We included 175 papers reporting 150 studies (11,446 participants). Tables S2-S5 in Multimedia Appendix 2 outline the study design, sample characteristics, and quality checks. Most DMHIs focused on general symptom management, relapse prevention, or similar. Some focused on a specific symptom (eg, cognitive difficulties and paranoia), and a minority on medication adherence, lifestyle, physical activity, or smoking cessation. Common technology types were mobile apps (77/150, 51.3% studies), websites (42/150, 28% studies), SMS text messaging (13/150, 8.7% studies), and wearables (15/150, 10% studies). Slightly more DMHIs were blended (ie, delivered with human support, 49/150, 32.7% studies) or stand-alone (24/150, 16% studies) than minimally blended (23/150, 15.3% studies) or included setup or technical input only (20/150, 13.3% studies). The median DMHI use was 8 (IQR 4-19) weeks. Study types included single-arm interventional studies (47/150, 31.3%), RCTs (25/150, 16.7%), qualitative studies (20/150, 13.3%), cross-sectional surveys (14/150, 9.3%), observational studies (7/150, 4.7%), intervention development studies (13/150, 8.7%), usability testing studies (11/150, 7.3%), and case studies (7/150, 4.7%). Most studies examined actual DMHI use (106/150, 70.7%), though some were hypothetical (ie, asking participants about potential DMHI use, 44/150, 29.3%), and some tested in-session usability rather than use in daily life (9/150, 6%). Samples included people with schizophrenia spectrum disorders (98/150, 65.3% studies), bipolar disorder (62/150, 41.3% studies), and clinicians (26/150, 17.3% studies). Participants were recruited from a range of settings, including inpatient services (21/150, 14% studies), community services (115/150, 76.7% studies), and online adverts (16/150, 10.7% studies). The Mixed Methods Appraisal Tool subsections (scored out of 5; Table S4 in Multimedia Appendix 2) indicated the moderate quality of qualitative (mean 4.1, SD 1.57) and quantitative (mean 4.0, SD 1.0) study elements, and lower mixed methods quality (mean 3.1, SD 1.9). The CONSORT harms checklist showed AE reporting to be mostly poor or missing (Table S5 in Multimedia Appendix 2); thus, it is difficult to draw informative conclusions regarding the harms of DMHIs.

Findings Not Fitting Within CFIR Framework

Although most relevant findings were coded into CFIR, a few could not be coded: patterns of DMHI use over time, associations between demographic variables and DMHI engagement, and safety reporting findings.

Patterns of Use

Sixteen studies reported reduced DMHI use over time in this study, 7 reported stable use and none reported an increase.

Demographics

Demographic findings are outlined in the Table S6 in Multimedia Appendix 2. Only 28% (11/39) studies examining age found significant effects: 6 found higher engagement in older people, 4 in younger people, and 1 found mixed effects. Conversely, all staff participants in qualitative studies hypothesized higher DMHI engagement among younger people [31-35]. Only 28% (7/25) studies examining gender or sex

XSL•FO
RenderX

reported significant effects; most (n=5) found higher DMHI engagement among women. Only 20% (4/20) studies examining education reported significant effects; all 4 found higher education associated with higher engagement. Only 20% (2/11) studies reported significant effects of race, ethnicity, or immigration: Ben-Zeev et al [36] reported significantly higher engagement among White participants than African American participants (and among White participants than Hispanic participants for some, but not all, engagement indices), while Bonet et al [37] reported significantly higher agreement to use a DMHI among non-native participants than native Spanish participants. Of studies examining the effects of IQ, 67% (2/3) showed significant effects, with higher IQ associated with higher DMHI engagement [38,39]. Reading level (0/1), employment (0/5), and marital status (0/2) showed no significant effects.

Safety Reporting

Multimedia Appendix 2 describes safety information extracted from 168 papers (139 studies) reporting actual DMHI use. Only 86 papers (76 studies) reported AE-related content; 23 reported AE frequency or percentage (median number of AEs reported per study 2, IQR 0.8-39.2). AEs included hospitalizations, psychological distress, suicidal ideation, physical health-related events, and death. Relatedness of AEs to the intervention was only reported in 11 papers, 8 of which deemed some events related.

CFIR Coding

Tables 1-5 provide detailed findings regarding the coding of reviewed studies into the 5 domains of the CFIR framework: *Innovation* (Table 1), *Outer setting* (Table 2), *Inner setting* (Table 3), *Individual characteristics* (Table 4), and *Implementation process* (Table 5). Findings were most frequently related to *Innovation* (Table 1; n=149 papers) and *Individual* (Table 4; n=137) domains of CFIR, with aspects of the *Outer setting* (Table 2; n=9), *Inner setting* (Table 3; n=20), and *Implementation process* (Table 5; n=5) domains rarely described. Figure 2 shows the number of papers coded into each CFIR domain per year of publication. Studies published between 2010 and 2015 were coded almost exclusively against the *Innovation* or *Individual* CFIR domains. Occasional studies were then coded against the *Inner setting* domain from 2016 onward, and against the *Inner setting*, *Outer setting*, and *Implementation process* domains from 2018 onward.

Prominent subcodes within the *Innovation* domain were *Relative advantage* (99/175, 56.6% papers), *Complexity* (56/175, 32% papers), and *Design* (128/175, 73.1% papers). As many papers commented on DMHI design, details of inductive subcodes are provided separately in Table 6. These included design features to increase DMHI engagement, customization, repetition vs variety, type of device used, user interface design, passive sensing, data security and privacy, and technical difficulties. *Need* (48/175, 27.4% papers), *Capability* (88/175, 50.3% papers), *Opportunity* (48/175, 27.4% papers), and *Motivation* (73/175, 41.7% papers) from the Individuals domain were all widely used, although almost exclusively in relation to innovation recipients rather than other roles. Details of how prominent findings from the CFIR-coded data related to the 5 crosscutting themes, are provided in the Crosscutting Themes section.

Table 1. Consolidated Framework for Implementation Research (CFIR) Innovation codes.

CFIR construct	Findings in relation to this construct	Papers, n (%)	Data type Qualitative; quantitative; mixed	Study type[a] Hypothetical; usability; actual	Sample Patient; staff; both
Source	Participants hypothesized that clear endorsement by a known institution (eg, health service or university) would increase engagement. One study [40] noted that online information from pharmaceutical companies was less trusted than other sources. Some preferred endorsement by individual staff because "organizations have hidden agendas" [41]. Perceived credibility of teams developing or testing the DMHI[b] impacted engagement [42-44]. Teams that included people with lived experience of psychosis or bipolar disorder were especially credible. However, one study [45] highlighted that co-design is not a panacea; despite being co-designed, the study innovation (MindFrame) "was neither applicable nor appealing to all."	14 (8)	11; 0; 3	7; 1; 8	10; 0; 4
Evidence base	A patient perspective piece [46] suggested that health care professionals discussing the evidence base for specific DMHIs with patients would likely increase engagement. Two surveys [47,48] collected mixed methods data on whether information on the evidence base of bipolar apps influenced users' app choice. Qualitatively, "participants seldom reported evidence of efficacy or scientific quality to justify app choice," but in quantitative responses, 93% [48] and 90% of participants [47] rated scientific quality as important. Health care professionals [49] cite a lack of knowledge regarding which apps were evidence based as the foremost barrier to discussing apps with patients with bipolar disorder.	4 (2)	1; 1; 2	4; 0; 0	3; 1; 0
Relative advantage	Connection with peers and normalization: qualitative data highlighted that DMHIs can facilitate peer connection and normalize psychosis or bipolar disorder experiences. Peer contact, both as a formal part of the intervention (peer facilitators or video resources) or via a bespoke or mainstream social media platform, provided "the opportunity to learn from others managing the same condition, reducing self-stigma through normalization of shared experiences" [50]. Peer support appeared to influence participants' actual level of engagement with DMHIs [51], or participants hypothesized that it would [33,52,53]. Participants valued encouragement and accountability from others on the platform [54-57] and the opportunity to socialize with peers [58-62]. Even DMHIs without specific peer content were normalizing as their presence implied others with similar needs [63-65], and they used a similar format to everyday things ("...everyone uses an app these days... It's normal now," [41,64]). However, some were anxious that others would ask what the device or app was for [41,58,66,67], or preferred apps for "the general consumer, so I do not feel stigmatized as a patient for using it" [46].	43 (25)	31; 2; 10	18; 0; 29	31; 3; 9

