and a qualitative interview at the end focused on how the two experiences compared.

Results: It was feasible to recruit participants, and all participants completed both exercises and assessments. Both the VR and audio exercises were acceptable to participants, with qualitative themes highlighting a preference for VR due to the novel and engaging format; however, there was a need for better guidance and more personalized environments. No severe adverse events were reported, although one participant experienced distress during the VR exercise. Pretest-posttest effects showed improvements in thought discomfort, cognitive defusion, and state anger for both the VR and audio conditions (P<.05), with the latter showing broader improvements, including thought negativity, rumination, tension, depression, distress, and confusion (P<.05).

Conclusions: The VR cognitive defusion application was feasible, safe, and acceptable for young people, with potential to enhance mental health treatment through an engaging and enjoyable approach to learning third-wave cognitive behavioral therapy techniques. While VR was preferred by participants, further refinements could improve effectiveness. Future research should focus on enhancing the VR application design based on user feedback, incorporating audio guidance, and conducting a larger trial in real-world settings to thoroughly evaluate the effectiveness and implementation of the VR application.

Introduction

Background

Virtual reality (VR) is an emerging technology with the potential to transform mental health treatment [1-3]. VR immerses users in a virtual environment through a headset, allowing for real-time interaction with virtual objects via hand controllers or motion sensors. The ability to tailor and control experiences within VR offers a unique opportunity to enhance mental health interventions by delivering treatments in personalized, simulated real-world environments that provide strong ecological validity [2]. While meta-analyses have supported the efficacy of VR treatments for various mental disorders in adults [2,4], its application in youth mental health remains critically underexplored [5,6].

Mental disorders emerge before the age of 25 years in 75% of cases [7,8], representing a critical time for early intervention [9]. Anxiety and depression are the most prevalent disorders among youth, with 1 in 4 young people meeting the diagnostic criteria [10]. Despite high rates of mental ill-health among young people, current treatments remain limited, with small treatment effect sizes, poor engagement, and high relapse rates [11-13]. VR offers innovative solutions to these challenges by providing a potentially engaging, effective, and accessible vehicle for treatment [1]. Young people widely use digital technologies in their day-to-day lives and have shown interest in VR for mental health support [14]. With consumer adoption of VR technology predicted to rise over the coming years [15], it is timely to expand the existing evidence base and explore the therapeutic potential of this technology for young people with mental ill-health.

The past decade has seen a rapid increase in the number of studies exploring the use of VR for the treatment of mental disorders [2,16]. Most of this research has focused on VR-based cognitive behavioral treatments (VR-CBTs) [16]. VR-CBT typically involves exposure to anxiety-inducing stimuli in virtual environments guided by a clinician (eg, Pot-Kolder et al [17]). Randomized controlled trials have provided robust evidence supporting the efficacy of VR-CBT in improving outcomes in anxiety disorders, psychosis, eating disorders, and trauma-related conditions in adults (see Bell et al [2] for a review). However, relatively limited research has explored the potential therapeutic applications of VR beyond exposure-based cognitive behavioral therapy (CBT) approaches, and research in youth is highly limited [2,5,6,16].

Third-wave psychological treatments such as acceptance and commitment therapy (ACT), dialectical behavior therapy, and mindfulness-based cognitive therapy [18] may be particularly well suited to VR. While second-wave CBT focuses on modifying maladaptive thoughts that drive problematic behaviors, third-wave approaches focus on adapting the relationship between the individual and their mental processes as well as targeting broader values and life goals [18]. Third-wave approaches typically use experiential techniques to shift the dynamic between the individual and their mental experiences to foster more adaptive and flexible ways of responding to them. For example, cognitive defusion, a core technique within ACT [19-21], aims to help individuals separate themselves or "defuse" from distressing thoughts and emotions, often using experiential and conceptual techniques such as metaphors and visualization. In the context of psychological treatment, cognitive defusion exercises typically involve a therapist guiding individuals to imagine negative thoughts in ways that are incongruent with their existing emotional relations with them (eg, singing the negative thought to the tune of "Happy Birthday"). By viewing and relating to these thoughts in nonliteral and often paradoxical ways, individuals can shift the negative associations they have with these thoughts and "defuse" or "decenter" from them, viewing them as fleeting and nonthreatening rather than literal facts. The process of decentering has been highlighted as a core "active ingredient" underpinning effective interventions for youth depression and anxiety [22,23], particularly in fostering objective and flexible ways of responding to negative thoughts and emotions.

Third-wave psychological treatments have demonstrated effectiveness in improving depression and anxiety in youth and adults [24-26]. However, while core techniques such as cognitive defusion can be highly effective for some individuals [19,21,27], young people can find it challenging to conceptualize their internal experiences in abstract ways, limiting the effectiveness of the technique and engagement with treatment [28]. Recognizing this, Halliburton and Cooper [28] emphasize the importance of adapting ACT for the developmental needs of adolescent populations. To accommodate emerging cognitive development in adolescence, the authors recommend that techniques be brief, simple and concrete, highly interactive, and experiential. The use of creative tools and activities can also promote engagement. VR technology is highly suited to supporting these adaptations by transforming the way in which these techniques are taught and learned. Immersive environments enable individuals to directly observe and interact with their mental processes through virtual representations, bypassing the need for abstract thinking and visualization. This approach facilitates skill mastery through playful, low-risk encounters and may boost the positive effects of techniques such as cognitive defusion by translating them from abstract and conceptual into something more literal and concrete. Furthermore, by learning and practicing these skills within personally relevant virtual environments, young people may be more likely to apply these skills in everyday life. Harnessing gamification in VR environments to create a more motivating, fun, and low-risk learning experience could also enhance the goal of these techniques to change the nature of the relationship between the individual and their thoughts while also addressing barriers to treatment engagement. When used as a blended tool [29], clinicians could use VR within sessions to guide young people to learn and practice third-wave skills in safe and controlled VR environments to facilitate their translation into real-world settings. In addition, young people could use the intervention independently to manage and cope with mental health challenges as they arise. Such brief, flexible, and engaging VR-based therapeutic tools have the potential to enhance engagement and treatment efficacy as well as increase access to on-demand support in daily life.

XSL•FO
RenderX

A study by Prudenzi et al [30] investigated a VR-based cognitive defusion task in a nonclinical sample of young adults and found that the task reduced the believability and discomfort associated with negative thoughts. A small number of studies have also examined the use of VR for related techniques such as mindfulness [31-34], with preliminary evidence of positive outcomes. However, this research is at the very early stages with predominantly single case studies and typically involves populations of adults without a mental health condition. Furthermore, while many claim that VR has advantages over and above standard face-to-face therapeutic approaches, limited research has been conducted to test this empirically. This research is critically needed to provide a strong foundation for ongoing development of VR-based interventions for youth mental health.

Study Aims

To investigate the potential of VR for supporting third-wave treatment of youth depression and anxiety, a prototype application was developed that translated the technique of cognitive defusion (the primary target mechanism) into a personalized, immersive, gamified VR experience. The aims of this mixed methods experimental study were to (1) evaluate the feasibility, acceptability, usability, and safety of the VR cognitive defusion application; (2) explore whether the VR cognitive defusion application could reduce negative thinking and improve mood states; and (3) gather feedback from young people on how the VR cognitive defusion application experience compared to a non-VR audio-guided cognitive defusion exercise.

Methods

Study Design

The study design was a crossover, repeated measures, mixed methods experimental study. This involved all participants being exposed to 2 forms of cognitive defusion exercises sequentially and in a randomized order: one through a VR application and the other via a traditional audio exercise. Exposing all participants to both exercises in a randomized order enabled the examination of how the two compared.

Participants

Participants (N=20) included young people who were recruited via *headspace* services across Metropolitan Melbourne, Victoria, Australia. *headspace* is a nationwide organization delivering mental health treatment for youth aged 12 to 25 years across Australia. Current and previous clients of 4 *headspace* centers in the metropolitan region of northwest Melbourne were approached for the study. The sample size was deemed appropriate to meet the primary aim of assessing the acceptability, usability, and safety of the VR intervention, as well as exploring whether there were preliminary effects on state-based outcomes [35]. Informed consent was obtained from participants before their commencement, with additional parent or guardian consent obtained for participants aged <18 years. Participants were eligible to take part if the following inclusion criteria were met: (1) aged between 16 and 25 years, (2) normal or corrected-to-normal vision and hearing, (3) clinical levels of depression or anxiety (score of ≥10 on the 8-item Patient Health Questionnaire [PHQ-8] [36] or 7-item Generalized Anxiety Disorder scale [GAD-7] [37]), (4) high levels of repetitive negative thinking (RNT; score of ≥15 on the Brief Penn State Worry Questionnaire (Brief PSWQ) or ≥9 on the Brief Ruminative Response Scale (Brief RRS) [38]), and (5) sufficient command of the English language.

Exclusion criteria were (1) inability to provide informed consent, (2) history of photosensitive epilepsy or previous experience of severe simulator sickness, and (3) being a psychiatric inpatient or under the care of a mental health crisis team.

Procedure

Overview

Participants were screened for eligibility over the phone, with those eligible then booked for the in-person consent and testing session. This 90-minute session involved informed consent and a baseline assessment followed by the experimental procedure.

The experimental procedure involved being allocated to complete one of two possible intervention sequences via simple randomization: (1) VR defusion exercise followed by audio defusion exercise or (2) audio defusion exercise followed by VR defusion exercise. Both exercises were matched in terms of duration and took approximately 10 minutes each to complete. The session was conducted in a private clinical space with a researcher.

Pretest-Posttest Assessments

Participants completed measures at baseline (T1); after they completed either the VR or audio exercise first (T2); and again following their completion of the alternate exercise, VR or audio (T3). Following T3 questionnaires, participants completed a brief qualitative feedback interview of their experience with a research assistant, which lasted an average of 8 (range 4-26) minutes.

Explanation of Cognitive Defusion

Regardless of which order the exercises were completed in, participants were provided with a short explanation of cognitive defusion and how it can help people disconnect from their distressing thoughts before completing the first exercise (adapted from an ACT manual [39,40]). This was delivered by the researcher using a script (Multimedia Appendix 1).

Rumination Induction

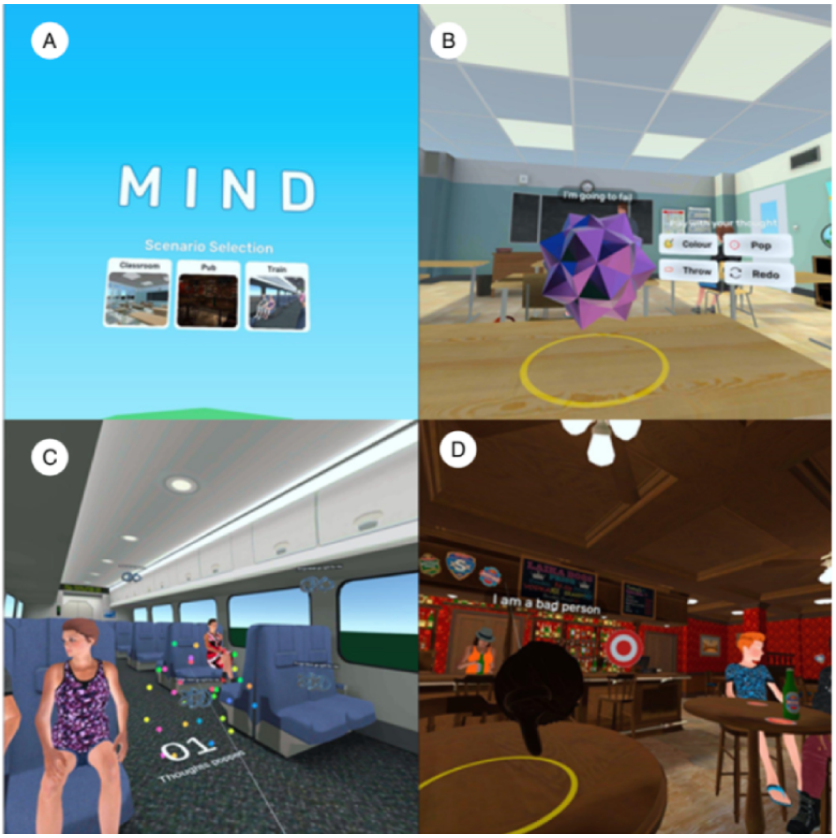
Following the protocol by Masuda et al [21], before each exercise, a brief rumination induction procedure took place in which participants were prompted to choose and reflect on a negative thought that had been distressing them recently and keep this in mind during the exercises. This procedure was embedded within the Negative Thought Assessment (NTA) [30,41,42] described in the Measures section.

Conditions

Overview

In total, 2 experimental conditions were designed for this study: the VR exercise and an audio exercise.

XSL•FO
RenderX



Both experimental conditions were designed to guide users through 2 different forms of cognitive defusion, as described in the Introduction section. The 2 conditions were informed by practices commonly used in ACT, the approach from which defusion was developed [39,40].

VR Condition

The VR application was preloaded onto an Oculus Quest 2 VR headset for the purpose of this study. The research assistant conducting the session invited participants to wear the VR headset and explained how to use the hand controllers. Participants were informed at the start that they could stop the exercise at any time if they became distressed or uncomfortable. They were encouraged to complete the exercise from a standing position to allow for range of movement, but an option for completing the exercise in a seated position was also available. Before beginning the exercise, a verbal check of visual and audio clarity was conducted by the researcher.

When participants launched the VR application, they were presented with a menu screen showing 3 different environments to choose from: a classroom, a pub, and a train (Figure 1A). These environments were designed based on user consultations with young people with lived experience of mental health difficulties and clinicians that highlighted these as common environments where negative thoughts were experienced. Participants were encouraged to choose the environment in which they felt that their negative thoughts were most likely to occur. When each participant entered the environment, they were faced with an animated object and instructed to imagine this as representing the thought they had been struggling with. They were then guided to customize the thought by typing it in using a virtual keyboard presented to them within the scene or selecting from prefilled thought prompts (eg, “I’m going to fail,” “I am being judged,” or “I am a bad person”). The thought was then represented in the environment as text above the animated object (Figure 1B). Participants were then instructed to interact with their chosen thought and manipulate it in different ways using the hand controllers. These options included customizing its shape and color, picking it up and moving it around in the environment, and making the thought float upward above them. Among the options were also two games that they could play with the thought object: (1) “popping” the thought objects as they appeared around them to receive points (Figure 1C) or (2) throwing the thought at targets that appeared in the environment to receive points (Figure 1D).

Figure 1. Scenes from the virtual reality cognitive defusion application.

Throughout the exercise, participants were guided by the researcher. The researcher followed a verbal script (Multimedia Appendix 1) supporting the participant in exploring their negative thought in a visual form with curiosity and acceptance. The verbal script mirrored the audio defusion script with slight variations to accommodate the VR experience. The full experience lasted 10 minutes. Once the exercise was finished, participants were prompted to remove the VR headset.

Audio Condition

The audio condition was designed to use the same defusion principles and identical instructions but in a non-VR format using the participant’s imagination. In a traditional psychological treatment setting, clinicians would typically guide the individual through the exercise following a verbal script spoken aloud in the session. For the purposes of this study, a standard

XSL•FO
RenderX

prerecorded guided audio exercise was used (see Multimedia Appendix 1 for the script). In the exercise, the participant was guided by a single voice without any background noise or effects. The voice instructed the listener to identify a target negative thought and think about it in different ways, such as imagining their thought as having different colors, shapes, forms, and contexts. These interactions were designed to match those of the VR exercise in that individuals were guided to think of environments where they were likely to experience negative thoughts and then instructed to visualize interacting with them in the same ways using their imagination. Participants listened to the audio exercise via headphones through an iPad device, remaining in a seated position, with the researcher remaining in the room to monitor for any signs of distress. The length of the audio exercise was 10 minutes to match the VR exercise.

Measures

The protocol for this study was developed in collaboration with young people with lived experience of a mental health condition. Questionnaire completion at each time point took approximately 10 minutes, and no participants reported discomfort, fatigue, or disengagement.

Demographics and Technology Use

Basic demographic information was collected, including age, gender, country of birth, Aboriginal or Torres Strait Islander origin, languages spoken at home, current living situation, and which *headspace* service they were a client of.

Questionnaires were used to collect experiences with technology use, including whether they owned a smartphone, laptop, or desktop computer and how many hours per day they used each owned device. Participants were asked about the ways in which they had sought or engaged with health support in the past (eg, email, phone, or online information). Previous experience with VR use was also collected. Those who reported previous use were prompted to complete additional items addressing the frequency of use (9-point scale ranging from "Very rarely" to "Several times an hour") and how comfortable they felt using VR (5-point scale ranging from "Very uncomfortable" to "Very comfortable"), as well as indicating whether they had used VR for therapeutic reasons (eg, mindfulness, relaxation, and exposure).

These measures were completed at baseline (T1).

Feasibility, Acceptability, Usability, and Safety

Feasibility

Feasibility was measured via recruitment and retention rates, as well as completion of study assessments and procedures.

Acceptability and Usability

A 14-item user experience questionnaire designed specifically for this study was used to evaluate and compare the usability and acceptability of both the VR and audio conditions. The questionnaire was designed to assess different aspects of the participants' experiences with the exercises. Respondents answered statements (eg, "I found the experience enjoyable") by rating their experience on a 5-point Likert scale ranging from 1 ("strongly disagree") to 5 ("strongly agree"), with higher scores indicating better user experience and acceptability. This measure was completed after each defusion exercise (T2 and T3).

ITC–Sense of Presence Inventory

This is a 44-item scale measuring sense of presence within a virtual environment. This measure captures the degree to which the user feels physically present in the virtual environment, the level of engagement, and negative effects (eg, motion sickness and eye strain). Respondents answer statements (eg, "I felt sad that my experience was over") using a 5-point Likert scale ranging from 1 ("strongly disagree") to 5 ("strongly agree"), with higher scores indicating greater user experience and acceptability. The ITC–Sense of Presence Inventory (ITC-SOPI) has been validated in adult populations and is commonly used in VR research [43]. This measure was completed following the VR condition only (T2 or T3 depending on the exercise order).

Safety

Safety was measured by monitoring potential adverse events during both exercises, responses to the negative effects, questions in the user experience questionnaire and ITC-SOPI [43], and questions in a qualitative interview described later in this section.

Clinical Measures

Participant characteristics were assessed using the following measures, which were completed at baseline (T1).

PHQ-8 Measure

The PHQ-8 is an 8-item scale commonly used to screen for depressive disorders. Respondents indicate the frequency of depressive symptoms experienced over the previous 2 weeks on a 4-point Likert scale ranging from 0 ("not at all") to 3 ("nearly every day"), where higher scores indicate greater severity of depression. Scores are summed, with scores of ≥10 indicating moderate to severe depressive symptoms. The PHQ-8 [36] has demonstrated good reliability and validity with adolescent populations [44].

GAD-7 Measure

The GAD-7 is a 7-item scale commonly used as a screener for anxiety disorders. Respondents indicate the frequency of symptoms of anxiety over the previous 2 weeks on a 4-point Likert scale from 0 ("not at all") to 3 ("nearly every day"), where higher scores indicate greater severity of anxiety. Scores are summed, with scores of ≥10 indicating moderate to severe levels of anxiety. The GAD-7 has good reliability and construct validity with adolescent populations [37].

Brief PSWQ Measure

The Brief PSWQ is a 5-item scale measuring tendencies toward worry. Respondents rate statements (eg, "Many situations make me worry") on a 5-point Likert scale from 1 ("not typical of me") to 5 ("very typical of me"), with higher scores indicative of greater trait worry. The scale has been validated in an adult population with good reliability and validity [38].

XSL•FO
RenderX

Brief RRS Measure

The Brief RRS is a 5-item scale measuring tendencies toward rumination. Respondents are asked to indicate how often they ruminate when they feel down, sad, or depressed. They indicate their response using a 4-point Likert scale ranging from 1 (“almost never”) to 4 (“almost always”), with higher scores equating to higher degrees of ruminative symptoms. This measure has shown good reliability and validity [38].

Repetitive Thinking Questionnaire–10

The Repetitive Thinking Questionnaire–10 (RTQ-10) is a 10-item scale used to measure tendencies toward RNT (a trait capturing the process of rumination and worry). Respondents rate statements capturing their tendency to engage in repetitive thinking when they feel distressed or upset using a 5-point Likert scale ranging from 1 (“not at all”) to 5 (“very true”), with higher scores reflecting greater tendencies toward RNT. The RTQ-10 has demonstrated robust internal consistency and convergent and divergent validity [45].

Therapeutic Process Measures

NTA Measure

The NTA scale was completed as part of the rumination induction procedure to elicit rumination and capture state-based responses to this experience. The NTA has been used in previous experimental studies to elicit rumination and measure the immediate effects of cognitive defusion exercises [30,41,42]. This measure prompts respondents to generate and reflect on a particular negative thought that they identify as upsetting, find hard to stop thinking about, or bothers them a lot. Respondents then rate the degree of discomfort (ie, “How uncomfortable is the thought”) and believability (ie, “How accurate or true do you think the thought is?”) and the perceived importance of the thought (“How important is it to you not to have this thought?”). One item used in the study by Prudenzi et al [30] was added to measure the degree of negativity of the thought (“How negative is the thought?”). All items are rated on a 10-point visual analogue scale ranging from 0 (not at all uncomfortable/accurate or true/important/negative) to 10 (very uncomfortable/accurate or true/important/negative). This measure was completed at baseline (T1) and following the first exercise (T2).

Toronto Mindfulness Scale–State Version

Toronto Mindfulness Scale (TMS)–State Version [46] is a 13-item scale measuring state mindfulness. Items are presented as statements referring to 2 constructs, decentering and curiosity, which are each scored as subscales. Decentering refers to psychological distance from thoughts, and curiosity refers to appreciation of thoughts with an accepting and curious attitude. Responses are scored on a 5-point Likert scale ranging from 0 (“not at all”) to 4 (“very much”), with higher scores indicating greater state mindfulness. The scale has demonstrated good reliability and validity, with good sensitivity to change over time [47]. This measure was completed following the first exercise (T2).

State Cognitive Fusion Questionnaire

The State Cognitive Fusion Questionnaire (SCDQ) is a 7-item scale measuring states of cognitive defusion. Items include statements referring to the experience of struggling or being entangled with distressing thoughts in the present moment. Respondents indicate their response on a 7-point Likert scale from 1 (“not at all true”) to 7 (“completely true”), with higher scores indicating greater levels of defusion. The SCDQ has demonstrated good internal consistency and construct validity in student samples [48]. This measure was completed at baseline (T1) and following the first exercise (T2).

Brief State Rumination Inventory

The Brief State Rumination Inventory (BSRI) [49] is an 8-item scale measuring state depressive rumination. Respondents indicate the extent to which each statement describes their feelings and thoughts in the immediate moment (eg, “Right now, I wonder why I react the way I do”) on a 100-point visual analogue scale ranging from 0 (“completely disagree”) to 100 (“completely agree”), where higher scores indicate greater state rumination. The scale has demonstrated good reliability and validity. This measure was completed at baseline (T1) and following the first exercise (T2).

Mood State Measures

Profile of Mood States–Adolescents

The Profile of Mood States–Adolescents (POMS-A) is a 24-item scale where respondents indicate how they feel in the moment across different mood items (eg, sleepy, energetic, and confused) using a 5-point Likert scale ranging from 1 (“not at all”) to 5 (“extremely”). Higher scores indicate greater overall mood disturbance. This scale has demonstrated good reliability and criterion validity in the assessment of mood in adolescent populations [50,51]. This measure was completed at baseline (T1) and following the first exercise (T2).

Subjective Units of Distress Scale

The Subjective Units of Distress Scale (SUDS) [52] is a 1-item scale in which respondents are asked to rate the level of anxiety that they are currently experiencing using a slider scale, with scores ranging from 0 (“no anxiety, calm”) to 100 (“very severe anxiety, worst ever experienced”). The scale is commonly used to measure states of distress during therapeutic exercises, with a higher score indicating greater state distress. This measure was completed at baseline (T1) and following the first exercise (T2).

Qualitative Interview

A brief semistructured qualitative interview was conducted by the research assistant at the end of the experimental study that inquired about the following:

- What was your experience of the VR exercise?
- How did the VR experience compare to the audio exercise?
- Which did you prefer out of the VR experience and audio exercise and why?
- Imagine that the VR exercise was taught to you in therapy by a psychologist:
  - Do you think there would be any benefits to the VR exercise over the audio exercise? Can you explain your answer?

XSL•FO
RenderX

- Do you think there would be any downsides to the VR exercise over the audio exercise? Can you explain your answer?

- Would you recommend the VR experience to other young people with difficult thoughts and why or why not?
- Is there anything you would change about the VR experience to make it better?

Analysis

Quantitative Data

Descriptive statistics were used to report the feasibility, acceptability, usability, and safety of the VR and audio conditions. Independent 2-tailed *t* tests and chi-square tests were conducted to test for differences between groups in baseline demographic and clinical characteristics. Repeated measures *t* tests and within-group effect sizes (Cohen *d*) were reported for changes in pre- to postexercise scores on state-based measures for the VR and audio groups. Only T1 and T2 scores on state-based measures within groups were compared (ie, pretest-posttest changes before and after the VR or audio exercises depending on the order) to avoid carryover effects into the second exercise. The primary measure of interest was the within-group effect size and associated CIs. The sample size was not powered to detect statistically significant differences between conditions but, instead, was selected to provide sufficient data to evaluate feasibility and inform understanding of whether the approach could engage target mechanisms and influence mood states as a proof of concept. This is a critical step in intervention development and validation, particularly in emerging areas such as VR-based therapy, and our study design reflects recommendations for pilot trials with small sample sizes [35].

Qualitative Data

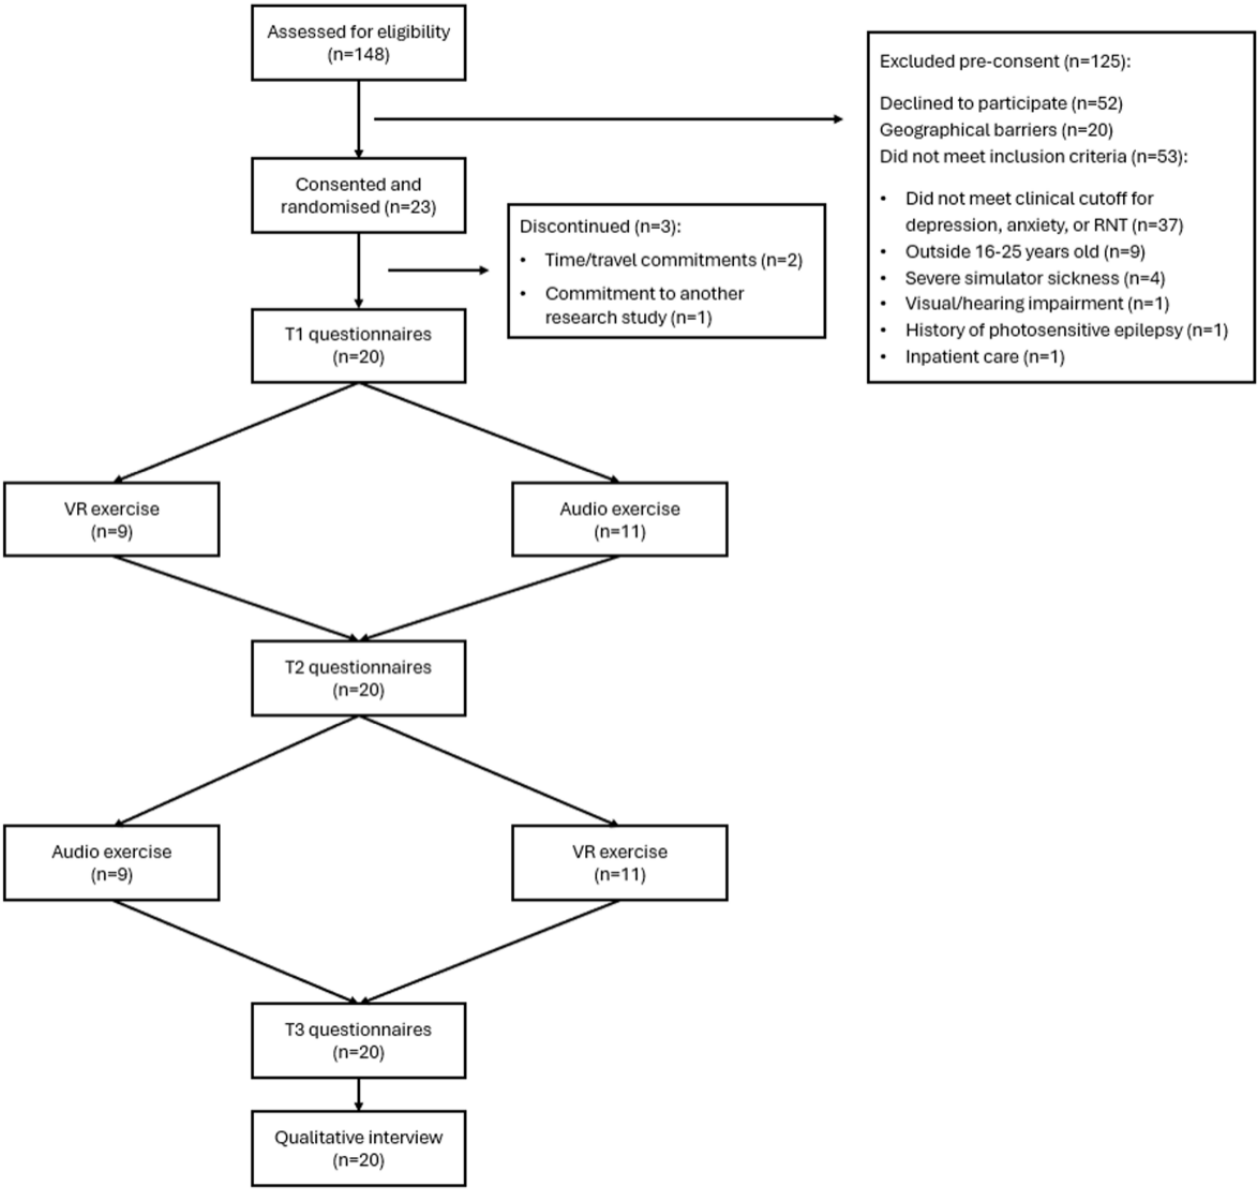
Qualitative data collected from interviews with participants were analyzed using reflexive thematic analysis guided by the approach by Braun and Clarke [53]. This method was chosen for its flexibility and suitability in exploring participants' subjective experiences. In total, 2 researchers (IHB and CL) independently read and coded an initial subset of 20% (4/20) of the transcripts to familiarize themselves with the data and inductively generate initial codes. They then met to discuss their interpretations, reflexively exploring their assumptions and positionalities, and developed a shared, flexible coding framework. The remaining transcripts (16/20, 80%) were coded using this framework, with regular discussions to review coding decisions.

Themes were developed through an iterative process of data engagement, coding, and theme refinement following the principles of reflexive thematic analysis. The final themes represent patterns of shared meaning relevant to the research question and were refined for coherence, internal consistency, and analytic depth. To enhance credibility and dependability, researcher triangulation, regular peer debriefing, and an audit trail of coding and theme development decisions were used. Reflexivity was maintained throughout via memos and ongoing discussion of interpretive lenses. Confirmability was supported by maintaining transparency in our analytic process and grounding the themes in rich data extracts. While we did not aim for statistical generalizability, sufficient contextual detail was extracted to support transferability to similar settings.

Ethical Considerations

This project was approved by the University of Melbourne Human Research Ethics Committee (ID 2056403.1). Participants provided written informed consent. All participants received a full explanation of the study in lay terms related to the aims, study procedures, and potential risks and benefits in taking part before providing informed consent. The participants were reminded that they could withdraw from the study at any time without prejudice. Participants were provided with a copy of the participant information and consent form and were reimbursed Aus $45 (US $28.94) for taking part in the study. All data were stored in a deidentified format within password-protected electronic files only accessible to the research team.

Results



Feasibility and Sample Characteristics

Figure 2 shows a CONSORT (Consolidated Standards of Reporting Trials) diagram of the recruitment and testing process. Of the 148 potential participants who were assessed for eligibility for the study, 95 (64.2%) were eligible. Of the 95 eligible participants, 23 (24%) were interested and completed consent procedures. In total, 13% (3/23) of the participants dropped out between consenting and the baseline assessment, with a total of 20 participants being randomized (n=9, 45% to the VR-first condition and n=11, 55% to the audio-first condition). The most common reason for nonparticipation was declining interest to participate, followed by difficulties attending the session due to travel or location issues and not meeting the inclusion criteria. Most participants did not meet the inclusion criteria because they scored below the cutoffs for severity of RNT. A total of 3 participants who consented did not attend the session, 2 (67%) due to difficulties with travel and the other (33%) due to enrollment in another study that precluded their participation. All 20 participants who attended the session completed both the VR and audio exercises, assessments, and the interview, indicating a 100% (20/20) retention rate.

Table 1 summarizes the demographic and clinical characteristics of the sample. The sample were mostly in their early 20s; relatively evenly split across male, female, and transgender individuals; and born in Australia, with none identifying as Aboriginal or Torres Strait Islander. Approximately half (8/19, 42%) of the sample were receiving current mental health services, and the other half (11/19, 58%) were not. Clinical scores indicated that the sample was experiencing moderate to severe depression and anxiety, with high levels of RNT. There were no significant differences between groups on any baseline demographic or clinical variable (P>.05).

A summary of the use and familiarity of the sample with VR technology and use of digital technologies for mental health support is provided in Multimedia Appendix 1. These data indicate that the sample had previously used a range of digital technologies to support their mental health; however, none had used VR for therapy previously. Two-thirds of the sample had used VR before, and most were very comfortable, but average use was very infrequent.

Pretest-Posttest Changes

A 2-tailed repeated measures *t* test was used to explore changes in state-based variables before and after the VR and audio exercises. As this study was not powered to detect effects, it should be noted that patterns of effect sizes across outcomes provide the most meaningful interpretation of changes in clinical measures. As shown in Table 2, for the VR condition, there were large and statistically significant improvements in thought discomfort, cognitive defusion, and state anger. There were

XSL•FO
RenderX

moderate but nonsignificant improvements in thought negativity; thought accuracy; thought importance; state rumination; and state tension, depression, fatigue, confusion and vigor, and subjective distress. For the audio condition, there were large and significant improvements in thought negativity, thought discomfort, cognitive defusion, state rumination, state tension, depression, anger and confusion, and subjective distress. There were moderate but nonsignificant improvements in thought accuracy and state fatigue and very small improvements in state vigor. Levels of mindfulness were slightly higher on average in the audio condition than in the VR condition, and this difference was more pronounced for the decentering subscale relative to the curiosity subscale.

User Experience and Satisfaction

Participant feedback on the user experience of the VR and audio exercises is shown in Table 3. Individual item scores suggest that both the VR and audio exercises were rated positively; however, VR tended to be viewed as more fun and engaging but less comfortable, more confusing, and less of a learning experience compared to the audio condition.

Table 3. Participant feedback for the virtual reality (VR) and audio exercises from the user experience questionnaire (N=20).[a]

	VR exercise, mean (SD)	Audio exercise, mean (SD)
"I found the experience enjoyable."	4.11 (1.05)	4.27 (0.65)
"I found the experience fun."	4.56 (0.53)	3.64 (0.93)
"I found the experience comfortable."	3.78 (1.09)	4.45 (0.82)
"I found the experience interesting."	4.56 (0.53)	4.73 (0.47)
"I found the experience engaging."	4.44 (0.73)	4.27 (0.65)
"I found the experience easy to do."	4.33 (0.87)	4.27 (1.01)
"I learnt something from the experience."	3.56 (1.42)	4.55 (0.52)
"I would like this sort of experience to be a part of therapy."	4.11 (1.05)	4.45 (0.69)
"I would be likely to do this experience in my own time."	4.22 (0.97)	4.36 (0.67)
"I would be motivated to do this experience again."	4.33 (0.71)	4.64 (0.67)
"I would recommend the experience to other people with depression and/or anxiety."	4.33 (0.87)	4.64 (0.67)
"I found the experience confusing."	2.44 (1.59)	1.45 (0.52)
"I found the experience boring."	1.11 (0.33)	1.55 (0.69)
"I found the experience upsetting or distressing."	2.22 (1.48)	2.00 (0.89)

[a]Scale range from 1 (*strongly disagree*) to 5 (*strongly agree*); ratings were pooled across the entire sample regardless of the order of the exercises.

Level of Presence in VR

Table 4 shows the subscale scores for the ITC-SOPI. The pattern of scores supported a moderate to high level of spatial presence, indicating that participants felt a reasonable degree of "being there" in the virtual environment. The highest score was for engagement, indicating that participants felt moderately involved and interested in the VR experience. Ecological validity and naturalness was relatively low, suggesting that, while the VR environment was somewhat convincing and behaved in a way that users expected, there could be improvements in making the environment and interactions feel more realistic. The low average score on negative effects suggests that participants generally did not experience significant discomfort, disorientation, or other adverse effects while using the VR application, supporting that it was well tolerated.

XSL•FO
RenderX

Table 4. Subscale scores on the ITC–Sense of Presence Inventory.[a]

Subscale	Scores, mean (SD)
Spatial presence	3.32 (0.79)
Engagement	3.82 (0.55)
Ecological validity and naturalness	3.07 (0.97)
Negative effects	1.81 (0.72)

[a]Scale range from 1 (*strongly disagree*) to 5 (*strongly agree*).

Qualitative Feedback

All 20 participants provided feedback in a qualitative interview after they had completed both the VR and audio exercises. The themes arising from these interviews and representative quotes are described in the following sections.