XSL•FO
RenderX

CFIR construct	Findings in relation to this construct	Papers, n (%)	Data type Qualitative; quantitative; mixed	Study type[a] Hypothetical; usability; actual	Sample Patient; staff; both
Relative advantage	Availability and autonomy: reviewed studies highlighted DMHIs' availability (anytime, anywhere) as a key advantage and reported that DMHIs increased participants' autonomy. Availability was particularly beneficial for people constrained by working hours [52], childcare [52], geography [62,68,69], reversed sleep cycles [41], or during recovery from psychosis [41,52,70]. Patients contrasted DMHI availability with that of their care team [64] and valued DMHIs' ecologic validity [71] and being able to visit, or revisit, content at their own pace [72-74]. Quantitative data [75] indicated similar app engagement off- and on-hours; ie, DMHIs are used outside clinic hours when available. Choosing when and where to use DMHIs enhanced feelings of autonomy, control, or empowerment [33,63], encouraging individuals to play an active role in managing their mental health ("They actually feel like they have part ownership in the process," [76]) and decreasing reliance on health professionals ("it gives you a bit of freedom to say 'hold on a second, I don't have to wait for my CPN[c]'" [71]). Accessing information without a clinician's direct involvement was particularly empowering, with patients frequently describing DMHIs as a friend or therapist. Patients and staff noted that internet-based mental health information ranges in accuracy, so providing "curated knowledge from a bunch of professionals rather than just what Google tells you" [68] was a significant advantage. Participants from 10 studies described a DMHI in human terms, including as a "CPN in your pocket" [71], "therapist in your phone," "personal smoking trainer" [77], "life-coach" [78], "friend" [43,52,64,79,80], "buddy" [71], "close companion" [81] or "constant companion" [82]. Staff [33,83,84] and patients [34,41,52,55,63,64,68,71,85] across 12 studies highlighted a DMHI's anonymity can be a substantial advantage. For example, some DMHIs provided an opportunity to vent without fears of a subsequent medication increase [63], to "scream on the keyboard" at any time [68], or to disclose sensitive or potentially disturbing information in a nonjudgmental, anonymous place instead of directly to a person [33,41,52,71,83,84]. A minority of participants viewed some automated DMHI functions as potentially detracting from autonomy; for example, automatic transfer of data from the app to services [31,66,78], and medication reminders [59]. Availability and autonomy contributed to perceptions of DMHIs as widening the reach of services. Symptom-monitoring or cognitive behavior therapy apps helped users feel safe with a more hands-off clinical approach ("it did... make me feel safe... I knew he was keeping an eye on those graphs," [86]) while allowing prompt intervention if needed. More trivially, technology provided a convenient way to keep in touch with clinicians (eg, SMS text messaging, email, and instant messaging).	65 (37)	42; 8; 15	29; 2; 38	43; 7 15
Relative advantage	Self-awareness and memory: DMHIs' availability helped patients notice patterns in their experiences ("to see what's making me happy, what's doing my head in" [31]), remember those experiences, and talk to others about them. Participants said DMHIs gave a useful structure for therapeutic conversations [66,86-91], promoting shared understanding, strengthening therapeutic relationships, helping patients feel "heard" [92] or "connected" [80,93,94], and facilitating help-seeking. One study highlighted a self-monitoring app's value in translating individuals' subjective experiences into an objective form, enabling others to access their inner experiences and take them more seriously ("If you were to answer the questions and go to the doctor and say, 'look... you can see clearly there's a change, and these are my experiences,' that would be substantial evidence for the doctor to then sit up and take note" [64]). In some cases, this process was formalized as part of an Ecological Momentary Intervention [95,96]. One study drew a specific link between self-awareness and user engagement ("EMA[d] self-monitoring and EMA-derived feedback were seen as helpful for improving awareness, highlighting a willingness to engage with more intense monitoring for clinical purposes" [95]. As well as sharing symptom data with clinicians, patients often shared it with family, facilitating communication, understanding, and support. However, 2 surveys reported that only a minority of patients [47,88] and staff [88] thought symptom information should be shared with family, and a qualitative study cautioned that users should always retain control over who had data access [78].	61 (35)	34; 9; 18	17; 0; 45	45; 1; 15

XSL•FO
RenderX

CFIR construct	Findings in relation to this construct	Papers, n (%)	Data type Qualitative; quantitative; mixed	Study type[a] Hypothetical; usability; actual	Sample Patient; staff; both
Relative advantage	Should enhance but not replace human care: qualitative studies outlined ways that DMHIs did not present a relative advantage over human care. Neither staff [84] nor patients [41] liked "fake empathy" offered by a machine, considering it degrading. Many saw DMHIs as a cost-cutting exercise [31,33,41,42,52], which might feel "dismissive" to patients, "as though they are not worthy of a clinician or therapist" [41], leading them to feel "fobbed-off" [33]. Some worried that using DMHIs blended within face-to-face sessions might render clinicians less "present" in the interaction [34,35,46] because they are "increasingly focused on a computer or on data rather than on the suffering human seated in front of them" [46]. Patients considered DMHIs a "poor substitute for seeing a person that knows you" [31], lacking personal contact [85,97], opportunities for "being listened to" [85], tone of voice, body language [68] and emotional reassurance [41], and unable to address everyday practical problems (eg, housing difficulties; [85]. Staff worried that DMHIs lacked nonverbal communication [33], context [31,33] and personalization [33,84], left patients "alone to deal with any issues that surface" [84], removed a key source of socialization and warmth, potentially reinforcing social avoidance [33], and that DMHI-generated data would be difficult to interpret without staff members' clinical experience [31].	16 (9)	13; 0; 3	11; 0; 7	9; 4; 3
Adaptability	No studies provided information on whether the ability to adapt a DMHI to a specific service affected engagement. Personalization of DMHIs for individual users is coded under *Innovation design*.	0	—[e]	—	—
Trialability	An expert consensus study [83] and a patient perspective piece [46] highlighted that the availability of a free trial version of a DMHI would increase the likelihood that staff and patients would use it.	2 (1)	1; 1; 0	2; 0; 0	1; 1; 0
Complexity	Technology-related complexity, stemming from poor user experience design, increased user burden, and "mental fatigue" [98], prompting disengagement [69,96,98,99]. Lengthy login processes reduced engagement [69,88,89,100,101], as did difficult-to-navigate websites or apps ("I wanted to go and do it, but then I just couldn't navigate it. And I was just like, 'Oh, I can't be bothered'," [31]. Qualitative and quantitative data found shallow website and app structures, and pages with <200 words, most usable by patients. Unwieldy, multistep systems (eg, SMS text messaging–based symptom monitoring) were perceived as "awkward, laborious, and burdensome" [85] and associated with significantly lower engagement than a more streamlined native smartphone app [102]. One study noted that tailoring DMHI content increased complexity [86]. Patients suggested that training and support may mitigate the effects of technology-related complexity [34]. Individual capability (eg, cognitive ability, digital literacy; [34,86] also moderated the extent to which complexity hindered engagement and the amount of training that was needed to mitigate this effect [34,100]. Some studies noted that practical complexity, such as remembering to carry, charge, or use an additional device [66,103-105], hindered engagement. Although most issues of complexity were related to the technology, rather than the intervention more broadly, staff in several studies [31,33,69,92,106] found the information they received from symptom-monitoring apps complex to interpret, making it difficult to know how to respond clinically. Patients expressed concerns that some apps and websites had overwhelming amounts of information or features [55,107,108]. A patient perspective piece highlighting the fallacy of the "killer app," preferring apps with a clear aim that do not try to do too much at once [46].	55 (31)	31; 10; 14	16; 7; 37	41; 2; 12
Design	As most reviewed studies commented on aspects of DMHI design, details are provided separately in Table 6.	128 (73)	56; 43; 29	38; 5; 93	101; 7; 20

CFIR construct	Findings in relation to this construct	Papers, n (%)	Data type Qualitative; quantitative; mixed	Study type[a] Hypothetical; usability; actual	Sample Patient; staff; both
Cost	Most participants (85%) in a large international survey of people with bipolar disorder (n=919) preferred free or low-cost apps [47] and qualitative survey data suggested DMHIs for bipolar should be “free or inexpensive so accessible to all or many” [73]. Five studies [109-113] listed financial costs associated with delivering a particular DMHI (eg, web hosting, licensing fees, texting fees, technical support, and staff time to deliver) but did not examine the effect on engagement.	9 (5)	1; 6; 2	4; 0; 6	7; 0; 2

Table 2. The Consolidated Framework for Implementation Research (CFIR) Outer setting codes.

CFIR construct	Findings in relation to this construct	Papers, n (%)	Data type Qualitative; quantitative; mixed	Study type[a] Hypothetical; usability; actual	Sample Patient; staff; both
Critical incidents	Patients and clinicians noted their use of technology had increased since the COVID-19 pandemic [106].	1 (1)	1; 0; 0	1; 0; 0	0; 0; 1
Local attitudes	—[b]	0	—	—	—
Local conditions	US clinicians [76] said local technological conditions were a major barrier to DMHI[c] implementation. A lack of regional infrastructure (mobile phone signal) prevented app use by clinicians and patients. Many participants had government-sponsored smartphones, incapable of running the study app. Technological infrastructure is not a universal barrier though a survey with EIS[d] clinicians across 30 US states indicated that 93% had high-speed internet available [114] and a study testing an app in a Canadian city indicated 100% mobile phone coverage [109].	3 (2)	1; 1 1	2; 0; 3	1; 2; 0
Partnerships	—	0	—	—	—
Policies and laws	Clinicians from Indian health services highlighted the need to understand regulations and abilities governing app-generated data before using apps with clients [106]; US clinicians in the same study did not raise such concerns. Study authors attributed the difference to recently introduced telehealth policies in India. Clinicians from Australia [35] and the United Kingdom [115] mental health services noted the lack of guidelines and policies as a barrier to DMHI engagement.	3 (2)	3; 0; 0	3; 0; 0	0; 1; 2
Financing	Empirical results did not directly report on financing in relation to DMHI engagement or implementation, but study authors noted that a sustainable business model for maintaining evidence-based DMHIs is often absent. One study noted that costs were offset by the billable nature of the service [110].	3 (2)	1; 0; 2	2; 0; 2	2; 0; 1

Table 3. The Consolidated Framework for Implementation Research (CFIR) Inner setting codes.

CFIR construct	Findings in relation to this construct	Papers, n (%)	Data type Qualitative; quantitative; mixed	Study type[a] Hypothetical; usability; actual	Sample Patient; staff; both
Structural characteristics	IT: poor IT infrastructure, including aging computers [62], poor bandwidth [35,62], and no wireless connection in hospitals [116] hindered engagement. Staff in one study expressed low confidence that their organization could implement DMHIs[b] due to its historical failures to successfully deliver past IT projects [33].	4 (2)	3; 0; 1	2; 0; 2	1; 2; 1
Structural Characteristics	Physical infrastructure: a lack of quiet space in the clinic hindered implementation [62].	1 (1)	0; 0; 1	0; 0; 1	0; 0; 1
Structural characteristics	Work infrastructure: work infrastructure impacted staff DMHI engagement in one study [79]. Local mental health teams had been relocated and merged shortly before the DMHI was introduced. Study authors hypothesized that staff hesitated to fully engage with the DMHI for fear that it would increase their workload further.	1 (1)	1; 0; 0	0; 0; 1	0; 0; 1
Relational connections	—[c]	0	—	—	—
Communications	—	0	—	—	—
Culture	Human equality-centeredness: none	0	—	—	—
Culture	Recipient-centeredness: staff felt was it important to offer patients a choice to use a DMHI: “It’s also nice to think, to be able to give someone an option that you’re not forcing down their throat” [117]. Patients in this study appreciated this attitude, although the impact on DMHI engagement was not directly investigated.	1 (1)	1; 0; 0	0; 0; 1	0; 0; 1
Culture	Deliverer-centeredness: none	0	—	—	—
Culture	Learning-centeredness: none	0	—	—	—
Tension for change	—	0	—	—	—
Compatibility	The lack of compatibility between DMHIs and existing workflows was a key barrier to engagement and implementation. Clinicians believed DMHIs would create extra work, a major barrier in overstretched services [31,35,76,79,83]. Some DMHIs duplicated existing work [34,76]: “reporting symptoms via the app system, instead of saving time, added another workflow to manage.” Participants often questioned who should be responsible for managing and responding to real-time symptom data [33,69,84,92,106], particularly out-of-hours [33,80,84,85,92], as doing so did not fit well with their current ways of working. Several studies emphasized that compatibility with existing electronic medical record systems would be important [88,118,119]. Clinicians in one study [84] strongly suggested patients should bring symptom-monitoring data to appointments, rather than uploading data in real-time. Although arguably undermining a key advantage of DMHIs (real-time data), this suggestion highlights how challenging the staff find the idea of being presented with a “constant stream of information” [33], and the perceived additional responsibility that comes with that information.	17 (10)	11; 3; 3	9; 0; 9	2; 5; 10
Relative priority	—	0	—	—	—
Incentive systems	“Reimbursement by payers for time spent training patients and family members about DMHI and for time spent using or reviewing data from the DMHI” was a strong potential facilitator of HCP[d] engagement with DMHIs [83]. Similarly, the “difficulty having the DMHI approved by insurance” was considered a substantial barrier to implementation [83].	1 (1)	0; 1; 0	1; 0; 0	0; 1; 0

XSL•FO
RenderX

CFIR construct	Findings in relation to this construct	Papers, n (%)	Data type Qualitative; quantitative; mixed	Study type[a] Hypothetical; usability; actual	Sample Patient; staff; both
Mission alignment	Although staff appeared to consider some aspects of DMHIs aligned with their mission (see *Relative advantage* in Table 1), 5 studies highlighted ways that implementing DMHIs was not aligned with the inner setting's central mission. Staff felt funding was "channeled into technological advancement when perhaps it would be better channeled into staffing and training" [33]. Given limited time, clinicians considered other on-mission tasks more important than using DMHIs; eg, emergent crises [119], the client's own priorities [34,35], and simply having "more pressing things to deal with" [34]. Staff in one study felt "a huge burden of responsibility toward protecting their clients from harm and take this responsibility incredibly seriously" [33]; they perceived some aspects of DMHIs to present additional risks, directly conflicting with this perceived mission. Other staff were cautious of DMHIs disrupting the trust they had built with clients ("I'm not prepared to do anything that could damage that relationship... you work so hard to get that trust," [35]); hence, they would always prescreen DMHI content before showing it to a client.	5 (3)	4; 0; 1	3; 0; 2	0; 3; 2
Available resources	Materials and equipment: in response to digital exclusion challenges, it has been suggested that health services could provide devices to facilitate DMHI access. None of the reviewed studies directly investigated the impact of this, but staff in one study "felt the NHS should not provide the required technology because of concerns that tablets and mobile phones may get lost, sold, or damaged" [84]. However, across 15 reviewed studies that reported device loss rates, only 112 (11.1%) of 1011 provided devices were lost, broken, stolen, or damaged. Staff [80] and patients [70] also mentioned the need for devices for staff themselves, to facilitate blended DMHIs; eg, for SMS text messaging–based DMHIs [80], or as a backup if the data connection is lost during video-based aspects part of a blended DMHI [70].	20 (11)	7; 6; 7	5; 0; 15	14; 2; 4
Available resources	Funding: none	0	—	—	—
Available resources	Space: none	0	—	—	—
Access to knowledge and information	Providing staff with training in basic digital skills [33,114], how to evaluate DMHI credibility and quality [49,114], and how to use specific DMHIs [34,49,83] was hypothesized to facilitate engagement. One participant said, "There's no point in [a patient] being a whizz on that computer and smartphone and me not having a clue cos I wouldn't be able to support adequately, there would be... ongoing training needs," [33]. Even staff who were digitally confident felt they would need more training to assist others [114] and lacked knowledge about which DMHIs are credible [49,114]. As well as clear training or instructions on how to support patients with specific DMHIs [49,83], staff also valued the opportunity to try the DMHI themselves as part of this training [34].	5 (3)	2; 3; 0	4; 0; 2	0; 4; 1

Table 4. The Consolidated Framework for Implementation Research (CFIR) Individual codes.

CFIR construct	Findings in relation to this construct	Papers, n (%)	Data type Qualitative; quantitative; mixed	Study type[a] Hypothetical; usability; actual	Sample Patient; staff; both
Need	Perceived benefit: users need to perceive a DMHI's[b] benefit to try it ("People do not do things just because their doctors tell them to. They need to see the benefit of what they do," [46] and continue using it ("If people think an app is helping them, they will continue using it," [48]). Clinicians noted that *quickly* finding benefits helped sustain use: "People tend to download the app and then it decreases in use if people don't see a quick benefit" [49].	34 (19)	16; 10; 8	10; 0; 25	24; 4; 6
Need	Stage of illness: qualitative data highlighted that needs may differ depending on patients' stage of illness or recovery and that DMHI content (eg, psychoeducation) and functions (eg, symptom tracking) are often best suited to the needs of people with recent onset illness or ongoing symptoms. Quantitative data implied effects on engagement: people with recent onset psychosis were more likely to use an app than those with established psychosis (037); those with longer psychosis duration rated digital monitoring as less important to managing their illness than more recently diagnosed people. Several studies reported DMHI discontinuations due to improved mental health [54,120,121]. Some adapted their DMHI use to meet their own needs [122].	27 (15)	14; 8; 5	7; 0; 21	21; 1; 5
Capability	Physical capability: 4 studies mentioned that medication side effects (eg, fine motor tremors and blurry vision), interfered with participants' ability to use a DMHI [80,93,123,124].	4 (2)	2; 0; 2	1; 0; 3	3; 0; 1
Capability	Psychological capability: Table S7 in Multimedia Appendix 2 outlines data from studies quantitatively examining the effects of specific symptoms, functioning, and diagnosis on DMHI engagement. Around a third of quantitative analyses found a significant effect of symptoms on engagement, with higher baseline positive, negative, or cognitive symptoms associated with lower DMHI engagement. Results for functioning and depression were more mixed. Quantitative studies did not examine the impact of relapse on DMHI engagement, but 11 qualitative studies noted decreased DMHI use during relapse due to thought disorder ("I wouldn't have been able to make sense of the topics," [51]), using a DMHI feeling "too confrontational" [92], avoiding certain symptom-related questions [64], difficulty staying awake during app training [93], or lack of energy or motivation to engage [121] when unwell. Nevertheless, relapsing participants were typically able to continue using a DMHI once symptom exacerbation had resolved [51,64], and one study noted that, for some, stopping the app might be a sign of imminent relapse [64]. A few participants avoided DMHIs due to interactions between their symptoms and technology, such as delusions or paranoia about technology [37,64,86,104], adverse effects of technology in mania [46,82], or social anxiety during DMHI social media use [54]. Some variables relating to psychological capability were examined in very few studies. Neither baseline biological rhythm disturbance [125] nor baseline medication adherence predicted DMHI engagement [94,126,127], although those who chose to use a DMHI were less likely to be using injectable medication [37]. Better premorbid adjustment was associated with higher DMHI engagement [128]. Cannabis use predicted lower DMHI engagement [99].	76 (43)	26; 33; 17	16; 0; 61	64; 4; 8
Capability	Digital literacy: lack of digital literacy was a barrier for some, and expert consensus participants considered self-efficacy beliefs about using devices as highly likely to promote DMHI engagement [83]. Some clinicians reported lacking the technological capability to deliver a DMHI [33,34,114]. Three studies quantitatively examined the effects of patients' digital literacy on DMHI engagement. Two reported no significant effect [96,109]; in one study participants with prior smartphone experience engaged significantly more in a digital than a nondigital intervention, whereas no such difference was observed for people without previous smartphone experience.	33 (19)	14; 10; 9	9; 3; 22	24; 6; 3