VR Is "New, Different, and Engaging"

> *I prefer the VR one mainly because...it's something I don't think I've ever really tried before and it's something new and different and engaging.* [Participant 51; male; aged 19 y]

All young people interviewed (20/20, 100%) reported preferring VR over the audio exercise. Reasons for this preference centered on VR being perceived as a more engaging, novel, and interesting way of learning psychological techniques. Young people were interested in the novelty of VR as "something that I haven't really done before" (participant 91; male; aged 21 y), "just a whole different perspective" (participant 91; male; aged 21 y), and a "very interesting and new type of therapy" (participant 42; female; aged 25 y). This uniqueness was perceived as "new and fresh" (participant 61; male; aged 21 y), "fun" (participant 66; nonbinary; aged 20 y), "cool" (participant 72; female; aged 19 y), and "progressive" (participant 44; female; aged 21 y) relative to the audio, which was seen as "nothing new" (participant 61; male; aged 21 y). It was described as "very important to attract young people's interest" (participant 42; female; aged 25 y) as a way of "getting young people to engage with their mental health" (participant 91; male; aged 21 y). In addition to the novelty of VR, the "fun" (participant 46; other; aged 16 y) and "enjoyable" (participant 66; nonbinary; aged 20 y) aspects of the experience were also seen as an important way of engaging young people:

> *...being able to do something fun as well as therapy, like it makes it a lot better in my opinion.* [Participant 85; female; aged 16 y]

VR Facilitated Cognitive Defusion

> *...being able to have this distressing thought and then turn it into something that seemed really not important, and being able to interact with it in a way where I can really visualise it...I think it just sort of helps with that, compartmentalizing of thoughts.* [Participant 64; female; aged 24 y]

Consistent with the aims of cognitive defusion, some young people described that the act of physically interacting with their thoughts made it easier to separate from them:

> *It's kind of harder to see it as a fact when it when you can like so easily manipulate it.* [Participant 44; female; aged 21 y]

Key to this was the interactive and visual element, where they could "see and actually like interact, rather than just sit there and try to imagine" (participant 86; female; aged 17 y).

The process of physically acting out the technique was described as "easier" (participant 71; female; aged 24 y) compared to "mindfulness stuff where you're just listening, you're just like, I feel like it takes a lot of like activation energy to get yourself to do it. Whereas with the VR, like throwing for example like you're just throwing and the mindfulness comes like secondarily" (participant 61; male; aged 21 y). However, many young people saw value in the audio exercise as well, with both offering different outcomes:

> *I think the audio exercise was more relaxing and then the VR exercise was more engaging and, yeah so two different things, and they had two different outcomes.* [Participant 91; male; aged 21 y]

Young people also described that the immersive environment helped them focus more actively on the exercise with less distraction:

> *I just had a fun time and wasn't distracted at all. I was paying a lot of attention.* [Participant 91; male; aged 21 y]

Some found that this meant that they "could learn a lot more" (participant 85; female; aged 16 y). Some felt that this greater focus meant that VR was "probably a little bit more effective" (participant 44; female; aged 21 y) because it enabled them to be "totally involved" (participant 44; female; aged 21 y), whereas "during the audio, I still had like random thoughts coming to mind and you know, partly focusing on that, partly focusing on the audio, but in the VR I was like totally in the VR" (participant 44; female; aged 21 y).

Gamification May Create Disconnection From the Technique

> *VR could potentially be distracting, that you're in a game and you're more like, oh, this is a game rather than doing therapy.* [Participant 46; other; aged 16 y]

Some young people questioned whether the gamified element undermined the therapeutic intent of the VR experience. The opportunity for distraction from thoughts had appeal but risked not addressing the core issue:

XSL•FO
RenderX

> *I do like to be distracted by my thoughts often and kind of like, yeah, even though it doesn't fix the problem.* [Participant 72; female; aged 19 y]

The generalizability of the skill beyond the immediate experience into everyday situations was also questioned by 10% (2/20) of the young people:

> *...how much crossover is there between when you do that with the VR headset...and being able to take that away and then still be get into that visualising sense without it.* [Participant 61; male; aged 21 y]

> *...whenever I do get a negative thought, I just can't throw it or pop it.* [Participant 86; female; aged 17 y]

Implementation Considerations

> *This is an experience that I'd want to do again in the future and in a therapeutic setting.* [Participant 91; male; aged 21 y]

Young people supported the idea of the VR application being used within therapy, describing it as "something that would be very interesting to a lot of people, especially young people" (participant 91; male; aged 21 y). The appeal of using the VR application within treatment centered on the opportunity to "get [young people] through the door" (participant 91; male; aged 21 y) and "probably make them inclined to stay because of how interesting it is" (participant 91; male; aged 21 y). Some also mentioned the potential for the VR application to help strengthen the therapeutic relationship by creating "common ground" (participant 61; male; aged 21 y) as the young person was able to talk through their interactions within the VR. However, the need for appropriate supports for both young people and clinicians was mentioned, including training and guidance on how to introduce and support young people in using VR more generally, such as a "PDF that they have on hand" (participant 91; male; aged 21 y). Young people also warned that it would "take some time to get familiar with it" (participant 42; female; aged 25 y).

The biggest perceived barrier to using the VR application was the cost of VR headsets and production of the software:

> *The only downside that I can see is that it costs money to do. Yeah, since VR isn't very cheap.* [Participant 91; male; aged 21 y]

Challenges accessing the equipment were mentioned in terms of both home use and clinical settings, with a need for "centres and clinicians being able to get access to VR headsets and set them up and keep up with the IT and the maintenance" (participant 61; male; aged 21 y).

A number of young people reported that the VR application may be particularly well suited to specific clinical populations, particularly those with attention difficulties or for whom abstract mental thought was challenging. They reiterated the appeal of the VR application for young people with depression and anxiety who might benefit from separation from thoughts:

> *I think a lot of people like struggling with depression anxiety could sometimes be like yeah, angry at themselves or angry at other people, and it just was very like satisfying being able to like, let that go.* [Participant 72; female; aged 19 y]

The VR application was also seen as potentially beneficial for young people with attention difficulties as a way to facilitate focus without distraction:

> *I think that VR could be a lot better for young people who suffer with ADHD and other types of attention deficits, especially since sitting there for 10-15 minutes might be hard for people who are a bit restless.* [Participant 91; male; aged 21 y]

Future Changes to the VR Application

When asked directly what changes they would make to the VR application, most young people reported minor suggestions. This included expanding the range of exercises, including "visualisation activities...could really be awesome, like the classic, like, you have a negative thought and just stick it on a cloud. And see it go away. You can literally make that" (participant 61; male; aged 21 y). Several young people also suggested combining the audio and VR exercises to gain the added benefit of both:

> *...the headset itself like provides that sort of like audio guidance would be nice.* [Participant 64; female; aged 24 y]

Improvements to the user interface were mentioned as a priority, including clearer instructions for controls and interactions. Many young people suggested expanded options for personalization. As there were only 3 options of environments to choose from, some young people suggested that "there might be like some people that like don't really resonate with any three of them" (participant 72; female; aged 19 y) and that the environments could be "a little more realistic to my situation" (participant 44; female; aged 21 y), with suggestions to add "more options" (participant 71; female; aged 24 y) such as "a university classroom rather than like a school" (participant 44; female; aged 21 y). One young person suggested that nonrealistic environments that draw on traditional visualizations, such as representing thoughts as clouds, may also be appealing.

Some commented that the characters and environments could appear more realistic, with some avatars described as "a little bit creepy looking" (participant 61; male; aged 21 y), which could break immersion:

> *I just found the people really weird and just sort of took me out of it because they were doing very stiff or weird sort of motions.* [Participant 51; male; aged 19 y]

However, most young people found the graphic style acceptable.

Safety and Adverse Events

One young person experienced some distress during the VR exercise and requested to stop. This participant found the experience of manifesting a distressing thought in VR confronting; however, they were able to continue and complete the postassessment and interview at their request following a break and some reassurance. They were contacted the following day and reported no persisting discomfort or distress. No other participants reported adverse events during the study. In the

XSL•FO
RenderX

qualitative interview, negative experiences of the VR application were mentioned by 10% (2/20) of the young people. One described feeling "a bit panicky and anxious in the VR experience, but it was OK to like kind of push through" (participant 67; nonbinary; aged 22 y). Another young person described that "thinking about the thought was quite distressing, but it was also helpful with the interactive bit" (participant 94; male; aged 24 y). No participants reported experiencing any cybersickness.

Discussion

Principal Findings

This study explored the potential of using VR to support third-wave CBT [18] for young people with depression and anxiety. To achieve this, a prototype VR application was developed, which involved a brief, interactive cognitive defusion exercise within personalized virtual environments. Using a mixed methods experimental approach, this study sought to investigate the feasibility, acceptability, usability, and safety of the VR application; explore whether it could improve negative thinking and mood states; and understand young people's experiences of this new VR treatment approach. Participants in this study completed both the VR and audio defusion exercises within a single session in a randomized order to enable an understanding how these experiences compared. Key results indicated that the VR application was feasible, safe, and acceptable to use. However, the pattern of effects across the 2 conditions suggested that the audio exercise may have led to greater immediate improvements in certain mood states despite qualitative themes indicating that VR was preferred by participants.

While the small sample precludes generalizable interpretations, the results of this study suggest that a single session of VR cognitive defusion can lead to reduced discomfort with negative thoughts and state anger and increases in cognitive defusion. This provides proof-of-concept evidence that the application can engage the target mechanism of cognitive defusion (pretest-posttest effect size=1.01). Acceptability ratings indicated that the intervention was perceived to be enjoyable and the environment was immersive and engaging, with the experience well tolerated with minimal adverse effects. Qualitative themes supported these quantitative results, with young people reporting that the physical interaction and visualization of VR provided a more concrete and interactive learning experience that helped them separate from their negative thoughts and that it was more fun and interesting compared to the audio exercise. Young people reported that these benefits may be particularly important for those who struggle with understanding abstract therapeutic concepts, such as those with autism spectrum disorders, or those who have attention and concentration difficulties such as attention-deficit/hyperactivity disorder. These perspectives align with literature emphasizing the need to tailor third-wave therapy approaches to the cognitive developmental stage of adolescents [28]. This is also consistent with the perspectives of clinicians and individuals with lived experience of developmental disorders, who advocate for novel therapeutic strategies that better accommodate sensory needs and learning styles, including VR [34]. This includes adapting exercises to be interactive, experiential, creative, interesting, and behaviorally focused. Both qualitative themes and acceptability survey responses suggest that VR can be used to support these adaptations and that this is valued by young people.

Despite the preference among young people for the VR application and its positive effects on some outcomes, effect sizes were larger in the audio condition. While the small sample size prevented between-group comparisons and, overall, the interpretation of results must be approached with caution, this finding suggests that the defusion exercise delivered via audio may have led to greater improvements in mental states than those achieved with VR. Previous research on VR-based cognitive defusion is limited, with only 1 study to the authors' knowledge by Prudenzi et al [30] finding that a VR defusion task reduced thought believability and discomfort compared to a nondefusion VR control. Our study also showed improvements in these domains for the VR defusion task; however, the audio showed more favorable effects. One explanation for this difference is the choice of comparator. In this study, the control condition was a non-VR, audio-based defusion task that produced stronger effects, suggesting that audio guidance may be more effective in facilitating cognitive defusion. Other relevant studies have examined VR-guided meditation, finding that users tend to prefer VR over nonimmersive formats (eg, audio, video, or text) due to its novelty, immersion, and engagement [54-56]. However, unlike our findings, VR-guided meditation has generally been associated with greater improvements in positive mood states than non-VR meditation, with less consistent effects on negative mood states. One possible explanation is that VR's sensory richness may support mood regulation in meditation by enhancing absorption and presence in the environment, whereas it may increase cognitive load and interfere with techniques such as cognitive defusion that require more cognitive effort to achieve abstract mentalization. Indeed, previous research [57] has found that the novelty of VR can hinder learning by increasing cognitive load as users adjust to the unfamiliar interface and immersive experience, potentially diverting attention from the intended task. Future research should explore ways to optimize VR-based defusion, such as simplifying visuals, adjusting interactivity, and selecting or tailoring virtual environments and scenes.

Another possible explanation for these findings is that the way in which the exercises were delivered influenced how participants engaged with their thoughts, particularly in terms of cognitive focus and mental manipulation. Cognitive defusion and related third-wave CBT techniques typically encourage individuals to sit with uncomfortable thoughts and view them as separate to the self [19-21]. This is a highly reflective process that requires individuals to focus and mentally manipulate their thoughts using their imagination. The audio exercise may have been more effective at achieving this due to the lack of external distractions, forcing participants to focus their attention on the thought. In contrast, the VR exercise involved creating a visual object to externalize the thought within a virtual environment and interacting with it in gamified ways. By externalizing the thought so directly, individuals may have lost the connection between the internal representation of their thought and, instead,

XSL•FO
RenderX

related to the object as an external entity, thus losing the level of focus and mental manipulation required for successful cognitive defusion. Furthermore, the gamification element may have counterproductively enabled participants to experientially avoid their negative thoughts and further sever the connection between the object and their internal representation. This theory is supported by qualitative interview themes, in which some participants described the VR exercise as potentially being a fun distraction, which may have undermined therapeutic learning, as well as by the description of the audio requiring "more energy." This explanation suggests that, for the VR cognitive defusion exercise to be effective, individuals must maintain a connection between the symbolic thought in the virtual environment and its internal representation for them to effectively internalize the experience.

Another explanation for the findings is that the level of guidance and explanation within the VR exercise was insufficient to support young people in applying the skill of cognitive defusion in the moment. Ratings on the acceptability measure suggest that the audio condition provided a better learning experience compared to the VR condition. Given that VR is a highly engaging visual medium, participants may have become either too distracted or potentially overwhelmed by the exercise in a way that reduced their focus on the core exercise, thus undermining their learning. This aligns with aforementioned research indicating that the novelty of VR can hinder learning, suggesting the need for a prelearning phase to help users acclimate to the environment before therapy or a structured approach to gradually build toward more complex tasks [57]. Indeed, a small number of young people did report becoming distressed by the experience in VR. While this did not appear to have a lasting effect, it may have undermined their ability to engage with the exercise. Other factors that may explain these effects could be the dosage as a single session may be insufficient to induce effects for VR, as well as a potential "delayed" response in which effects might be observed for a longer period than in the audio exercise. Indeed, participants described VR as being more fun and exciting compared to the audio, which was more relaxing. It might be that the audio achieved its therapeutic benefits by lowering arousal, leading to more immediate improvements in mood states. In contrast, given the level of immersion and engagement in the VR experience, participants may have been left feeling more activated. This is supported by the effect of the VR application on increasing vigor, whereas the audio did not show such effects on this outcome. In contrast, the audio had a much stronger effect on reducing tension. Thus, the immediate aftereffects of VR might not be the ideal time frame to uncover beneficial outcomes.

Despite these findings, young people in this study clearly endorsed the VR application as a valuable clinical tool, with all young people reporting that they preferred it over the audio experience. A central theme to this preference was the novelty of VR and the opportunity to engage young people in treatment using a new and interesting approach. This is consistent with a previous study examining the addition of VR within a mindfulness intervention for generalized anxiety in adults, which found that those who received the addition of VR were more likely to complete the intervention compared to those who did not [31]. Given that engagement with treatment is a key challenge in youth mental health care [11], this opportunity is significant. However, in considering the contrasting findings indicating that the audio condition yielded greater effects despite VR being preferred by participants, it is important to recognize the potential novelty effect of VR. The initial appeal of VR may contribute to a "digital placebo" effect [58] where therapeutic effects and engagement benefits stem from the technology itself rather than the therapeutic content. Moreover, while novelty may drive short-term engagement, its impact may diminish over time, potentially reducing sustained effectiveness. Such novelty may have a greater impact on those with less VR experience and could be examined by comparing engagement across varying levels of previous VR exposure. Although we did not examine differences in engagement between participants with previous VR experience and those new to VR given sample size limitations, future research should investigate how previous exposure influences engagement and therapeutic outcomes. Studies incorporating nonactive VR comparators (eg, VR games) will also help disentangle the effects of novelty from the core therapeutic mechanisms, informing strategies to sustain engagement beyond the initial novelty phase.

Young people reported being particularly interested in using the VR application within a therapy session delivered by a clinician; however, they also reported a need for clear guidance and clinical protocols. This is consistent with qualitative studies [59,60] of clinician attitudes toward VR that emphasize the need to address implementation barriers, as well as with broader literature on the importance of working with end users to ensure that technologies are fit for purpose and appropriately designed for the implementation context [2,61]. In addition to opinions about the use of the VR application in clinical settings, young people also called for improvements to the user experience. This included an expansion to the range of activities and environments, improvements to the graphics and user interface, and more options for personalization. This study's findings also suggest that there should be improvements to the guidance offered within the experience to better support therapeutic learning. For example, several young people reported enjoying both VR and the audio exercises and suggested that a combination of both would be optimal.

In considering future iterations of the VR application, there may also be benefit in refining the therapeutic target. Specifically, the application may be better positioned as a treatment targeting decentering as a core underlying mechanism rather than an adaptation of cognitive defusion. Decentering is a broader concept that includes cognitive defusion and refers to the process of mentally separating oneself from one's thoughts and emotions, becoming aware of underlying thinking processes, and reducing emotional reactivity to mental events [22,23]. Decentering has been identified as a core component of psychological interventions for anxiety and depression by reducing the negative emotional impact of stressors, including inner events such as thoughts, feelings, and memories. Indeed, interventions that improve decentering-related processes have been shown to decrease depression and anxiety severity [22]. Decentering techniques typically rely on experiential exercises

XSL•FO
RenderX

drawn from third-wave approaches, which includes cognitive defusion as well as mindfulness and ACT. This collection of techniques share an experiential learning focus that may be well suited to VR due to the ability to physically separate and visually manipulate mental processes in an immersive way. Broadening the VR treatment package to include a wider range of techniques to achieve decentering may provide a clearer theoretical model for the intervention while offering additional learning opportunities that can be tailored to the specific needs and preferences of young people.

Limitations

Future research would benefit from addressing the limitations of this study design. Specifically, a larger trial with a bigger sample size and a more established intervention protocol over a longer period is needed to thoroughly evaluate effectiveness. This may include increasing the number of sessions and incorporating follow-up assessments to examine long-term effects. In addition, the protocol could involve delivering the VR intervention in a blended format, aligning with the perspectives of young people in this study, and exploring how the intervention might be implemented in routine clinical practice. A hybrid implementation-effectiveness trial [62] that simultaneously tests both implementation and effectiveness outcomes would be ideal for establishing evidence and fast-tracking implementation in real-world settings. Notably, the conversion rate suggests that only a proportion of young people who are eligible may be interested in the VR application, suggesting that a clearer understanding of who the approach is best suited for is needed. This may involve expanding the age range of the VR offering from 16 to 25 years to 12 to 25 years, in line many with youth mental health services in Australia, to understand whether this type of intervention would be more appealing to a younger demographic. Another factor to consider in future trials is the selection of a control group. The active comparison of an audio cognitive defusion exercise with a repeated measures design in this study was a strength, providing insights into how VR compares to traditional methods. However, carryover effects from the first condition to the second prevented direct comparisons, and the chosen control group did not isolate specific VR-related effects. Furthermore, as previously mentioned, it is important that future research address the potential "digital placebo" effect [58] involved in VR by including control groups with a therapeutically inactive VR experience to better isolate the intervention's effects. Other comparison groups of interest would include a passive control group or an alternative non–VR-based intervention to further clarify the distinct effects of VR-based therapy. Finally, limitations should be noted regarding the measures collected in this study. We created a specific measure of acceptability based on the need to capture more nuanced aspects of user experience relevant to this VR intervention. However, future research should incorporate validated measures of acceptability of digital mental health platforms alongside study-specific measures where possible. Furthermore, it is possible that participants experienced fatigue effects from the number of questionnaires completed in a single session. While no participant reported such fatigue, future research should examine this by analyzing consistency in the responses.

Conclusions

In conclusion, the findings of this study indicate that the VR cognitive defusion application is feasible, safe, and acceptable to young people and shows potential for supporting mental health treatment by increasing engagement and offering a novel, enjoyable approach to skill development within third-wave CBT approaches. The greater immediate improvements observed in the audio condition compared to the VR condition suggest that the application needs to be refined to optimize the learning experience. Future research should focus on improving the overall experience based on young people's feedback and conducting a larger trial with an established intervention protocol within a real-world implementation setting.

Acknowledgments

The researchers would like to acknowledge the young people who dedicated their time to participating in this study and the young people and clinicians who provided input into the design of the virtual reality application. MA-J was supported by an Investigator Grant from the National Health and Medical Research Council and a Dame Kate Campbell Fellowship from the University of Melbourne. IHB is supported by an Investigator Grant from the National Health and Medical Research Council. This research was supported by a Victorian Government Innovation Grant.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

IHB, AT, GW, SB, JG, and MA-J played key roles in the conceptualization of the virtual reality intervention. GW, MA-J, and AT supervised the development of the first prototype, and GW conducted initial user testing. IHB subsequently continued testing, refining, and overseeing the development of enhancements to the final intervention, which were completed by YL. IHB designed and oversaw the conduct of the study with input from AT and MA-J. CL led the recruitment and testing with oversight from IHB and CE. SO conducted the quantitative analysis, and IHB and CL conducted the qualitative analysis. IHB wrote the manuscript with contributions from CL and KAR. AT, MA-J, GW, SB, and JG obtained funding for the study. All authors reviewed and provided feedback on the manuscript.

Abstract

Background: Adolescence is a critical period for mental health development, yet prevalences of mental health problems are high among young people. Enhancing mental health literacy in school settings could be an effective strategy for the promotion of mental well-being and prevention of mental health struggles. One promising approach to achieving this goal involves equipping both students and teachers with accessible multimedia resources—such as YouTube Health videos—to enhance their mental health literacy.

Objective: The study evaluates the effectiveness of a short educational YouTube Health video for promoting mental health literacy in adolescents and teachers.

Methods: Two independent samples of 352 adolescents and 502 teachers from Germany were recruited from a large panel, representative of the German population with internet access. Participants of each sample were allocated to an experimental group (176 adolescents and 254 teachers) and a control group (176 adolescents and 248 teachers) through randomization. The experimental group watched a YouTube Health video designed to increase mental health literacy, while the control group watched a video similar in style but on a different topic. Before and after watching the publicly available YouTube Health videos, mental health knowledge was assessed as a primary outcome through topic-specific quizzes and a self-report in a web-based survey. In addition, all participants were asked to rate the educational, visual, and overall quality of the YouTube Health videos and their usability in school settings. The primary hypotheses were tested with ANOVAs. The quality and usability items were analyzed descriptively.

Results: For the adolescents, there were significant main effects of time ($F_{1,350}$=46.34, P<.001, η^2_p=0.117) and group ($F_{1,350}$=6.05, P=.01, η^2_p=0.017) and a significant time×group interaction ($F_{1,350}$=39.15, P<.001, η^2_p=0.101) on stress-specific knowledge, indicating a higher increase in knowledge in the experimental group than in the control group. Similarly, for teachers, significant main effects of time ($F_{1,500}$=107.31, P<.001, η^2_p=0.177) and group ($F_{1,500}$=58.07, P<.001, η^2_p=0.104) and a significant time×group interaction ($F_{1,500}$=82.59, P<.001, η^2_p=0.142) were found. The same pattern of results was observed for the knowledge self-reports in both the students (time: $F_{1,347}$=103.65, P<.001, η^2_p=0.230; group: $F_{1,347}$=8.59, P=.004, η^2_p=0.024; time×group interaction: $F_{1,347}$=29.11, P<.001, η^2_p=0.077) and teachers (time: $F_{1,500}$=115.40, P<.001, η^2_p=0.188; group: $F_{1,500}$=41.16, P<.001, η^2_p=0.076; time×group interaction: $F_{1,500}$=64.24, P<.001, η^2_p=0.114). Overall, the educational, visual, and overall quality of the videos and their usability in school settings were rated as positive by both adolescents and teachers.

Conclusions: The study findings demonstrate that short educational YouTube Health videos are effective tools for the promotion of mental health literacy among both students and their teachers. Overall, this evaluation paves the way for a wider implementation of mental health education in schools in order to create a more supportive and informed environment to promote mental well-being.

KEYWORDS

adolescents; mental health; mental health literacy; health literacy; schools; teachers; students; YouTube Health videos; RCT

Introduction

Mental health problems are among the leading causes of disability worldwide, especially in young people [1-3]. Approximately 30% of the German adult population are estimated to have mental disorders [4], a concerning problem also observed in younger generations: In school-aged children and adolescents, approximately 20% report mental health problems, with a slight decrease before the COVID-19 pandemic [5] and a pronounced rise since then [6]. Furthermore, recent studies have shown that signs of depression [7] and eating disorders [8] are especially prevalent among children and adolescents. Given the high prevalence of mental health problems among students and the significant amount of time students spend in school, schools have been identified as critical settings for the promotion of mental health and well-being among children and adolescents [9,10]. In this context, teachers take on multiple roles related to mental health support for their students, including monitoring of student status, referral to other service providers, and teaching behavioral interventions [11]. At the same time, teachers are also affected by personal mental health problems and report high levels of work-related stress [12-14], which makes them not only a provider but also a potential recipient of mental health support.

One promising approach to improving mental health is by focusing on mental health literacy [15,16]. Building on the concept of general health literacy, mental health literacy is defined as "understanding how to obtain and maintain positive mental health; understanding mental disorders and their treatments; decreasing stigma related to mental disorders; and enhancing help-seeking efficacy" [16]. An important facet of mental health literacy is mental health knowledge, which is considered to be an essential prerequisite for enabling individuals to take practical action to improve their own mental well-being and that of others [15,17]. For example, lack of knowledge has been identified as a critical barrier to mental health care access in young people [18]. To date, there is little evidence concerning mental health literacy levels among adolescents, partly due to a lack of broad measuring tools for this target group [19,20]. In a recent systematic review in low- and middle-income countries, low levels of recognition and knowledge about mental health problems were observed in children and adolescents [19]. In the general population in Germany, intermediate mental health literacy levels were delineated, with marked interindividual differences [21].

In adults, positive associations of both mental and general health literacy and lower stigma against mental disorders and more positive attitudes toward psychotherapeutic treatment have been observed [22-26]. Similarly, in adolescents, higher mental health literacy has been found to correlate with help-seeking attitudes and intentions [27]. In addition, mental health literacy has been identified as an important determinant of mental well-being in schools [28] but not consistently with general well-being in adolescence [27]. There is tentative evidence that universal prevention interventions may improve mental health literacy but with overall low quality of evidence [29], which is why further research in this area is warranted.

Despite their unique role, schools are not fully equipped to support students' mental health, and many teachers report insufficient knowledge, confidence, and resources to do so [11,30-34]. In addition, there are mixed results concerning teachers' mental health literacy levels, which highlights that they might benefit from more targeted support [34,35].

In the past, video-based interventions were found to be effective tools to enhance various components of mental health literacy, including knowledge [36]. At the same time, in a recent systematic review, the quality of many publicly available health-related videos on YouTube was found to be low, and a need for more high-quality content was identified [37]. With the aim of supporting general and mental health literacy across different target groups, the independent nonprofit foundation Stiftung Gesundheitswissen previously conceptualized and produced short educational videos in various health-related fields for target groups of the general population and adolescents. The videos are presented on a YouTube channel that is part of the YouTube Health program. This programs flags health-related content from authoritative and credible sources and makes content from these channels more easily accessible in searches on health-related topics [38]. Channels eligible for this program need to fulfill a set of standards including adhering to principles of health-related information sharing [39] and employing licensed health professionals that oversee and review the channels' content.

Specifically, to support mental health literacy, several YouTube Health videos covering the topic of stress were developed recently. This study focuses on one of these videos that gives a general introduction on the topic. The video addresses the first facet of mental health literacy, namely understanding how to obtain and maintain positive mental health [16], and is directed at both adolescents and adults from the general population. The primary aim of this investigation was to evaluate this stress-related YouTube Health video as a proof-of-concept study to demonstrate that short educational videos of this type can promote mental health knowledge as a facet of mental health literacy. The video was compared with a similar YouTube Health video on a different topic in a randomized pre-post control group design in 2 independent samples of school-aged students and general education teachers. Significant differences in stress-specific knowledge between the experimental group and control group were expected after, but not before, watching the respective YouTube Health video (primary hypothesis of this study). The secondary aim was to examine the overall quality, educational value, visual appeal, and usability of the YouTube Health videos for their use and dissemination in school settings. Importantly, for these factors, no differences between the experimental and the control videos were hypothesized, as

XSL•FO
RenderX

the videos were designed in a similar way and only differed in content. Therefore, their overall quality, educational quality, and visual appeal were not tested for group differences.

Methods

Ethical Considerations

A study protocol including detailed information on the study procedures, measures, and data security was submitted to the ethics committee of the Berlin Medical Association, which did not raise any professional or ethical objections against the study (reference: Eth-42/23). All participants were informed about the study procedures and aims. Specifically, participants were informed that the study aimed to investigate the extent to which explanatory videos can be used to promote health literacy and to examine their quality. They were asked for their consent via checkboxes in a web-based questionnaire before data collection. For the students, informed consent was provided by a parent or next of kin. Participants could withdraw from the study at any given time without any negative consequences. Participants were compensated with the standard compensation scheme of the panel (for details about the panel, see the Recruitment and Data Collection section). They received bonus points that can be exchanged for vouchers, cashed out, or donated. Anonymized and complete data sets were provided to the foundation by the market research institute responsible for data collection.

This study was part of a larger research project that evaluated several short educational videos produced by Stiftung Gesundheitswissen and assessed health literacy and further health-related constructs in 3 independent samples of the general population, teachers, and students. Each of these samples was divided into 4 groups (ie, 4 video interventions) through randomization (for more details on randomization, see the Procedures section). For this study, only 2 samples (teachers, students) and 2 groups (stress video, fake news video) are relevant, as they focus on the topic of mental health literacy in school settings. This study therefore does not cover the primary outcome of the larger research project, namely digital health literacy. The larger research project was retrospectively registered at the German Clinical Trial Register (DRKS), the German World Health Organization (WHO) primary register, with the registration number DRKS00036854. Further publications focusing on different topics will likely arise from this project.

Sample

Recruitment and Data Collection

Data were collected with the help of the *forsa* (Gesellschaft für Sozialforschung und statistische Analysen mBH) market research institute. Participants were recruited in November 2023 and December 2023 from the forsa.omninet panel. The forsa.omninet panel is a large panel with more than 100,000 participants representative of the population with internet access and sufficient knowledge of the German language in Germany. Participants for the panel are recruited via telephone to ensure that rare internet users are also represented. It is not possible to apply for the panel, which means that a single person cannot participate with multiple accounts. Two independent samples were recruited: students aged 14 years to 18 years and teachers. The information, if the panelists were teachers, was available to the market research institute due to prior surveys and was confirmed by the panelists before data collection. For the students, initial recruitment took place via their parents. In the first step, parents of potential students within the relevant age group were invited. If they confirmed they had at least one child in the relevant age group and provided informed consent for them to participate in the study, data collection was initiated with their child. If they had more than one child, the child with the most recent birthday was selected for study participation. All participants were invited to take part in the study via email, with a maximum of 2 reminders sent.

Inclusion and Exclusion Criteria

Inclusion criteria for both samples were sufficient knowledge of the German language and internet access (guaranteed for all panelists through the recruitment strategy of the panel). In addition, students had to be between 14 years and 18 years old, and teachers had to currently work as a teacher in a general education school (*allgemeinbildende Schule* in German). Exclusion criteria were not fulfilling the inclusion criteria and not being able to operate a computer, laptop, tablet, or mobile phone.

Sample Size Considerations

To determine the minimum sample size, an a priori sample size calculation was conducted in G*Power (version 3.1.9.7) based on the following parameters: a small-to-medium effect size of η^2_p=0.025, an α level of .05, and a power of .90 for the interaction effect in a 2-factorial mixed ANOVA between the factors group and time point, with the knowledge quiz and self-reports (see the Measures section) as dependent variables. These were the primary hypotheses for this study. The analysis yielded a minimum total sample size of 412 participants per sample (eg, 206 individuals per group in each sample). Taking potential attrition into account, our aim was to recruit approximately 500 participants for each sample.

Procedure

The study was conducted as a randomized controlled pre-post study with 2 measurements (T1, T2). Two independent samples and 2 groups per sample are relevant to this investigation. The trial was entirely web-based. The samples were students aged 14 years to 18 years and school teachers living in Germany. The market research institute was responsible for randomization. Randomization was performed independently for each sample after the participants initiated the study. A computer-based adaptive randomization technique without stratification was used, taking into account the current group sizes. The aim was to create groups of similar sizes. Participants were formally blinded to whether they were assigned to the control or experimental group, but there was relatively high face validity concerning the content of the intervention. Participants did not know which was the intervention of interest and which was the comparator.

After the initial data collection via web-based questionnaires at T1, participants from each sample were allocated to an experimental group or a control group in a randomized

XSL•FO
RenderX

procedure. Each group was then shown an animated YouTube Health video (details are provided in the following sections). After watching the YouTube Health video, the participants completed a second set of questionnaires (T2). In total, data collection took about 20 minutes per participant, including watching the YouTube Health video and all measurements.

At T1, sociodemographic information was collected. In addition, the participants were presented with a stress-specific knowledge quiz and self-report questionnaire to assess mental health knowledge as well as a knowledge quiz and self-report questionnaire on fake news not relevant to this study. Results on these later questionnaires are not the focus of this publication but can be found in Multimedia Appendix 1, including Table S1. At T2, all quality measures were presented, and the knowledge quizzes and self-report questionnaires were repeated to assess any changes relative to T1.

Materials and Measures

YouTube Health Videos

Two YouTube Health videos of approximately 2 minutes to 3 minutes in length were used in this study. The videos were presented to the participants on the same platform as the online questionnaires. The participants in the experimental group watched a YouTube Health video on stress to promote mental health literacy, and the participants in the control group watched a YouTube Health video on fake news with no focus on mental health literacy. Both YouTube Health videos are animated, show human protagonists, and provide central information on the corresponding topic with the help of a short entertaining storyline. The YouTube Health videos were produced by the independent nonprofit foundation Stiftung Gesundheitswissen and are publicly available on their website and YouTube channel. The experimental YouTube Health video designed to promote mental health literacy contains a general introduction on the topic of stress. It includes brief definitions of internal and external stressors, acute and chronic stress, and healthy and unhealthy coping mechanisms [40]. The control group YouTube Health video addresses the topic of fake news and covers the topics misinformation (unintentional) and disinformation (deceitful and intentional) in the contexts of click-baiting, satire, personal testimonials, deepfakes, and conspiracy theories [41]. A brief sound test was conducted before the YouTube Health videos were presented to ensure that all participants not only watched the videos but also listened to them. In the sound test, the participants heard a short audio and had to indicate what they heard in a multiple choice question (eg, dogs barking, bells ringing, piano music playing, or children laughing). Only if the correct answer was given, the survey continued, and the YouTube Health video was presented.

Measures

Sociodemographic Information

All participants reported their age and gender.

Knowledge Quiz

Before and after the video presentation, the participants completed 2 brief topic-specific knowledge quizzes. Crucially, these quizzes were answered by both groups; that is, all participants in the experimental and control groups answered items on both stress and fake news before and after watching their individual video. For each topic, a total of 16 items were presented in 4 blocks of 4 items. For each item, the participants had to indicate if the presented statement was correct or not. They could also choose an “I don’t know” option. For each correct response, 1 point was awarded to the participants. No points were awarded for any incorrect or “I don’t know” responses. Points were summed up separately across all items of each topic, and 2 topic-specific sum scores were calculated with a range of 0 to 16 points each. The items covered content presented in the videos (eg, on the definition of stress and stressors, coping mechanisms, and the distinction between chronic and acute stress for the mental health literacy video). For the fake news video, the items covered the topics click-baiting, deepfakes, misinformation, and disinformation. The items were constructed by the author team and pretested and discussed with experts involved in the production of the videos. The stress knowledge quiz is one of the two primary outcomes of this study, alongside the stress self-reports described in the following section. All other measures are secondary outcomes.

Self-Report

In addition, all participants answered 2 self-report measures on the topics of stress and fake news. Each measure consisted of 4 items answered on a 6-point Likert scale ranging from “strongly disagree” to “strongly agree.” Each item was a short statement referring to the ability of the respondent to explain certain concepts (eg, “I can explain how psychological stressors work” for the stress self-report and “I can explain how disinformation works” for the fake news self-report). A mean score was calculated for each topic, with a range of 1 to 6. The participants could also select an “I don’t know” option. All items in the knowledge quizzes and self-reports are in Tables S2-S5 in Multimedia Appendix 1.

Quality Measures

After watching the YouTube Health videos, the participants were asked to complete the Global Quality Scale (GQS), which consists of a single item. The participants were asked to evaluate the overall quality of the videos on a scale from 1 to 5, with higher values indicating higher overall quality [42]. A value of 4 or 5 can be considered as high quality [43]. The scale was initially developed for patients to evaluate videos containing health information [42]. The instructions were translated to German and slightly adjusted by replacing the word “patients” with “viewers.”

To assess the educational quality of the videos, the German version of the “learning and value” subscale of the Student Evaluation of Educational Quality (SEEQ) instrument was used at T2 [44,45]. The scale has 5 items rated on a 5-point Likert scale ranging from “strongly disagree” (1) to “strongly agree” (5). The instrument was initially developed to measure educational quality in higher education. The items were slightly adapted to apply to the evaluation of videos. A mean score was calculated across the 5 items, with higher values indicating higher educational quality.

XSL•FO
RenderX

Furthermore, the German version of the Visual Aesthetics of Websites Inventory (VisAWI) was used to assess the visual experience and aesthetics of the videos [46]. All 4 subscales, namely simplicity (5 items), diversity (5 items), colorfulness (4 items), and craftmanship (4 items), were presented. The items were slightly adjusted to apply to the evaluation of videos rather than websites, for which the instrument was originally developed. Each item is rated on a 7-point Likert scale ranging from "strongly disagree" to "strongly agree." A mean score was calculated separately for each subscale, and an additional total mean score was calculated across all items. Higher mean scores denote higher quality, and scores greater than 4.5 indicate an overall positive evaluation [47].

Usability, Endorsement, and Motivation Items

In order to assess the potential usability of the YouTube Health videos in school settings and outside of it more thoroughly, all participants were asked whether they would watch explanatory videos of this kind in their free time, recommend them to friends, recommend them to relatives, and share them on social media, in 4 separate questions. Each of these endorsement questions was rated on a 4-point Likert scale with the options "no," "likely no," "likely yes," and "yes." Higher values denote a higher probability of watching, recommending, or sharing the video.