CFIR construct	Findings in relation to this construct	Papers, n (%)	Data type Qualitative; quantitative; mixed	Study type[a] Hypothetical; usability; actual	Sample Patient; staff; both
Opportunity	Space: participants reported a lack of a suitable environment as a barrier. Busy homes, hospitals, public libraries, or homelessness presented challenges of noise, repeated interruptions, and lack of privacy. For blended DMHIs, the in-person location was sometimes a barrier [89,110,129].	12 (7)	7; 2; 3	1; 0; 11	9; 1; 2
Opportunity	Time: lack of time due to work [98,130], physical illness [131], preoccupation with delusions [43], or other commitments was a barrier to engagement for some patient participants. Conversely, being able to fit the DMHI within their daily or weekly routine was a facilitator, and inpatient participants enjoyed using a DMHI as "something to do" [116].	22 (13)	7; 10; 5	1; 0; 21	20; 0; 2
Opportunity	Technology: lack of access to technology was a barrier. This included not owning a phone, tablet, or computer [34,62,113,128], or having a device with limited functionality [76], insufficient storage [52], insufficient data allowance [41,132], poor internet connection [132], or frequently changed phone numbers [80,84]. Staff highlighted a key difficulty with using technology for health care: "phones are... a luxury item... if people aren't working because of health needs... they are being denied healthcare because they can't afford a phone" [33].	30 (17)	15; 12; 3	16; 0; 15	19; 6; 5
Motivation	General: some were motivated by financial or material factors (eg, vouchers or free study devices). Others described intrinsic motivations: commitment to participating [44], wanting to provide accurate data [31], agreement with DMHI tasks or goals [83], less "controlled motivations for treatment" [133], and interest in technology [83]. One study noted that people who tended to be more engaged with services were also more engaged with the DMHI [76].	12 (7)	7; 3; 2	4; 1; 9	9; 2; 1
Motivation	Support: across 45 qualitative studies, the following types of human support were mentioned: training in basic digital skills, managing technical difficulties, support navigating the DMHI, ongoing coaching to sustain use, discussion of psychoeducational materials, and interpreting or responding to changes in real-time symptoms data. Four randomized controlled trials quantitatively compared unsupported vs supported DMHI engagement. Two reported significantly higher engagement in a peer-supported group than in an unsupported group (P<.05 [121,134]; P=.005 [135]). One reported a significant interaction effect such that reviewing symptoms had a significant positive effect on app adherence only for younger women (P=.001), with no significant overall effect [136]. Finally, a pilot randomized controlled trial found moderate effect sizes in favor of the group allocated to support from a clinical helper (not powered to detect significant differences [137]). Regarding social support more generally, there were mixed quantitative results. One study reported lower social support among more actively engaged participants [61], with a second reporting the opposite pattern [138].	48 (27)	24; 13; 11	13; 1; 39	36; 4; 8
Motivation	Fear of relapse (barrier): anticipated or actual anxiety about DMHI use was sometimes a barrier. Staff [52] and patients [44,132] hypothesized that using a DMHI may increase awareness of symptoms, heightening users' anxiety about deterioration, and potentially making symptoms worse. There was some evidence to indicate that this belief may hinder engagement. Quantitatively, users reporting higher fear of relapse at baseline showed lower engagement with a symptom-monitoring app over the following 6 months [126]. Elsewhere, one participant reported: "Being notified of all the changes sometimes made me anxious. It made me wonder if the illness was maybe about to get out of control" [45] and a minority of participants in other studies reported increased rumination [66,86,102]. This could be mitigated to some extent by support: "It really helped to have her sit there and talk things through with me... and just to have her to bring me back down, or bring me back into reality" [117]. Others were hesitant to (accurately) report symptoms via a DMHI for fear that it may lead to more restrictive treatment, such as hospital admission or increased medication [52,64,68,84].	26 (15)	11; 5; 10	8; 0; 19	20; 3; 3

XSL•FO
RenderX

CFIR construct	Findings in relation to this construct	Papers, n (%)	Data type Qualitative; quantitative; mixed	Study type[a] Hypothetical; usability; actual	Sample Patient; staff; both
Motivation	DMHI too confronting (barrier): some participants found DMHIs to be confronting: being reminded about their diagnosis or noticing how unwell they were, was disheartening and often prompted disengagement. A striking number of quotations related to this, for example, “My best days are when I typically forget that I have any kind of illness... to be very heavily reminded about the gravity of it all can be a bit unpleasant [51];” “It started me comparing how I am now to how I used to be... and its not good. That’s why I canceled it. I found it too personal in the end [85];” “I wasn’t ready to accept the illness... I wasn’t willing to change my life according to the program [121].” In one study [92], half the patients felt negatively influenced by frequent confrontations with their symptoms. In another study [88] only a minority (4%) found the DMHI confronting and others reported that it helped them recognize their progress. One study quantitatively examined if recovery style predicted DMHI engagement, finding no significant effect [133].	11 (6)	7; 3; 1	2; 0; 9	8; 0; 3

Engaging	Innovation recipients: there were mixed findings regarding whether a recommendation from a health professional increased DMHI engagement. Three out of 4 studies reported that such a recommendation would usually prompt engagement [41,106,119], particularly in the context of a strong relationship between a patient and staff member: "I trust the early intervention team... so I would be fairly confident that it would be secure if they said so" [41]. Patients in another study were asked whether they would use an app recommended by a clinician and all said "no" [115], though reasons for this were not outlined.	4 (2)	3; 0; 1	3; 0; 1	1; 0; 3

CFIR construct	Findings in relation to this construct	Papers, n (%)	Data type Qualitative; quantitative; mixed	Study type[a] Hypothetical; usability; actual	Sample Patient; staff; both
Digital reminder	Most participants found digital reminders (eg, push notifications or email) to engage with the DMHI[b], or remember medication or appointments, helpful; some found them nagging [123], irritating [86], "pushy" [47], or repetitive [96]. Ideal timing and frequency of alerts were often discussed, eg, personalizing alert timing and frequency [47,99,139], allowing users to "snooze" alerts to receive a later reminder [64], considering users' specific needs and schedules (eg, afternoon alerts for those sleeping late due to medication; [64,79], and allowing self-initiated use [64,107]. Studies testing self-initiated use report 47% [75], 52% [43], 63% [140], and 97% [141] of app engagements were self-initiated rather than in response to app alerts. Two quantitative studies examined the impact of alerts on engagement: individuals randomized to receive weekly emails had significantly higher DMHI engagement than a comparison group [133]; 10-times daily reminders were significantly more inconvenient than daily monitoring [66].	57 (33)	26; 14; 17	16; 0; 43	45; 2; 10
Gamification	Most participants across 12 studies thought gamification would increase engagement though one reported mismatching qualitative (positive) and quantitative (neutral or negative) survey data on this, and another that focus groups barely mentioned it [78]. Three studies testing DMHIs with gamification elements [77,89,142] reported impacts on enjoyment and engagement (eg, "I really like the badges idea... that really helped me to keep going," [142]).	13 (7)	9; 1; 3	8; 0; 6	11; 1; 1
Feedback from the DMHI	Qualitative data suggested DMHI feedback would increase engagement; eg, a symptom data summary, symptom graph, summary of passive data (eg, step count), a summary of DMHI engagement (eg, minutes used) or encouraging messages. Two studies quantitatively investigated the effects of feedback on engagement; one reported significantly higher Fitbit wear rates in those receiving feedback than a nonrandomized comparison group [143]; another found no significant between-group difference in symptom-monitoring app use [144].	29 (17)	13; 7; 9	8; 0; 22	23; 0; 6
Tailoring, customization, personalization	"Tailoring," "customization," or "personalization" of DMHIs was a facilitator, as mental health experiences vary hugely ("10 people with the same diagnosis as me will have 10 different ways of experiencing the illness," [79], and DMHI users have different symptoms, treatment goals, schedules, illness durations, and learning styles. Customizing aspects of a DMHI is advantageous, eg, alert schedules [47,71,145], symptom questions [39,64,146], self-management strategies [46,50], psychoeducation content [63,73,97,107,109] and delivery method [147]. Personalizing more superficial elements (eg, colors, [64]), was occasionally mentioned but much less prominent. Indeed, a survey of people with bipolar disorder [48] found 92% of participants rated "flexibility/customization" (DMHI frequency or what things are tracked) as important, 84% rated "tailored content" as important but only 33% rated "personalization" (changing interface or colors) as important.	34 (19)	19; 4; 11	12; 0; 23	26; 2; 6
Repetitiveness and variety	DMHI repetitiveness was a barrier (18 studies) and greater variety in DMHI content was a potential facilitator (12 studies). Participants "wanted more tips and strategies... to minimize repetition and boredom, particularly toward the end of the intervention period when users had selected the same domain repeatedly and started receiving the same tips and strategies" [139]. "Periodic content updates or staggered unlocking of content based on the user's evolving needs" would encourage repeated use [48,97]. A patient testing a cognitive behavior therapy–based app suggested adding different "levels" for different needs: "Level one... at the beginning of their recovery... starting to learn about the illness. Level 2 is in the middle... they're getting more self-awareness or understanding of the illness and how to cope with certain symptomatic episodes. And then you have the advanced level" [97]. There was some coding overlap with personalization [44,65,97], as a wider variety of content would allow people to select content that is more relevant to their needs.	27 (15)	13; 5; 9	7; 0; 21	22; 0; 5