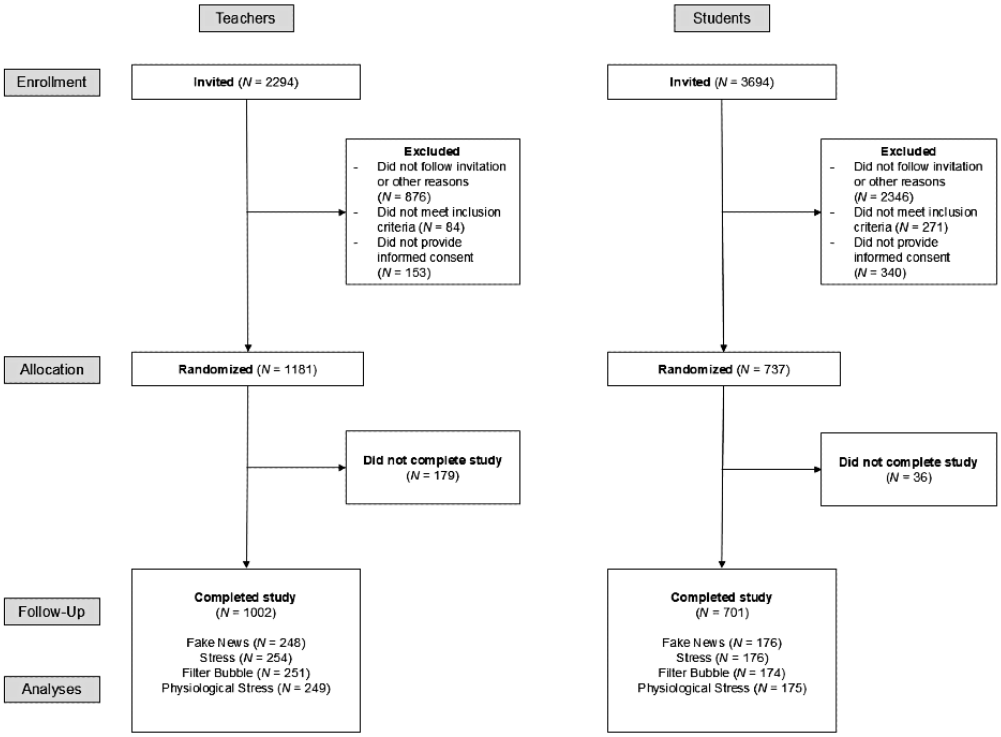
In addition, students were asked if it would motivate them if explanatory videos of this kind were used in (1) lessons, (2) in digital lessons, (3) as homework, (4) in project weeks, and (5) in class chats or digital classroom platforms and if it would motivate them if (6) their teacher recommended the videos to them. Teachers were asked if they would use these or similar videos in (1) lessons, (2) in digital lessons, (3) as homework, (4) in project weeks, and (5) in class chats or digital classroom platforms and whether they would recommend them to (6) teacher colleagues and (7) their students. These questions were also answered on a 4-point Likert scale with the options "no," "likely no," "likely yes," and "yes." For teachers, higher values denote a higher probability of using or recommending the videos. For students, higher values denote a higher probability of being motivated by these kinds of videos.

Statistical Analysis

Data preprocessing was conducted with the statistical software SPSS (version 29.0.2.0; IBM Corp). All further statistical analyses were conducted with JASP (version 0.19.1). For the power analyses, G*Power (version 3.1.9.7) was used. The Cronbach α was calculated as a measure of internal consistency for all questionnaires with multiple items. The main analyses were separate 2-factorial ANOVAs with 1 between-participants factor (experimental group vs control group) and 1 repeated-measures factor (pre- and postassessment) for each dependent variable (ie, total score on knowledge quiz, mean score on the self-report measures) and each group (students, teachers). The primary hypotheses were tested with interaction effects between the groups and the repeated-measures factors. Significant interaction effects were followed by *t* tests for conditional comparisons: Separate *t* tests were calculated for the pre-post comparison of each group and for each group comparison at each measurement (pre, post). These post hoc *t* tests underwent Bonferroni correction, and corrected *P* values are reported. Effect sizes for the ANOVA main and interaction effects are reported as η^2_p. Effect sizes for the post hoc *t* tests are reported as Cohen *d*. For all analyses, α thresholds were set to .05, and *P* values are 2-sided. The secondary outcomes were only analyzed on a descriptive level.

Results

Sample Description



We recruited and assigned 352 students and 502 teachers to the experimental and control groups using a randomized procedure. Detailed sample characteristics for each group can be found in Table 1. For the students, the targeted sample size of a minimum of 412 individuals could not be completed in the study period. Therefore, for this sample, post hoc analyses of achieved power for the primary analyses (eg, ANOVA interaction effects) were conducted and are reported with the respective results. Details on recruitment and attrition are in Figure 1 and Table S6 in Multimedia Appendix 1.

Table 1. Characteristics of the teachers and students.

Characteristics	Students		Teachers	
	Experimental group (n=176)	Control group (n=176)	Experimental group (n=254)	Control group (n=248)
Age (years), mean (SD)	15.55 (1.31)	15.44 (1.29)	50.48 (10.43)	51.32 (9.79)
Gender, n (%)

Knowledge Quizzes and Self-Report in the Students' Sample

Detailed descriptive statistics for the stress-specific knowledge quizzes and self-report questionnaires for the students can be found in Tables 3 and 4 and Figures 2 and 3. There were significant main effects of time ($F_{1,350}$=46.34, P<.001, η^2_p=0.117) and group ($F_{1,350}$=6.05, P=.01, η^2_p=0.017) and a significant time×group interaction ($F_{1,350}$=39.15, P<.001, η^2_p=0.101) on stress-specific knowledge. Post hoc t tests revealed a significant increase from T1 to T2 in the experimental group (t_{175}=9.24, P<.001, d=0.71) but not in the control group (t_{175}=0.39, P=.70, d=0.03). The experimental group had higher knowledge than the control group at T2 (t_{350}=5.15, P<.001, d=0.57) but not at T1 (t_{350}=−1.12, P=.26, d=−0.12). In addition, significant main effects of time ($F_{1,347}$=103.65, P<.001, η^2_p=0.230) and group ($F_{1,347}$=8.59, P=.004, η^2_p=0.024) and a significant time×group interaction ($F_{1,347}$=29.11, P<.001, η^2_p=0.077) were observed for the stress self-report on subjective knowledge. Post hoc t tests revealed a significant increase from T1 to T2 in both the experimental group (t_{173}=11.00, P<.001, d=0.81) and control group (t_{174}=3.39, P<.001, d=0.25), with a higher effect size in the experimental group. The experimental group reported higher subjective knowledge than the control group at T2 (t_{347}=5.30, P<.001, d=0.56) but not at T1 (t_{347}=−0.07, P=.94, d=−0.01).

For the respective effect sizes of η^2_p=0.101 and η^2_p=0.077 and of the interaction effects, post hoc power analyses showed that power exceeded .99 in both analyses.

Table 3. Descriptive statistics and results of the group comparisons for the stress-specific knowledge quizzes and self-reports completed by the experimental and control groups of teachers and students.

Groups and timeframe	Experimental group, mean (SD)	Control group, mean (SD)	Group comparison, t test (df)	P value	Cohen d
Students

Knowledge Quizzes and Self-Report in the Teachers' Sample

Detailed descriptive statistics for the stress-specific knowledge quizzes and self-reports for the teachers can be found in Tables 3 and 4 and Figures 2 and 3. There were significant main effects of time ($F_{1,500}$=107.31, P<.001, η^2_p=0.177) and group ($F_{1,500}$=58.07, P<.001, η^2_p=0.104) and a significant time×group interaction ($F_{1,500}$=82.59, P<.001, η^2_p=0.142) on stress-specific

XSL•FO
RenderX

knowledge. Post hoc *t* tests revealed a significant increase from T1 to T2 in the experimental group (t_{253}=13.83, P<.001, d=0.93) but not in the control group (t_{247}=0.89, P=.37, d=0.06). There were significant group differences at T2 (t_{500}=10.80, P<.001, d=1.01) but not at T1 (t_{500}=1.62, P=.11, d=0.14). In addition, significant main effects of time ($F_{1,500}$=115.40, P<.001, η^2_p=0.188) and group ($F_{1,500}$=41.16, P<.001, η^2_p=0.076) and a significant time×group interaction ($F_{1,500}$=64.24, P<.001, η^2_p=0.114) were delineated for self-reported stress-specific knowledge. Post hoc *t* tests revealed a significant increase from T1 to T2 in the experimental group (t_{253}=13.34, P<.001, d=0.69) but not the control group (t_{247}=1.92, P=.06, d=0.10). There were significant group differences at T2 (t_{500}=9.51, P<.001, d=0.82) as well as at T1 (t_{500}=2.46, P=.01, d=0.23).

Quality Measures

On average, both samples rated the overall quality (GQS), the educational quality (SEEQ), and the visual experience (VisAWI) of both videos as positive (details in Table 5). For the GQS, values ≥4 were achieved in both samples and for both videos, indicating high overall quality. Likewise, for the VisAWI, the cutoff of 4.5 was exceeded in all subscales and the overall score in both samples and for both videos.

Usability, Endorsement, and Motivation Items

Descriptive statistics for the usability, endorsement, and motivation items can be found in Table 6 for the students and Table 7 for the teachers. Means and SDs for each item can be found in Tables S7-S9 in Multimedia Appendix 1.

Overall, most students reported that they would not watch videos of this kind in their free time nor share them on social media. However, most students would recommend them to their friends and relatives. Most students reported that they would feel motivated if videos of this kind were used in lessons or digital lessons, as homework, in class chats, or in project weeks or if they were recommended to them by their teachers.

Most teachers reported that they would watch videos of this kind in their free time and recommend them to friends, relatives, their teacher colleagues, and students but that they would not share them on social media. For use in schools, most teachers reported that they would use the videos in lessons and digital lessons, as homework, in project weeks, and in class chats or digital learning platforms.

Discussion

Study Summary

This study investigated the effectiveness of a short educational YouTube Health video for enhancing mental health knowledge as a facet of mental health literacy among adolescents and teachers and its usability in a school setting—a critical environment for mental health (literacy) promotion [9,10,28]. It was hypothesized that both students and teachers would report higher mental health knowledge after watching the video on mental health (experimental group) when compared with a control group who watched a video similar in style but regarding a different topic. In addition, the overall quality, educational quality, and visual appeal of the videos were investigated, and we assessed whether the videos were deemed suitable for use in and outside school settings.

Key Findings and Implications

The study results revealed higher statistically significant increases in both objective knowledge (quiz scores) and subjective knowledge (self-report questionnaires) in the experimental groups than in the control groups of both students and teachers. These findings underline that videos can be effective tools for disseminating mental health information and improving aspects of mental health literacy [36] as has already been shown for other types of interventions [9,29,35]. Conversely, the control group watched a video on fake news, matched for length and visual style, which allowed the attribution of the observed knowledge increase to the mental health content rather than the general video format. At T1, there was a small group difference in self-reported knowledge in the teachers, with higher a priori knowledge in the experimental group than in the control group. This was most likely a random—and not systematic—variation as the participants were allocated to the 2 groups through randomization.

High ratings for overall quality, educational quality, and visual appeal across both samples showed that the YouTube Health videos' design and content were well-received. For both teachers and students, established thresholds for high quality were exceeded, if available [43,47]. Furthermore, most students reported that they would be motivated if the presented or similar videos were used in lessons or digital lessons, as homework, in project weeks, or in class chats and if teachers recommended these videos to them. Similarly, most teachers indicated that they would use these and similar videos in various educational contexts and that they would recommend them to both their colleagues and students. This underlines the potential for integrating such resources into school curricula [9,10]. For use outside of school settings, most students reported that they would not likely watch these and similar videos in their free time nor share them on social media. However, many students also reported that they would recommend videos of this kind to friends and family.

Together, this pattern of results underscores the pivotal role of schools in providing access to mental health resources for adolescents. Schools and school authorities should leverage this unique position to implement evidence-based initiatives that enhance mental health literacy and promote mental health in general [9,10,29,48]. For example, YouTube Health videos such as the ones evaluated in this study could be used to prompt classroom discussions on the topic of mental health care. Implementation of these videos in school curricula should be complemented by the use of other resources such as topic-specific worksheets or e-learning courses [49,50]. In this context, adequate qualification and training of teachers who bear substantial responsibility for the implementation of mental health initiatives in daily school life should be given special emphasis [51]. Training programs should include components to increase mental health knowledge, reduce stigma, and foster confidence in teachers [51]. In addition, tight collaboration with other professionals and mental services should be promoted [10]. Importantly, mental health promotion in schools should be regarded not only as dealing with already existing mental health problems but also—and maybe more importantly—in terms of prevention of these problems and promotion of positive mental health and well-being [10].

Interestingly, on a descriptive level, the usability, endorsement, and motivation items were rated similarly for both the mental health and fake news videos. These findings highlight that the positive evaluation of the videos is most likely not related to their specific topic but to their design and style. Based on this, it may be concluded that the development and dissemination of videos in a similar style, and covering a wide range of topics, could be useful for implementation in schools to promote mental health literacy. The potential of uploading more high-quality content to public sources such as YouTube and making use of programs to promote science-based health content with programs like YouTube Health should therefore be fully exploited [37].

The observed effect sizes for the interaction effects and post hoc tests were medium to large [52], but the numerical increases on the sum scores were rather small (approximately 2 points in the quiz sum scores in both samples), which might have been due to a ceiling effect as participants from all groups already reached high quiz scores at T1, before the intervention. This finding has two implications: First, future evaluation studies could benefit from more difficult tests to ensure more variance, possibly safeguarded by more thorough piloting, and second,

XSL•FO
RenderX

the finding speaks for already medium-to-high levels of mental health knowledge on the topic of stress before the intervention. It might be helpful to explore specific mental health knowledge gaps more in-depth to inform the development of more targeted videos in the future.

Limitations

The study results presented here have a few limitations. First, the evaluation of the intervention's effects relied partially on self-reports, and low Cronbach α indices of internal consistency were obtained for the quiz scores, indicating low reliability of the measures. This might be due to the small number of items that were constructed to cover a wide range of topics addressed in the video. Future evaluations should therefore include more items and conduct more thorough pretesting to ensure higher reliability. Additionally, validated and broader instruments should be used alongside self-constructed items to provide a more comprehensive assessment of mental health literacy. However, results were replicated in objective knowledge tests, which speaks for the validity of the self-reports. Second, there was only a very short follow-up period. Future investigations should test for the stability of the findings over longer periods of time. Third, the target sample size of 412 individuals was not reached for students. Of note, however, effect sizes were so large that high power was still achieved. Fourth, rather than being tested in a school setting, the intervention was tested online, which might come with disadvantages, such as a less controlled testing environment, potentially affecting the validity of the result [53]. To determine the generalizability of the findings, future studies should therefore also test the intervention in its intended primary setting of use, namely in school contexts. Last, only a single video on a specific topic was investigated and compared with a video similar in style but regarding a different topic. Our findings underline the feasibility of using short educational videos for the promotion of mental health literacy in schools. However, the scope of this promotion is limited by the video's short length and simplicity. Therefore, we propose that videos of these types should be part of more comprehensive programs that combine various types of intervention methods such as other videos on the topic [36], e-learning courses [49,50], classroom discussions, and teaching materials [9] for the extensive promotion of mental health in school settings.

Conclusion

The study findings highlight the feasibility of using short, educational YouTube Health videos as tools for enhancing mental health literacy in both students and their educators. The positive evaluation in terms of educational, aesthetic, and overall quality along with high levels of teachers' and students' endorsement and possible positive effects on students' motivation are promising for developing and producing more videos of this kind and implementing them into school curricula. Overall, this evaluation is a first step toward the more widespread promotion of mental health literacy in schools to create a more supportive and informed school environment where mental health care is prioritized.

Abstract

Background: Anxiety disorders are among the most prevalent mental disorders, and stress plays a significant role in their development. Ecological momentary interventions (EMIs) hold great potential to help people manage stress and anxiety by training emotion regulation and coping skills in real-life settings. InsightApp is a gamified EMI and research tool that incorporates elements from evidence-based therapeutic approaches. It is designed to strengthen people's metacognitive skills for coping with challenging real-life situations and embracing anxiety and other emotions.

Objective: This randomized controlled trial aims to examine the effectiveness of InsightApp in (1) improving individuals' metacognitive strategies for coping with stress and anxiety and (2) promoting value-congruent action. It also evaluates how long these effects are retained. This experiment advances our understanding of the role of metacognition in emotional and behavioral reactivity to stress.

Methods: We conducted a randomized controlled trial with 228 participants (completion rate: n=197, 86.4%; mean age 38, SD 11.50 years; age range 20-80 years; female: n=101, 52.6%; and White: n=175, 91.1%), who were randomly assigned to either the treatment or the active placebo control group. During the 1-week intervention phase, the treatment group engaged with InsightApp, while participants in the control group interacted with a placebo version of the app that delivered executive function training. We assessed the differences between the 2 groups in posttest and follow-up assessments of mental health and well-being while controlling for preexisting differences. Moreover, we used a multilevel model to analyze the longitudinal data, focusing on the within-participant causal effects of the intervention on emotional and behavioral reactivity to daily stressors. Specifically, we measured daily anxiety, struggle with anxiety, and value-congruent action.

Results: The intervention delivered by InsightApp yielded mixed results. On one hand, we found no significant posttest scores on mental health and well-being measures directly after the intervention or 7 days later (all P>.22). In contrast, when confronted with real-life stress, the treatment group experienced a 15% lower increase in anxiety (1-tailed t test, t_{197}=–2.4; P=.009) and a 12% lower increase in the struggle with anxiety (t_{197}=–1.87; P=.031) than the control group. Furthermore, individuals in the treatment group demonstrated a 7% higher tendency to align their actions with their values compared to the control group (t_{197}=3.23; P=.002). After the intervention period, InsightApp's positive effects on the struggle with anxiety in reaction to stress were sustained, and increased to an 18% lower reactivity to stress (t_{197}=–2.84; P=.002).

Conclusions: As our study yielded mixed results, further studies are needed to obtain an accurate and reliable understanding of the effectiveness of InsightApp. Overall, our findings tentatively suggest that guiding people to apply adaptive metacognitive strategies for coping with real-life stress daily with a gamified EMI is a promising approach that deserves further evaluation.

Introduction

Background

According to the World Health Organization, anxiety disorders currently affect approximately 3.6% of the world's population, which translates to about 264 million individuals worldwide, making them one of the most common mental health conditions globally [1]. Moreover, in the United States, approximately 31.1% of adults experience some form of anxiety disorder during their lives [2]. These numbers do not include the distress experienced by individuals dealing with subclinical levels of anxiety daily. Anxiety often arises when people feel threatened or face stressful situations. Prolonged or intense stress can disrupt the body's stress response system, leading to heightened anxiety levels [3,4]. By regulating the stress response system, individuals can learn to modulate their reactivity to stressors, reduce anxiety symptoms, and enhance overall well-being [5-7].

Ecological momentary interventions (EMIs) are digital interventions delivered in real time in real-world settings to help individuals integrate specific strategies into their everyday life [8]. The widespread use of smartphones and other mobile devices makes EMIs easily accessible and provides a broad reach. Therefore, EMIs offer a scalable, cost-effective, and flexible platform for delivering mental health interventions, including psychotherapy [9,10]. In particular, EMIs have great potential for helping individuals cope with stress in real time, because they can provide immediate support and resources to address stressors as they arise throughout the day. Consequently, EMIs present a promising avenue for enhancing therapeutic outcomes and promoting mental well-being by giving the general public access to important tools and strategies for psychological resilience and well-being.

One approach that is consistently emphasized in various psychotherapies, including metacognitive therapy [11], cognitive behavioral therapy (CBT) [12], acceptance and commitment therapy (ACT) [13], mindfulness-based stress reduction [14], and various mindfulness-based interventions [15], is the development of metacognitive skills. Metacognitive skills allow individuals to effectively navigate and regulate their cognitive and emotional processes, leading to improved coping strategies and overall well-being [6,16-18]. Therefore, combining the benefits of metacognitive skill training with the accessibility and effectiveness of EMIs is a promising avenue to helping individuals actively cultivate self-awareness, regulate their cognitive processes, and integrate specific coping strategies into their daily lives.

InsightApp is a gamified EMI and research tool designed to strengthen people's metacognitive skills for coping with challenging real-life situations and embracing strong emotions [19]. The main strategies the app integrates are the *activating event, belief system, consequences, disputation of beliefs, and effective new beliefs(ABCDE) method* for cognitive restructuring from CBT; reflections on values and committed action from ACT; and emotion regulation strategies from ACT, CBT, and mindfulness-based interventions.

In addition to the benefits of helping individuals improve their mental well-being, EMIs facilitate running longitudinal studies with the help of ecological momentary assessment. This approach allows researchers to collect real-time data on the effectiveness of interventions over extended periods [20]. A longitudinal approach addresses methodological shortcomings, such as retrospective recall bias, and enables examination of both between-participant (personality level) differences and within-participant variations [21]. By incorporating longitudinal designs and daily assessments in real-life settings, researchers can gain valuable insights into the dynamic nature of stress and coping, contributing to the development of more effective and personalized interventions.

Objectives

This experiment aimed to conduct a longitudinal randomized controlled trial to evaluate the effectiveness of InsightApp in enhancing individuals' mental health and well-being as well as addressing their daily anxiety levels and their capacity to engage in valued actions when confronted with challenging situations. Our experiment evaluates the impact of the intervention on mental health and well-being before and after the intervention. Furthermore, through a longitudinal experimental design with a robust placebo control group, we gain insights into how InsightApp affects participants' anxiety, their ability to cope with stress, and their engagement in valued actions in everyday life.

Methods

InsightApp

Overview

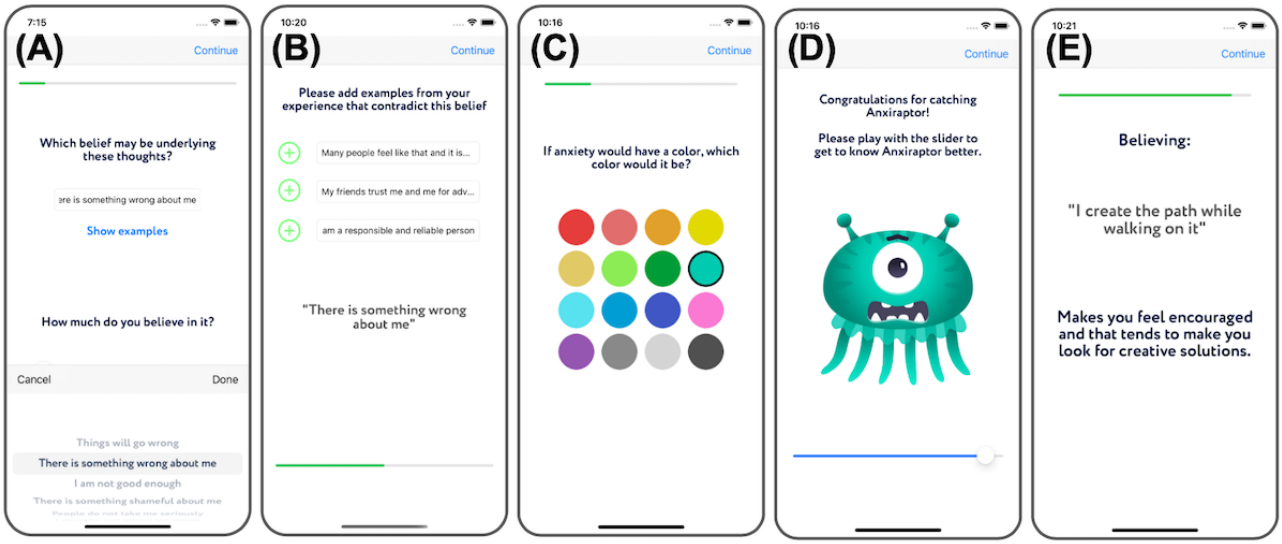
InsightApp was designed and programmed by VA as part of her PhD project at the Max Planck Institute for Intelligent Systems under the supervision of FL. The app was developed for academic purposes without any affiliation to commercial interests. It serves a dual purpose: studying metacognitive mechanisms behind belief, behavior, and emotion regulation and enhancing individuals' skills in these areas. The development of InsightApp involved a series of iterative processes, incorporating feedback from formative evaluations and usability testing. Detailed information about its formative stages and the impact of these evaluations on the app's design can be found in a previous publication [19].

The primary components of the intervention delivered by InsightApp are the reflection modules and the metacognitive coaches, which are explained in detail subsequently.

Reflection Modules

InsightApp comprises 3 reflection modules: reactivity, values, and choice point. The reactivity module focuses on the ABCDE

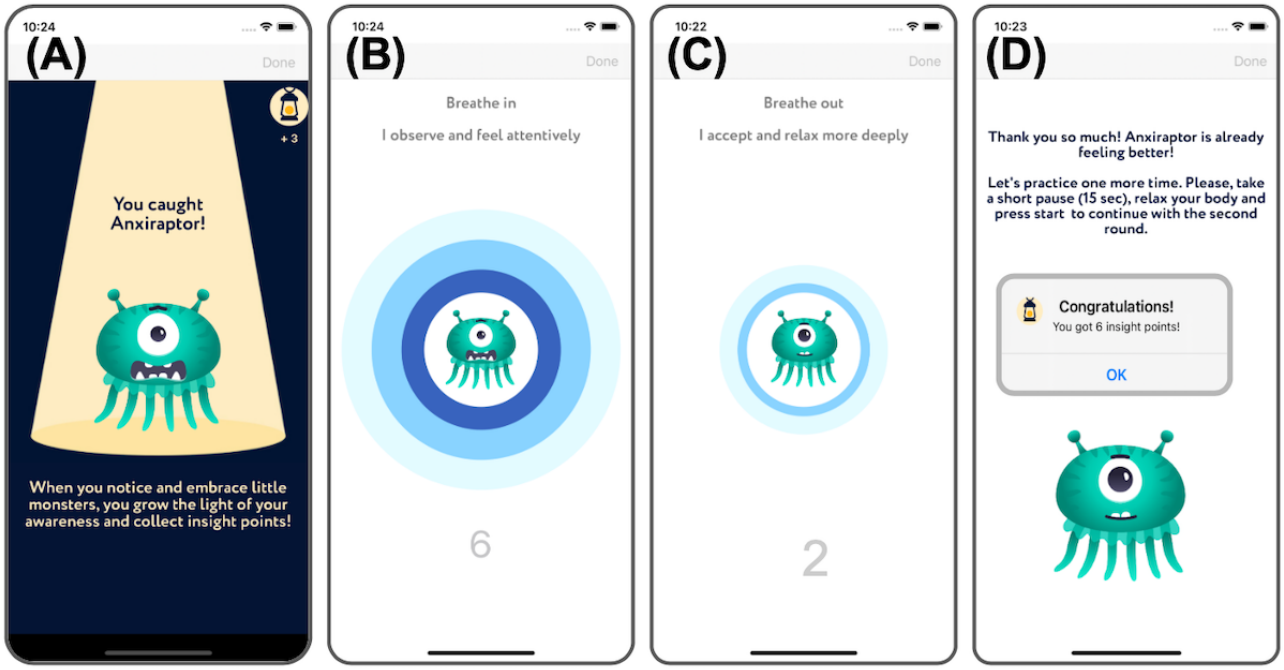
XSL•FO
RenderX



method (activating events and consequences) for cognitive restructuring. It guides participants to reflect on a challenging situation and to identify their typical reactions (Table S1 in Multimedia Appendix 1). The values module, based on ACT, guides users to identify the personal values that they would like to express in their situation. The app assists users in discovering a meaningful course of action by offering suggestions aligned with their chosen values. The choice point module draws from ACT's concept of choice points (Table S3 in Multimedia Appendix 1). It presents individuals with divergent paths, where one leads to growth and valued action, while the other leads to old habits and reactive behavior.

Metacognitive Coaches

InsightApp trains 2 types of metacognitive skills with the help of 2 coaches: the meta-reasoning coach and the meta-awareness coach. The meta-reasoning coach trains participants' capacity to think critically about the content of their thoughts as subjective interpretations of their reality. The meta-awareness coach trains participants' capacity to notice, accept, and kindly embrace their thoughts and emotions as mental events as they occur in real time.



The meta-reasoning coach integrates steps B, C, D, and E of the ABCDE method for cognitive restructuring. It helps users identify anxiety-inducing thoughts (Figure 1A) and their consequences (Figure 1B) and challenge their negative thoughts (Figure 1C). Furthermore, the coach prompts the user to customize a "little monster" avatar to represent the combination of anxious feelings, thoughts, and actions identified in the previous steps (Figures 1D and 1E). It also assists them in finding an adaptive way to think about their situation and understanding how the adaptive belief influences the way they feel and act. Table S4 in Multimedia Appendix 1 details the coach's questions and answer types. The meta-awareness coach leads users through a breathing meditation on acceptance. In the initial session, users are introduced to insight point rewards (Figure 2A), which encourage a positive attitude toward challenges and frame them as opportunities for practicing emotion regulation skills (Figure 2A). The meditation guides users to observe anxious body sensations, symbolized by the avatar, during inhalation, with expanding rings (Figure 2B) and to accept these sensations and relax during exhalation, accompanied by contracting rings (Figure 2C). At the end of every practice session, users receive a congratulatory message and are awarded insight point rewards (Figure 2D). The meditation consists of 2 sessions, each comprising 6 breaths.

Figure 1. Screenshots of the meta-reasoning coach. The figure shows example screens illustrating how the app guides the user to (A) reflect on the content of their thoughts when experiencing a strong negative emotion, (B) find evidence that contradicts the maladaptive belief, (C and D) personalize a "little monster" avatar to represent the pattern, and (E) ponder the influence of an alternative helpful adaptive belief on their emotions and behavioral tendencies.

XSL•FO
RenderX

Figure 2. Screenshots of the meta-awareness coach. The figure shows example screens illustrating how the app (A) introduces users to insight point rewards and guides the user to (B) inhale while observing how the emotion feels in the body, (C) exhale while accepting those sensations and relaxing, and (D) take a short break between breathing sessions where they are awarded with insight point rewards.

The app, as an EMI, prompts people to integrate the training of metacognitive skills into their daily lives. The app encourages participants to stay aware of their emotions and thoughts throughout the day (metacognitive awareness practice) and to "catch" the little monster avatar whenever they recognize themselves experiencing or acting in anxious ways they have previously identified (decentering or cognitive defusion practice). Participants are presented with a choice point immediately after completing the cognitive defusion practice. At this point, the app prompts participants to click on the course of action they choose to take next. Furthermore, the app sends 2 random notifications per day to remind participants to stay aware of their emotions and to use the catch function when they notice themselves feeling anxious or acting in the reactive ways they have previously identified. These notifications serve as prompts to practice emotional awareness throughout the day. Thereby, the app prompts users to integrate metacognitive skill training into their daily routines through real-time notifications and personalized content of the intervention that adapts to the users' specific situations, emotions, and tendencies to action. Table S5 in Multimedia Appendix 1 provides the details of the EMI functionalities of the app.

The app incorporates gamification by guiding participants to create an avatar that represents their emotions, embedding metacognitive skill training within a narrative framework, and awarding insight points for catching the little monster associated with identified anxious thoughts or behaviors. This approach uses game elements, such as rewards and interactive storytelling, to transform the training process into a game-like experience, fostering engagement and motivation through personalized challenges and immediate feedback.

Ethical Considerations

The experiment was conducted under protocol number 510/2020BO approved by the Independent Ethics Commission at the Medical Faculty of the University of Tübingen. The Max Planck Society Data Protection Office has granted authorization for the data protection and privacy policy protocol. This authorization confirms that the project proposal adheres to the internal data protection requirements of the Max Planck Society as well as the General Data Protection Regulation (EU 2016/679) and the German Federal Data Protection Act. The data protection and privacy policy agreements are incorporated in both the ethics protocol and the consent form.

To enroll in the experiment, participants provided informed consent to (1) their voluntary participation in the experiment and (2) the sharing of their nonidentifiable data for research purposes. By giving their consent, participants agreed to adhere to the requirements for participation, including aspects such as payments, bonuses, time commitment, privacy policy, data protection, data collection, data use, and the withdrawal process. To ensure privacy, all data collected during the study are stored locally on participants' devices and synchronized securely with Firebase (Google) cloud services, certified under major privacy and security standards. Only the participant and experimenters have access to these data. Participants can withdraw their participation at any time without penalty, with compensation provided pro rata to the time engaged in the study.

The experiment's payment was split into 2 parts. The initial payment was given to participants upon downloading the app and finishing the 30-minute onboarding. The payment was adjusted to maintain an average wage of GBP £6 (US $7.58) per hour. After completing the experiment, participants were compensated for daily participation, offboarding tasks, and extra bonuses. Through active participation and successful completion

XSL•FO
RenderX

of the experiment, participants could earn up to GBP £9.80 (US $10.59) per hour. Excluded participants were compensated for the work completed before their exclusion, using a rate of GBP £6 (US $7.58) per hour. The estimated average experiment time was 154 (SD 8.85) minutes for participants in the control group and 161 (SD 8.04) minutes for those in the treatment group.

Participants

The sample for this experiment comprised 228 participants, of whom 197 (86.4%) completed the experiment. Participants were recruited from a pool of approximately 39,000 English-speaking adults with iPhones. We used Prolific (Prolific Academic Ltd), a web-based platform used by >25,000 researchers, to recruit and compensate these individuals. Prolific offers access to a diverse pool of >130,000 potential participants, enabling efficient web-based research engagement.

In our study, participants were enrolled at 2 separate points. Initially, 228 participants were enrolled at the start of the study. To compensate for the participants who were excluded and those who dropped out before the experimental conditions diverged on day 3, as preregistered, we conducted a second round of recruitment to maintain the required sample size. Specifically, of the 228 participants, 22 (9.6%) were excluded for failing attention checks, 13 (5.7%) for not starting the experiment, and 2 (0.9%) due to technical issues. These 37 (16.2%) participants were replaced by new enrollees.

During the experiment, 30 (13.2%) of the 228 participants were lost to follow-up due to not meeting the participation criteria (n=22, 9.6%) or technical problems (n=8, 3.5%). In addition, 1 participant (0.4%) was excluded from the data analysis for failing midexperiment attention checks. Multimedia Appendix 2 includes a detailed description of the inclusion and exclusion criteria, along with the recruitment and data collection timeline (Table S1 in Multimedia Appendix 2).

The final sample of 197 participants comprised 97 participants (49.2%) in the experimental condition and 100 participants (50.8%) in the control condition. Most (192/197, 97.5%) of these participants shared demographic information (mean age 38, SD 11.50 years; range 20-80 years; female: n=103, 53.6%). The sample included participants who identified as Asian (7/192, 3.6%), Black (3/192, 1.6%), mixed race (5/192, 2.6%), White (175/192, 91.1%), or other (2/192, 1%). More detailed demographic characteristics, including descriptive statistics by group, are provided in Multimedia Appendix 3.

Experimental Design

Overview

The experiment design and data analysis plan were preregistered to ensure transparency and minimize biases in the analysis and interpretation of the results. Details of the study methodology and reporting adhere to the CONSORT (Consolidated Standards of Reporting Trials) checklist, provided as Multimedia Appendix 4. We conducted a placebo-controlled randomized trial to assess the efficacy of the longitudinal intervention delivered by InsightApp. The experiment encompassed 2 groups: a placebo control group and a treatment group. The experiment used 2 distinct experimental designs: a pre-post follow-up design and a longitudinal experience sampling design. Each experimental design encompasses different sets of outcome measures. The pre-post follow-up design administered self-report measures of mental health and well-being at 3 time points: before the intervention, immediately after the intervention, and after the postintervention phase. The longitudinal experience sampling methods involved multiple daily assessments of anxiety throughout the 18-day experimental period, which included a 4-day preintervention phase, a 7-day intervention phase, and a 7-day postintervention phase.

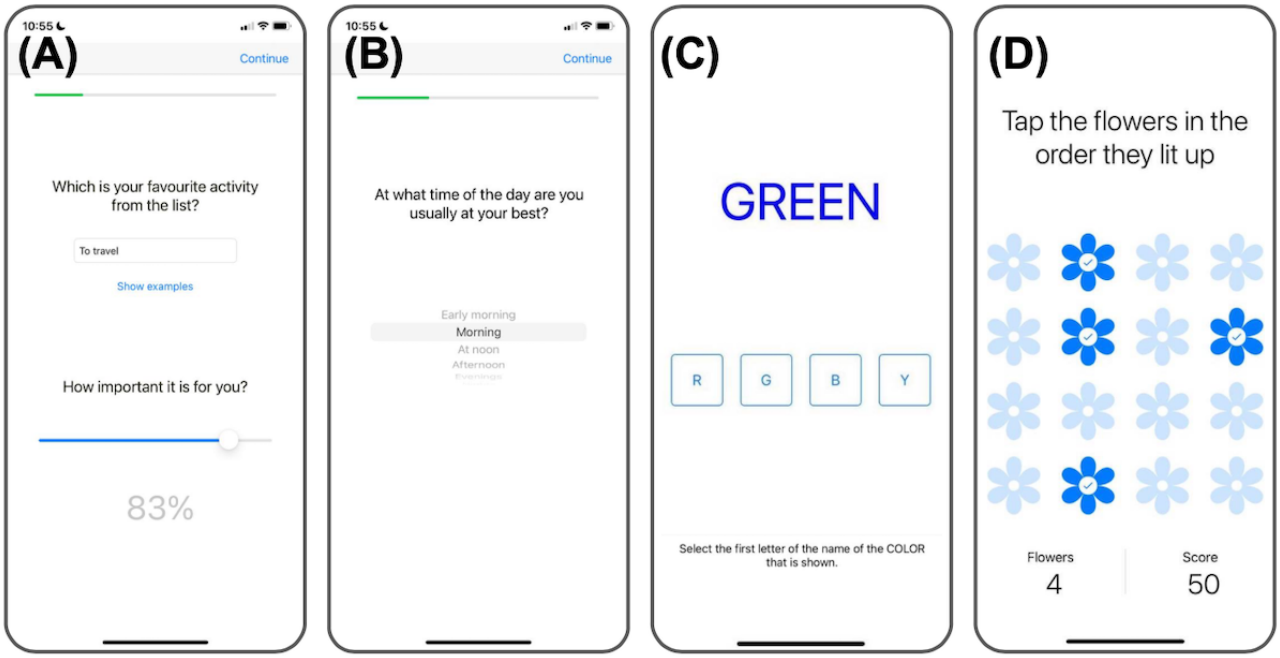
Experiment Timeline

The experiment timeline encompassed 6 distinct phases (Table 1), including general onboarding, preintervention, intervention, midintervention assessments, postintervention, and offboarding.