XSL•FO
RenderX

CFIR construct	Findings in relation to this construct	Papers, n (%)	Data type Qualitative; quantitative; mixed	Study type[a] Hypothetical; usability; actual	Sample Patient; staff; both
Type of device used	Participants preferred smartphone apps more than computer-based [35,61,88,101,132] or SMS text messaging–based systems [85,102], reporting that smartphone apps were more convenient and easier to integrate into daily life. SMS text messaging contact was preferred to emails by most (87%, 74%, and 82%, respectively [148-150]). A comparison of smartphone app and wearable use for >6 weeks in people with bipolar disorder [136] reported a significant time-by-device interaction: participants used the wearable more at study start and the app more at the study end. Subjective reports indicated more (72%) participants would use a wearable for a year than the app (47%) and that the wearable required less effort and was slightly easier to use. Most participants (80%) in a small survey of people with bipolar disorder said they would use a wearable device but would not want stationary installations of sensors in their homes [81]. Five studies mentioned the importance of DMHIs being compatible across Android and iOS devices [76,99,107,109,141].	28 (16)	13; 9; 6	7; 1; 23	22; 2; 4
User interface design	Clear language was a facilitator of patient engagement and complex language was a barrier. Clinicians recommended that DMHIs should be usable by people with low literacy [151] and in languages other than English [49]. The “tone” of messages or information presented in DMHIs was important to users. The ideal tone was positive, relevant, validating, motivating, and encouraging without being patronizing, glib, or “mind-numbingly positive.” Given that users were people with experiences of mental health problems, some felt that an overly positive tone hindered discussion of difficult topics [54]. Users preferred visually appealing DMHIs (eg, attractive colors, modern-looking interface, and suitably sized fonts), which presented information in a variety of formats (video, text, audio, graphics) and were engaging and interactive. If DMHIs include personas or characters, these should be diverse in ethnicity and gender [107,152]. Graphs, while popular, were not always easy for patients to understand [153]. Connectivity with other apps was not generally important to users [47].	46 (26)	28; 5; 15	19; 5; 27	35; 2; 9
Passive sensing	Patients often considered passively gathered data to be more objective and accurate than self-reported data [82,105,106] though some highlighted the possibility of false positives and inaccuracies and suggested that DMHIs include disclaimers acknowledging this [66,82,145]. Two studies highlighted a tradeoff between increased data accuracy provided by passive sensing and increased agency and self-efficacy provided by active symptom monitoring [69,82]. Some participants found the idea of passive sensing invasive [106,154,155], whereas others were unconcerned [59], or embraced the idea: “I know that my phone knows everything about me. Why not get it to help me?” [106]. Data indicated that participants were most enthusiastic about passive sensing being used to track sleep [58,59,81,82,145] and activity patterns [58,59,81,82]. There was some evidence patients were willing for data to be passively gathered about neurocognition [81], psychophysiology [81], medication adherence [59], and heart rate [82]. Audio and video data collection was less popular [81]; GPS and social media usage data collection was less popular still [81]. Participants with bipolar were positive about an “intelligent” system that “learns” their routines and automatically detects changes [69,82], and staff said that passively collecting data provided an overwhelming amount of information [106].	11 (6)	5; 2; 4	7; 0; 4	8; 0; 3
Data security and privacy	Data security and privacy concerns were frequently mentioned barriers, including general concerns about security breaches and mental health-specific concerns. Some associated DMHIs with surveillance [45,89] or emphasized that mental health stigma made them worried about sensitive symptom data being disclosed [33,47,80,82]. Measures to protect data or mitigate the effects of data loss included the use of pseudonyms, password protection, and the use of general terms (eg, “illness”) rather than specific diagnoses. Five studies suggested, including a clear statement about what would happen to data, though, staff and patients in a study that included such a statement admitted they did not read it [106].	36 (21)	23; 5; 8	20; 0; 18	25; 2; 9

CFIR construct	Findings in relation to this construct	Papers, n (%)	Data type Qualitative; quantitative; mixed	Study type[a] Hypothetical; usability; actual	Sample Patient; staff; both
Technical difficulties	Twenty-five studies reported that participants experienced technical difficulties with the software (eg, notifications firing multiple times in error) or hardware (eg, poor battery life). These usually affected a minority; responses varied from mild irritation to total DMHI disengagement.	25 (14)	5; 13; 7	1; 0; 24	23; 0; 2

[a]Some papers fall into more than one category; therefore, categories may add to more than the overall total N.

[b]DMHI: digital mental health intervention.

Crosscutting Themes

Crosscutting Theme 1: DMHIs to Meet Specific Needs, Not Replace Human Care

Findings emphasized that DMHI functions and content should align with specific patient needs and that patients and staff must perceive a benefit if they are to engage with a DMHI (n=34 studies; *Individuals*, *Need*; Table 4). Patients preferred DMHIs with a clear aim, which did not try to do too many things (*Innovation: Complexity*; Table 1). Several DMHI benefits came through clearly in reviewed studies (*Innovation: Relative advantage*), including their value in being available anywhere and anytime (n=37 studies), promoting autonomy (n=26), facilitating self-awareness and memory (n=61), connecting people with peers (n=29), and normalizing mental health experiences (n=26; *Innovation: Relative advantage*). These advantages contributed to perceptions that, if successfully implemented, DMHIs could widen the reach of services. Nevertheless, while patients and staff acknowledged that DMHIs might enhance care in specific ways, they emphasized that they should not replace human care (n=16; *Innovation: Relative advantage*) and staff worried that the increasing emphasis on DMHIs might detract from health services' ability to deliver care (*Inner setting: Mission alignment*; Table 3).

Seeing the benefit of a DMHI in meeting their needs prompted patients' initial use and helped sustain use (*Individuals: Need*). Studies (n=27) highlighted that patient needs may change over time, depending on illness stage and symptom levels. Certain DMHI content (eg, psychoeducation) and functions (eg, symptom tracking) may be best suited to the needs of people with recent onset illness or ongoing symptoms. Indeed, 3 studies [54,120,121] testing DMHI use qualitatively reported discontinuations due to improved mental health, as participants no longer felt they needed the DMHI. Tailoring or customization (*Design*; Table 6) allows DMHIs to be adapted for varied needs; eg, different psychoeducation "levels," staggered unlocking of content based on users' evolving needs, or adaptive frequency of symptom monitoring depending on symptom levels.

While staff considered some aspects of DMHIs (*Innovation: Relative advantage*) aligned with their core "mission", they saw human contact as a central tenet of their mission that was potentially undermined by DMHIs (*Inner setting: Mission alignment*). Staff worried that "patients would see using the app system as a replacement for care, something it was not designed to do" [76], and doubted DMHIs could be effective without a therapeutic relationship: "If you are going to talk evidence-based, the biggest thing in every single intervention... is therapeutic relationship, so you are just removing the most effective part" [33]. Such views could be a prominent barrier to DMHI implementation, particularly for stand-alone or minimally blended DMHIs. This underlines the importance of clearly communicating the specific purpose of the DMHI, and its limits, and reassuring staff that it is not intended to replace them.

Crosscutting Theme 2: Human Support for DMHIs

Forty-nine studies highlighted human support as a key facilitator of DMHI engagement (*Individuals: Motivation;*Table 4), underlining a need to align DMHI implementation with clinical workflows. Reviewed studies found a lack of compatibility with current job roles and workflows (n=17), with DMHIs seen as creating extra work in already stretched teams (*Inner setting: Compatibility;* Table 3) and as less important than other tasks (*Inner setting: Mission alignment*). Clinicians did not want to receive a "constant stream of information" about patients [33]. They thought symptom monitoring-based DMHIs would increase their responsibilities, and questioned who would respond out-of-hours. Staff lacked time to facilitate DMHI use, found data from symptom-monitoring apps complex to interpret (*Innovation: Complexity;* Table 1), and sometimes lacked digital skills (*Inner setting: Access to knowledge and information*).