Table 1. Phases of the experiment timeline.

	Onboarding phase	Preintervention phase (4 days)	Intervention phase (7 days)	Midintervention assessments	Postintervention phase (7 days)	Offboarding phase
Treatment group	Reflection module	Evening survey	• Morning practice • Cognitive defusion practice • Evening survey	• Psychological scales • Motivation survey	Evening survey	• Psychological scales • Exit survey
Placebo control group	Reflection module	Evening survey	• Evening survey	• Psychological scales	Evening survey	• Psychological scales • Exit survey

During the onboarding phase (phase 1), all participants completed the reflection module. During the 4-day preintervention phase (phase 2), participants in both conditions used a basic version of the app that only allowed them to complete the daily evening report between 7:00 PM and 11:59 PM. During the 7-day intervention phase (phase 3), participants continued to complete the evening report. In addition, participants in the experimental condition were introduced to the metacognitive coaches, while participants in the control condition were introduced to execute function tasks described in the Experimental Design section. During this intervention phase, each group completed a practice session every morning between 5 AM and 11:59 AM. In this session, the treatment group interacted with the meta-awareness coach to practice embracing anxiety. In contrast, the placebo control group used the app to keep the training of executive functions. Besides the morning practice, the treatment group was asked to use InsightApp to embrace their emotions throughout the day.



XSL•FO
RenderX

Directly after the intervention period (phase 4), all participants retook the psychological surveys. During the 7-day postintervention phase (phase 5), all participants were requested to solely complete the evening report daily. In the offboarding phase (phase 6), participants retook the psychological surveys, filled out an exit survey, and received their payment. A detailed breakdown of the main tasks and their timing for each round of participants is provided in Table S1 in Multimedia Appendix 2.

Design of the Placebo Control Condition

Previous research highlights the importance and challenges of creating robust control conditions to account for improvements unrelated to digital interventions [22,23]. Accordingly, we designed the control condition to address improvements influenced by participants' implicit goal to improve their emotional states, which can trigger emotion regulation by itself (emotion goals [24]), participants' potential motivation to align with the experiment's objectives (demand characteristics [25]), and participants' expectations for the digital intervention to be effective (digital placebo effect [23]). In this active placebo control condition, the active ingredients of the intervention were replaced by executive function training exercises and self-report questionnaires. Specifically, the placebo condition differed from the treatment only in the specific components under the study. The treatment group worked with the meta-awareness and meta-reasoning coach, while the control group answered questions about psychological traits, preferences, and attentional skills (refer to Figures 3A and 3B). A complete list of control group questions has been provided in Table S1 in Multimedia Appendix 5. In addition, the placebo control group replaced the meta-awareness coach with a Stroop task (Figure 3C) and a spatial memory task (Figure 3D) sourced from the ResearchKit (Apple Inc) library [26]. These tasks enhance cognitive control and attentional skills linked to improved well-being [27-29]. Multimedia Appendix 5 provides a detailed description of the active placebo control condition and how it addresses emotion goals, demand characteristics, and the digital placebo effect.

Figure 3. Screenshots from the control condition's tasks. Panels A and B show example screens illustrating how the app guides the user to answer unrelated questions regarding their preferences, panel C shows the Stroop task, and panel D shows the spatial memory task.

Procedure

Participants were first directed to a web-based form, which provided instructions for downloading InsightAppExperiment from the App Store and starting the experiment. Participants were randomly assigned to the control or treatment group through an automated process within the app. Participants were blinded to their group allocation. Further details on the randomization and blinding process are provided in Multimedia Appendix 6. After logging into the app, participants provided informed consent, confirming their agreement to participate in the experiment and share their data. The experiment started with a brief 1-minute introductory video that explained the onboarding process, followed by a short survey about the participants' sex, age, and nationality. To proceed, all participants completed the reactivity and values reflection modules. Participants then set reminder preferences and received payment instructions. Finally, they accessed the app's main screen to initiate the preintervention phase. They then accessed the app's main screen to begin the experimental timeline explained earlier.

During the study, participant engagement was actively monitored. Participants received daily reminders within the app to complete their morning routines and fill out their evening reports. In addition, we sent daily messages via Prolific to remind them to participate in the study. If participants did not complete an evening report, they were allowed to do so the following morning.

Outcome Measures

Pre- and Posttest Measures: Questionnaire Measures of Mental Health and Well-Being

Overview

We evaluated participants' mental well-being and mental health at 3 different time points: during the onboarding phase (preintervention phase), immediately after the intervention (postintervention phase), and directly after the postintervention (follow-up phase). All measures were administered as web-based surveys within the app. This assessment was conducted using the psychological surveys mentioned subsequently.

Mental Well-Being

Thriving

The Brief Inventory of Thriving Scale [30] is a 10-item, 5-point scale (1=strongly disagree and 5=strongly agree) that measures various aspects of psychological well-being. It assesses 10 facets of positive functioning, representing 7 dimensions of psychological well-being.

Self-Compassion

The Self-compassion Scale (Short form) [31] is a 12-item, 5-point scale (1=never disagree and 5=always) that assesses individuals' ability to embrace their feelings of emotional pain with a sense of warmth, connection, and concern.

Psychological Flexibility

The Acceptance and Action Questionnaire [32] is a 7-item, 7-point scale (1=never true and 7=always true) that assesses individuals' ability to fully experience the present moment, thoughts, and feelings without resistance and to adapt their behavior in pursuit of goals and values as needed.

Mental Health

Anxiety Sensitivity

The Anxiety Sensitivity Index [33] is a 16-item, 5-point scale (1=very little and 7=very much) that measures individuals' fear of sensations of anxiety.

Anxiety Symptoms

The Hamilton Anxiety Rating Scale (HAM-A) [34] is a 14-item, 5-point scale (1=not present and 5=very severe) used to assess the severity of anxiety symptoms, both psychological and physical.

Cognitive Fusion With Anxiety

The Believability of Anxious Feelings and Thoughts Questionnaire [35] is a 16-item, 7-point scale (1=not at all believable and 7=completely believable) used to measure the extent to which individuals cognitively fuse with their anxious thoughts and feelings.

Neuroticism

The Brief Version of the Big Five Personality Inventory [36] is a 10-item, 5-point scale (1=disagree strongly and 5=agree strongly) that assesses various personality traits, including neuroticism. In this experiment, we only administered the 2-item subscale on neuroticism.

Longitudinal Measures: Outcome Measures Administered in the Evening Report

Every evening, between 7:00 PM and 11:59 PM, participants reported how intense their anxiety felt during the day, the degree to which they struggled with anxiety, the degree to which they enacted the predefined valued action, the perceived severity of the challenging situation encountered during the day (stressor), and the presence of any unrelated circumstances causing additional anxiety (unrelated stressor). The outcome measures collected through these reports are summarized in Table 2.

Table 2. Single-item outcome measures administered during the evening report[a].

Outcome variable	Question	Scale
Anxiety intensity (%)	How intense did anxiety feel today?	0-100
Struggle with anxiety (%)	How strong did the struggle with anxiety feel today?	0-100
Intention enactment (%)	To which extent did enact a valued action today?	0-100
Stressor	On a scale from 1 to 10, how severe or problematic was the situation today?	0-10
Unrelated stressor	On a scale from 1 to 10, did you have another situation causing you anxiety today? How severe or problematic was it?	0-10

[a]We used the measure of single-item sliding scales proposed by Amo et al [19] for momentary and daily levels of anxiety, struggle with anxiety, unwanted action, valued action, and the endorsement of the maladaptive and adaptive beliefs.

In this study, we operationalized resilience as participants' capacity to regulate emotional intensity and struggle in response to increasing stress. Specifically, we measured each group's average level of resilience by how little their anxiety intensity and struggle with anxiety increased with within-person variation in stress. This allowed us to measure the intervention's effect on resilience by the coefficient of the interaction effect between the experimental condition and within-person variation in stress. We evaluated whether participants in the intervention group exhibited a smaller increase in anxiety intensity and struggle with anxiety in response to rising within-person levels of stress compared to those in the control group. In addition, we assessed whether they demonstrated a smaller decline in valued action under the same conditions. In this context, resilience is conceptualized as a dynamic, situation-specific ability to manage stress, with the intervention's effectiveness being reflected in participants' ability to adapt to context-specific stressors.

Statistical Analysis

Overview

The experiment design, exclusion criteria, hypotheses, and data analysis plan were preregistered [37]. The complete repository, including the preregistration, data analysis scripts, and data, is also available on the web [38]. Hypothesis testing and multiple comparison corrections were conducted in accordance with the preregistration. A power analysis was conducted for the longitudinal analysis to ensure an appropriate sample size for detecting the expected effects. However, the analysis of posttest and follow-up measures was not fully powered to detect small effects, which limits the conclusions that can be drawn from our analyses of those measures. Further details on the power analysis are provided in Multimedia Appendix 6.

We conducted a per-protocol analysis, including only participants who adhered to the compliance criteria specified in the inclusion and exclusion criteria. Participants who dropped out, experienced technical problems, did not meet participation criteria, or failed attention checks were excluded from the analysis as per protocol. This approach was chosen to ensure that the analysis reflected the effect of the intervention among those who followed the protocol as intended.

Pre- and Posttest and Follow-Up Analyses

We used analysis of covariance to compare the improvements in participants' scores on 2 sets of questionnaires (well-being and mental health) between the groups. We assessed the effect of the experimental condition on each set of outcome variables using the following linear models:

$$\textit{Postintervention score} \sim \textit{preintervention score} + \textit{condition} \times \textit{scale}$$

$$\textit{Follow-up score} \sim \textit{preintervention score} + \textit{condition} \times \textit{scale}$$

These analyses control for individual differences before the test and integrate data from multiple measures while also acknowledging that the effect might differ between them. For post hoc comparisons, we applied the Bonferroni correction to control for multiple comparisons [39]. The power analysis for these analyses indicated that our sample size of 228 participants was underpowered to detect small-sized effects, with an achieved power of 0.32 (Cohen f=0.10, α=.05). As a result, caution should be taken when interpreting the findings, as small effects may not have been detected.

Longitudinal Data Analysis

To ensure sufficient statistical power for detecting the expected effects, a power analysis was conducted using Monte Carlo simulations in Mplus [40]. The analysis indicated that the sample size of 228 participants was adequately powered (power=0.9) for the longitudinal analyses, with a simulated dropout rate of 40%.

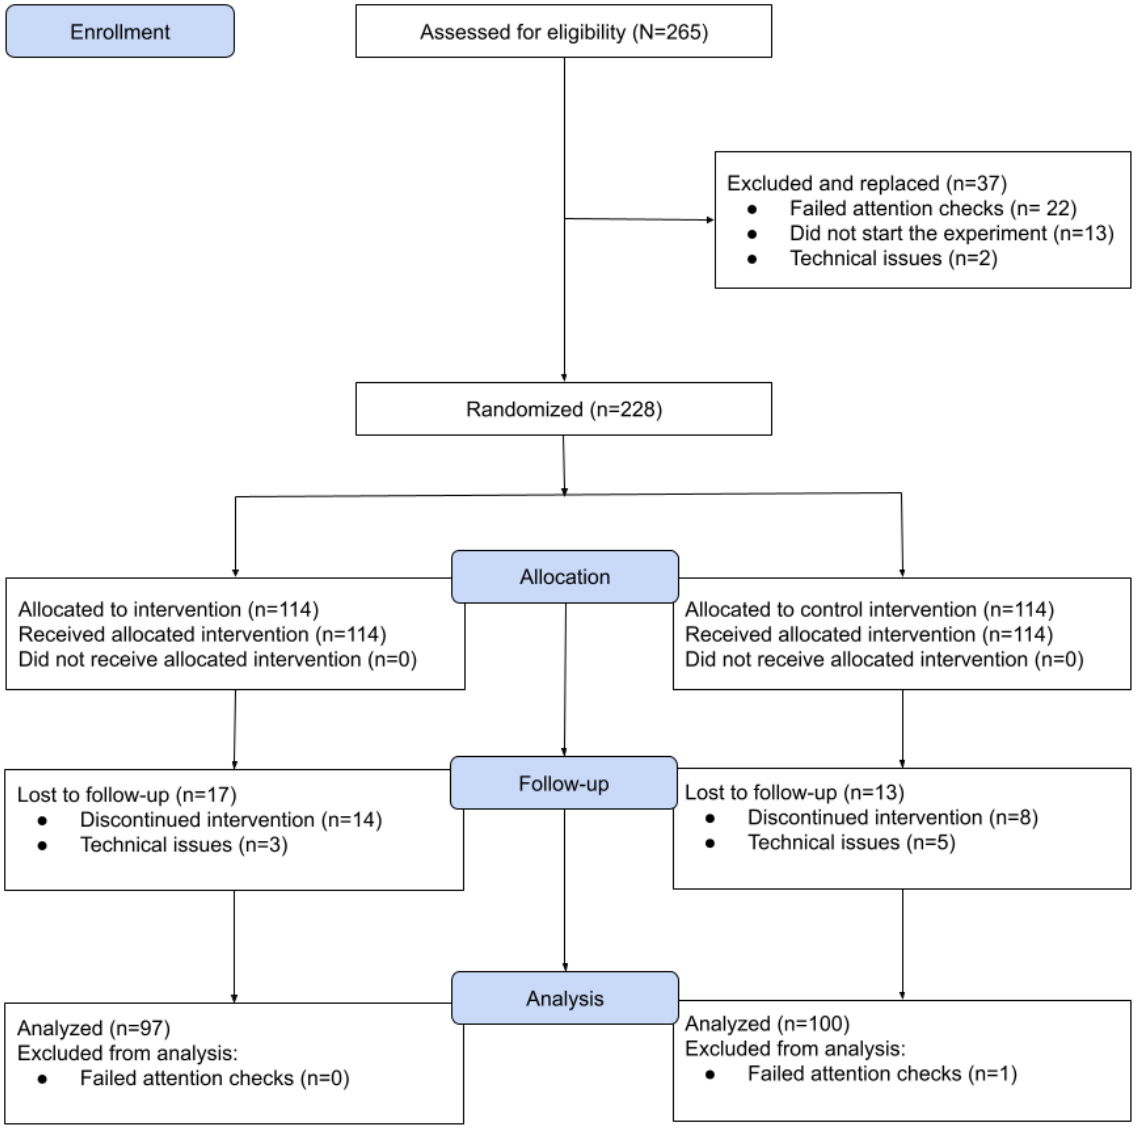
The data analysis followed the procedures outlined in the book by Bolger and Laurenceau [21]. We used an intensive longitudinal research design to model the within-participant causal process through which the intervention affects daily reactivity to stress in terms of affect and behavior. Our data analysis used a multilevel model. We predicted lower within-participant reactivity to stress in the treatment group compared to the control group.

In line with the recommendations, we opted for SAS PROC MIXED (SAS Institute) as our statistical analysis tool due to its ability to handle repeated measurements with unequal time intervals and effectively manage missing data. In addition, adhering to best practices, we distinguished between-participant and within-participant variations to accurately assess the impact of within-participant variation in stress. By focusing on within-participant variation, we can confidently eliminate any confounding effects of between-participant factors. Furthermore, we adopted a conservative approach in determining the df, using the number of participants (N=197) rather than the total number of observations. Finally, the variable time was rescaled such that 0 corresponds to the middle of the intervention period. A 1-unit difference in the variable time represents the passage of 1 day.

According to the preregistration, the hypotheses concerning the daily within-participant reactivity to stress, given the condition (within-participant stress × condition), are directional hypotheses. In contrast, the hypotheses regarding the general effect of condition on the outcome measures (condition) fall under the category of exploratory hypotheses, making them 2-tailed. To control the false discovery rate at a 5% level, we applied the Benjamini-Hochberg procedure [41] to all exploratory hypotheses.

Results

Overview



The Results section is structured into two main parts: (1) the intervention's effect on mental health and well-being immediately after the intervention phase and 7 days later and (2) the longitudinal data on anxiety, emotional struggle, and valued action. We verified that there were no significant differences (all P>.30) between the control and treatment groups in terms of baseline demographic or psychological characteristics. Detailed baseline comparisons between groups across both categories are provided in Multimedia Appendix 7.

We provide additional details on the study's dropout, compliance, engagement, and missing data and sparseness in Multimedia Appendix 8. This appendix outlines participant retention, compliance with study protocols, and an analysis of data sparsity, providing insights into participant engagement and potential data-related concerns.

The CONSORT diagram illustrates the participant flow throughout the study, including enrollment, allocation, follow-up, and analysis phases (Figure 4). The diagram shows the enrollment of 228 participants, with 114 (50%) randomly allocated to the treatment group and 114 (50%) to a placebo control group. Attrition included 17 participants lost to follow-up in the treatment group and 13 in the control group. The final analysis comprised 97 participants in the treatment group and 100 in the control group.

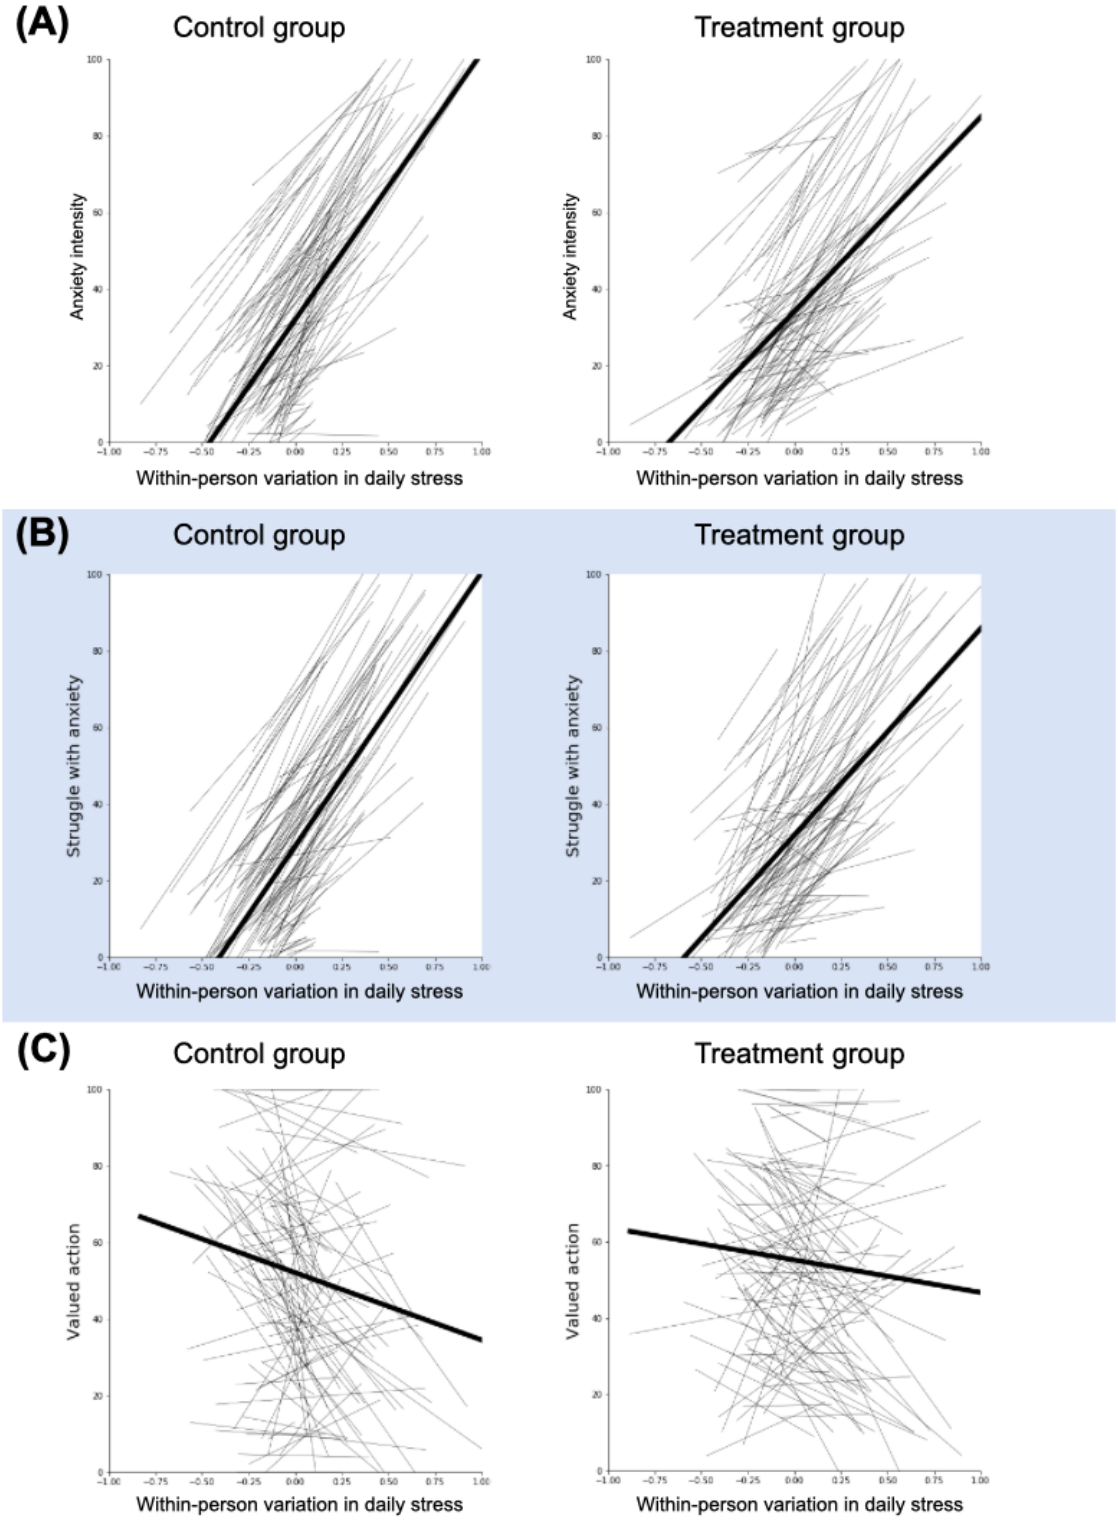
XSL•FO
RenderX

Figure 4. CONSORT (Consolidated Standards of Reporting Trials) flow diagram of the randomized controlled trial.

Mental Health and Well-Being After the Intervention

In this section, we present the results of the comparison between the treatment group and the control group at posttest and follow-up stages on participants' scores related to mental health and well-being. This analysis examines the intervention's effects on mental health and well-being while controlling for participants' baseline scores before the intervention. Further details on the baseline anxiety sample characteristics, as well as the pre- and posttest means, SDs, medians, IQRs, please refer to Multimedia Appendix 9. This appendix provides a comprehensive overview of these metrics for each condition, time point, and anxiety-related variable.

The 2 groups' posttest scores on measures of mental health neither significantly differed directly after the intervention ($F_{1,799}$=0.173, P=.68, partial η^2=0.0002) nor during the follow-up period ($F_{1,799}$=0.235, P=.63, partial η^2=0.0003). The posttest measures of mental health also did not significantly differ, neither directly after the intervention ($F_{1,799}$=1.515, P=.22, partial η^2=0.002) nor during the follow-up period ($F_{1,799}$=0.719, P=.40, partial η^2=0.0009).



Longitudinal Data on Anxiety, Emotional Struggle, and Valued Action

Overview

We used mixed-effects linear regressions to examine the effect of stress on participants' daily scores of anxiety intensity, struggle with anxiety, and intention enactment during the 7-day intervention period. The spaghetti plots in Figure 5 illustrate the qualitative relationships between within-person variation in stress and daily scores for each outcome measure. Visually, the regression lines for participants' anxiety intensity (Figure 5A) and struggle with anxiety (Figure 5B) appear to be less steep for the treatment group than the control group. This suggests that individuals in the treatment group exhibited lower reactivity to stress on both measures of affect. However, this does not appear to be the case for intention enactment (Figure 5C). It is also worth noting that intention enactment appears to be generally higher in the treatment group than in the control group.

XSL•FO
RenderX

Figure 5. Spaghetti plots illustrating regression lines for individual participants (thin lines) and the average effect (thick lines). The panels present daily outcome measures in response to within-person variations in daily stress during the intervention period for the control and the treatment groups. Panel A depicts the intensity of anxiety, panel B shows the struggle with anxiety, and panel C displays intention enactment.

In the subsequent sections, we present the results for each outcome measure separately. First, we report the main effect of group. Subsequently, to understand participants' reactivity to stress during the intervention period, we analyze how the outcome variable varies because of a unit of increase in within-participant stress for each condition. Finally, we report the relative difference in reactivity to stress between groups.

Intensity of Anxiety

The regression analyses summarized in Table S1 in Multimedia Appendix 10 indicate that there was no significant main effect of condition on the average intensity of participants' anxiety (2-tailed *t* test, t_{197}=–1.62; *P*=.11; 95% CI –4.54 to 0.44) during the intervention period. In the control group, we found that the intensity of participants' anxiety increased by 9 units (on a scale

XSL•FO
RenderX

from 0 to 100) per unit of within-person variation in stress (t_{197}=22.53; P<.001; 95% CI 8.21-9.78). In the treatment group, the intensity of participants' anxiety increased by 7.64 units per unit of within-person variation in stress (t_{197}=18.55; P<.001; 95% CI 6.83-8.46). This indicates that using InsightApp decreased reactivity to stress by 1.35 units of anxiety per unit of stress (1-tailed t test, t_{197}=–2.38; P=.009; 95% CI –2.48 to 0.23). In relative terms, the treatment group's level of anxiety was 15.05% less reactive to daily stressors than the control group's level of anxiety.

Struggle With Anxiety

The regression analyses summarized in Table S2 in Multimedia Appendix 10 indicate that there was no significant main effect of condition on the degree to which participants struggled with anxiety (2-tailed t test, t_{197}=–0.9; P=.37; 95% CI –3.76 to 1.4) during the intervention period. In the control group, we found that the strength of participants' struggles with anxiety increased by 8.86 units of struggle per unit of within-person variation in stress (t_{197}=22.1; P<.001; 95% CI 8.07-9.65). In the treatment group, the strength of participants' struggles with anxiety increased by 7.79 units of struggle per unit of within-person variation in stress (t_{197}=18.73; P<.001; 95% CI 6.97-8.61). This indicates that using InsightApp decreased the amount of emotional struggle the treatment group experienced in response to 1 unit of stress by 1.07 units per unit of stress (1-tailed t test, t_{197}=–1.87; P=.031; 95% CI –2.2 to 0.06). In relative terms, for each unit of stress, the treatment group's struggles with anxiety increased 12.09% less in response to stress than the control group's struggles.

Valued Intention Enactment

The regression analyses summarized in Table S3 in Multimedia Appendix 10 show a significant general difference between conditions in the degree to which people enacted their valued intentions. On average, participants in the treatment condition enacted their valued intention 7.07 (0-100) points more than participants in the control condition (2-tailed t test, t_{197}=3.23; P=.002; 95% CI 2.75-11.4). In the control group, the degree to which participants enacted the valued intentions decreased by 2.8 units per unit of within-person variation in stress (t_{197}=–3.77; P<.001; 95% CI –4.26 to 1.34). In the treatment group, the degree to which participants enacted the valued intention in the treatment condition decreased by 1.75 units (t_{197}=–2.3; P=.02; 95% CI –3.25 to –0.25) per unit of within-person variation in stress. The interaction between stress and condition had no significant effect on intention enactment (1-tailed t test, t_{197}=1.0; P=.16; 95% CI –1.03 to 3.13).

The autocorrelation (Tables S1-S3 in Multimedia Appendix 10) of the data was statistically significant for the intensity of participants' anxiety (SP POW=0.102; z score=2.31; P=.04; 95% CI 0.016-0.189) and how much they struggled with anxiety (SP POW=0.13; z score=0.93; P=.002; 95% CI 0.052-0.22). However, the magnitude of these coefficients indicates only a weak positive autocorrelation in the level 1 (ie, within-participant) residuals. As shown by the magnitude (0.039) and P value of the coefficient (P=.45), there is no evidence of autocorrelation for the case of valued action.

We ran the same analysis for the 7-day postintervention period. The results indicated that the degree to which the treatment group struggled with anxiety in response to 1 unit of stress was still 1.43 units lower than that of the control group (t_{197}=–2.84; P=.002; 95% CI –2.42 to 0.44). In other words, even after the support of InsightApp was removed, each unit of stress increased the treatment group's struggle with anxiety <18% of the control group's struggle with anxiety. We found no other significant differences between the 2 conditions during the postintervention period (Multimedia Appendix 11).

Finally, to determine whether baseline anxiety levels influenced the effectiveness of the intervention, we conducted exploratory analyses. After incorporating relevant interaction terms into our models, we found that baseline anxiety traits were not statistically significant (all P>.05), either during the intervention or in the postintervention phase. Consequently, we cannot conclude that baseline anxiety traits moderated the intervention's effectiveness. Details of the exploratory analysis have been provided in Multimedia Appendix 10.

Discussion

Principal Findings

In this randomized controlled trial, we examined the effectiveness of InsightApp in helping individuals cope with stress and anxiety in real-life settings. During the intervention period, the treatment group was significantly more resilient to stress in terms of the intensity of their anxiety and the degree to which they struggled with it. Moreover, the treatment group demonstrated a higher enactment of their valued intentions compared to the control condition. These effects were sustained in the postintervention period regarding the struggle with anxiety. However, the postintervention scores and follow-up scores on measures of well-being and mental health did not significantly differ between conditions (all P>.22).

Limitations

The experiment had the following limitations. First, the sample was relatively homogeneous, lacking diversity in ethnicity, education, and location. This limits the generalizability of findings across different cultural backgrounds. In addition, as the sample was drawn from the general population, the intervention's effectiveness may vary for individuals with higher anxiety levels. Participants were also compensated, potentially affecting their engagement and motivation, which could differ from those in the general population without such incentives.

Second, the relatively brief training and postintervention period (ie, 7 days) limit our understanding of the intervention's long-term effectiveness. Extended use may yield more pronounced effects. The duration of sustained improvements beyond the 7-day postintervention phase is also uncertain. Furthermore, the results of our longitudinal data analysis should be taken with a grain of salt because some time series were weakly autocorrelated. Third, the experiment design has room for improvement. Presurvey measures may have unintentionally

XSL•FO
RenderX

provided psychoeducation to the control group. Moreover, as the control condition included elements of the reflection modules, such as the reactivity and values modules, our results may underestimate the benefits of the complete InsightApp as a package intervention.

Two significant limitations impacted the pre-post measurement of anxiety in this study. First, the study was underpowered (power of 32.4%, f=0.10, α=.05) to detect small effects on posttest and follow-up measures of psychological traits, and because our intervention was short, small effects were to be expected. Therefore, the nonsignificant findings do not imply that the corresponding effects do not exist. Rather, our study was underpowered to conclusively determine the significance of long-term effects on psychological traits**.**

Furthermore, the administration of the HAM-A posed challenges. This scale was administered via an online self-report format rather than the traditional clinician-administered interview. The HAM-A is typically conducted by a trained clinician to ensure an accurate interpretation of the items, which may not be as intuitive for participants to self-assess. Although we provided clear instructions, the absence of direct clinician oversight may have affected the reliability and validity of the results. This deviation from the standard administration method should be considered when interpreting the findings, as it may introduce variability in how participants understood and responded to the scale.

Another limitation of this study is the brief duration of the intervention, which may have restricted the ability to detect changes in trait-level measures of anxiety that typically require longer periods to show. Extending the intervention beyond 7 days may enhance its impact, particularly on more stable, trait-like outcomes, and should be explored in future research.

Another potential concern that could affect the interpretability of the results is the evaluation of the app in a population that may not have fully endorsed anxiety symptoms. To address this concern, we conducted an analysis of baseline anxiety levels, as detailed in Multimedia Appendix 9, specifically in the Anxiety Sample Characteristics section. This analysis shows that even though we recruited our sample from the general population, it included a broad spectrum of anxiety levels, with >70% of participants reporting moderate to high anxiety traits. There was no evidence that the effectiveness of the intervention varied for participants with differing baseline levels of anxiety (P>.05; refer to Multimedia Appendix 9). However, because the app was not tested in a clinical sample, we cannot conclude that the intervention would be effective or have a similar size effect in a clinical population. This makes testing the intervention in a clinical sample an important direction for future research.

Finally, while we observed significant effects in the longitudinal data, we did not find such significant results in the comparison of pre- versus posttest measures. The lack of pre-post significant results could raise questions regarding the overall impact of the intervention on participants' psychological well-being. In the subsequent section, we explore potential factors that could explain the lack of statistically significant pre-post effects.

Interpretations

The intervention effectively reduced daily anxiety levels and struggle with anxiety compared to the control group. However, no statistically significant differences were observed in postintervention self-report questionnaires. When interpreting these results, it is important to consider that this discrepancy may stem from the study's short duration and its lack of power to detect small effects in pre-post measures. In addition, differences in outcome variables could also contribute to these findings. The experience sampling data showed anxiety reduction in specific stress situations, while postintervention questionnaires assessed general mental health and well-being regardless of stress. In addition, although the wording of the instructions for the self-report measures—originally designed to assess traits—was adjusted to reflect the past two weeks, it may still have lacked sensitivity to detect short-term intervention effects. Longer interventions may have a more substantial impact on traits, whereas shorter-term measures, such as ecological momentary assessment or daily diaries, are more sensitive to short-term fluctuations in psychological states [20,42]. Further investigation and extended interventions are needed for a comprehensive understanding of the intervention's effectiveness in promoting psychological well-being.

Notably, participants' improvement in anxiety struggle levels during the intervention was sustained and even reduced after the intervention. However, the effect on anxiety intensity did not persist. This suggests that the app's focus on metacognitive skills may help users acknowledge and accept intense emotions, reducing their struggle with anxiety even without app support. However, participants might have relied on the app for anxiety intensity reduction rather than the app's general strategies. Further investigation is required to understand how the app impacted anxiety intensity and develop strategies for users to experience these benefits independently of the app. Differential retention of effects between anxiety intensity and struggle underscores their distinct dimensions in an individual's anxiety experience. Measuring and addressing both aspects is crucial for a comprehensive understanding of anxiety's impact on well-being.

Another point worth noting when interpreting the results is that baseline anxiety traits did not significantly moderate the intervention's outcomes. This indicates that there is no evidence to suggest that the intervention's effectiveness varies across different levels of baseline anxiety. Although the app was tested on the general population, the sample exhibited a broad range of anxiety levels, with a substantial proportion of participants experiencing moderate to high anxiety traits, underscoring broad applicability.

Comparison With Prior Work

In this section, we compare the results of our experiment with previous research in the field. InsightApp collects data using experience sampling and pre-post follow-up assessments of mental health and well-being. Most studies on EMIs for anxiety only rely on pre-post comparisons [9,43,44]. By contrast, our experiment additionally used experience sampling to track participants' reactivity to stress on a daily basis during and after the intervention. To the best of our knowledge, there is currently

XSL•FO
RenderX

no other experiment that examined how EMIs moderate the effects of stress on daily reports of anxiety, struggle with anxiety, and intention enactment. Furthermore, InsightApp incorporates multiple psychotherapeutic strategies from ACT, CBT, and mindfulness-based cognitive therapy into an integrated gamified approach. To the best of our knowledge, previous mental health apps for stress and anxiety have not integrated all of these components into a game for people to practice metacognitive skills with their real-life challenges. Therefore, we compare our findings with previous studies on digital interventions that include ≥1 component similar to those of InsightApp.

Mindful awareness and acceptance of emotions are key components actively trained by InsightApp. Previous studies in the literature on stress coping have provided evidence supporting the idea that being aware of the present moment can reduce emotional reactivity to stressors [6,7,45-47]. Our results indicate that when participants engage in a daily practice of noticing, accepting, and embracing their emotions, they experience significantly less anxiety when facing stressors and report fewer struggles with their feelings of anxiety compared to the control group. Our findings highlight the potential benefits of incorporating these practices into daily life beyond the controlled settings of a laboratory environment. In addition, our experiment supports the notion that training metacognitive skills with daily challenges leads to sustained improvements. The findings indicate that metacognitive skills for coping with stress and anxiety are trainable and can be effectively improved with a relatively small amount of practice. Importantly, the positive effects of this training on the degree to which participants struggle with anxiety were sustained after the training period ended. This suggests that metacognitive skills can be cultivated and applied in everyday life. This makes them valuable tools for managing stress and anxiety.

Some studies have also examined the interaction between mindfulness, coping with stress, and value-congruent action. These studies have found evidence supporting the hypothesis that individuals who possess higher levels of present-moment awareness are less emotionally reactive to stressors and are more likely to engage in value-congruent actions [17,46-48]. The results of our experiment consistently align with previous findings. Participants who practiced awareness and acceptance of their emotions using InsightApp demonstrated significantly lower emotional reactivity to stressors, experienced less anxiety, and exhibited a higher frequency of enacting their valued intentions compared to the control group.

As reported in the Results section, participants' scores on postintervention measures of mental health and well-being did not show significant improvement compared to the control group, neither directly after the 7-day intervention phase nor in the follow-up assessments. The meta-analysis conducted by Versluis et al [43] covered 15 interventions targeting anxiety, indicating a small to medium effect size of Hedges g=0.47 on pre- and posttest anxiety measures.

When contrasting the effectiveness of InsightApp with these interventions, it is important to take into account factors such as the intervention duration, experimental design, the inclusion of control conditions, and the strength of those control conditions. As discussed in the Methods section, previous work has emphasized the significance and complexities involved in crafting robust control conditions that can effectively address the digital placebo effect [22,23]. This phenomenon involves improvements in outcome variables that are driven by their belief in the effectiveness of the digital intervention. To effectively address the digital placebo effect, control conditions should closely resemble the treatment condition. Hence, it is crucial for them to exhibit structural equivalence and similar aesthetics, quality, and usability as the experimental condition [23]. In addition, the control condition should feel credible to participants, and the description of the benefits that participants can expect from participating in the experiment should be identical. Waitlist controls fail to address the placebo effect, as participants do not anticipate receiving benefits between assessments. Consequently, studies with control conditions dissimilar to the treatment intervention or waitlist controls might overestimate the intervention's impact on participants. Experiments with strong control conditions are still rare in research on EMIs for anxiety. For example, from the 15 interventions targeting anxiety reviewed by Versluis et al [43], only 7 included a control group. Of those interventions, only 4 incorporated a placebo control groupor an active control group. Therefore, the effect size of g=0.47 might overestimate the real effect of the digital interventions on participants' pre-post measures of anxiety. Our experiment addressed this problem by using an active placebo control group that is highly isomorphic to the treatment group. Our experiment thereby isolated the active component under examination. Moreover, our experimental design was attuned to participants' improvements in daily life. This strategy helped to prevent the potential overestimation of the intervention effects in pre-post outcome measures while also allowing for the capture of more nuanced and gradual improvements in participants' mental health and well-being.