Data on types of support needed suggested that not all support must be provided by someone clinically trained (*Individuals: Motivation*). Support needs varied, depending on the innovation's or individual's status on other CFIR constructs (see CFIR codes in parentheses), but included: training in basic digital skills (*Individuals: Capability*), recommending suitable DMHIs, onboarding, managing technical difficulties (*Design*; Table 6), support navigating DMHIs (*Innovation Complexity*), ongoing coaching (*Individuals: Motivation*), moderation of social media components, and interpreting and triaging real-time symptom data. Arguably, these tasks could be undertaken by a suitably trained nonclinical staff member, with referrals made to clinicians as needed (eg, when symptoms increase above a predefined threshold, or risk is indicated). Similar observations have prompted the idea of restructuring services to include new job roles for DMHI facilitation (eg, digital navigator, peer supporter). Reviewed studies did not test the implementation of such roles within clinical services; although, many DMHIs were successfully delivered by someone in an equivalent role in a research context. Of 4 RCTs quantitatively examining the

XSL•FO
RenderX

effects of support, 2 demonstrated significantly higher DMHI engagement in peer-supported than unsupported trial arms [121,134,135], 1 found a significant positive effect of brief interviewer-facilitated symptom reviews on app adherence for younger women (no significant overall effect [136]), and 1 found moderate effect sizes in favor of the supported group [137] but was not powered to detect a significant difference (*Individuals: Motivation*).

Six studies provided evidence regarding whom staff or patients might prefer to deliver DMHI support (ie, clinicians or nonclinicians). Studies with staff suggested a preference for nonclinician support for initial onboarding [83], technical [83,114,156], or peer-supported [114] aspects of DMHI use, with input from a clinician or team leader for more clinical aspects [114,157]. Patients expressed mixed views, with some preferring support from a known clinician [68,157], but others viewing this as more "intrusive" than nonclinician support [122]. Qualitative studies reported that, as well as overcoming practical barriers (eg, poor digital literacy, technical difficulties, complex DMHI layout), human connection helped address barriers like low motivation and anxiety about DMHI use, and provided accountability: "I'm going to see [coach]... within a few days, and we were going to discuss this, then there was accountability, I had to get some things done" [87]. Peer support was valued, whether as a formal part of the intervention (peer facilitators) or via social media (*Innovation: Relative advantage*), as peers "...can relate to each other and they know what they've been through" [54], and participants did "not feel scared people will judge you because they have been through the same thing and will be supportive" [55].

Crosscutting Theme 3: Practical Helps and Hindrances

Reviewed studies outlined practical factors that can help or hinder DMHI implementation. Arising across CFIR constructs, these factors tended to hinge on the principle that DMHI use should be as low-effort as possible for users, and practical barriers to access should be addressed.

To maximize engagement, DMHIs should ideally be free or inexpensive to patients (*Innovation: Cost;*Table 1), use similar formats to everyday technology (eg, smartphone app), and allow on-demand, out-of-hours use (*Innovation: Relative advantage*). DMHIs should use straightforward language, be visually appealing (*Design*; Table 6), minimize complexity, avoid lengthy login processes, use an easy-to-navigate app or website structure (shallow structure, <200 words/page), and be compatible with users' own devices (*Innovation: Complexity*). Patients found smartphone apps more convenient than computer or SMS text messaging systems, though apps must be thoroughly tested to minimize technical difficulties (*Design*). Other design elements to increase engagement included push-notification reminders; gamification features (eg, badges for completed tasks); automated feedback about symptoms or DMHI use (eg, symptom graph, step count, and minutes DMHI used); and tailored or varied content to minimize repetition.

These factors interact with each other. For example, tailoring DMHIs may increase engagement, but can also increase complexity, an engagement barrier. In turn, other factors, such as training and support, and individual capability (eg, cognitive ability and digital literacy) may moderate the negative effects of complexity on engagement. Nevertheless, even with training and support, and high individual capability, more complex interventions require more time and effort from users, making disengagement more likely. DMHI design teams must weigh the relative advantages and disadvantages of such interacting factors.

Some engagement barriers could be mitigated given sufficient resources. Lack of access to technology (*Individuals: Opportunity*; Table 4) and lack of digital literacy (*Individuals: Capability*) could be addressed, in theory, by providing devices and training in how to use them. Although staff thought patients would lose, damage, or sell devices, reviewed studies found only an 11% loss of study-provided devices. Data security and privacy concerns were frequently mentioned barriers; patients were concerned about sensitive symptom data being disclosed, due to the potential stigma associated with it. Measures to protect data or mitigate the effects of data loss included the use of pseudonyms, password protection, and the use of general terms (eg, "illness") rather than specific diagnoses.

Some broader practical barriers may be difficult for implementation teams to address directly. These included the lack of mobile phone signal, publicly-funded smartphones being too basic, lack of national guidelines and policies on DMHI use in health services (*Outer setting*; Table 2), aging computers, poor bandwidth, no wireless connection in hospitals, poor organizational support for IT developments, and lack of quiet space (*Inner setting*; Table 3), patient time, or suitable environment (*Individuals: Opportunity*).

Crosscutting Theme 4: Interactions Between Symptoms and DMHI Engagement

Approximately one-third of quantitative analyses (18/52, 35%) reported a significant effect of symptoms on DMHI engagement (*Individuals: Capability*; Table 4; Table S7 in Multimedia Appendix 2). Among these, higher baseline positive, negative, or cognitive symptoms were associated with lower DMHI engagement. Qualitative data suggested that staff and patients anticipated such a pattern (and so may recommend or agree to DMHI use accordingly), and some patients avoided DMHIs due to experiencing difficult interactions between symptoms and technology (eg, technology-related delusions or paranoia). Findings for functioning and depression were more mixed, with higher baseline functioning or depression sometimes predicting higher and sometimes lower DMHI engagement. Qualitative studies suggested that while symptoms of depression (eg, poor concentration and motivation) may interfere with DMHI engagement, low mood may prompt higher engagement for some "because of a desire to find meanings and solutions for their depressive symptoms" [72]. No quantitative studies examined the effects of relapse on engagement; qualitative studies noted decreased DMHI use during relapse; however, participants usually restarted DMHIs on remission. Some were hesitant to (accurately) report symptoms via DMHIs for fear it may lead to more restrictive treatment (hospital admission and increased medication).

Negative interactions between DMHIs and symptoms, or perceived risk of such interactions, emerged as possible

XSL•FO
RenderX

motivational barriers. Patients sometimes experienced DMHIs as "deflating, confronting, or triggering," reminding them how unwell they were, or about their diagnosis, which could be disheartening, "self-stigmatizing," and often prompted disengagement (*Individuals: Motivation*). There were numerous quotations about this, across 10 studies; however, it was difficult to tell how many participants were typically affected. While 1 study reported that half the sample felt negatively influenced by logging their moods and symptoms 5 times per day [157], in other studies with less intensive report schedules, very few (1/27, 4%) participants found the DMHI to be confronting [88]. Relatedly, fear of relapse was a barrier to DMHI use. Staff and patients anticipated that, by increasing awareness of symptoms, DMHIs would heighten users' anxiety about deterioration, which may worsen symptoms. In studies testing actual DMHI use, there was qualitative [45,66,88,102] and quantitative [126] evidence that fear of relapse and increased rumination about symptoms prevented DMHI engagement but the proportion of participants affected was unclear. Reviewed papers did not typically report such negative reactions to DMHI use (ie, finding the DMHI "confronting," or experiencing fear of relapse) as adverse reactions in the context of formal AE monitoring (Multimedia Appendix 2). Arguably, doing so would allow a quantitative examination of how many participants were affected across studies.

Crosscutting Theme 5: Financial Provision for Implementing DMHIs

There was scant empirical information across CFIR constructs about the effects of financial provision on DMHI implementation, probably because most studies examined DMHI use in research studies rather than services. However, findings implied that financial limitations concerning software development and maintenance may indirectly reduce engagement. One study noted that some participant-suggested technical improvements were not possible due to financial limitations [107]. Another noted that the look and feel of the study app were considered "old school" but insufficient funding precluded improvements [109] (*Innovation: Cost*; Table 1); study authors highlighted the challenge of competing with commercial apps: "It is difficult to obtain... funding at a level that can compete with the funding that goes into app design for functions that people routinely use... leaving [study app] looking 'old school'" [109]. Others noted that, while patients prefer free-to-use DMHIs (*Outer setting: Financing;*Table 2), sustainable business models for maintaining evidence-based DMHIs are often absent: "...apps that have been empirically evaluated and developed in accordance with clinical guidelines are rarely made available via the app marketplace... Thoughtful plans for commercialization and fiscal sustainability are important, given respondents with BD endorsed free/low-cost apps" [47]. This statement was supported by a striking absence of information from other reviewed studies about their intended model for DMHI dissemination and implementation, except a US-based study which mentioned costs were offset by the service's billable nature [110] and a Canadian study that anticipated care provider networks would purchase DMHI licenses [109].

Some studies (5/150, 3.3%) listed costs associated with delivering DMHIs in the research context, including web hosting, software licensing fees, texting fees, technical support, and staff time for DMHI delivery. Financial provision for these and other DMHI-associated costs will be key to scaling up DMHI use in services but was not directly discussed in reviewed studies. Nevertheless, to maximize engagement with DMHIs for psychosis or bipolar disorder per the cross-cutting themes outlined above, considerable financial support would be necessary, particularly to provide human support for DMHI use (theme 2), to source or develop well-designed DMHIs that are as low-effort as possible for users (theme 3), and to address practical needs, such as digital poverty (theme 3).

Discussion

Principal Results

This systematic review found that patient and staff engagement with DMHIs is likely to be strengthened by using DMHIs to meet specific needs, not replace human care; providing human support for DMHIs and considering compatibility with current workflows; making DMHIs as low effort as possible for patients and staff, inquiring about common practical barriers to use (eg, digital poverty or training needs) and addressing these where possible; acknowledging interactions between symptoms and DMHIs, including motivational barriers and fear of relapse; and ensuring appropriate financial provision to implement DMHIs in line with these recommendations.

Comparison With Prior Work

Similar to the review by Aref-Adib et al [17] on DMHIs for psychosis or bipolar disorder, most data were coded into CFIR *Intervention* (149/175, 85.1% papers) or *Individuals* (137/175, 78.3% papers) domains, with very little covering *Outer setting* (9/175, 5.1% papers) or *Implementation process* (5/175, 2.9% papers). We found more data related to the *Inner setting* (20/175, 11.4% papers) than the previous review, with studies highlighting a lack of compatibility with clinical workflows (17/175, 9.7% papers) and lack of alignment with staff perceptions of their clinical "mission" (5/175, 2.9% papers) as important barriers to DMHI implementation. This difference appears to reflect progress in the psychosis and bipolar disorder DMHI literature over the intervening years (Figure 1). Workflow-related barriers are mentioned in reviews covering DMHIs for common mental health disorders [21,158,159], a literature which has a chronological head-start on the equivalent literature for psychosis and bipolar disorder.

Our finding that human support was a key facilitator of DMHI engagement is consistent with previous reviews of factors affecting the implementation of DMHIs for psychosis or bipolar disorder [17,160], common mental health problems [11,21,158,161,162], and a meta-synthesis of staff views [158]. Relatedly, our review and others reported that clinicians' negative attitudes to DMHIs, resistance to change, and lack of digital skills were sometimes barriers to DMHI implementation [17,158,163]. Nevertheless, such considerations are likely eclipsed by a need for compatibility with clinical workflows (which our findings suggest is currently absent; see *Inner setting: Compatibility*). Restructuring services to include new

XSL•FO
RenderX

"digital navigator" roles, alongside traditional clinical roles, has been suggested as a model for implementing DMHIs in mental health services [10,164], and meta-analysis shows similar effectiveness across DMHIs guided by clinicians and nonclinicians [165]. Whether this model or any other service model is used, staff members (clinicians and nonclinicians) would need allocated time, training, and supervision to support patients' DMHI use [158], all of which have financial implications [166].

DMHIs are frequently cited as potential methods of extending care in a cost-effective manner [167]. There is some empirical evidence supporting this, albeit from DMHIs tested in a research context [168], but economic evaluations of mental health DMHIs are rare [169]. Nevertheless, up-front costs of restructuring services and ongoing costs of delivering DMHIs will likely be substantial [17]. Few reviewed papers (5/175, 2.9%) directly evaluated financial factors, but our findings highlight the importance of considering staff-related costs and costs of addressing engagement barriers (eg, dated-looking digital interfaces; patients lacking suitable devices or skills). Without financial investment, DMHI engagement will likely be poor, potentially perpetuating existing treatment disparities [170,171]. More broadly, reviewed studies highlighted the difficulties of developing evidence-based DMHIs against a background of rapid technological advances and attractive but poorly evidenced commercial apps. Hill et al [172] outlined similar issues in relation to developing evidence-based DMHIs for common mental health problems; they recommended that researchers collaborate with industry partners to commercialize well-evidence DMHIs, generating funds to cover ongoing maintenance and development, and enhancing long-term sustainability.

We found that mental health symptoms and DMHIs sometimes interacted in ways that prevented DMHI engagement, which echoes and expands on findings from the review by Aref-Adib et al [17]. We found more evidence of motivational barriers relating to increased rumination or fear of relapse (26/175, 14.9% papers) than that found in the previous review (1/26, 4%). We also found that patients disengaged with DMHIs because they found increased self-reflection and attention toward negative emotional states too "confronting," which has not been reported in previous reviews. Evidence from reviewed studies did not allow an estimate of how many patients are affected by these barriers. Future studies should consider examining such reactions quantitatively, perhaps as part of formal AE monitoring, to help future users make informed choices about DMHI risks and benefits. More generally, our supplementary analysis of safety reporting suggested that AE reporting warrants considerably more attention, in line with recent findings from other reviews [22,23,173] and recommendations regarding AE monitoring and reporting for DMHIs for psychosis [174].

Strengths and Limitations of the Evidence Base

The reviewed literature contained a wealth of qualitative and quantitative data outlining factors that may affect staff and patient engagement with DMHIs for psychosis or bipolar disorder. However, the current evidence base has important limitations. First, most studies were conducted in traditional research settings rather than evaluating the process of implementing DMHIs directly in health services. Consequently, identified barriers and facilitators may not all translate and generalize to care provision settings. Nevertheless, the review provides an early indication of likely barriers and facilitators, across the CFIR domains, enabling these to be considered when designing future DMHIs and DMHI implementation strategies. This information will also be valuable in highlighting key implementation factors to prospectively examine in future implementation studies. Second, most studies seeking health professional views sought this information hypothetically (ie, they asked staff, who had not necessarily already used DMHIs, what they thought about using DMHIs in their clinical practice, in theory), whereas studies seeking information from patients more often asked about actual experiences of DMHI use (ie, they asked patients, who had already used a specific DMHI, about what it was like to use that DMHI). Berry et al [175] suggested that hypothetical views and actual experiences of DMHIs do not always align. Therefore, the difference in methods between patient and health professional studies must be kept in mind when considering the findings of this review.

Strengths and Limitations of This Review

A key strength was the use of CFIR as a framework, allowing examination of interactions between staff and patient barriers and facilitators and wider contextual factors, and sensitizing us to implementation factors that may not otherwise have been identified in reviewed studies. Studies were identified using an inclusive search strategy, with intentionally wide inclusion criteria (eg, DMHI types, settings, and engagement indicators) to allow examination of a broad range of barriers and facilitators. However, the resulting studies were extremely heterogeneous, precluding meta-analysis and potentially conflating results from dissimilar studies. Likewise, the review covered a 21-year period (2010 to 2021), spanning a time of great technological advancement during which societal acceptance of DMHIs may have changed considerably, adding further heterogeneity. Finally, we limited our search to the period before the COVID-19 pandemic. Although this avoided COVID-19 pandemic–related heterogeneity, if the search had been conducted later, findings related to the impacts of the COVID-19 pandemic on digital uptake (*Outer setting: Critical incidents*) would likely have been prominent. We recommend that a future review should focus on mixed methods studies published since the pandemic, to examine the shifting views of staff and patients regarding potential barriers and facilitators of digital health tools for psychosis and bipolar disorder in the intervening period.

Conclusions

While DMHIs have a role in supporting those with psychosis or bipolar disorder, intervention, individual, and contextual factors all impact uptake. To enhance engagement, DMHIs must be simple, low effort, meet specific needs, and not be heralded as a replacement for face-to-face care. Human support can overcome engagement barriers related to motivation and practicalities of DMHI engagement. Financial provision is likely to be key to sustainable DMHI implementation.

Acknowledgments

The authors wish to thank Oshin Jacob, who assisted with data extraction. This research was funded by the UK National Institute for Health (NIHR) and Care Research (grant NIHR300794) and supported by the NIHR Manchester Biomedical Research Center (grant NIHR203308). There was no editorial direction or censorship from the study funder or the study sponsor. The study funder and study sponsor had no role in the study design, data collection, data analysis, data interpretation, or writing the report. The views expressed are those of the authors and not necessarily those of the NIHR or the Department of Health and Social Care.

Authors' Contributions

EE analyzed the data and drafted the paper as the first author, with support from SB and SF. All coauthors had the opportunity to contribute to drafts of the paper, to critically review the manuscript, and to approve the final version. EE and SB devised the study aims and methods and supervised the researchers during data collection and analysis. PW and JN provided methodological advice. SA, HB, DDB, JN, XZ and AP contributed to data collection.

Conflicts of Interest

SB is a director and shareholder of CareLoop Health Ltd, which develops and markets digital therapeutics for schizophrenia and a digital screening app for postnatal depression. All other authors declare no conflicts of interest.

Abstract

Background: There is potential for digital mental health interventions to provide affordable, efficient, and scalable support to individuals. Digital interventions, including cognitive behavioral therapy, stress management, and mindfulness programs, have shown promise when applied in workplace settings.

Objective: The aim of this study is to conduct an umbrella review of systematic reviews in order to critically evaluate, synthesize, and summarize evidence of various digital mental health interventions available within a workplace setting.

Methods: A systematic search was conducted to identify systematic reviews relating to digital interventions for the workplace, using the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analysis). The review protocol was registered in the Open Science Framework. The following databases were searched: PubMed, Web of Science, MEDLINE, PsycINFO, and Cochrane Library. Data were extracted using a predefined extraction table. To assess the methodological quality of a study, the AMSTAR-2 tool was used to critically appraise systematic reviews of health care interventions.