Finally, the intervention presented in this study was tested as an intensive, short-term treatment, with 1 session per day over a week. The complete study lasted 3 weeks, including a pre- and postintervention period. This contrasts with traditional psychotherapy, which typically spans several weeks or months but usually involves only 1 session per week. Unlike in therapy, short, intensive interventions are not uncommon in research on EMIs. For example, a systematic review of 19 papers on EMIs reported that study durations ranged from 2 to 15 weeks, with an average of 4 weeks [49]. Another study evaluating 26 EMI studies based on CBT principles reported that study durations ranged from 2 weeks to 6 months, with a median duration of 30 days [50].

Conclusions

In this experiment, we conducted a randomized controlled trial combining 2 distinct experimental designs: an experience sampling design and a pre-post follow-up design, each applied to different outcome measures. The experiment's results showed significant improvements in participants' anxiety, struggle with anxiety, and intention enactment as reactivity to stress on momentary daily measures. Moreover, the improvement in participants' struggle with anxiety persisted after the end of the

XSL•FO
RenderX

intervention, indicating that participants internalized at least some of the emotion regulation strategies InsightApp had directed them to use during the intervention. However, these positive changes did not lead to significant improvements in self-report measures of overall well-being and mental health. Further research is needed to resolve the apparent contradictions between the observed improvements during the training and the lack of improvements in pre-post measures of general mental health. Future studies should explore intervention durations longer than those used in this study and be adequately powered to detect small improvements, ensuring that subtle effects are not missed due to insufficient sample sizes.

Abstract

Background: People with past suicidal thoughts and behavior (STB) are often excluded from digital mental health intervention (DMHI) treatment trials. This may perpetuate barriers to care and reduce treatment generalizability, especially in populations with elevated rates of STB, such as body dysmorphic disorder (BDD). We conducted a cohort study of randomized controlled trial (RCT) participants (N=80) who received a smartphone-based cognitive behavioral therapy (CBT) treatment for BDD that allowed for most forms of past STB, except for past-month active suicidal ideation.

Objective: This study had two objectives: (1) to characterize the sample's lifetime prevalence of STB and (2) to estimate and predict STB incidence during the trial.

Methods: We completed secondary analyses on data from an RCT of smartphone-delivered CBT for BDD. The primary outcomes consisted of STB severity and suicide attempt assessed at baseline with the Columbia-Suicide Severity Rating Scale (C-SSRS) and weekly during the trial via one item from the Quick Inventory of Depressive Symptomatology-Self Report (QIDS-SR item #12; 1043 observations). We computed descriptive statistics (n, %) and ran a series of bi- and multivariate linear regressions predicting STB incidence during the 3-month trial.

Results: At baseline, 40% of participants reported a lifetime history of active suicidal thoughts and 10% reported lifetime suicide attempts. During the 3-month trial, 42.5% reporting thinking about death or suicide via weekly assessment. No participants reported frequent or acute suicidal thoughts, plans, or attempts. Lifetime suicide attempt (odds ratio 11, 95% CI 2.14 - 59.14; P<.01) and lifetime severity of suicidal thoughts (odds ratio 1.76, 95% CI 1.21 - 2.77; P<.01) were significant bivariate predictors of death- or suicide-related thought incidence reported during the trial. Multivariate models including STB risk factor covariates (eg, age, and sexual orientation) modestly improved prediction of death- or suicide-related thoughts (eg, positive predictive value=0.91, negative predictive value=0.75, and area under the receiver operating characteristic curve=0.83).

Conclusions: Although some participants may think about death and suicide during a DMHI trial, it may be safe and feasible to include participants with most forms of past STB. Among other procedures, researchers should carefully select eligibility criteria, use frequent, ongoing, low-burden, and valid monitoring procedures, and implement risk mitigation protocols tailored to the presenting problem.

Introduction

Mental illness directly affects nearly half of all adults in the United States [1]. Although effective treatments have been developed for a wide range of disorders, demand far outstrips availability [2]. Indeed, care gaps are estimated at above 50% [3]. Some barriers to accessing mental health care include the limited number of clinicians, high cost of services, limited insurance coverage, and entrenched stigma. Digital mental health interventions (DMHIs) promise to address many of these concerns. DMHIs can be relatively inexpensive, reduce clinician time, and may reduce stigma through increased privacy [4,5]. Participants in DMHI trials often compete study components remotely, asynchronously, and relatively independently [6,7]. The light-touch nature of many DMHIs presents issues for researchers designing treatment trials, who might wonder if they are safe for people with higher clinical acuity, such as those with past or current suicidal thoughts and behavior (STB), as past STBs are the strongest known risk factors for future suicide thoughts, attempt, and death [8,9]

People with past and current STB are often excluded from treatment studies, including those testing DMHIs [6,10,11]. Indeed, recent meta-analytic reviews of depression and anxiety DMHI trials have found that between 60% to 90% of studies contained exclusion criteria based on "suicide risk" [6,7] with 33% of computerized depression and anxiety trials excluding people with "current" suicidal ideation, plan, or intent, 70% excluding based on recent-past suicidal thoughts (eg, thoughts occurring in the past 2 weeks, but not necessarily at the time of index assessment), and nearly 15% excluding based on a reported "history of suicidality" (eg, suicide attempt) [6]. Among the handful (n=5) of body dysmorphic disorder (BDD)–focused DMHI trials (excluding the presently discussed trial [12]), most used a past-STB–related exclusion criterion, too—specifically, either past-week or month active or acute suicidal ideation (n=2; [13, 14]) or past suicide attempt (n=2; [15, 16]). Because it is difficult to accurately predict STB [8,17] and few studies report on STB incidence during a trial or provide details on the content of adverse events [18], it is difficult for researchers to establish appropriate evidence-based STB exclusion criteria versus likely overly restrictive criteria.

Trials with appropriately restrictive STB exclusion criteria may mitigate (but likely not eliminate) risks associated with adverse events and reduce time and effort associated with managing unduly high STB incidence while also allowing for a relatively representative sample. By contrast, trials with overly restrictive STB criteria may more effectively reduce these risks but, crucially, would also likely reduce real-world generalizability and reproducibility. Also, overly restrictive STB exclusionary practices may perpetuate endemic barriers to care that people with STB already experience in face-to-face clinical research studies and real-world treatment settings [19].

The purpose of the present study was to describe the suicide risk mitigation procedures used in a recent randomized controlled trial (RCT) of smartphone-delivered cognitive behavioral therapy (CBT) for BDD and to describe and predict the actual occurrence of STBs during the 12-week trial. This study provides a relatively strong test of the risk mitigation procedures followed because (1) in general, people with BDD have high rates of suicidal thoughts [20,21,22,23], suicide attempts [eg, 21, 24, 25], and completed suicides [21]; (2) although the current RCT excluded based on "active" suicidal thoughts occurring in the past month, it did not exclude any form of STB occurring>30 days before baseline assessment, including past suicide attempt, active suicidal ideation, plans, and intent, which makes it less restrictive than other BDD focused DMHI trials; and (3) participants with some forms of recent (ie, ≤30 d before baseline) death- or suicide-related thoughts were still eligible to participate (eg, wish to be dead).

Methods

Overview

A randomized waitlist-controlled trial was conducted with 80 adults with a primary BDD diagnosis. The treatment group had access to the Perspectives BDD, a coach-guided smartphone app that provided CBT for BDD for 12 weeks [12]. Perspectives BDD included modules on psychoeducation, restructuring maladaptive thoughts, exposure with response prevention, mindfulness and attentional retraining, values and enhancing self-esteem and self-compassion, and relapse prevention. Participants also had access to bachelor's-level coaches who aimed to enhance motivation and engagement via two telephone calls (onboarding and midtreatment) along with asynchronous in-app text-based messaging throughout the treatment period. Participants answered brief (four-item) weekly in-app surveys related to their current symptom levels and suicidal thoughts. They were also assessed by a trained doctoral-level clinician at screening and baseline, mid (week 6), and end-of-treatment (week 12). Participants initially allocated to the waitlist received access to the app-based treatment after 3 months. Weekly data collected from participants while on the waitlist is included and analyzed along with all data collected during active treatment period.

To be eligible for the study, individuals were required to have a primary BDD diagnosis, be at least 18 years old, and reside in the United States. Individuals were excluded if they were currently in therapy, had previously completed 4 or more sessions of CBT for BDD, had undergone psychotropic medication changes less than 2 months before starting the study, reported acute and active suicidal ideation (refer to "Procedures Used for Mitigating Clinical Deterioration and Suicide Risk" section below), or were unable to engage with the smartphone treatment. Other exclusion criteria included a current severe substance use disorder, current severe comorbid major depressive disorder, or a lifetime bipolar or psychotic disorder. The sample was predominantly female (84%), non-Hispanic (88%), and White (71%) with a mean age of 27 (SD 9.6; refer to ClinicalTrials.gov NCT04034693 trial registration and [12] for additional information regarding the treatment, participants, and study design and procedures). To reduce burden, demographic information was not collected from people excluded from participating in the trial. All procedures were approved by the Mass General Brigham Institutional Review Board.

Measures

Clinician-Administered

Relevant clinician-administered measures included the Yale-Brown Obsessive Compulsive Scale Modified for BDD (BDD-YBOCS; [26]), Mini International Neuropsychiatric Interview (MINI 7.02; [27]), and the Columbia-Suicide Severity Rating Scale (C-SSRS [28]; refer to [12] for additional measures administered). The BDD-YBOCS is the gold-standard measure of BDD symptom severity and was used to characterize the sample and track symptom severity. The MINI, a standardized diagnostic interview, was used to determine *DSM-5* (*Diagnostic and Statistical Manual of Mental Disorders* [Fifth Edition]) psychiatric diagnoses and to evaluate whether BDD was primary. The C-SSRS was used to assess lifetime and past 30-day suicidal ideation, intent, and behavior. Measures were administered at baseline by blinded, doctoral-level independent evaluators.

Self-Report

Relevant self-report measures include the Quick Inventory of Depressive Symptomatology-Self Report (QIDS-SR; [29]) and the Clinical Global Impressions scale [30] adapted for assessing BDD symptoms (CGI-BDD), and the Patient Health Questionnaire-2 (PHQ-2; [31]).

The QIDS-SR and CGI-BDD were administered at baseline, mid, and end-of-treatment assessments. To assess past-week death- and suicide-related thought severity, item #12 of the QIDS-SR was administered to participants via weekly in-app surveys and via web-based surveys to those on the waitlist. The item's label was: "Thoughts of Death and Suicide." Answer choices included: 0 ("I do not think of suicide or death"), 1 ("I feel that life is empty or wonder if it's worth living"), 2 ("I think of suicide or death several times a week for several minutes"), and 3 ("I think of suicide or death several times a day in some detail, or I have made specific plans for suicide or have actually tried to take my life").

An item from the CGI-BDD was used to determine whether participants perceived their past-week BDD symptoms improving or worsening. Participants rated their current symptoms "compared to how [they] felt when first entering the study." Answer choices ranged from 1 (very much improved) to 7 (very much worse). The PHQ-2 was used to assess core diagnostic symptoms of depression severity (low mood and anhedonia), answer choices ranged from 0 (not at all) to 3 (every day). The QIDS-item #12, CGI-BDD and PHQ-2 were used as indicators of suicide and psychiatric risk, which triggered the risk-mitigation procedures detailed in "During the Trial" section.

Procedures Used for Mitigating Clinical Deterioration and Suicide Risk

During Screening

Exclusion criteria sought to limit participants with "very severe depression" (≥21 on the QIDS-SR; [27]) and active, acute suicidal ideation (≥2 on the C-SSRS suicide ideation severity subscale for past-month suicidal thoughts). Prospective participants endorsing these symptoms were contacted by a doctoral-level independent evaluator, who followed up with the participant via phone within 24 hours to evaluate safety and make a referral to a higher level of care if clinically indicated.

During the Trial

The app homepage presented a reminder to participants that if they were experiencing suicidal thoughts, they should go to the emergency room right away. Links to 911 and the national suicide hotline were also presented. Participants designated an emergency contact (eg, friend or relative) in case that the participant was unreachable, and the study team was concerned about their well-being. Also, participants could be withdrawn if, in the judgment of the principal investigator (PI), remaining in the study posed a substantial risk to the participant or a higher level of psychiatric care was needed due to significant clinical deterioration or active, acute suicidal thoughts.

Participants' clinical deterioration and suicide thoughts or behaviors were assessed weekly via a brief in-app survey and at study mid and endpoints via self-report. Clinical deterioration was defined by a combination of (1) a rating of 6 (much worse) or 7 (very much worse) on the weekly, participant-rated CGI-BDD across 2 subsequent weeks and (2) PI judgment that remaining in the study was not clinically indicated. Of note, a single rating of 6 or 7 on the weekly, participant-rated CGI-BDD triggered an alert to the clinician and coach via SMS text message or email, which was followed up by a licensed, doctoral-level study clinician within 24 hours of the alert. Study clinicians received supervision by the PI and Coinvestigators, all of whom had decades of experience conducing large-scale RCTs with BDD and other disorders with elevated STB risk.

Active, acute suicidal ideation was assessed via QIDS-SR item 12. A score>0 triggered a "pop up" message presented to the patient within the mobile app reminding them that if they were experiencing suicidal thoughts they should seek professional help without delay or if they felt unsafe to call 911 or go to their nearest emergency room. Links to 911 and the national suicide hotline were provided within this pop-up notification. Here, we note that a recently published expert consensus statement [17] on managing suicide risk in digital studies indicates that most suicide experts polled agreed it was appropriate to present pop-ups containing resources like 911 and the national suicide hotline to participants with elevated suicide risk, where risk is typically determined by the presence of suicidal thoughts or current intent>0. However, most experts also agreed that pop-ups should not expressly suggest that all participants with any or all suicidal thoughts should go to their nearest emergency room, as this would be unwarranted for many and potentially iatrogenic for some. Instead, the decision to initiate a higher level of care or active rescue should be determined via clinical outreach. Therefore, we would advocate future studies follow this updated guidance. A score>1 triggered an alert to the clinician and coach. A study clinician followed up with a phone evaluation within 24 hours of an alert. Risk was assessed via clinical interview, referencing the participant's recently reported scores and asking follow-up questions derived from validated measures (eg, C-SSRS and Beck Depression Inventory) related to the frequency and intensity of suicidal thoughts, presence and specificity of suicide planning and preparation, level of current suicide intent and access to means, previous STB and

XSL•FO
RenderX

current impairment and distress. Clinicians completed a safety plan with participants when warranted by increased death or suicide-related thoughts or risk of suicidal behavior. Participants were to be referred to a higher level of care, including going to an emergency room, if clinically indicated by this risk assessment.

Data Analyses

To examine the differences between participants included versus excluded from the trial, we computed a *t* test with unequal variance to compare mean depression severity and a chi-square test to compare prevalence of death- and suicide-related thoughts collected at screening. To characterize participants' lifetime STB, we computed descriptive statistics (eg, mean and percentage) on C-SSRS variables collected at baseline. To calculate the incidence of STB during the trial, we took several steps. First, we aggregated all weekly, mid, and endpoint QIDS-SR item #12 responses. There were 1440 possible observations, of which 397 (27.5%) were missing. Second, we created three dichotomous variables: (1) to capture any "life not worth living, death- or suicide-related thought," we recoded item responses as 0 versus ≥1 (2) to capture "several death- or suicide-related thoughts in any week," we recoded responses as ≤1 versus ≥2 and (3) to capture increased severity of death- or suicide-related thoughts, we evaluated whether any subsequent QIDS-SR item #12 response was>baseline response (increased severity) versus whether any subsequent response was ≤ the baseline response (no increase in severity). Third, we calculated descriptive statistics (eg, count and percentage) for each variable. To predict STB incidence, we ran a series of bi- and multivariate logistic regressions to predict dichotomous outcomes. Bivariate models predicted STB with either (1) lifetime suicidal ideation intensity or (2) lifetime suicide attempt, both collected via the C-SSRS at baseline. Multivariate models included the following baseline variables: birth sex (female: n=67, 83.8%), age (mean 27, SD 9.64; C-SSRS lifetime suicidal ideation severity (mean 1.83, SD 1.86, median 1, IQR 3.25), lifetime suicide attempt (n=8, 10%), QIDS-SR depression severity total score, excluding the death or suicide related thoughts item #12 (mean 10.94, SD 3.90), BDD symptom severity (BDD Y-BOCS, mean 30.35, SD 4.4), and sexual orientation. Sexual orientation was a categorical variable with three levels: "Straight/Heterosexual" (n=49, 61.3%), "Lesbian, Gay/Homosexual, or Bisexual" (n=20, 25%), and "Other," (n=11, 13.8%), which includes participants endorsing sexual orientation options, "Something else," "don't know," or "choose not to disclose." We included these covariates because they are known risk factors of STB [8]. We included both bi- and multivariate models to evaluate whether single variables (eg, suicide attempt) or a collection of variables would be helpful in predicting which trial participants would report STB during the treatment phase. All analyses were carried out using R Statistical Software (version 4.4.2; R Core Team 2021) [32].

Ethical Considerations

Participants provided electronic, written informed consent before the initiation of any study procedures. The study protocol was reviewed and approved by the Mass General Brigham institutional review board (approval number 2017P000293).

Results

Reasons for Exclusion

A total of 107 people were screened for the trial. Of those, 27 (25.2%) were not included for the following reasons: 14 (13.1% of those consented) for a nonprimary BDD diagnosis, 4 (3.7%) for endorsing acute suicidal ideation in the past month (ie, active suicidal ideation as indicated by clinical judgement or a score of 2 or greater on the suicidal ideation subscale of the C-SSRS), 4 (3.7%) for not meeting criteria for BDD, 4 (3.7%) for having received greater than 3 sessions of CBT, 3 (2.8%) for bipolar symptoms, 3 (2.8%) for declining to participate (eg, due to life stress and learning more about the treatment offered), and 1 (0.9%) for acute depression, as indicated by clinical judgement or a QIDS-SR total score of 21 or greater.

Differences Between Participants Excluded Versus Included

Participants included in the study did not significantly differ from those excluded in past-week depression severity (QIDS-SR, total mean 11.28, SD 4.14 vs mean 12.44, SD 3.90; t=1.33; Cohen d=–0.29, 95% CI –0.73 to 0.16; P=.19), nor in prevalence of past-week death- or suicide-related thoughts (ie, >0 on QIDS-SR item 12; n=26, 32.5% vs n=12, 44.4%; χ^2_X=1.25; P=.26). Demographic and other data were not collected for people deemed ineligible during screening to reduce burden.

Suicide Risk Alerts and Outcomes

During the treatment phase—that is, the first 3 months for participants randomized to immediately receive the app and the first 6 months for those randomized to the waitlist—12 risk alerts were triggered by 11 different participants. All risk alerts were generated from responses to weekly in-app surveys. Around 10 alerts were related to elevated death- or suicide-related thoughts and 2 alerts were related to increased clinical severity (1 for depressive symptoms and 1 for BDD symptoms). Per protocol, study clinicians followed up with participants via telephone. In all but one instance, participants were reached within hours of triggering the alert. With those reached, a study clinician completed an in-depth risk assessment and created or reviewed a safety plan. All participants were deemed to be at low risk for attempting suicide in the near future and as such did not require a higher level of care or withdrawal from the study. The participant who was not reached after multiple attempts (via telephone and email) was monitored for responsiveness to in-app notifications and engagement (eg, completion of CBT exercises). This participant continued to engage with treatment and did not meet criteria for the study team to call their emergency contact. However, due to nonresponsiveness and increased clinical severity, this participant was withdrawn from the study and provided symptom-specific resources and clinical referrals via email.

Trial Participants' Lifetime and Past-Month Prevalence of STB as Assessed by C-SSRS

Lifetime

At baseline, most trial participants (65.0%, n=52) reported experiencing a wish to die at some point in their lives (C-SSRS, Q1). Just under half (41.3%, n=33) reported nonspecific active suicidal thoughts (Q2), 37.5% (n=30) reported active thoughts without a plan or intent (Q3), 20% (n=16) reported active suicidal thoughts with some intent but without a specific plan (Q4), and 13.5% (n=11) reported active suicidal thoughts with some intent and a specific plan (Q5). About 10% (n=8) of participants reported having attempted suicide, 16% (n=13) reported engaging in some form of suicidal behavior (ie, suicide preparation or aborted, interrupted, or actual suicide attempt), and 30% (n=24) reported past nonsuicidal self-injury. These results are in line with previous literature indicating that STB is relatively common among people with BDD [21].

Past Month

A total of 25% (n=20) of participants reported a wish to die (Q1) in the month before starting the trial. No participants reported experiencing more severe suicidal thoughts, as this was an exclusion criterion.

Incidence of STB During the Trial

Table 1 displays the incidence of STB during the trial. Notably, no participants reported experiencing daily suicide- or death-related thoughts or making a specific suicide plan. However, 20 (25%) participants reported that their death- or suicide-related thoughts were worse during the trial relative to the week before baseline, and only one participant reported that these thoughts were worse or more severe during the trial relative to their lifetime.

Table . Incidence, new onset, and increased severity of participants' death and suicide-related thoughts or behaviors during the 3- to 6-month treatment phase of a smartphone-delivered treatment trial for body dysmorphic disorder (BDD, N=80).

Variable	Participants, n (%)
Incidence	34 (42.5)
Life feels empty or I wonder if worth living	24 (30.0)
Several suicide- or death-related thoughts this week	10 (12.5)
New onset	3 (3.8)
Life feels empty or I wonder if worth living	2 (2.5)
Several suicide- or death-related thoughts this week	1 (1.3)
Increased severity	
Relative to the week before baseline[a]	20 (25.0)
Relative to lifetime[b]	1 (1.3)
Suicide attempt	0 (0)
Withdrawn for worsening symptoms or suicidal thoughts	1 (1.3)

[a]Greatest severity in the week before baseline as assessed by QIDS-SR (Quick Inventory of Depressive Symptomatology-Self-Report).

[b]Greatest lifetime severity as assessed by C-SSRS (Columbia-Suicide Severity Rating Scale) at baseline.

Predicting STB

Table 2 presents the results of logistic regressions using baseline variables to predict the incidence of death- and suicide-related thoughts during the 12-week trial. In the leftmost column, bivariate models revealed that higher severity of suicidal thoughts and, separately, reporting a previous suicide attempt at baseline were significant predictors of reporting any death- or suicide related thought during the trial. However, after adjusting for covariates known to be associated with STB (eg, age, birth sex, and sexual orientation), only baseline suicide-thought severity remained a significant predictor of death- or suicide thought incidence. Similarly, bivariate models presented in the middle column revealed that both higher baseline suicide-thought severity and lifetime suicide attempt significantly predicted experiencing several death- or suicide-related thoughts for several minutes in any given week. However, these relationships did not remain significant after adjusting for covariates related to STB risk. Bivariate models presented in the rightmost column revealed that only baseline suicide-thought severity predicted which participants would report an increase in the severity of death- or suicide-related thoughts during the trial, relative to the week before baseline. No variables were significant predictors of this outcome after adjustment for covariates.

Discussion

Principal Findings

The purpose of this study was to examine the rates of STBs in participants of a recent RCT of smartphone-delivered CBT for BDD. There were four main findings. First, those included versus excluded did not significantly differ in past-week depression severity or the prevalence of past-week death- or suicide-related thoughts. Second, consistent with the results of previous research (eg, 21), a lifetime [27] history of relatively severe STB was prevalent among this sample of participants with primary BDD, with many reporting previous active suicidal thoughts (40%) and a previous suicide attempt (10%). Third, over the course of the three-month treatment phase, nearly half of the participants reported experiencing a death- or suicide-related thought, but no participants experienced acute and frequent suicidal thoughts, made a suicide plan, or attempted suicide. Fourth, previous suicide attempt and the severity of suicidal thoughts were significant predictors of who would experience death- or suicide-related thoughts during the trial. However, only baseline suicide thought severity remained a significant predictor after adjusting for known STB risk factors (eg, demographics and sexual orientation). Notably, even the best models had only relatively modest predictive accuracy (eg, AUCs ranging from 0.63 to 0.83), highlighting the difficulty of short-term prediction of STB [9].

The main implication of these findings is that with carefully selected eligibility criteria and robust yet relatively low burden and ongoing monitoring procedures, it is possible to conduct a safe, light-touch DMHI, even when including some participants (eg, those with past STB) with moderately elevated risk profiles. Despite excluding participants with "active" STBs occurring in the past month, a meaningful proportion of participants with a psychiatric disorder such as BDD may still experience death- or suicide-related thoughts during a several months long treatment trial, particularly those with previous acute STB, such as suicide attempt or active suicidal ideation. Importantly, despite these fluctuations in suicidal thoughts, no participants

XSL•FO
RenderX

reported attempting suicide. Together, this highlights the importance of assessing STB on an ongoing (eg, weekly) fashion that imposes low burden on participants but also provides actionable data to the research team. Questions and answer options that are concise and easily understood are always preferrable, especially so in DMHIs, because participant adherence and engagement tends to decline precipitously as treatments progress [33]. Items with high face and construct validity that researchers can use to quickly inform decisions about when to follow-up with participants are essential in DMHIs, given these interventions are remotely administered and have historically suffer from low engagement, limiting opportunities for observing and assessing risk relative to more traditional, face-to-face treatments.

The findings from this study must be interpreted in the context of several limitations. First, nearly a third of participants' weekly death- and suicide-related thought responses were missing. Although this amount of missing data is on the low end compared with other DMHIs [33], any missing data limits our ability to estimate the true incidence of death- and suicide-related thoughts. Future studies could attempt to address this by making some proportion of weekly surveys mandatory or by incentivizing their completion. However, the former runs the risk of increasing participant burden and, therefore, decreasing adherence, whereas the latter may not be financially feasible in real-world implementations, limiting the generalizability of findings. Second, the item we chose to assess weekly death- and suicide-related thoughts included answer options that vary in the constructs they assess (eg, three options specifically mention death- and suicide-related thoughts, one does not, two options assess frequency, and two do not), limiting precision. We chose this item to maximize the trade-off between high face validity and low participant burden, while matching our a priori risk-mitigation decision rules for when to actively check in with participants to assess current risk. Future studies could attempt to pilot and validate additional items with more favorable precision. Additionally, assessing the presence of death-or suicide-related thoughts with just one item can lead to misclassification of suicide risk [34,35]. Future studies could assess risk with additional items but must be mindful of balancing the benefits of increased precision with the costs of increased burden and the potential for resulting lower adherence, which can also lead to misclassification. Third, we excluded participants (n=4) with "active" suicidal thoughts or intent in the past month, given the light-touch nature of the treatment. In doing so, it is possible that some participants were needlessly excluded, thus limiting the generalizability of the treatment and the risk assessment and mitigation procedures reported here. Using this potentially overly restrictive criterion also runs the risk of perpetuating treatment barriers. If future studies implement less restrictive STB exclusion criteria, they may find it helpful to make risk assessment and mitigation procedures more robust (eg, increase assessment frequency and alter "risk-alert" thresholds to be more sensitive).

Conclusion

Our findings indicate that it is feasible to conduct an RCT of a DMHI among a sample of clinically acute participants with relatively high rates of lifetime STB. There are inherent risks in conducting treatment trials and trade-offs when establishing thresholds for eligibility, particularly for highly prevalent and stigmatized symptoms such as STB. Trials with very strict eligibility criteria may effectively limit the risk of STB, but findings will likely lack generalizability and potentially perpetuate treatment barriers for patients in high need. Trials with overly lenient eligibility criteria may fail to mitigate the risk of serious adverse events, jeopardizing participant safety, trial feasibility, and the implementation of an otherwise promising treatment. Researchers can include participants with moderately elevated risk profiles by carefully selecting eligibility criteria based on rational and empirical grounds, carefully screening participants with trained study staff, using frequent, ongoing, low burden, and valid monitoring procedures, implementing risk mitigation protocols that are tailored to the presenting problem, ensuring staff are adequately supervised and trained to handle anticipated STB and adverse events as well as active risk mitigation efforts, and that patients are aware of these procedures and understand why they are answering such questions. More research should examine the safety procedures implemented in RCTs and report more fully on adverse events and other key outcomes such as STB. Doing so will help ensure that, as a field, we are following adequate and generalizable risk mitigation practices, while not needlessly excluding participants who could benefit from treatment.

Conflicts of Interest

The authors declare the following financial interests/personal relationships which may be considered as potential competing interests: ACJ and IS have received salary support from Koa Health (formerly Telefónica Alpha, Inc). JLG and HW have received salary support from Koa Health and are presenters for the Massachusetts General Hospital Psychiatry Academy in educational programs supported through independent medical education grants from pharmaceutical companies. Additionally, HW has a consulting agreement with Hello Therapeutics, Inc. SW is a presenter for the Massachusetts General Hospital Psychiatry Academy in educational programs supported through independent medical education grants from pharmaceutical companies. She has received royalties from Elsevier Publications, Guilford Publications, New Harbinger Publications, Springer, and Oxford University Press. SW has also received speaking honoraria from various academic institutions and foundations, including the International Obsessive Compulsive Disorder Foundation, the Tourette Association of America and the Centers for Disease Control and Prevention. In addition, she received payment from the Association for Behavioral and Cognitive Therapies for her role as Associate Editor for the journal *Behavior Therapy*, as well as from John Wiley and Sons, Inc for her role as Associate Editor for the journal *Depression and Anxiety*. SW has also received honoraria from One-Mind for her role on the PsyberGuide Scientific

Abstract

Background: Nonsuicidal self-injury (NSSI) is common among adolescents and is associated with adverse clinical outcomes, as well as suicidal behavior. Current treatments are resource-intensive and may not be accessible to all adolescents with NSSI. Internet-delivered emotion regulation individual therapy for adolescents (IERITA) with NSSI disorder is a promising treatment option, but its cost-effectiveness is unknown.

Objective: This study aims to evaluate the cost-effectiveness of IERITA for adolescents with NSSI disorder.

Methods: Within-trial cost-effectiveness analysis of a randomized controlled trial at three child and adolescent mental health services in Sweden (n=166). A total of 12 weeks of IERITA plus treatment as usual (TAU) versus TAU only were compared. The primary outcome was the frequency of NSSI at 1-month posttreatment. Secondary outcomes were NSSI remission and quality-adjusted life years (QALYs).

Results: IERITA led to reductions in NSSI frequency, a higher proportion of participants with NSSI remission, and more QALYs at 1-month posttreatment, at additional health care costs of US $3663 (95% CI US $2182-$5002) and societal costs of US $4458 (95% CI US $−577 to $9509). The incremental cost of one additional NSSI remission at 1-month posttreatment was US $18,677, and the incremental cost per QALY gained was US $792,244 for IERITA+TAU relative to TAU. IERITA had an 8% probability of being cost-effective at a societal willingness-to-pay threshold of US $84,000 for one QALY at 1-month posttreatment, which increased to 18% at 3-months posttreatment.

Conclusions: IERITA delivered adjunctive to TAU led to improvements in NSSI frequency, remission, and QALYs, at additional costs compared to TAU only. This study provides an estimate of the additional cost of delivering IERITA; however, future studies should include longer follow-up periods to better assess the magnitude of the effects on QALYs and societal costs.

KEYWORDS

cost-effectiveness; emotion regulation therapy; internet-delivered treatment; nonsuicidal self-injury; self-harm

Introduction

Nonsuicidal self-injury (NSSI), the damaging of one's own tissue without suicidal intent, is a strong risk factor for future suicidal behavior and adverse outcomes [1,2]. As knowledge about NSSI has improved, NSSI disorder (NSSID) was included as a condition for further study in the 5th edition of the Diagnostic and Statistical Manual of Mental Disorders [3]. The proposed criteria for NSSID include: (1) engagement in NSSI on at least 5 days in the past year (Criterion A); (2) expectation that NSSI will solve an interpersonal problem, provide relief from unpleasant thoughts or emotions, or induce a positive state (Criterion B); (3) experiencing one or more of the following: interpersonal problems or negative emotions prior to NSSI, difficulty managing preoccupation with NSSI, or frequent thoughts about NSSI (Criterion C); (4) NSSI is not socially sanctioned or to minor self-injurious behaviors (Criterion D); (5) clinically significant distress or interference in functioning due to NSSI (Criterion E); and (6) NSSI is not solely due to psychosis, delirium, substance use or withdrawal, or another psychiatric disorder or medical condition (Criterion F). While as many as 35.6% of a community sample of adolescents have been shown to engage in past-year NSSI, 6.7% met the

XSL•FO
RenderX

suggested Diagnostic and Statistical Manual of Mental Disorders, 5th edition criteria [4,5]. By age 19, the likelihood of favorable outcomes—defined as the absence of mental health or substance use problems and engagement in education or employment—is reduced by half among individuals who experienced NSSI or self-injury with suicidal intent at age 16 compared to peers without such histories [6].

In addition to the clinical implications, NSSI is associated with economic strain for the afflicted individual and their close relatives, as well as costs for the health care sector and society. For example, a recent Danish registry-based study estimated that the mean hospital cost per presentation due to self-harm was US $7029 [7]. A large proportion of that cost is due to inpatient psychiatric care, which is common after NSSI in both adults and adolescents [8,9]. Extended periods of inpatient psychiatric care are disruptive for the individual, who may experience stigma and loss of social support [10]. NSSI in youth is associated with school absenteeism and academic underachievement, which pose short- and long-term challenges [11]. Further, parents of youth with self-harm report having to take time off work to care for their child, which may extend to sick leave and unemployment [12]. To mitigate the immediate consequences and prevent negative long-term outcomes, it is crucial to offer effective treatment for NSSI promptly, considering both the direct and indirect costs involved.

When deciding among several treatment options, decision makers in health care are weighing treatment effects against costs. In the case of NSSI in youth, the only well-established treatment with two independent trials to support its efficacy is dialectical behavior therapy for adolescents (DBT-A [13]). While effective in reducing NSSI, this lengthy and resource-intensive treatment remains inaccessible for most adolescents with NSSI [14-16]. In a randomized controlled trial of DBT-A in Norway, for example, therapists (psychologists or psychiatrists) received 80 hours of training and 12 months of supervised practice and were assessed as being adherent to the treatment protocol before providing treatment to patients [14]. In the same trial, delivering DBT-A over 19 weeks incurred additional costs of €15,850 (US $15,052) per patient [17]. Despite the relatively large costs associated with DBT-A in the Norwegian trial, it was cost-effective at 1-year follow-up compared to enhanced usual care, due to reducing self-harm and lowering inpatient treatment costs [17]. However, given the level of resources and costs associated with DBT-A, previous trials have offered DBT-A to adolescents also presenting with symptoms of borderline personality disorder and high risk of suicide [14-16]. To address the need for a brief and scalable intervention that can be implemented early in the trajectory of NSSI, our group has developed a digital internet-delivered emotion regulation individual therapy for adolescents (IERITA) targeting those presenting with NSSI. IERITA has been shown to be acceptable and effective in reducing NSSI in multiple pilots [18-20] and a randomized controlled trial enrolling 166 adolescents and their parents [21]. However, a formal cost-effectiveness analysis is needed before the treatment can be implemented alongside other treatment options. The aim of this study was to conduct a health economic evaluation of IERITA, using data from a recent randomized controlled trial [21].

Methods

Trial Design

This study reports within-trial cost-effectiveness analyses from a 3-site randomized clinical trial of IERITA plus treatment as usual (TAU) versus TAU only for adolescents with NSSID and their parents (n=166) [21]. After an initial telephone screening, participants completed self-reported assessments and a face-to-face assessment at one of the participating clinics. Eligible participants were then randomly allocated to IERITA plus TAU or TAU only and started the respective treatments, after which 1-month posttreatment (primary end point) and 3-months posttreatment assessments were completed. For a full description of the study procedures, please see the initial report of the trial [21]. The results are reported in accordance with the Consolidated Health Economic Evaluation Reporting Standards 2022 (CHEERS 2022) statement [22].

Ethical Considerations

The trial was approved by the Stockholm Regional Ethical Review Board (2017/1807 - 31). All participants provided informed consent, with older participants providing written consent and younger participants providing verbal consent along with parental written consent. Participants could withdraw from the study at any given time without any negative consequences. Adolescents in both the IERITA plus TAU and TAU only conditions were entitled to receive reimbursement if they completed certain self-report measures and participated in the clinician-administered interviews (up to approximately US $50 in the IERITA plus TAU condition and US $110 in the TAU only condition).

Participants

Eligible participants were adolescents aged between 13 and 17 years who fulfilled diagnostic criteria for NSSID, had experienced one or more NSSI episodes during the past month, and had one guardian who could participate in the parent program. Exclusion criteria were an immediate suicide risk, diagnosis of psychotic or bipolar I disorder or past-month substance use disorder, another primary psychiatric disorder requiring immediate treatment (eg, severe anorexia nervosa), insufficient understanding of the Swedish language, life circumstances that could prevent treatment participation or that require immediate intervention, and a Children's Global Assessment Scale score below 40. Detailed information on the study sample is presented in Table 1.

Interventions

The therapist-guided IERITA treatment is an acceptance-based behavioral treatment delivered through a web-based platform [18,20,23]. The treatment includes 11 digital modules for the adolescent participant and 6 modules for the parents, delivered over the course of 12 weeks with asynchronous support from a dedicated therapist. The treatment targets the role of emotion dysregulation in maintaining NSSI, and the treatment aims to teach participants more adaptive ways of responding to their emotions. The treatment also includes modules on impulse control training, self-validation, valued direction, and relapse prevention. IERITA was delivered adjunctive to TAU. Adolescents receiving IERITA completed a mean (SD) of 9.6 modules out of 11, and five participants dropped out of the treatment [21].

TAU consisted of continued care within regular child and adolescent mental health services or referral to such services if deemed necessary after the baseline assessment. TAU was delivered in both groups through standard child and adolescent mental health service care by community clinicians (not part of the research team), usually consisting of supportive therapy sessions biweekly. TAU was enhanced by weekly self-rated assessments and follow-ups from research clinicians as needed. Communication between community therapists and IERITA therapists only occurred as a safety measure when deterioration in mental health was detected.

Resource Use and Costs

Intervention costs were estimated by multiplying the therapist's time spent on treatment by the average hourly cost of a psychologist in outpatient child and adolescent psychiatric services. The therapist's time spent on the platform was automatically recorded, and therapists manually logged time spent on phone calls following guidelines developed by the study team. Other resources used by participants were collected using the parent-rated version of the Trimbos-iMTA questionnaire for costs associated with psychiatric illness (TIC-P) [24] at pretreatment, 1-month posttreatment (16 wk after pretreatment), and at 3-months posttreatment (24 wk after pretreatment) with a 12-week recall period (adjusted to 8 wk at 3 mo posttreatment to cover the period since 1 mo posttreatment). The TIC-P included health care visits, prescription medication, and supplements, as well as resource use beyond health care, including social support and assistance, school absenteeism and presenteeism for children, and absenteeism from both paid and unpaid work for parents (also including time spent engaging with treatment content and supporting their child). Costs were estimated by multiplying resource use frequencies by unit costs and adding them to the intervention costs. Health care costs were estimated by multiplying the number of visits by the unit cost of a visit using tariffs from official listings for the Swedish health care system (South-East region); costs for medications were estimated by using individual product prices from The Dental and Pharmaceutical Benefits Agency of Sweden [25], and costs for supplements were estimated using individual product prices from Swedish pharmacies. Costs for social support and assistance were estimated using tariffs for support family placement and personal assistant from Sweden's municipalities and regions, and study help costs from companies who provide the service at an hourly rate (from TIC-P: "how many hours of [study help or support family placement or personal assistant] have you used in the past 3 months?"). Support from family and friends was costed using the average posttax wage per hour in Sweden [26,27]. Parental productivity losses related to absenteeism from paid work were estimated using the human capital approach and calculated as the average salary in Sweden plus social fees multiplied by the number of days absent from work [27,28]. Parental productivity losses related to absenteeism from unpaid work were estimated using the average posttax wage per hour in Sweden multiplied by the number of hours reported being absent from unpaid work [27]. Productivity losses for children related to absenteeism from school were calculated as the average annual cost per pupil and year divided by the number of school days per year and multiplied by the number of days reported being absent from school. Productivity losses for children related to presenteeism at school were estimated in a similar manner as school absenteeism–related costs but multiplied by the number of days with lower performance at school and by the percentage loss in performance (from TIC-P: "on days not feeling well, how much is your child able to participate in school compared to days feeling well? Rate on a scale of 0% - 100%"). Additional details are provided in Table S1 in Multimedia Appendix 1.

The health care perspective included costs related to health care visits, prescribed medication, and supplements not requiring a prescription, in addition to the intervention costs. The societal perspective additionally included costs for social support and assistance, productivity losses related to school absenteeism and presenteeism for children, and productivity losses related to absenteeism from paid and unpaid work for parents.

Total costs over the trial period were calculated for each randomized participant and aggregated over time. Resources were costed in 2018 Swedish Krona, uprated to 2022 using Consumer Price Index from Statistics Sweden [29], and converted to 2022 US $ using purchasing power parities for gross domestic product [30]. As all data were considered within 1 year, no discounting was applied.

Health Outcomes

The primary clinical measure, change in NSSI frequency from pretreatment to posttreatment, was assessed using the Deliberate Self-Harm Inventory-Youth version (DSHI-Y) [31]. The DSHI-Y is an adapted and shortened version of the DSHI [32]. The DSHI has demonstrated high internal consistency (α=0.82) and test-retest reliability over a period of 2 to 4 weeks [32]. The DSHI-Y consists of 6 items that encapsulate the most common methods of NSSI in youth: cutting, burning, severe scratching, self-biting, banging (banging head or other body parts against an object), and self-punching, resulting in injury severe enough for tissue damage (eg, scarring or bruises) to occur. Clinician ratings of DSHI-Y, assessing NSSI frequency in the past month (ie, NSSI remission), were administered pretreatment, 1-month posttreatment, and 3-months posttreatment by masked assessors. The proportion of individuals with no NSSI in the past month was calculated based on the clinician ratings at posttreatment.

XSL•FO
RenderX

In addition, self-reported DSHI-Y was administered pretreatment, once every week in treatment, and 4 weeks posttreatment.

Participants' health-related quality of life was measured using the Kid-Screen 10. The Kid-Screen 10 is a short self-rated assessment of health-related quality of life that was administered at pretreatment, 1-month posttreatment, and 3-months posttreatment. The questionnaire measures the young person's subjective health and quality of life in the domains of physical and mental well-being, independence, school environment, and relationship to parents and friends [33]. Kid-Screen 10 has adequate internal consistency (α=0.81) [34]. Since the Kid-Screen 10 does not make it possible to calculate quality-adjusted life years (QALYs) needed for cost-utility analysis, participant responses on the Kid-Screen 10 were mapped onto Child Health Utility 9D (CHU9D) utility scores in order to estimate QALYs, using an algorithm with a mean absolute error of 0.0946 [35]. The CHU9D questionnaire measures health-related quality of life on 9 dimensions (eg, worried, sad, schoolwork, and activities) in children [36], and has a validated algorithm for calculating QALYs [37]. Total QALYs during the trial period were calculated by using the area under the curve method, assuming a constant rate of change between assessment points [38].

Statistical Analyses

The cost-effectiveness analyses used the following outcomes: NSSI frequency and proportion of participants who experienced NSSI remission in the past month, assessed by the masked clinician-assessed DSHI-Y, and weekly NSSI frequency during treatment, assessed by the DSHI-Y. The cost-utility analyses used QALYs from CHU9D as the outcome. All analyses were conducted from the health care sector and the societal perspectives.

Total costs over the trial period were aggregated by trial arm and presented as descriptive statistics. No extrapolation beyond the recall period of 12 weeks was used, and the costs at 1-month posttreatment, therefore, included all costs from week 4 in treatment up until the 1-month posttreatment assessment point. The statistical analyses were conducted on an intention-to-treat basis, and missing data were imputed using multiple imputation by chained equations and predictive mean matching, under the assumption that data were missing at random [39,40]. The statistical models did not include the study site as a covariate or clustering variable. Sensitivity analyses using only complete data with no missing data imputation were also performed.

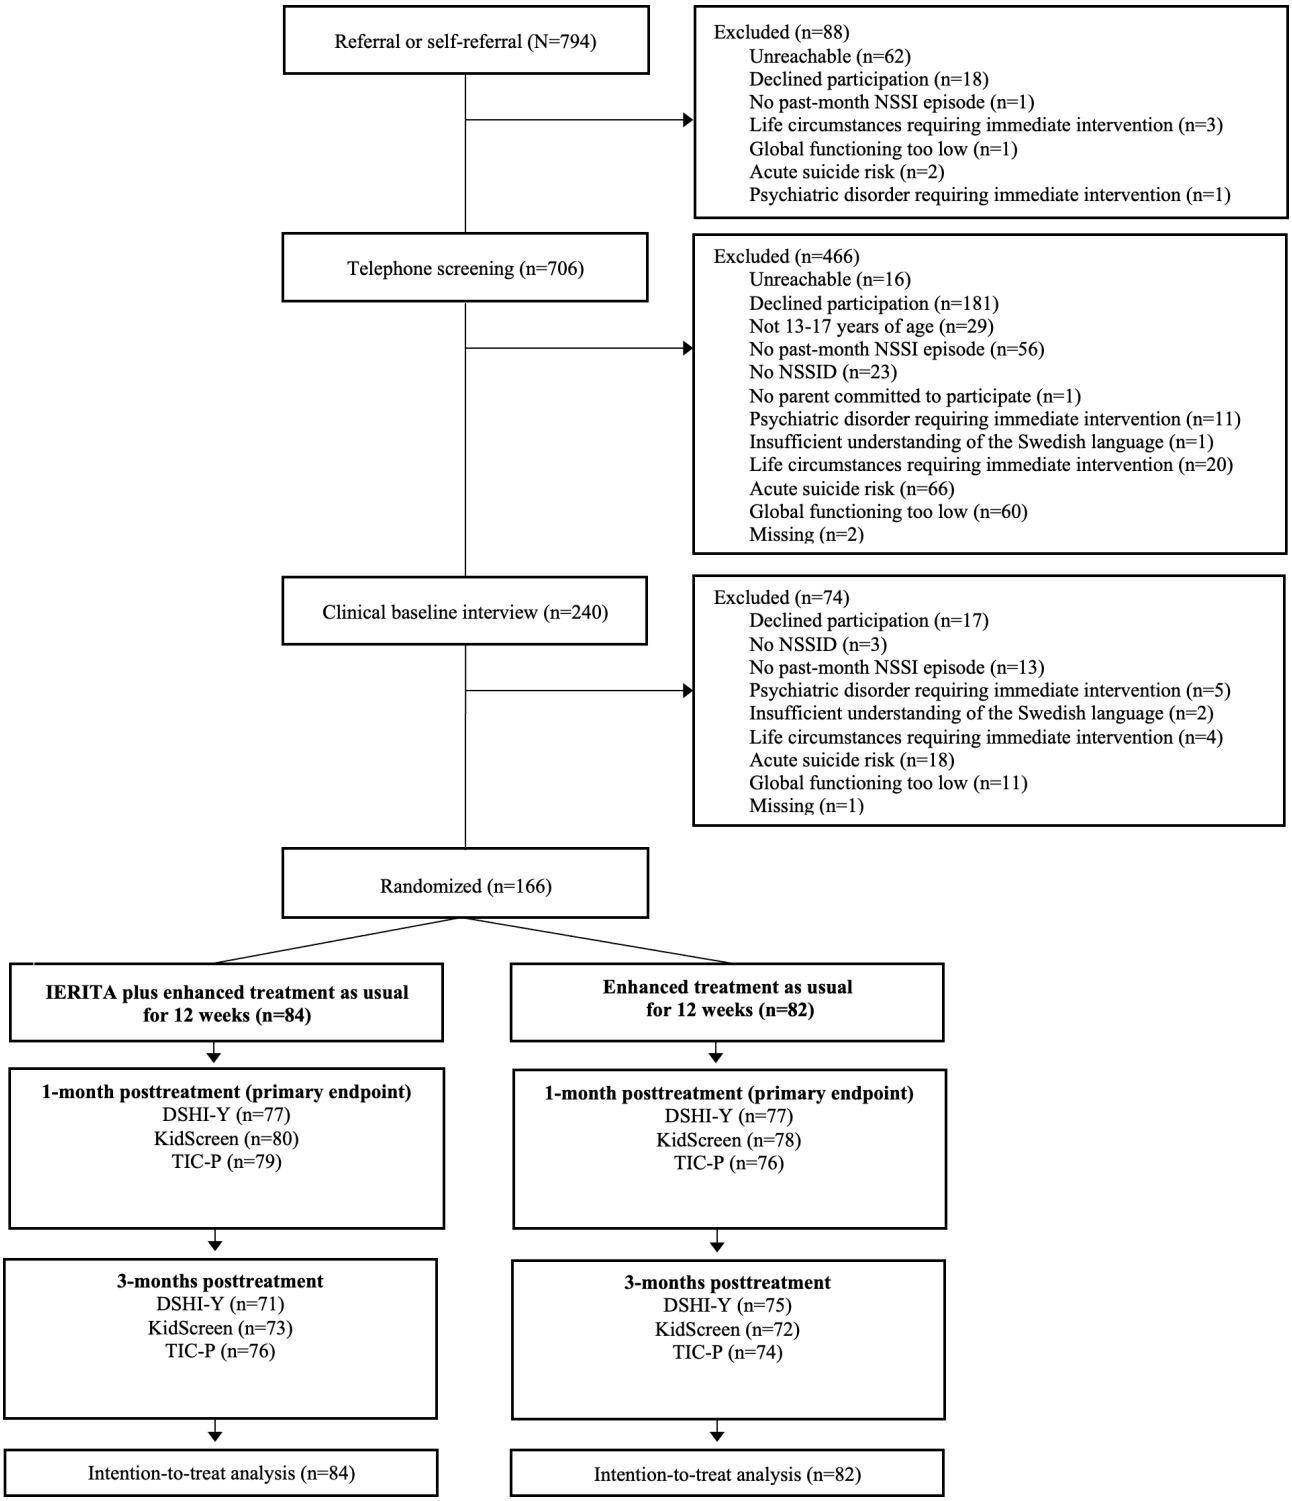
Group differences in NSSI reductions over time were estimated using a zero-inflated negative binomial generalized linear mixed effects regression model, including an interaction term between treatment condition and time, as well as random intercept and slope. The resulting incidence rate ratios (IRRs) were then used as the outcome of interest. This model was also used as the primary outcome analysis in the clinical trial from which data were used [21].

Cost data, NSSI remission, and QALYs were fitted using seemingly unrelated regression models at 1-month posttreatment and 3-months posttreatment, respectively, combined with nonparametric bootstrap estimation (5000 iterations) within each multiply imputed dataset [41,42]. This allowed for robust modeling of skewed distributions in both costs and effects while simultaneously adjusting for baseline imbalances and missing data [43,44]. Between-group differences in costs were analyzed while controlling for baseline costs, and QALYs were analyzed while controlling for baseline CHU9D utilities [45]. The analyses are presented as incremental cost-effectiveness ratios (ICER; the between-group mean difference in costs divided by the between-group mean difference in health outcome) [46] with CIs calculated using the bootstrap percentile method [47], and cost-effectiveness planes (bootstrap estimates of cost differences displayed on the y-axis and estimates of health outcome differences on the x-axis, indicating if the intervention is more or less costly and effective compared to the alternative) [48]. Net monetary benefits at different thresholds of willingness to pay (ie, how much the society is willing to pay for a one-unit difference in the health outcome) were calculated for mean values and are presented on cost-effectiveness acceptability curves (CEACs), which capture decision uncertainty and show the probability of IERITA being cost-effective at different thresholds of willingness to pay for improvement on the health outcomes [46,49]. Willingness to pay depends on the country and the structure of the health care system [50]. There is currently no threshold defined in Sweden, and we used a threshold reported in a review of reimbursement decisions for pharmaceuticals in Sweden [51].

The preregistered data analysis plan and statistical code used in this study can be found on the Open Science Framework [52]. The methods described in this publication differ from the preregistration in that the costs have been uprated to 2022 and that the statistical models for costs and QALYs used seemingly unrelated regression rather than specifying the underlying distributions in generalized linear models, in accordance with guidance on within-trial cost-effectiveness studies [43,44].

Results

Completion Rates and Participant Characteristics



All participants completed the baseline assessments on all outcomes. At the 1-month posttreatment assessments, completion rates in the IERITA plus TAU group were 92% - 95% (DSHI-Y: n=77, 92%; KidScreen: n=80, 95%; TIC-P: n=79, 94%), and completion rates in the TAU only group were 93% - 95% (DSHI-Y: n=77, 94%; KidScreen: n=78, 95%; TIC-P: n=76, 93%). The completion rates at 3-months posttreatment were 85% - 90% in the IERITA plus TAU group (DSHI-Y: n=71, 85%; KidScreen: n=73, 87%; TIC-P: n=76, 90%) and 88% - 91% in the TAU only group (DSHI-Y: n=76, 91%; KidScreen: n=72, 88%; TIC-P: n=74, 90%; Figure 1). Data on therapist time spent on treatment were missing for 10 (6%) participants. The majority of participants were female, and most were enrolled in either pharmacological or psychological treatment as baseline (see Table 1 for patient characteristics).

There was no difference in health care sector costs between the two groups at baseline (IERITA plus TAU: US $4492, 95% CI US $4119-$4865; TAU only: US $4297, 95% CI US

XSL•FO
RenderX

$3919-$4675; *P*=.47), however, the IERITA plus TAU group had higher societal costs (IERITA plus TAU: US $24,212, 95% CI US $22,430-$25,994; TAU only: US $21,239, 95% CI US $19,436-$23,042; *P*=.02).

Figure 1. Flow diagram of patient enrollment. DSHI-Y: Masked Assessor-rated Deliberate Self-Harm Inventory-Youth Version; IERITA: internet-delivered emotion regulation individual therapy for adolescents; NSSI: nonsuicidal self-injury; NSSID: nonsuicidal self-injury disorder; TIC-P: Trimbos-iMTA questionnaire for costs associated with psychiatric illness.

There were statistically significant correlations between estimated societal costs and both NSSI remission (r=−0.32; P<.001) and QALYs (r=−0.2; P<.001) at 1-month posttreatment, supporting the use of seemingly unrelated regression to model costs and health outcomes simultaneously.

Costs

At 1-month posttreatment, the cost of providing IERITA adjunctive to TAU was estimated to US $3552 (SE 54.1), and IERITA plus TAU was associated with higher costs compared to TAU only from a health care perspective (US $3663, 95% CI US $2182-$5002) and societal perspective (US $4458, 95%

XSL•FO
RenderX

CI US −$577 to $9509). These differences remained similar in magnitude at 3-months posttreatment (US $3440, 95% CI US $1455-$5319 and US $4565, 95% CI US −$2820 to $11,919 for health care and societal costs, respectively). Table 2 provides an overview of estimated costs and health outcomes over the trial period, including bootstrap estimates adjusting for baseline imbalances. Table 3 shows health care resource use in enhanced TAU (eTAU) during the trial period for both groups.

Table . Estimated costs and health outcomes over the trial period[a].

Outcome	Estimated mean[b] (SE)		Mean difference

[a]TAU: treatment as usual.

[b]IERITA: internet-delivered emotion regulation therapy for adolescents.

[c]For baseline to 1-month posttreatment, IERITA plus TAU included 79 participants and TAU only included 76 participants.

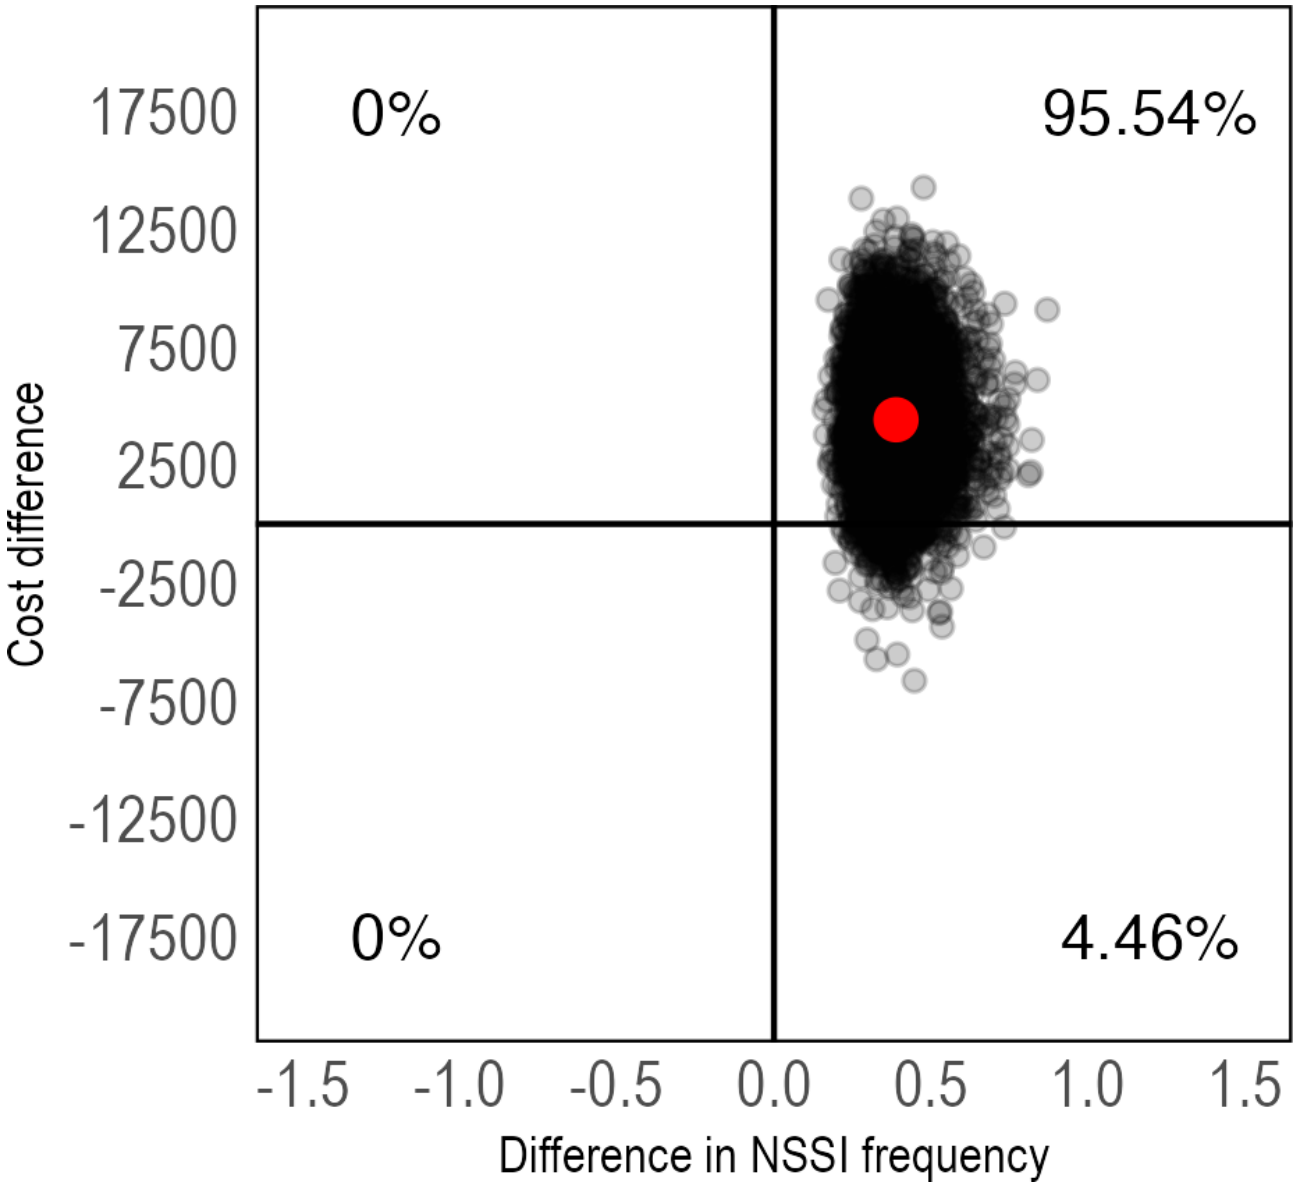
[d]For 1-month posttreatment to 3-months posttreatment, both IERITA plus TAU and TAU only included 74 participants.

[e]Pharmacological results included 76 participants in the IERITA plus TAU group.

Health Outcomes

There were fewer NSSI episodes on the masked clinician-assessed DSHI-Y at 1-month posttreatment in the IERITA plus TAU group compared to TAU only (IRR 0.38, 95% CI 0.24-0.60; *P*<.001), and IERITA plus TAU also resulted in fewer NSSI episodes at 3-months posttreatment compared to TAU only (IRR 0.57, 95% CI 0.36-0.90; *P*=.02). The estimated proportion of participants with no NSSI at 1-month posttreatment was greater in the IERITA plus TAU group (61%, 95% CI 56%-66%) compared to TAU only (38%, 95% CI 34%-43%), a difference that was statistically significant (odds ratio=2.5; SE=0.4; *P*<.001). At 3-months posttreatment, the difference was attenuated but remained statistically significant (IERITA plus TAU: 58%, 95% CI 53%-63%; TAU only: 51%, 95% CI 46%-56%; odds ratio=1.33; SE=0.19; *P*=.04). Results on the self-rated DSHI-Y were similar, with larger improvements in the IERITA plus TAU group compared to TAU only (Multimedia Appendix 1). The IERITA plus TAU group generated more QALYs compared to TAU only between pretreatment and 1-month posttreatment (*b*=0.006, 95% CI 0.002-0.010; SE=0.002; *P*<.001), and between pretreatment and 3-months posttreatment (*b*=0.01, 95% CI 0.005-0.016; SE=0.003; *P*<.001).

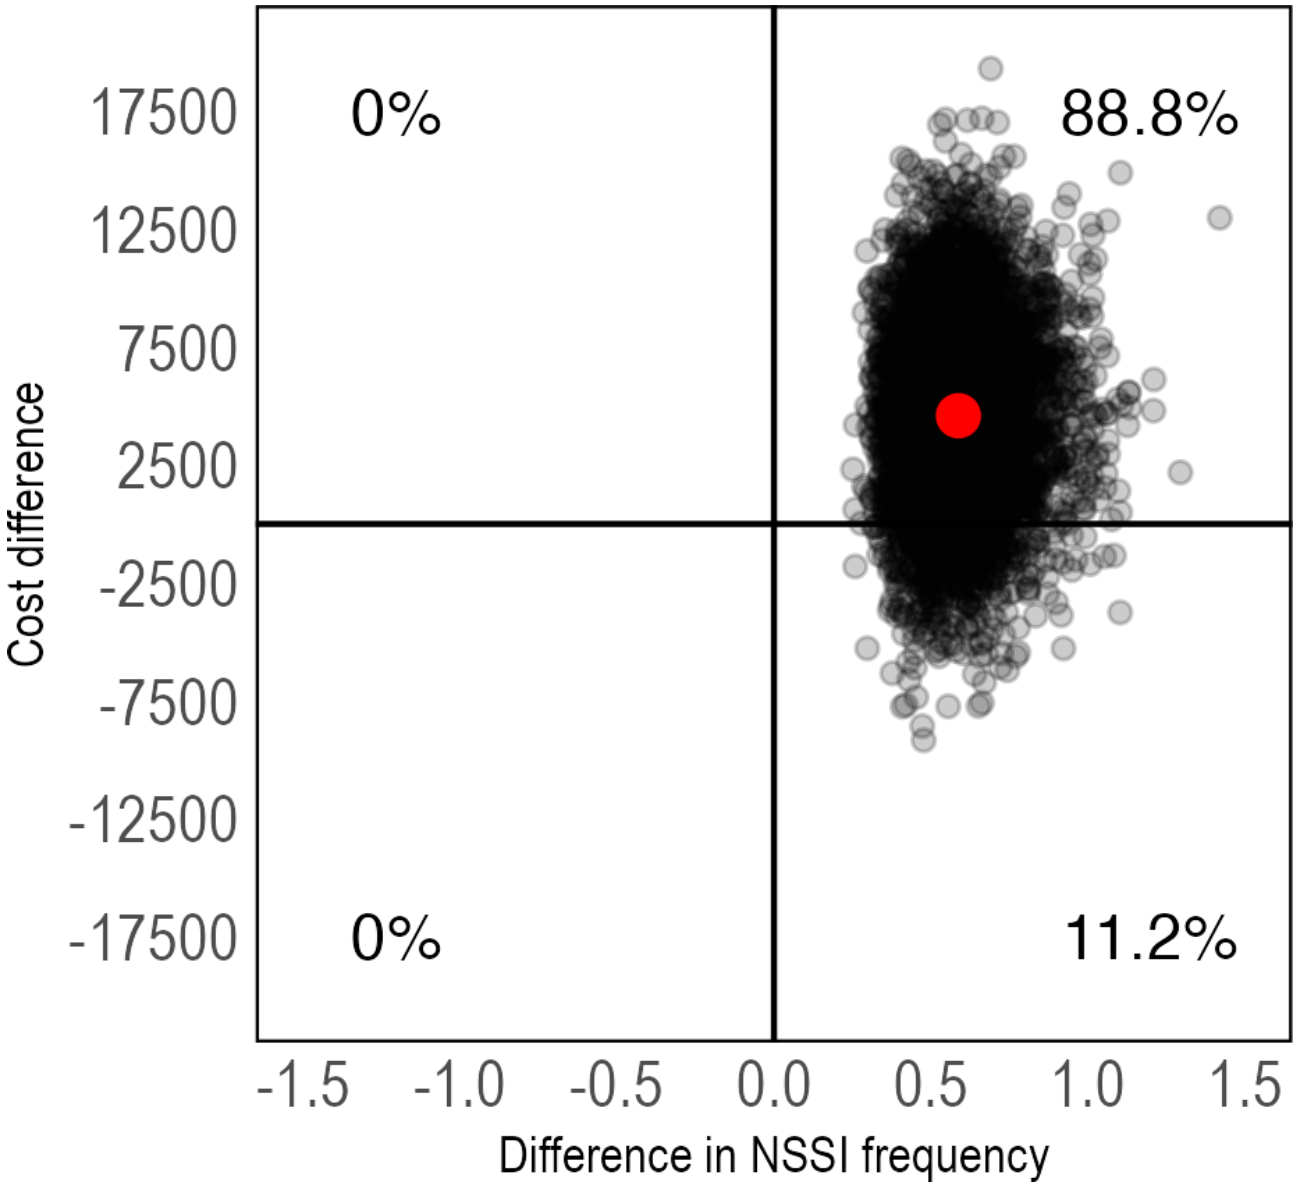
Cost-Effectiveness and Cost-Utility



The Societal Perspective

To estimate the cost-effectiveness of IERITA, differences in costs were divided by differences in the outcome variables of interest between IERITA plus TAU versus TAU only. The ICER for NSSI frequency on the masked clinician-assessed DSHI-Y was US $11,383 (95% CI US −$1611 to $29,299) per NSSI episode at 1-month posttreatment, and US $7814 (95% CI US −$5055 to $23,248) at 3-months posttreatment. A majority of ICERs from bootstrapped samples were located in the northeast quadrant at both 1-month posttreatment (Figure 2) and 3-months posttreatment (Figure 3), indicating higher costs and improved

XSL•FO
RenderX



outcomes in the IERITA group. CEACs are included in Multimedia Appendix 1.

Figure 2. Pretreatment to 1-month posttreatment cost-effectiveness plane of IERITA plus TAU compared to TAU only, NSSI frequency. The x-axis displays between-group differences in outcomes, with positive values indicating more improvement in the IERITA plus TAU group compared to TAU only. Differences in costs, shown on the y-axis, are from a societal perspective, with positive values indicating increased costs in the IERITA plus TAU group compared to TAU only. IERITA: internet-delivered emotion regulation individual therapy for adolescents; NSSI: nonsuicidal self-injury; TAU: treatment as usual.

XSL•FO
RenderX

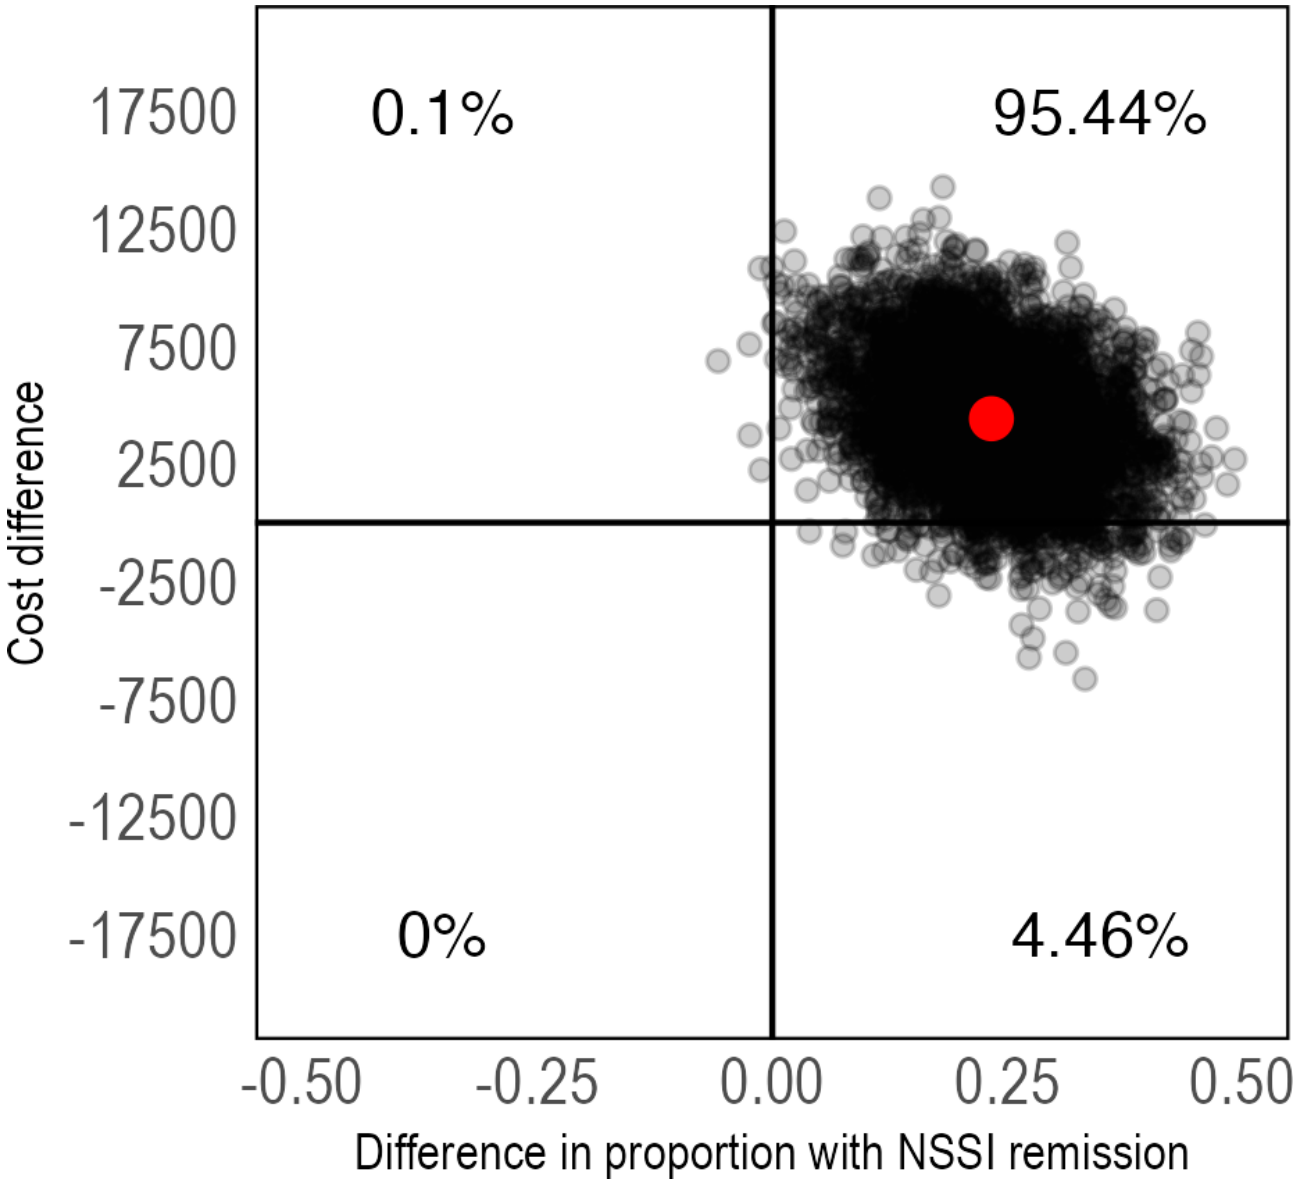


Figure 3. Pretreatment to 3-months posttreatment cost-effectiveness plane of IERITA plus TAU compared to TAU only, NSSI frequency. The x-axis displays between-group differences in outcomes, with positive values indicating more improvement in the IERITA plus TAU group compared to TAU only. Differences in costs, shown on the y-axis, are from a societal perspective, with positive values indicating increased costs in the IERITA plus TAU group compared to TAU only. IERITA: internet-delivered emotion regulation individual therapy for adolescents; NSSI: nonsuicidal self-injury; TAU: treatment as usual.

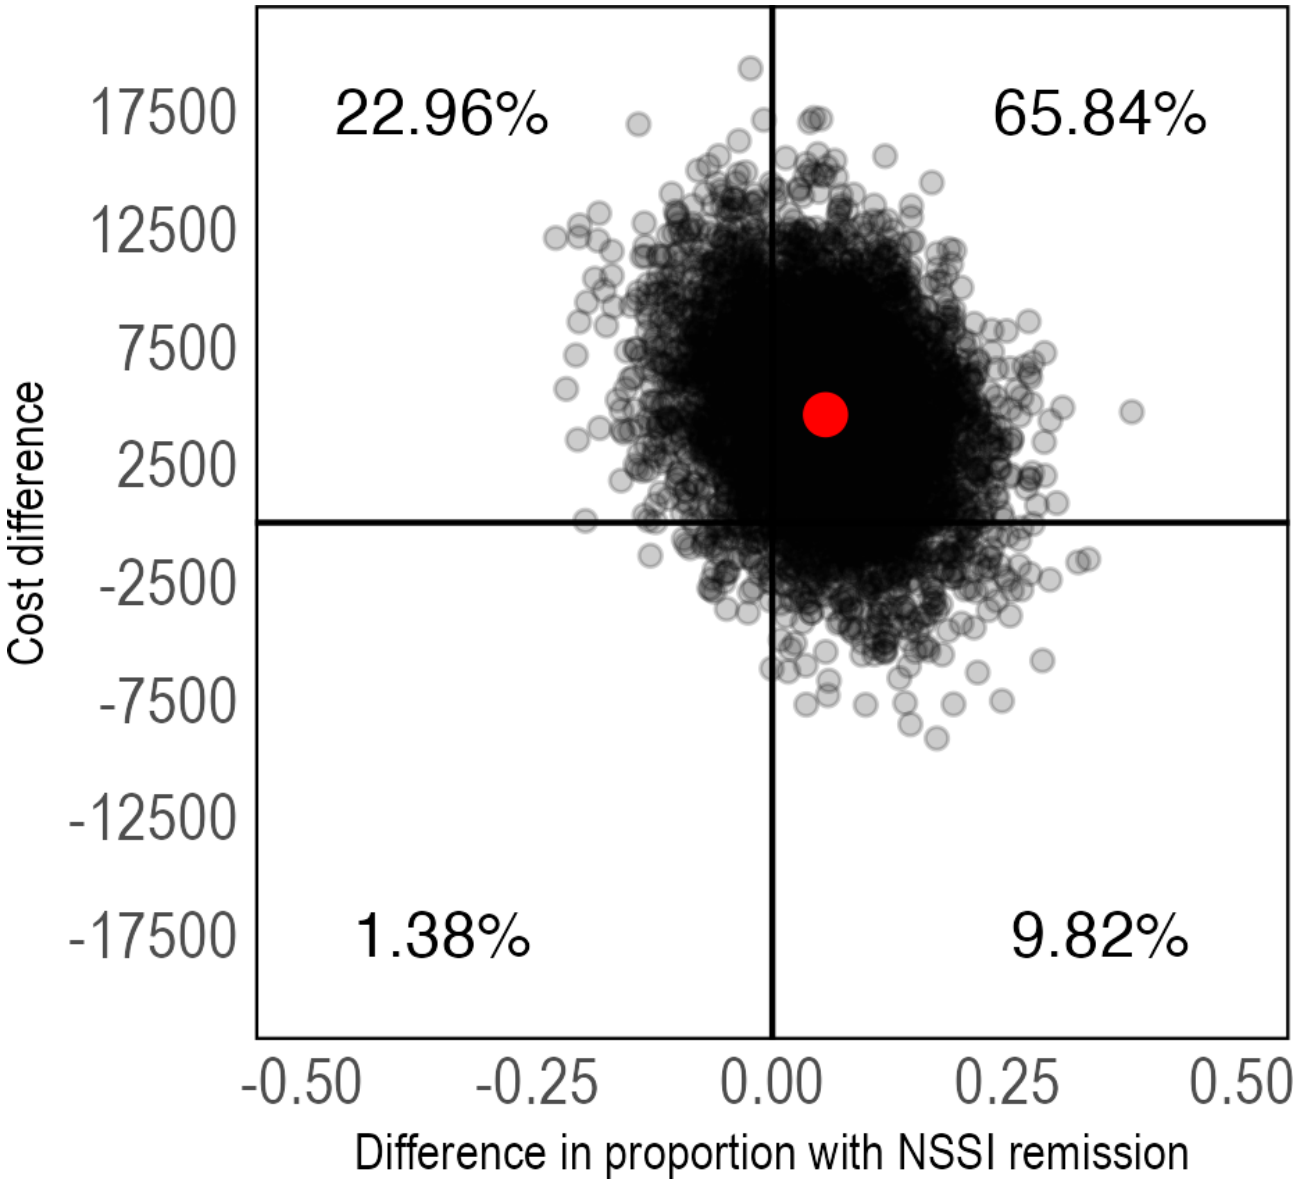
The ICER for the outcome NSSI remission was US $18,677 (95% CI US $–2271 to $92,098) per additional participant with NSSI remission at 1-month posttreatment and US $27,563 (95% CI US $–775,711 to $737,706) at 3-months posttreatment, again with a majority of ICERs in the northeast quadrant at both time points (Figures 4 and 5); however, with more uncertainty around the estimates at 3-months posttreatment. These results can assist decision makers by comparing the costs of existing treatment options for treating NSSI or by evaluating the value of NSSI remission in the current setting. This assessment should consider available health care resources, the potential need for costly inpatient care if NSSI is left untreated, and other relevant factors that may differ between health care systems (eg, unit costs for health care services and patient preferences).



XSL•FO
RenderX

Figure 4. Pretreatment to 1-month posttreatment cost-effectiveness plane of IERITA plus TAU compared to TAU only, NSSI remission. The x-axis displays between-group differences in outcomes, with positive values indicating more improvement in the IERITA plus TAU group compared to TAU only. Differences in costs, shown on the y-axis, are from a societal perspective, with positive values indicating increased costs in the IERITA plus TAU group compared to TAU only. IERITA: internet-delivered emotion regulation individual therapy for adolescents; NSSI: nonsuicidal self-injury; TAU: treatment as usual.

XSL•FO

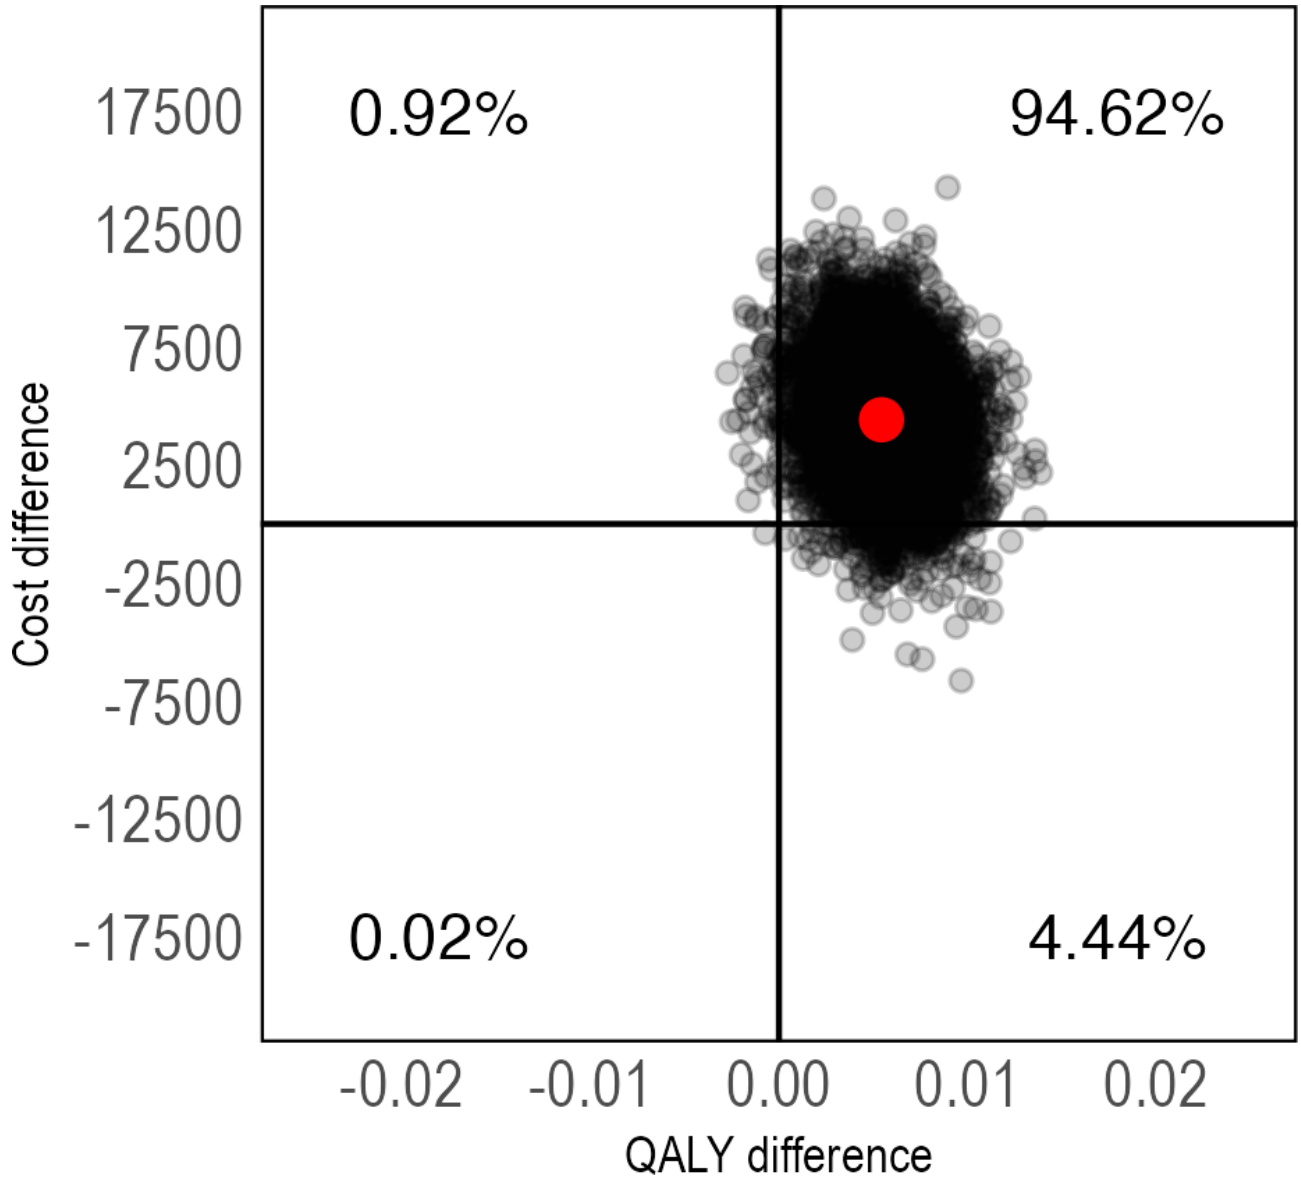

Figure 5. Pretreatment to 3-months posttreatment cost-effectiveness plane of IERITA plus TAU compared to TAU only, NSSI remission. The x-axis displays between-group differences in outcomes, with positive values indicating more improvement in the IERITA plus TAU group compared to TAU only. Differences in costs, shown on the y-axis, are from a societal perspective, with positive values indicating increased costs in the IERITA plus TAU group compared to TAU only. IERITA: internet-delivered emotion regulation individual therapy for adolescents; NSSI: nonsuicidal self-injury; TAU: treatment as usual.

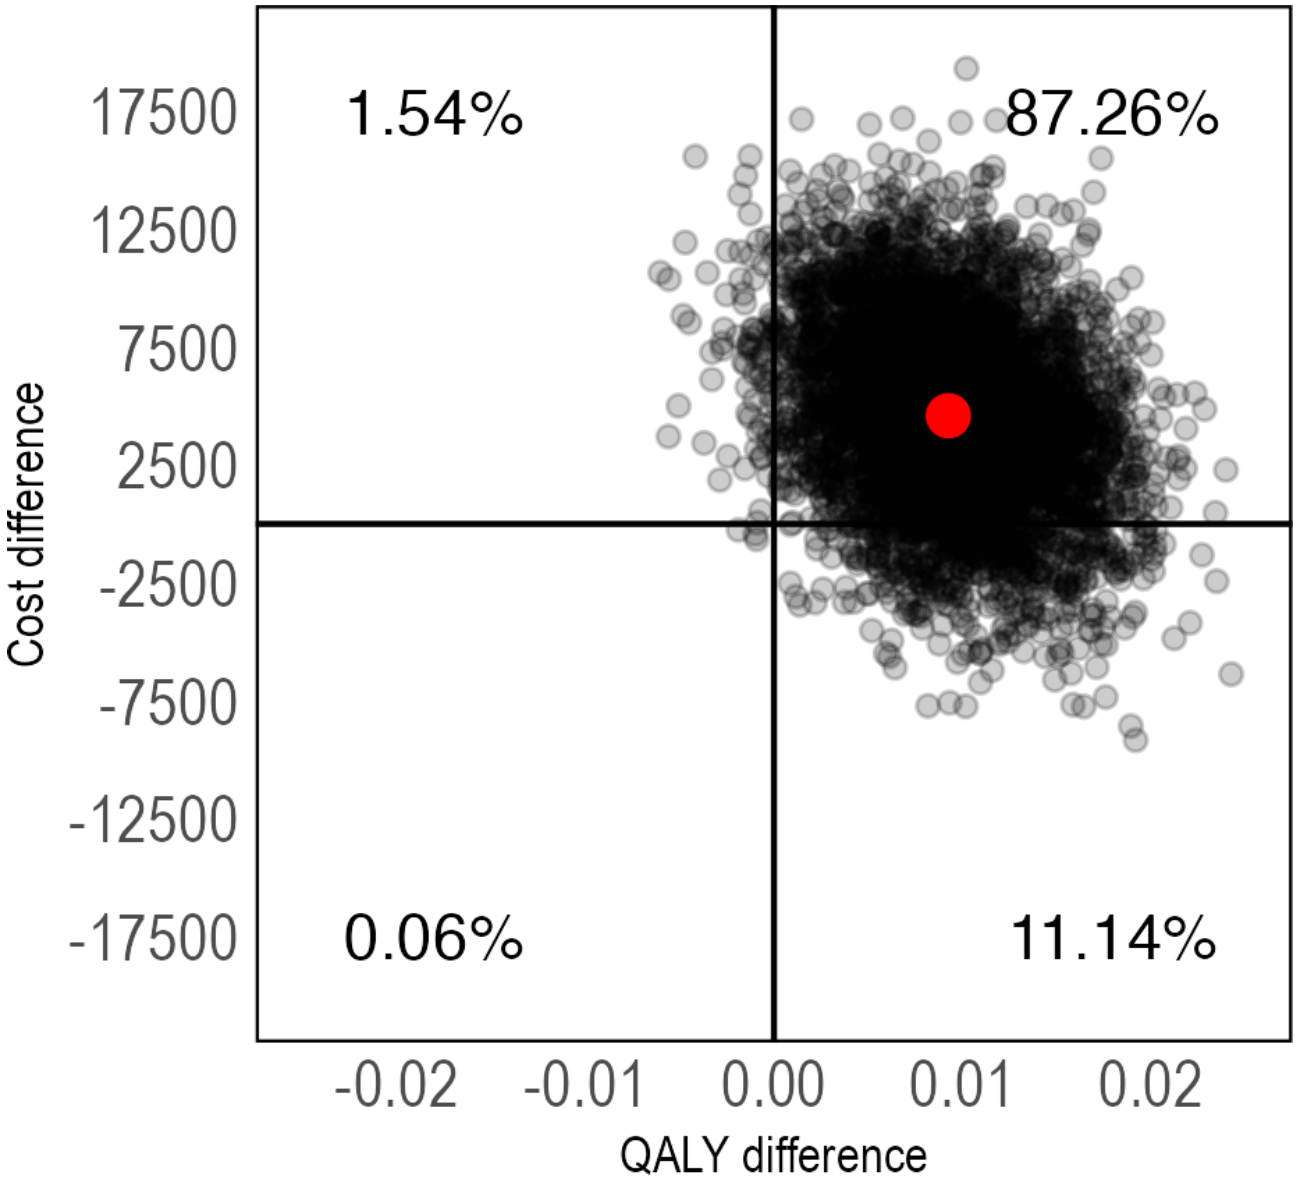
The cost-utility analyses showed that IERITA had an ICER of US $792,244 (95% CI US −$184,693 to $4,428,098) per QALY gained at 1-month posttreatment and US $471,800 (95% CI US −$428,322 to $4,272,413) at 3-months posttreatment. Again, the majority of ICERs were located in the northeast quadrant (Figures 6 and 7). IERITA had a probability of being cost-effective of 8% at the Swedish reference value of US $84,000 at 1-month posttreatment [51]. Cost-effectiveness at 3-months posttreatment was 18% at a societal willingness-to-pay of US $84,000. Cost-effectiveness results on the self-rated DSHI-Y were similar (Multimedia Appendix 1).



XSL•FO
RenderX

Figure 7. Pretreatment to 3-months posttreatment cost-utility of IERITA plus TAU compared to TAU only, QALYs. The x-axis displays between-group differences in outcomes, with positive values indicating more improvement in the IERITA plus TAU group compared to TAU only. Differences in costs, shown on the y-axis, are from a societal perspective, with positive values indicating increased costs in the IERITA plus TAU group compared to TAU only. IERITA: internet-delivered emotion regulation individual therapy for adolescents; NSSI: nonsuicidal self-injury; QALYs: quality-adjusted life years; TAU: treatment as usual.

The Health Care Perspective

From the health care perspective, which includes costs of health care visits and medications (but excludes nonmedical or indirect costs), the ICER on the masked clinician-assessed DSHI-Y was US $9534 (95% CI US $4895-$16,836) per NSSI episode at 1-month posttreatment and US $5952 (95% CI US $2328-$11,303) at 3-months posttreatment. The ICER of NSSI remission was US $15,502 (95% CI US $7203-$51,543) per additional participant with NSSI remission at 1-month posttreatment and US $29,972 (95% CI US −$488,780 to $467,794) at 3-months posttreatment. The ICER for the cost-utility analysis was US $660,793 (95% CI US $265,242 to $3,072,206) per QALY gained at 1-month posttreatment and US $361,041 (95% CI US $78,104 to $2,162,667) at 3-months posttreatment. The probability of IERITA being cost-effective was 1% at 1-month posttreatment and 3% at 3-months posttreatment. Cost-effectiveness planes and CEACs from the health care perspective are included in Multimedia Appendix 1.

Sensitivity Analyses

Cost-effectiveness and cost-utility estimates were similar when using observed data only (ie, no missing data imputation). At 1-month posttreatment, the ICER on the DSHI-Y was US $3558/1.04=US $3434, the ICER of NSSI remission was US $3558/0.23=US $15,548, and the cost per QALY was US $3558/0.005=US $660,968. At 3-months posttreatment, the ICER on the DSHI-Y was US $4429/1.04=US $7872, the ICER of NSSI remission was US $4429/0.08=US $58,111, and the cost per QALY was US $4429/0.009=US $488,623 (see Multimedia Appendix 1 for cost-effectiveness planes and CEACs).

As school-related costs accounted for the single largest proportion of costs, we calculated societal costs excluding this

XSL•FO
RenderX

category. This resulted in similar between-group differences in costs at both 1-month posttreatment (US $4206, 95% CI US $1720-$6442) and 3-month follow-up (US $4548, 95% CI US $1103-$7767). Removing this category from the analyses, therefore, did not impact the overall conclusions.

To evaluate whether the participating youth received additional counseling outside the purview of their parents, youth- and parent-reported counseling use was compared at 1-month and 3-months posttreatment. There was agreement in 79% - 81% of cases. Disagreement was due to additional service use reported by either the youth (8% at 1-month posttreatment, 11% at 3-months posttreatment) or their parents (11% at both time points), and there was no evidence of systematic under or overreporting by parents (Multimedia Appendix 1).

Discussion

Principal Findings

The purpose of this study was to evaluate the cost-effectiveness and cost-utility of adding therapist-guided internet-delivered emotion regulation treatment (IERITA) to TAU for adolescents with NSSI, compared to TAU only. Our results showed that adding IERITA to TAU led to statistically significant reductions in NSSI, a higher proportion of participants with NSSI remission, and more QALYs, at 1-month posttreatment, at additional costs from health care and societal perspectives. The CIs of the ICERs of both NSSI frequency and NSSI remission were wide, ranging from lower costs and greater effects to higher costs and greater effects for IERITA+TAU relative to TAU. IERITA had an 8% probability of being cost-effective at a societal willingness-to-pay threshold of US $84,000 for one QALY at 1-month posttreatment, which increased to 18% at the 3-months posttreatment. This study provides an estimate of the cost of delivering IERITA delivered adjunctive to TAU, which is important for future implementation efforts.

The costs of providing IERITA adjunctive to TAU (US $3552) are higher than other internet-delivered treatments for other disorders in youth, for example, obsessive-compulsive disorder (US $2140 [53]), but substantially lower compared to high-intensity treatments such as DBT-A, which has an estimated treatment cost of €15,850 (US $15,052) per patient [17]. In the same study, DBT-A was found to be cost-saving over a 71-week period compared to eTAU, a difference that was largely driven by two long episodes of inpatient treatment in the eTAU group during the follow-up period [17]. Similarly, a brief cognitive behavioral therapy intervention for adults with self-harm was found to save £838 (US $680) in health care visits and sick-leave costs over 12 months compared to TAU [54]. In contrast, in this study, IERITA was associated with increased costs compared to TAU. However, direct comparisons between studies are challenging due to differences in evaluated costs (eg, only self-harm-related health care visits were measured in the DBT-A study versus all health care visits in this study), assessed health outcomes (eg, outcome was total number of self-harm episodes during follow-up in the DBT-A study vs weekly NSSI frequency in this study), follow-up duration, and health care context. The cost-effectiveness of IERITA may be improved if the treatment can be delivered at a lower cost (eg, automating parts of the therapists' work such as responding to frequently asked questions), if IERITA is associated with lowered health care resource use through fewer parallel care contacts (discussed below), and longer follow-up periods to assess the full effect of IERITA on QALYs and costs (eg, whether IERITA protects against further deterioration of NSSI and thus need for more costly interventions in the future).

Strengths and Limitations

This study has several strengths. First, the participants were recruited at three different child and adolescent psychiatric units, and the majority were referred by clinicians. The included participants are therefore more likely to be representative of the population seen in general psychiatric care than what would have been the case with a primarily self-referred sample. Second, the comparator was TAU within this psychiatric context, providing a realistic estimate of the costs and effects associated with the care typically provided to adolescents with NSSI in Sweden. Third, the platform carefully logged therapist activity, and it is therefore likely that the estimates of the treatment costs associated with the delivery of IERITA are accurate.

Nonetheless, some limitations deserve mention. First, most of the data collection relied on self-reports by parents, as well as therapists (time spent on phone contacts). This may have introduced bias into the estimates, which may differ from official records. However, the patient report is the preferred method to collect data on resource use and lost productivity [55], and the therapists followed guidelines for how to record the time spent on phone contacts, which was identical across both groups. Second, the 12-week recall period increases the risk of recall bias compared to shorter time frames. However, recall periods up to 6 months have been found to converge closely with weekly cost diary estimates [56]. Third, although QALY estimates were derived from KidScreen-10 scores using a validated algorithm [35], there is a risk that this indirect estimate reduced the precision in QALY estimates, particularly since the validation was made in another country (Australia) and on a general population sample of adolescents. Fourth, the costs and effects were limited to 3 months posttreatment, and we were not able to evaluate whether the treatment was associated with cost savings in the longer term, which has been found for DBT-A in adolescents and brief CBT in adults [17,54]. There are opportunities to address these limitations in future studies by incorporating registry-based estimates of resource use to evaluate the validity of self-reported costs in this context, using a questionnaire such as the CHU9D, where QALY estimates are directly available, and measuring resource use over a longer time period to evaluate long-term costs and effects of the intervention.

This is the first randomized clinical trial of internet-delivered treatment for adolescents with NSSI and NSSID, and one of the few trials demonstrating treatment effects in favor of the experimental intervention, regardless of treatment modality. The results, particularly the robust estimates of intervention cost, from this study can inform decision makers interested in implementing treatments for youth NSSI in clinical practice. For example, our findings show that providing IERITA as an adjunctive treatment to TAU is associated with statistically

XSL•FO
RenderX

significant reductions in NSSI, a higher proportion of participants with no NSSI, and more QALYs at 1-month posttreatment, at an intervention cost of US $3552. Thus, for a relatively low cost compared to existing treatment options, this scalable and transportable treatment can provide public health benefits for a vulnerable population, otherwise at great risk for adverse outcomes. Because the treatment was considered an experimental intervention when the clinical trial took place, participants were recommended to continue or even establish other types of care contacts while also receiving IERITA. Future evaluations may consider using IERITA as a stand-alone first-line treatment with a reduced need for other ongoing care contacts, thus potentially offsetting the intervention costs of IERITA with lower health care costs from other sources. As discussed above, whether IERITA leads to similar long-term reductions in health care costs seen in other treatments is currently unknown. Prior to implementation, however, differences between this study and the specific context in which the intervention is to be implemented need to be considered. For instance, this study assessed resource use in a Swedish context, where prices for medications and health care visits are subsidized at the national level and are thus not paid in full by patients themselves. Differences in health care systems in other countries may thus affect changes in patient behavior during treatment (eg, rejecting other types of interventions while receiving IERITA in order to minimize costs). Furthermore, this study did not account for costs related to the development of the treatment protocol, server expenses, or licensing fees, which should be considered prior to implementation in other health care settings.

Conclusions

Existing treatment options for adolescents with NSSI are often resource-intensive and costly. Here, we show that an internet-delivered emotion regulation therapy (IERITA) delivered adjunctive to TAU led to improvements in NSSI frequency, remission, and QALYs at additional costs, compared to TAU only. This study provides an estimate of the additional cost of delivering IERITA compared to TAU. However, the full effects of an intervention on QALYs and societal costs are likely seen over longer time periods (eg, whether the treatment is associated with a reduced need for other costly interventions or can improve school attendance), and studies of IERITA including longer follow-up periods are therefore needed.

Acknowledgments

The authors acknowledge all participants who were involved in the project and contributed detailed information regarding costs in order to enable this study. The authors thank Hugo Hesser, Henrike Häbel, Hanna Sahlin, Kim L Gratz, Matthew T Tull, Emma Claesdotter Knutsson, Erik Hedman-Lagerlöf, and Brjánn Ljótsson, who contributed to the clinical trial on which this study is based. The authors received no specific funding for this work. The clinical trial from which data were used received funding from the Swedish Research Council (grants 2014.1008 and 2017 - 01506), Markus and Amelia Wallenberg Foundation (grant MAW 2014.0021), Fredrik and Ingrid Thuring's Foundation, L. J., Clas Groschinsky's Foundation (grant SF18121), Sven Jerring Foundation, Kempe-Carlgrenska Foundation, and Bror Gadelius Foundation. JB was supported by a grant from the Knut and Alice Wallenberg Foundation (grant 2018.0426) and The Royal Swedish Academy of Letters, History and Antiquities, and Stiftelsen Natur & Kultur. OF was supported by the Swedish innovation agency (2022 - 00549). The clinical trial was supported by the National Self-Injury Project in Sweden. Funding sponsors did not influence the design, collection, analysis, or interpretation of data, writing the manuscript, or the decision to submit the manuscript for publication.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request. Statistical code used for the analyses is publicly available from the Open Science Framework repository [52].

Conflicts of Interest

JB receives royalties from Natur & Kultur, outside the submitted work. OF has received speaking fees from the Swedish OCD Association, Insight Events AB, WeMind Psykiatri AB, and Kry International AB, as well as reimbursement for writing articles for Inside Practice Psychiatry, all outside the submitted work.

Abstract

Background: Secondary use of routinely collected health care data has great potential benefits in epidemiological studies primarily due to the large scale of preexisting data.

Objective: This study aimed to engage respondents with and without a history of self-harm, gain insight into their views on the use of their data for research, and determine whether there were any differences in opinions between the 2 groups.

Methods: We examined young people's views on the use of their routinely collected data for mental health research through a web-based survey, evaluating any differences between those with and without a history of self-harm.

Results: A total of 1765 respondents aged 16 to 24 years were included. Respondents' views were mostly positive toward the use and linkage of their data for research purposes for public benefit, particularly with regard to the use of health care data (mental health or otherwise), and generally echoed existing evidence on the opinions of older age groups. Individuals who reported a history of self-harm and subsequently contacted health services more often reported being "extremely likely" or "likely" to share mental health data (contacted: 209/609, 34.3%; 95% CI 28.0-41.2; not contacted: 169/782, 21.6%; 95% CI 15.8-28.7) and physical health data (contacted: 117/609, 19.2%; 95% CI 12.7-27.8; not contacted: 96/782, 12.3%; 95% CI 6.7-20.9) compared with those who had not contacted services. Respondents were overall less likely to want to share their social media data, which they considered to be more personal compared to their health care data. Respondents stressed the importance of anonymity and the need for an appropriate ethical framework.

Conclusions: Young people are aware, and they care about how their data are being used and for what purposes, irrespective of having a history of self-harm. They are largely positive about the use of health care data (mental or physical) for research and generally echo the opinions of older age groups raising issues around data security and the use of data for the public interest.

Introduction

Background

The era of "big data" has offered our current digital economy different perspectives across a variety of areas, bringing together epidemiologists, computer scientists, economists, sociologists, bioinformaticians, and other scholars with large volumes of data and information, produced by and about people. Researchers are accessing routinely collected data and then aggregating and linking those data across sectors (eg, business, science, justice, health, and social care), each with its own advantages, limitations, and ethical issues [1]. Secondary use of routinely collected health care data holds great potential benefits in epidemiological studies primarily due to the large scale of preexisting data [2]. This use of routinely collected health care data to inform policy allows evidence to be collected without placing a burden on individuals. This is of particular importance when looking to tailor support for individuals who may face stigma or other barriers to taking part in research, such as individuals with a history of self-harm (SH). The COVID-19 pandemic exemplified the importance of using health care data to inform policy and practice.

Big data lies at the heart of efforts to aggregate information that will assist in identifying disparate needs across geographic regions, groups, as well as epidemiological trends [3]. The advantages of routinely collected data need to be balanced against ethical and legal challenges, such as patient anonymity, data security, fairness, and transparency [4]. Health care researchers identified the need to gain a better understanding of the public's attitudes toward the use of their data by enhancing their participation in the research process and ensuring use of their data aligns with public interests [5]. While the public is generally supportive of the use of their health care data [4,6-8], certain fields, such as mental health data, arguably remain differentiated due to their perceived sensitive nature [9] and have unique ethical considerations [10]. Studies exploring public views on sharing mental health data found community attitudes to be largely positive [9,11-13]. The need to question the long-term efficacy of measures used, the validity of the types of data resources, and the risks of bias and privacy were highlighted [10,13-17].

In contrast to health data, social media and other internet-based platforms often lack clear and consistent procedures for the use of data generated online [18]. This rapidly growing technological landscape is changing our definition of knowledge and raising significant ethical questions, namely "Can data be used simply because it is openly accessible?" as well as critically evaluating the methods of collection and biases associated with it [19]. Guidelines have been developed outlining ethical factors, such as confidentiality, security, consent, potential harm, and levels of researcher control, when engaging with internet-mediated research [20]. While there is much debate surrounding the ethical principles that need to be applied in social media or internet-based research [18,21-23], these often do not involve the views of online users or make efforts to improve their level of awareness as to what is or can be done with their data [24].

Young people are particularly susceptible to both generating and sharing vast amounts of personal data, to the point of being characterized as a valuable currency in the digital economy [25]. Online presence within this age group as well as its forms changed over time from being more text based to increasingly changing into communication through imagery and videos [25], including sharing images of SH [26,27]. Contingent on appropriately securing and ethically handling these types of data footprints, they can arguably be used to identify patterns and risk indicators of those who struggle with mental health and would potentially benefit from early interventions that may prevent SH and suicide [28,29].

There is a wide misplaced acceptance that young people's willingness to heavily engage with online platforms suggests that they do not care about their privacy [30]. However, some authors advocate little variance between adults and young people when it comes to their views on privacy in data sharing [31-33]. Researchers have used online platforms to examine the mental health and well-being of young people across various topics [34,35]; however, young people's views on the use of their data for mental health research purposes, though somewhat explored [36], remain underreported. Moreover, the views of young people who have experienced SH have not been examined previously in relation to the use of their data for research. The often hidden and stigmatized nature of SH may give rise to specific concerns from young people that have implications for data management and ethical use.

This Study

Engagement with young people is essential to develop a better understanding of these issues and their views and was a key focus of this study. This survey set out to engage respondents with and without a history of SH in order to gain insights into their views and knowledge of how different kinds of data are anonymized and used for research and to determine whether there are any differences of opinions between those 2 groups. We also aimed to explore differences between those who had contacted health services for SH and those who had not.

Methods

Study Design

This study was a web-based cross-sectional survey. The Checklist for Reporting Results of Internet E-Surveys was followed [37].

Ethical Considerations

Ethics approval was granted by the Swansea University Medical School Ethics Committee (2018-0062). Respondents gave informed consent, were made aware that participation in the survey was entirely voluntary and no incentives were offered. Data were given anonymously with no personally identifiable information collected. Any potentially identifiable information given in free-text responses was removed before analysis (see details in Data Analysis section).

Description of Respondents

Respondents aged 16 to 24 years and residing in the United Kingdom were eligible. The survey was open to individuals

XSL•FO
RenderX

both with and without a history of SH. SH is defined as intentional self-poisoning or self-injury, irrespective of the nature of motivation or degree of suicidal intent. This definition is necessarily very general because the nature of motivation or degree of suicidal intent is complex and may vary over time or between individuals [38]. A history of SH was based on self-report from respondents at the onset of the survey.

Recruitment occurred through a social media campaign conducted on Facebook (Meta platforms, Inc) and Instagram (Meta platforms, Inc) using visual material (eg, video clips and posters). Respondents were targeted based on age and location. Participants were also recruited via the Self-Harm Research UK research register. This is a register of individuals who have consented to be contacted for SH research [39].

Data Collection

Responses were collected between July 18, 2019, and January 31, 2020. The survey (including respondent information, consent, and debrief forms) was hosted on Survey Monkey (SurveyMonkey Inc) [40] due to its user-friendly interface and its capability to record anonymous responses. SurveyMonkey uses a unique user identifier based on cookies to ensure each respondent takes the survey only once.

Measures

Overview

The big data and mental health research survey consisted of 4 topic areas: demographic information, preferences and experiences of mental health and SH-based research, use of artificial intelligence, and big data for mental health research (a copy of the questionnaire can be found in Multimedia Appendix 1). There were 29 questions developed with student interns and piloted with a small group of participants from the Self-Harm Research UK research register. A subset of items was duplicated in both our survey and another survey exploring views on the use of data in a sample of National Health Service (NHS) patients [12]. This was done to allow meaningful comparison between the 2 populations. All items were optional except those collecting demographic information. For the purpose of this study, the items mentioned in the subsequent subheadings were used.

Demographic Information

In total, 4 mandatory questions related to age, gender, location, and history of SH were included. There were 3 additional optional questions related to SH including frequency.

Big Data for Mental Health Research

This section started with a brief description of what was meant by big data and how routinely collected data are collected, anonymized, and used for research, followed by 12 questions (5 closed-ended questions and 7 questions with free text responses questions; refer to survey questionnaire in Multimedia Appendix 1).

Data Analysis

Overview

SurveyMonkey collects data from all respondents independent of the number of items completed. Eligibility for inclusion in data extraction based on item completion was determined retrospectively by the research team. It was decided a priori that respondents who answered all 4 demographic questions and a minimum of 2 other survey questions would be included. Respondents who chose “prefer not to answer” when asked about SH were excluded.

Respondents were stratified into 2 groups as follows: those reporting a history of SH and those reporting no history of SH (NoSH). Within the SH group individuals were further stratified into those who have made contact with health services following SH and those who have not. Health services were defined as general practitioners (GPs), any hospital treatment (eg, accident and emergency), and psychiatric or mental health services, including liaison services. Due to small numbers, it was not possible to break down service contacts by type (eg, GP).

Analysis of Quantitative Data

Descriptive statistics were used to summarize group characteristics and proportions of respondents across closed questions (counts, percentages, and 95% CIs). Wilson score with continuity correction was used to calculate CIs [41]. Cross-tabulation, together with chi-square test of association, was used to assess the significance of the difference in distributions between groups. We adopted available case analysis and performed pairwise deletion of nonresponses for each cross-tabulation. Chi-square tests were conducted to investigate the number of nonresponses for each item by age, gender, SH (NoSH vs SH group), contact with health services following SH. We did not correct for running multiple comparisons (eg, Bonferroni) when analyzing the quantitative data. This decision was taken due to the exploratory nature of the work to allow the exploration of more subtle effects in the data. The level of statistical significance was set at P=.05, and all statistical analyses were performed with SPSS (version 26, IBM Corp).

Extraction of Qualitative Data and Free Text Responses

To analyze responses to open-ended questions, identifiable information (eg, names and locations) were removed from any quotations and replaced with a random initial. A dualistic thematic analysis technique was used, using a deductive and inductive approach informed by the work of Fereday and Muir-Cochrane [42]. The deductive component involved creating a preliminary codebook to help guide the analysis, which was based on the open-ended questions asked in the survey as well as an initial scan of the quantitative responses. This was followed by facilitating an inductive generation of codes that allowed for unexpected themes to develop during the coding process [43]. For the latter, 2 members of the study team (DD and AM) independently identified recurrent and prominent themes in an initial sample of responses (1071/10,710, 10% of each item) for discussion. Codes were further reviewed and discussed with a third expert researcher (AJ). New codes were added, and themes were consolidated.

XSL•FO
RenderX

The coding frame was piloted on 20% (2142/10,710) of the responses by 2 independent coders. Interrater agreement was assessed by computing Cohen κ coefficient. Codes were further discussed and refined, and sources of disagreement were resolved. Following this, items were recoded and interrater agreement was recalculated. All items included in the final coding frame had a Cohen κ score ≥0.7 [44].

Respondent responses for each free text question were broadly divided into "positive or yes"; "negative or no"; "neutral, unsure, or unclear" (eg, "don't know" and "bleh"); and "conditional" indicating that the individuals' response would be conditional on other factors.

Free text responses were organized and analyzed using NVivo (version 22, Lumivero). Cohen κ coefficients were calculated using Microsoft Excel.

Results

Respondents

A total of 3700 individuals took part in the survey. On the basis of the inclusion criteria, 1765 (47.7%) respondents were included in the analysis. Respondents gave 10,710 responses to 7 open-ended questions. Supplementary analysis was conducted to examine differences in item completion rates across questions and demographics (Multimedia Appendix 2). Nonresponses made up less ≤6% for each closed-ended question. Participants with a gender other than man/boy, woman/girl, older age, a history of SH, and those having contact with services were less likely to skip individual items.

We stratified participants into 2 groups based on the presence (SH) or absence (NoSH) of a history of SH. Of the 1765 included in the analysis 1448 (82.04%; 95% CI 79.9-83.9) reported previous SH. The demographics of respondents are shown in Table 1. Individuals aged 20 to 24 years were grouped together due to a small sample size.

Table 1. Demographics of respondents included in data extraction (N=1765).

Demographic characteristics	Self-harm (n=1448), n (%; 95% CI)	No self-harm (n=317), n (%; 95% CI)	Total (N=1765), n (%; 95% CI)
Gender			
Female	1271 (87.8; 85.8-89.5)	281 (88.6; 84.2-90.3)	1552 (87.9; 86.2-89.5)
Male	87 (6; 2.3-13.8)	33 (10.4; 3-19.3)	120 (6.8; 3.2-13.3)
Other or unknown	90 (6.2; 2.5-13.9)	3 (0.9; 2.7-6.6)	93 (5.3; 1.9-12.5)
Age (y)			
16	699 (48.3; 44.5-52)	175 (55.2; 47.5-58.9)	874 (49.5; 46.2-52.9)
17	469 (32.4; 28.2-36.9)	81 (25.6; 16.8-29.8)	550 (31.2; 27.3-35.2)
18	86 (5.9; 2.2-13.8)	9 (2.8; 0.2-9.7)	95 (5.4; 2-12.6)
19	58 (4; 0.8-13.7)	9 (2.8; 0.2-12.1)	67 (3.8; 0.9-12.4)
20-24	136 (9.4; 5.3-15.9)	43 (13.6; 5.6-20.7)	179 (10.1; 6.3-15.8)

A total of 41.02% (594/1448; 95% CI 37.0-45.1) of those who reported SH did so with suicidal intent. Self-injury (1370/1448, 94.61%; 95% CI 93.2-95.7) was the most frequently used method.

This was followed by ingesting medication in excess of the prescribed dose (570/1448, 39.36%; 95% CI 35.4-43.6).

When asked whether help was sought following incidents of SH, 39.71% (575/1448; 95% CI 35.7-43.8) of the respondents reported not seeking help from any of the sources listed. Friends, family, and neighbors were the most common sources of help (555/1448, 38.33%; 95% CI 34.3-42.5) followed by psychiatric or mental health services.

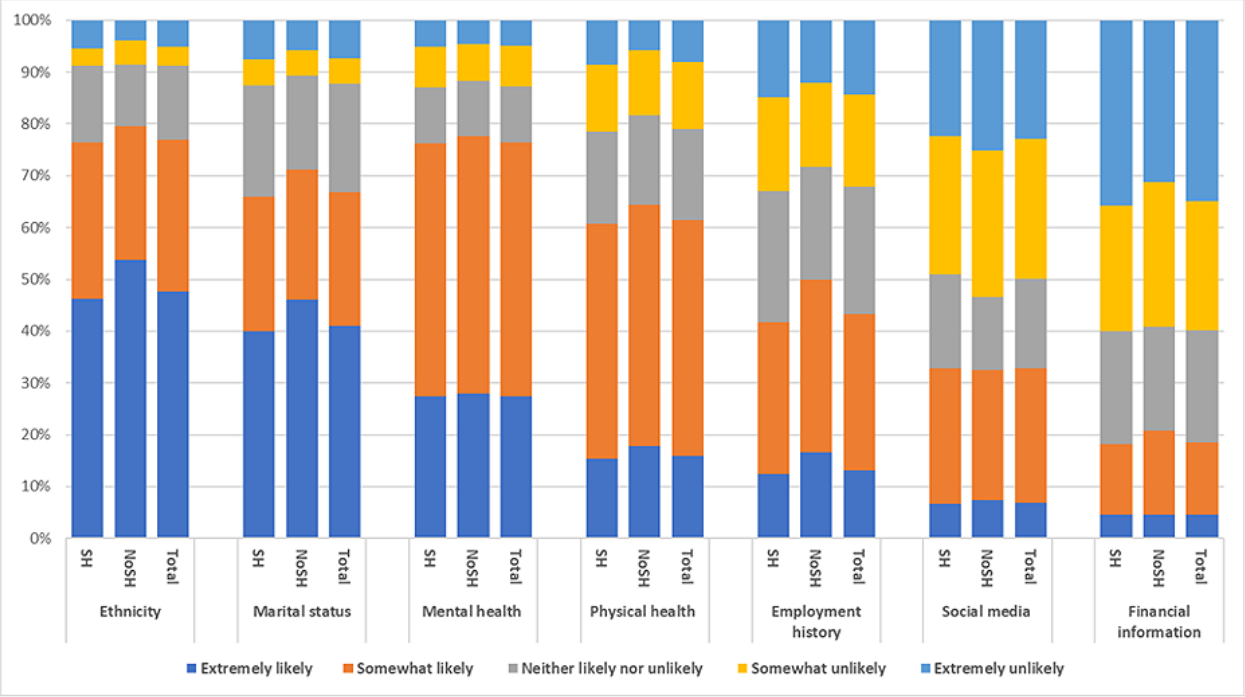
Among the 1448 respondents in the SH group, 42.06% (609/1448; 95% CI 38.2-46.1) reported contacting health services following an incident of SH. Of the 609 respondents who contacted health services, psychiatric or mental health services (n=518, 85.1%; 95% CI 82.0-87.8) were the most frequently reported followed by GPs (n=346, 56.8%; 95% CI 52.8-60.8) and hospital treatment (n=240, 39.4%; 95% CI 35.5-43.4).

Topic Areas

Overview

Results of both closed- and open-ended questions are presented subsequently and organized by topic area (sharing types of data research, use of mental health data, factors influencing feelings toward data use, trustworthiness of organizations, and the use of anonymized health care data). Responses from the SH and NoSH group were broadly similar. Consequently, we only highlighted group differences wherever necessary.

Topic 1: Sharing of Types of Data for Research



Respondents were asked the question, "Thinking about data more generally (not only health data), how likely would you be to share the following types of data for research (ethnicity, marital status, social media, physical health, mental health, etc)?"

Respondents were more likely to share their ethnicity, marital status, and mental and physical health data and less likely to share their social media posts and financial information. There were no substantial differences between the NoSH and the SH

XSL•FO
RenderX

groups in the distributions of responses across all types of data (Figure 1, Multimedia Appendix 3). The NoSH group showed a slightly higher likelihood of sharing their data through most categories. For example, when asked about ethnicity, 53.3% (169/317; 95% CI 45.5-61) of the respondents in the NoSH group were extremely likely to share that type of data, compared to 45.17% (654/1448; 95% CI 41.3-49.1) in the SH group (χ^2_4=9.1; *P*=.06).

Figure 1. Responses to the question "Thinking about data more generally (not only health data), how likely would be to share various types of data for research purposes?" NoSH: no history of self-harm; SH: history of self-harm.

When we further categorized the SH group by whether individuals had contacted health services following SH (Multimedia Appendix 4), we found significant group differences for sharing data regarding marital status (χ^2_4=10.1; *P*=.04), mental (χ^2_4=31.2; *P*<.001), and physical health (χ^2_4=15.6; *P*=.004). Respondents who contacted health services were more likely to share mental health and physical health data, 34.3% (95% CI 28.0-41.2; 209/609) of those who had contacted services responded that they were "Extremely likely" to share mental health data compared with 21.6% (95% CI 15.8-28.7; 169/782) of those who had not contacted services. Similarly when asked about physical health data, 19.2% (95% CI 12.7-27.8; 117/609) of those who had contacted services for SH responded that they would be "extremely likely" to share this data compared with 12.3% (95% CI 6.7-20.9; 96/782) of those who had not contacted services.

The respondents were asked in a free text response "How do you feel about your social media posts being used for research? Would the data being anonymised make you feel differently?" A total of 39.49% (697/1765) of the respondents responded negatively, with 33.03% (583/1765) stating that they would only be happy to share this information if certain conditions were met (no significant difference between the SH and NoSH groups). Concerns were most commonly related to privacy and anonymity. Social media was often considered very personal information, and for some, it was more personal than medical data. Individuals who were positive about their data being used were under the assumption that their data were not private, with a respondent stating the following:

> *I make my social media accounts public by choice, therefore I wouldn't mind my posts being used for the purpose of research–the social media companies themselves already do this whether you like it or not for advertising etc.* [participant F51]

This is in contrast with the views of those who responded negatively:

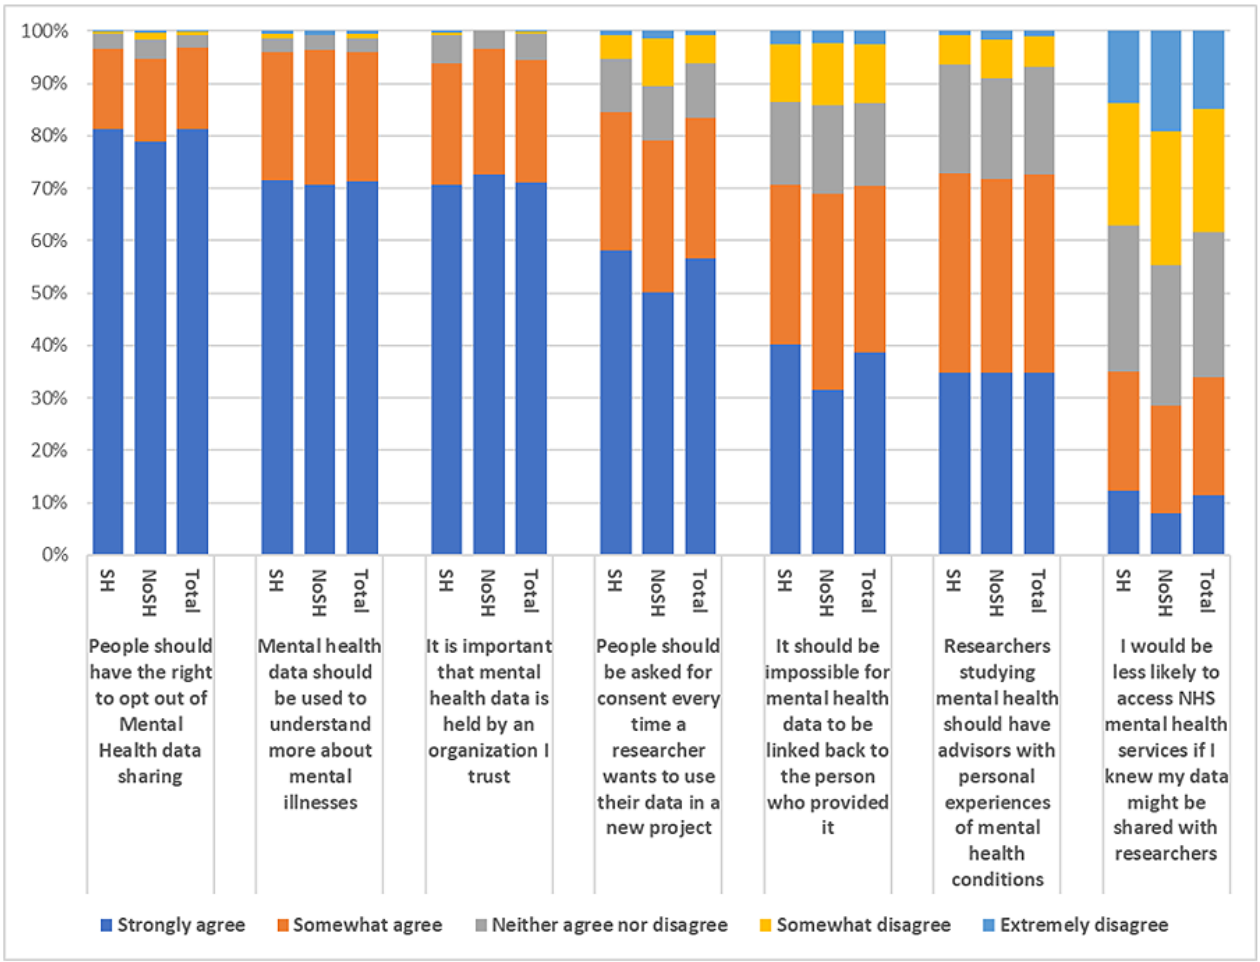
> *Social media should only be used in research if the person is completely happy and aware with where their data is taken. Pictures or videos should never be taken. If social media is used, then I feel it is no longer anonymised. People can look up specific captions and hashtags taken from posts, and you have lost complete anonymity.* [participant F38]

Respondents were skeptical about how it is possible to anonymize social media posts with concerns raised around images:

> *Most of the stuff I post is pictures therefore I'm not sure how that can be anonymised.* [participant F715]
>
> *Uncomfortable due to the lack of anonymity as it's my face, you can't really make that anonymous.* [participant M51]

Distinctions were made between different social media platforms and privacy settings:

XSL•FO
RenderX



> *I'd hate to have my social media posts used for research as it's private for a reason. If it was anonymous, I'd feel better but only for things like twitter where there's mostly just tweets rather than photos.* [participant F412]

Topic 2: Use of Mental Health Data

Responses to the question "When thinking about sharing mental health data, to what extent do you disagree or agree with the following statements?" are shown in Figure 2 (Multimedia Appendix 5). Most respondents (1357/1765, 76.88%; 95% CI 74.5-79.1) strongly agreed that they should have the right to opt out of mental health data sharing, it is important that mental health data are held by an organization they trust (1188/1765, 67.31%; 95% CI 64.5-70.0), and mental health data should be used to understand more about mental illness (1203/1765, 68.16%; 95% CI 65.4-70.8). When asked whether they would be less likely to access NHS mental health services if they knew that their data would be shared with researchers just 10.9% (95% CI 7.0-16.4; 192/1671) responded "strongly agree." Those who had contacted health services following SH were more likely to agree to the sharing of their data than those who had not contacted services (contacted—strongly disagree: 97/609, 15.9%; CI 9.6-25.1; contacted—somewhat disagree: 146/609, 24%; 95% CI 17.5-31.9; not contacted—strongly disagree: 84/782, 10.7%; 95% CI 5.3-19.9; not contacted—somewhat disagree: 162/782, 20.7%; 95% CI 14.9-27.9; χ^2_4= 12.5; *P*=.01). However, 10.88% (192/1765; 95% CI 7.0-16.4) of all the respondents strongly agreed that they would be less likely to access NHS mental health services if they knew that their data would be shared with researchers, with those with SH slightly more likely to agree than those without (Multimedia Appendix 6).

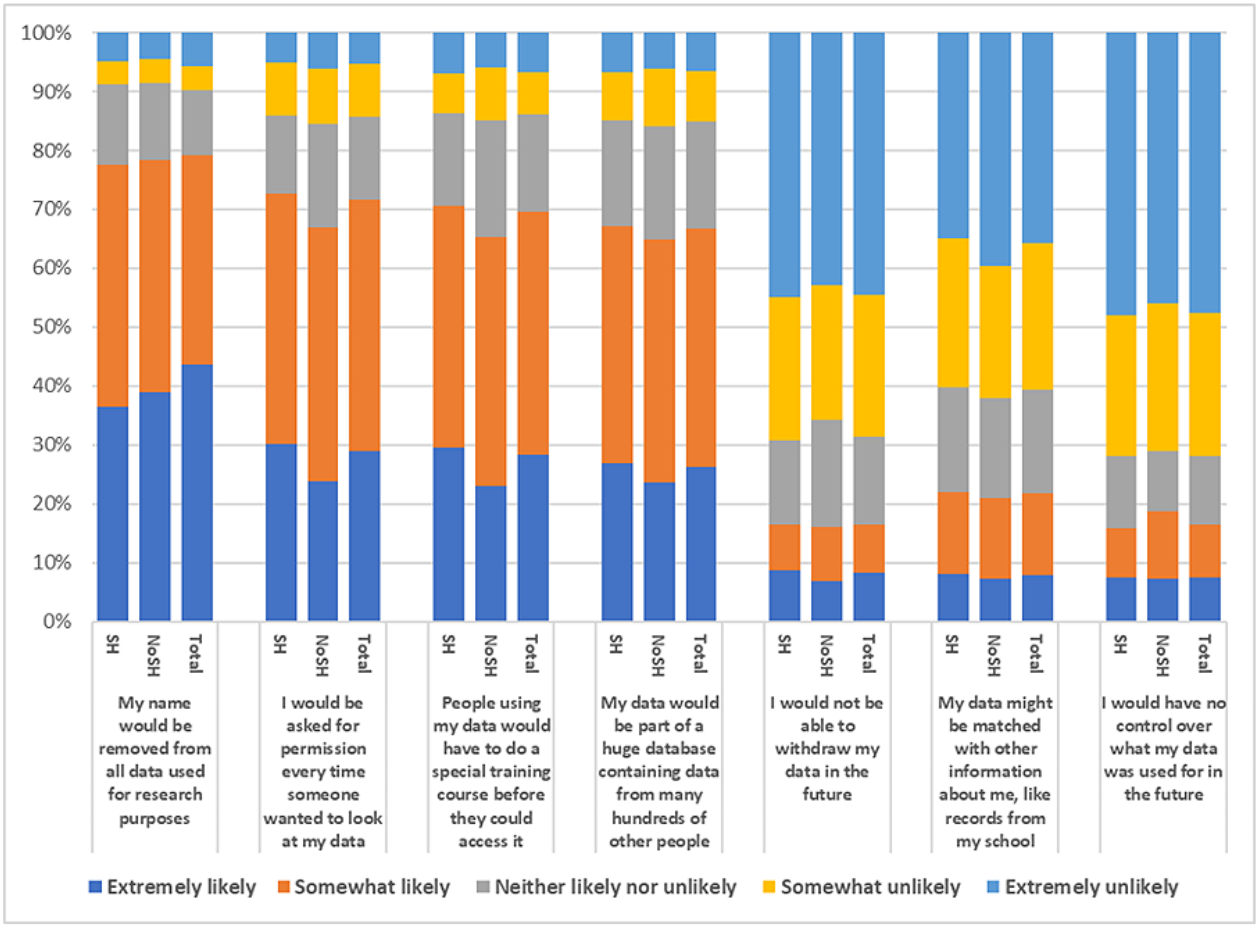
Those who contacted health services were more likely to agree that researchers studying mental health should have advisers with personal experiences of mental health conditions (contacted: 227/609, 37.3%; 95% CI 31.0-44.0; not contacted: 234/782, 29.9%; 95% CI 24.2-36.3; responded "strongly agree"; χ^2_4=12.5; *P*=.01). The SH and NoSH groups were comparable on most statements (*P* values=.35-.56). While there were some significant differences between groups, the NoSH group was small, and as such CIs were wide (Multimedia Appendix 5).

Figure 2. Responses to the question "When thinking about sharing mental health data, to what extent do you disagree or agree with the following statements?" NoSH: no history of self-harm; SH: history of self-harm.

XSL•FO
RenderX

Topic 3: Factors Influencing Feelings Toward Use of Data

Responses to the question "How would the following measures change the likelihood you would be willing to share your mental health data for research purposes?" are shown in Figure 3 (the distribution of answers is provided in Multimedia Appendix 7). Respondents were more likely to share data if names were removed from research data (extremely likely: 736/1765, 41.7%; 95% CI 38.1-45.4; somewhat likely: 599/1765, 33.94%; 95% CI 30.2-37.9), and permissions were asked every time the data were used (extremely likely: 496/1765, 28.1%; 95% CI 24.2-32.3; somewhat likely: 728/1765, 41.25%; 95% CI 37.7-44.9). In contrast, respondents were extremely unlikely to share data if they had no control over what their data were used for in the future (802/1765, 45.44%; 95% CI 42.0-49.0), would not be able to withdraw their data in the future (744/1765, 42.15%; 95% CI 38.6-45.8), or have their data matched with other data (603/1765, 34.16%; 95% CI 30.4-38.1). Comparison between the SH and NoSH groups revealed no statistical differences in the distributions of responses (P=.09-.72) nor were there any differences when comparing individuals who had or had not contacted health services following SH (P=.07-.80; Multimedia Appendix 8).



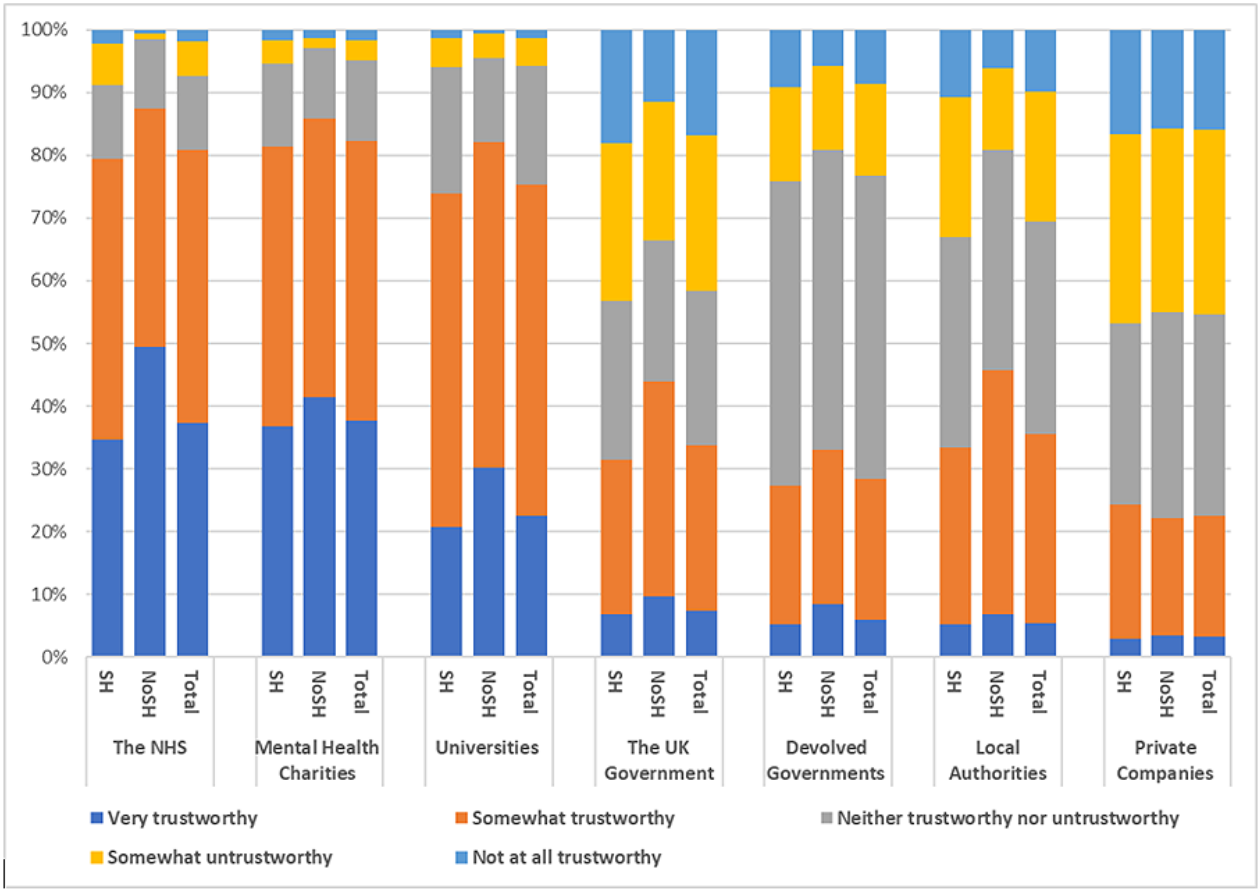
Analysis of free text responses suggested that young people would feel more positive about sharing their data if they were better informed about the nature of the research and potential benefits of services. They were asked the question "Would you like a better explanation of how your data is used and shared for research?" A total of 53.37% (942/1765) of the respondents responded positively or yes, with explanations required to be short and easy to understand. A common theme across all respondents (positively or yes and negatively or no) was wanting to know more about the research and its impact. For example, one respondent who stated that they would like a better explanation stated the following:

> *Yea, it would be good to know how this research will help people in the future who struggle with mental health problems.* [participant F598]

While another respondent who did not want any further explanation on how their data were used stated the following:

> *To be honest, as long as my personal info is not given away, I am not fussed. However, I think that anyone who took part should be allowed to view the paper in full once drafted or published. Normally you have to pay a fee to read a research paper, but this seems a bit unfair if you were part of the experiment!* [participant F421]

Figure 3. Responses to the question "How would the following measures change the likelihood that you would be willing to share your mental health data for research purposes?" NoSH: no history of self-harm; SH: history of self-harm.



XSL•FO
RenderX

Topic 4: Trustworthiness of Organizations

Respondents were presented with a list of organizations and asked, "In your opinion how trustworthy are the following organizations when it comes to storing and using mental health data for research?" (refer to Figure 4 and Multimedia Appendix 9 for details). Most respondents reported that mental health charities were the most trustworthy (very trustworthy: 651/1765, 36.88%; 95% CI 33.2-40.7; somewhat trustworthy: 767/1765, 43.46%; 95% CI 39.9-47.1) followed by the NHS (very trustworthy: 649/1765, 36.77%; 95% CI 33.1-40.6; somewhat trustworthy: 754/1765, 42.72%; 95% CI 39.2-46.3) and universities (very trustworthy: 383/1765, 21.7%; 95% CI 17.7-26.2; somewhat trustworthy: 900/1765, 50.99%; 95% CI 47.7-54.3). Private companies, local authorities, and devolved governments were rated as the least trustworthy organizations for storing and using mental health data. We observed significant differences in distributions of the degree of trustworthiness between the 2 groups for the NHS (χ^2_4=35.3; *P*<.001), universities (χ^2_4=17.5; *P*=.002), UK government (χ^2_4=19.7; *P*=.001), and local authorities (χ^2_4=27.0; *P*<.001). The NoSH group showed slightly higher trust in NHS, universities, and UK government in comparison to the SH group. For example, 48.9% (155/317; 95% CI 40.8-57.0) respondents of the NoSH group and 34.12% (494/1448; 95% CI 30.0-38.5) respondents of the SH group said that the NHS was "very trustworthy," and 29.7% (94/317; 95% CI 20.9-40.1) respondents of the NoSH group and 19.96% (289/1448; 95% CI 15.6-25.1) respondents of the SH group said that universities were "very trustworthy." We found similar distributions in the degree of trustworthiness related to all organizations between respondents with a history of SH independent of contact with health services (*P*=.08-.90; Multimedia Appendix 10).

Figure 4. Responses to the question "In your opinion, how trustworthy are the following organizations when it comes to storing and using mental health data for research?" NoSH: no history of self-harm; NHS: National Health Service; SH: history of self-harm.

The participants were asked the open-ended question, "Do you feel differently about research done by universities than that done by companies?" A total of 56.09% (990/1765) of the respondents responded that they felt more positively about research done by universities than companies (no significant differences between the SH and NoSH groups).

Positive responses were most frequently related to universities being regarded as more trustworthy, with educational institutions and the role of students being regarded positively:

> *Yes, as people from universities are younger and are more likely to understand.* [participant F56]

Universities were perceived to have better data security, and research was commonly described as feeling safer and more ethical with a focus on the greater good of developing the field and helping others:

> *Yes, if university research is being done, then it is often for the greater good but often with companies, I feel that our data can be misused.* [participant F899]

Around a third of respondents answered either positively, negatively, or conditionally to the question "How about information from companies such as Amazon, Google, or Fitbit being used for research?" Among positive responses were statements that these data were less invasive and personal than other data types. The most common negative responses were around data security and privacy:

> *I think the data these companies collect is wrong as I feel it violates our online privacy and kind of scares me to know they track your every action online.* [participant M52]

Consent and ethical issues were common among negative responses, as was the discussion of the use of data for profit:

> *No. Those purposes would be advertising purposes and that isn't helping the public, only themselves at the expense of the person whom the data comes from.* [participant F22]

> *If the person is not aware that research is being done in them then I don't think it is the right thing to do.* [participant F1001]

Responses appeared dependent on whether these types of data were considered relevant to mental health research. Fitbit was singled out as a company that individuals felt more comfortable with. The most frequent conditional responses were related to data being appropriately anonymized, having control over what data are shared (eg, exercise and sleep data from Fitbit but not location), and being given the option to consent. The use of data for the "greater good" also frequently appeared in conditional responses. A participant stated the following:

> *Only if it benefits other people and provides them help.* [participant M87]

Topic 5: The Use of Anonymized Health Care Data

Respondents were asked, "How would you feel about researchers linking things like your answers to questionnaires with anonymised healthcare data, and why?" A total of 91.9% (1622/1765) of the respondents answered, "I would be OK with this" and 745 (42.21%) individuals gave a free text response to the question "Why?" Of those who answered "I would be OK with this," 52.1% (388/745) gave reasons related to the use of these data to help people:

> *If it helps other people and saves lives of people in healthcare crisis then it is a great thing to do. And if it has any chance of waking the government up to the fact that the older generation is not the only one that matters and that we desperately need help and that the world has changed and they have to change too, then of course I want to help.* [participant F98]

Of those who answered "I would not be OK with this," the most frequent free text responses were related to data security, followed by ethical issues particularly related to consent:

> *I'm not wholly against my data anonymously being used for research, but I wouldn't be happy if this was done without my knowledge/consent. It would feel like a violation and breach of trust between me and the healthcare professionals I had disclosed information to originally. It makes me feel like I'm just a set of data to scientists/researchers/doctors.* [participant F225]

Participants were asked to provide a free text response to the question "How do you feel about anonymous healthcare data being used for research?" Responses indicated there were no significant differences between the 2 groups. Across both groups, 66.4% (1172/1765) of the respondents stated that they felt positive about these data being used, with an additional 21.13% (373/1765) of the respondents stating that they would feel more positively about this if certain conditions were met, with data security and privacy (385/1765, 21.81%) and the way data are used (351/1765, 19.89%) standing out as the most prominent conditions. The most common negative responses fell under "features of research." These were mostly related to concerns over how useful these kinds of data could be without the context or surrounding circumstances. This was followed by concerns over data security and privacy. The most common reason for a positive response was the use of data for "the greater good":

> *I think it's amazing because it might actually cause a big improvement in schools and how mental health is talked about, treated, and supported.* [participant F289]

The use of data for the "greater good" or for the purpose of helping others was also a common theme of conditional responses. Conditional responses were most frequently related to concerns over data security followed by ethical issues. A participant stated the following:

> *I think using this information is very beneficial, but people should be made more aware that their data could potentially be used and given an option to opt-out if they do not feel comfortable with this.* [participant F74]

While most respondents (1622/1765, 91.9%) were comfortable with questionnaire responses being linked with routinely collected health care data, some were not comfortable providing the data required for linkage. Participants were asked, "How would you feel about giving personal information such as address and date of birth for linking research and routine healthcare data?" A total of 24.14% (426/1765) of the individuals were happy to give both address and date of birth; however, 30.25% (534/1765) of the respondents stated that they would not be willing to provide either one. A further 18.53% (327/1765) of the respondents indicated that they may be more willing to give this information if certain conditions were met. No differences between the 2 groups were identified.

Individuals were more comfortable giving their date of birth than their address as this was thought to be less identifiable information, and 3.68% (65/1765) of the respondents were willing to give a generic location or postcode rather than a specific address. Other suggestions included the use of an NHS number. The most common reasons for not wanting to give this information were concerns related to data security, including the security of giving this information online. Others were concerned about other people that they live with, being written to at their home address and the impact of being identified:

XSL•FO
RenderX

> *Date of birth fine. Address no. I just know my mum wouldn't be ok with it.* [participant F301]
>
> *I would be scared. What if i told a researcher about my self-harm issues and I get sectioned again?* [participant F149]

Those who were willing to share the required information were most likely to give the "greater good" as a reason and a willingness to contribute data to help others.

Discussion

Principal Findings

We examined young people's opinions on the use of their routinely collected data for mental health research using a web-based survey. We evaluated any differences in the views of young people with or without a history of SH and those in contact with services for SH. Views on the use of mental health data for research were mostly positive with most emphasizing the importance of the benefit to the public and patients. Respondents were less likely to want to share their social media data, which they considered to be more personal compared to their health care data. Respondents stressed the importance of anonymity and the need for an appropriate ethical framework. Individuals who reported a history of SH and subsequently contacted health services were more willing to share mental and physical health data compared with those who had not contacted services. We did not observe any significant differences between the SH and NoSH groups.

Use of Data for Research

The use of data for mental health research of public and patient benefit was viewed positively across all questions asked. Young people were less likely to share their social media and financial data than ethnicity, marital status, and mental and physical health data for research.

Individuals both with and without a history of SH reported broadly similar views regarding their data being used; however, there were clear indications across responses that the importance of data sharing and its use for mental health research for young people and their attitudes toward it was associated with their characteristics and experience. Responses indicated that those with a history of SH might be less likely to use NHS mental health services if they knew that their data would be shared with researchers (although numbers were small); however, this was reversed in those with a history of SH but contacted services. Individuals who reported SH and contacted health services were more willing to share mental and physical health data compared with those who had not. This is further supported in the work done by Kirkham et al [12] with NHS users and Watson et al [13] indicating that while there were concerns that data misuse might worsen stigma, attitudes were largely positive. Favorable experiences of mental health services were likely to result in a higher willingness to share mental health data.

Influencing Factors on the Use of Data

In keeping with older generations [1,6-8], young people share a mostly positive attitude toward their health care data being linked and shared for research purposes, with many relating their positive opinions with the use of this data for public and patient benefit. Respondents stressed the importance of anonymity and the need for appropriate ethical frameworks in keeping with previous work emphasizing the importance of identity protection, data security, transparency, and safeguarding policies while ensuring the use of data is within the public's best interest [4,5].

Young people were less willing to share their social media data and considered this more personal than health care data. While anonymity was consistently reported as important, respondents varied in their understanding of how their social media data could be used and anonymized, particularly images. This is supported by existing literature in relation to young people's lack of awareness and understanding of privacy issues online [31,33]. This contradicts the concept that young people do not care about privacy simply because they are heavily and publicly engaged in the online world [45]. Views on the use of social media data were shared by an adult population in a qualitative study performed by Beninger [46], where users expressed diverse responses toward social media research, ranging from skepticism on how it could be used for research to acceptance and ambivalence that stemmed from the idea that social media is already public and as such may inevitably be used. While some views were similar across generations, adults were less reluctant to share their social media content, as long as conditions, such as privacy and consent were met [47].

Respondents expressed negative feelings about the use of their data for profit or advertising, and this was frequently referenced in relation to the use of their data by private companies.

Anonymity, consent, and research skills were key factors that influenced positive feelings toward sharing mental health data. Losing control over their data, linking with other datasets, and inability to withdraw from data sharing were concerns that influenced negative feelings and unwillingness to share data. Another common theme signified respondents' willingness to share their mental health data only if other conditions were met, such as the ability to opt out of data sharing and if data are used to understand more about mental illness. Respondents appreciated the importance of mental health research to better understand mental health and inform services, especially when given more control over their data.

Trust in Organizations

Most respondents strongly agreed that they should have the right to opt out of mental health data sharing and that it is important that mental health data are held by an organization they trust with charities, the NHS, and universities being the most trusted and private companies and industry the least. This aligns with views from the adult population showing strong support for the NHS and academic institutions for data sharing [16,48]. Only one-tenth strongly agreed with the statement that they would be less likely to access NHS mental health services if they knew that their data would be shared with researchers.

Strengths and Limitations

This is a large survey with >1700 respondents and represents the first of its kind with young people aged 16 to 24 years with a history of SH. It is also the first to compare the views of those

XSL•FO
RenderX

who have contacted health services for SH and those who have not. The combination of fixed- and open-response questions provides a richness of data and a wider scale of insights that can be used to guide future research. Using a convenience sample allowed a rapid low-cost engagement with young people. However, convenience samples are inherently biased and not representative, and results must be viewed with a level of caution [49]. The sample of respondents primarily consisted of younger women and girls, and the creative used to recruit respondents held a message of "mental health data and research," which is likely to be the reason for a large proportion of people with a history of SH. The small number of participants in the age group of 18 to 24 years as well as the small number of men and boys, meant that a meaningful breakdown by age and gender was not possible. Online survey respondents are often younger, well-educated, and have English as their first language [50,51].

Online surveys may be subject to fraudulent responses, a limited ability to target certain features in the sample needed, and may be limited by the absence of an interviewer to clarify questions [52]. Some of these limitations were mitigated by ensuring the visual material incorporated a clear message to target respondents and designing the survey questions to be simple and easy to comprehend. The use of social media to recruit respondents was highly effective in terms of recruitment, cost, and time when compared with traditional recruitment approaches. It also facilitated the participation of underserved groups, who may face stigma or other barriers to taking part in research [53,54]. People with mental health issues are more likely to fill out mental health–related questionnaires than the remainder of the population, with this difference amplified for online surveys. This does not present an issue for research looking to gather opinions of individuals with mental health issues but is problematic for prevalence research [50]. Individuals with a history of SH were purposefully sampled in this study, and, notably, there was high engagement from this group. This was likely related to the nature of the social media campaign, which used visual materials, such as videos and posters, and was conducted largely over Instagram.

Implications for Policy and Practice

Our findings, particularly patterns based on respondents' characteristics and experiences, highlight the importance of involving young people from diverse backgrounds at all stages of research development. Those with a history of SH valued participation of those with lived experience in mental health data research more highly than those without a history of SH. They also had reduced levels of trust in the use of their data for research across all organizations compared to those without. There is work to be done to increase confidence in individuals with a history of SH. We need to develop a shared understanding of consent, the "five safes framework" [55], anonymization processes, and the public benefits of mental health data science. This could be supported by coproduced resources and platforms for discussion, for example, online or in educational settings. Carter et al [56] stressed the importance of public engagement on a social level, rather than simply focusing on the requirements of formal regulations, in order to facilitate understanding and trust from the public on the topic of sharing their health data. Respondents repeatedly stated that they would like to know about the research being done. One of the key factors influencing positive opinions toward the use of data for research was the desire for it to be used to help others. Raising awareness of the ways in which research can be used to improve services and lives would likely have a positive impact on attitudes toward data sharing. Any campaigns to raise awareness should be widely accessible to young people with social media likely to be a useful way to reach them. Accessible case studies, demonstrating the impact of research on peoples' lives, lay research summaries, and real-world impacts on services should be widely disseminated beyond academic audiences. Research findings should be made accessible to individuals who have participated, in ways that are suitable for their age or background.

There appears to be a greater need to educate young people about how their social media data are used and their data availability for research on platforms as part of the terms of service. Standardized anonymization processes such as those suggested by the British Psychological Society [20] would represent a positive step toward clarifying how identities are protected when using these data for research. Procedures should include consideration of the republishing of photos and direct quotes in research outputs, as even with usernames or personal details removed, there is still the potential for these to be traced back to the individual [22,57]. Resources demonstrating how images can be labeled, processed, and analyzed without a researcher accessing them directly should be developed. Special consideration should be given to communicating with vulnerable groups including children and adolescents and people with mental health issues [22].

Future research could explore the acceptability of data use from a wider range of services such as schools, universities, or social care. In addition, recruitment to increase the number of boys or men and young adults would provide a more comprehensive overview of the opinions of this group.

Conclusions

This is the first survey to gather in-depth opinions on the use of big data for mental health research from young people, specifically including those with a history of SH. Young people are most definitely aware, and indeed they care about how their data are being used and for what purposes. They are largely positive about the use of health care data (mental or physical) for research and generally echo the opinions of older age groups raising issues around data security and the use of data for public interest. In addition, this study demonstrates that young people feel strongly about the use of their social media data for research, which was felt to be more personal. Those who had been in contact with health care services for SH were more positive about these data being used to improve services. There is a need for greater awareness of how different sources of data are used for research with a focus on anonymization, privacy, and the way in which data are used to help others.

Acknowledgments

This work was funded by MQ Mental Health Research (Adolescent Mental Health Data Platform; grant MQBF/3 ADP), Health and Social Care Research Wales (grant SCS-14-11), UK Research and Innovation—Medical Research Council (DATAMIND, grant MR/W014386/1), and Wolfson Foundation (grant 517483). Funders were not involved in the analysis and interpretation of findings.

Authors' Contributions

AJ and AM conceived the study and developed the questionnaire. AM and DD collected the data and analyzed the qualitative data. MM, AM, MDPB, and SCL analyzed the quantitative data. AJ supervised all analyses. All authors interpreted the data. DD, AM, and AJ produced the first draft of the manuscript, and all authors commented and edited the manuscript.