Results: The literature search resulted in 11,875 records, which was reduced to 14 full-text systematic literature reviews with the use of Covidence to remove duplicates and screen titles and abstracts. The 14 included reviews were published between 2014 and 2023, comprising 9 systematic reviews and 5 systematic reviews and meta-analyses. AMSTAR-2 was used to complete a quality assessment of the reviews, and the results were critically low for 7 literature reviews and low for the other 7 literature reviews. The most common types of digital intervention studied were cognitive behavioral therapy, mindfulness/meditation, and stress management followed by other self-help interventions. Effectiveness of digital interventions was found for many mental health symptoms and conditions in employee populations, such as stress, anxiety, depression, burnout, and psychological well-being. Factors such as type of technology, guidance, recruitment, tailoring, and demographics were found to impact effectiveness.

Conclusions: This umbrella review aimed to critically evaluate, synthesize, and summarize evidence of various digital mental health interventions available within a workplace setting. Despite the low quality of the reviews, best practice guidelines can be derived from factors that impact the effectiveness of digital interventions in the workplace.

Introduction

Digital Mental Health Interventions in the Workplace

Digital mental health interventions can provide support to individuals, in a potentially low cost, efficient and scalable way. Digital interventions that have been generalized from clinical or community settings, to the workplace, primarily cognitive behavioral therapy (CBT) [1], stress management [2], and mindfulness-based stress reduction programs [3] have shown promise.

However, a criticism of digital interventions for mental health is their absence of evidence-based frameworks. A review of 293 commercially available apps for anxiety and depression found just over 55% contained information on an evidence-based framework, and of these only 6.2% published evidence to support their efficacy [4]. Furthermore, in 2020, the Organization for the Review of Care and Health Apps, a UK organization that assesses the quality of digital health apps, reviewed almost 600 mental health apps that are commercially available, and only 29.6% met their quality thresholds across different criteria including clinical assurance, data privacy, and user experience [5].

Implementation of evidence-based digital mental health interventions into real-world care is therefore lacking, resulting in the need to prioritize research exploring workflow considerations [6]. Linardon et al [7], found that studies that took a blended approach improved engagement (a blended approach includes human support supplementing a digital intervention). There is also a lack of gold-standard evidence and best practices to determine which interventions are effective for specific industry sectors or workforce populations alongside identifying those that may potentially cause harm [8].

Torous et al [6], also highlight the need to rethink and expand traditional integrated care pathways to include digital interventions to maximize their full benefit, where rapid advances in digital health technology capabilities, digital health standards, and regulation, the post–COVID-19 era presents a unique opportunity to realize this ambition. Digital interventions, used in conjunction with and to enhance traditional support options could provide a way to encourage help-seeking within an employee assistance program, and provide different industries and occupational groups with personalized well-being support.

Many systematic reviews focus on specific delivery methods of digital interventions, such as “web-based” or a “mobile app” delivered in the workplace. There are also reviews focused solely on specific mental health conditions and methods of treatment, such as stress or mindfulness. There are also existing reviews that focus on specific workplace populations, such as “white-collar” workers, health care professionals, and teachers.

Aim

The aim of this study is to conduct an umbrella review of systematic reviews to critically evaluate, synthesize and summarize the best available evidence for a variety of digital mental health interventions currently available within a workplace setting, identifying those which enhance mental health and well-being alongside highlight gaps in the knowledge base to guide further research.

Methods

Overview

A systematic search was conducted in January 2024 to identify systematic reviews relating to the effectiveness of digital interventions for a workplace population. The following five databases were searched: (1) PubMed, (2) Web of Science, (3) MEDLINE, (4) Cochrane Library, and (5) PsycINFO. Three categories of search terms were used as follows: (1) “mental health,” (2) “digital interventions,” and (3) “workplace”, with the Boolean operator “AND” to separate categories and “OR” within categories. The search strategy for each database is presented in Multimedia Appendix 1. Google Scholar was also used to identify any further systematic reviews. The review protocol was registered in the Open Science Framework [9].

Search Terms

Mental Health and Well-Being

The search terms were as follows: depress* OR anxiet* OR anxious OR mood OR “mental health” OR “psychological wellbeing” OR “mental wellbeing” OR “behavioral health” OR “mental illness” OR stress [10].

Digital Interventions

The search terms were as follows: “online intervention” OR “online treatment” OR “digital intervention” OR “digital treatment” OR “mobile intervention” OR “mobile treatment” OR “smartphone intervention” OR “smartphone treatment” OR “web-based intervention” OR “web based treatment” OR “internet intervention” OR “internet treatment” OR “computer intervention” OR “computer treatment” OR “cyber intervention” OR “cyber treatment” OR “electronic intervention” OR “electronic treatment” OR (mobile AND program*) OR mhealth OR ehealth OR mtherap* OR etherap* OR telehealth OR telemedicine OR “mobile app*” [10].

Workplaces

The search terms were as follows: workplace OR occupation* OR “work place” OR worksite OR office OR work [11].

Study Selection and Inclusion

Covidence, a software designed to streamline the systematic review process was used to determine which studies were systematic reviews. Using keywords “systematic” and “review,” systematic reviews were identified by their title or abstract.

Systematic reviews covering the effectiveness of digital mental health interventions within a working adult population were included. Exclusion criteria were (1) studies that did not assess effectiveness or impact on mental health or well-being outcomes, (2) nonsystematic reviews, and (3) studies that were not available in English.

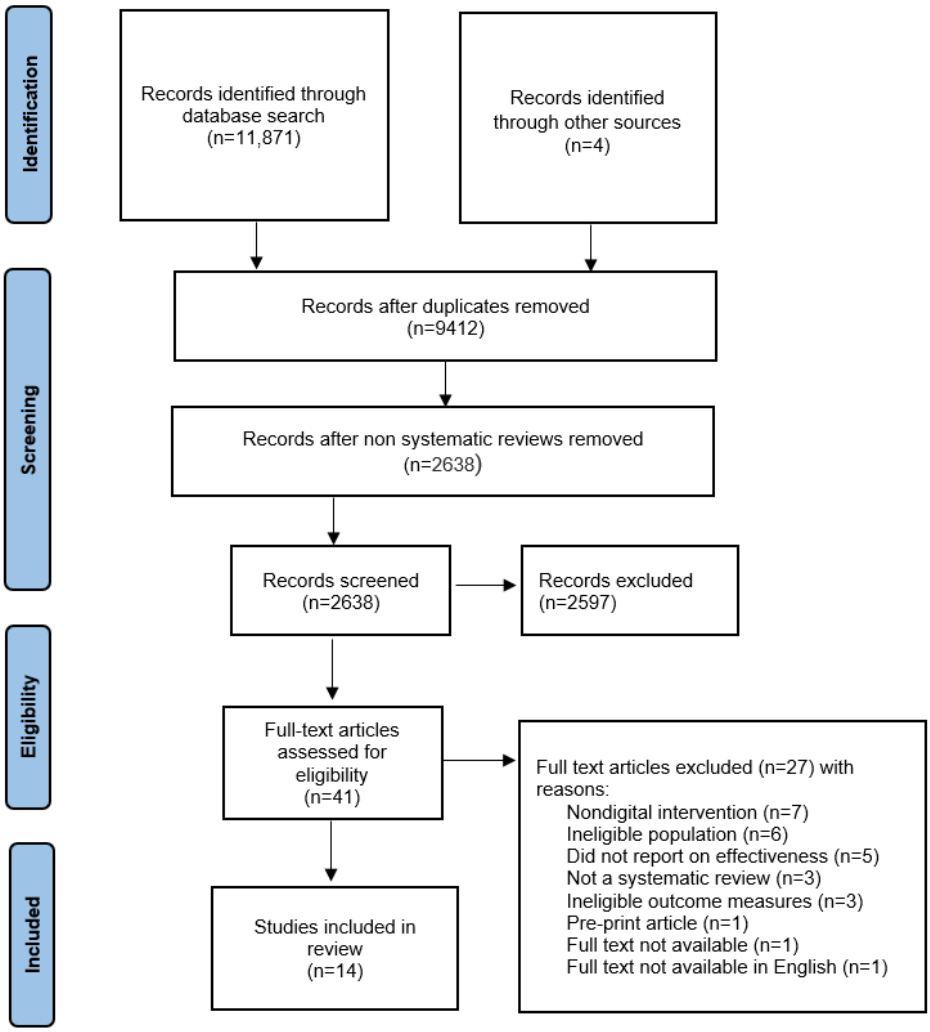
Data Extraction and Quality Assessments

The following data were extracted using a predefined extraction table as follows: journal, publication year, databases searched, number of studies, types of study design, time period, population

XSL•FO
RenderX

details, sample size (overall and mean if reported), intervention type, main findings, and limitations. The extracted data is presented in Multimedia Appendix 2 [1,8,12-23]. To assess the methodological quality of a study, the AMSTAR-2 tool was used to critically appraise systematic reviews of health care interventions, that include randomized and nonrandomized studies [24].

The critical domains AMSTAR-2 evaluates are having a protocol registered before the review begins, adequacy of the literature search, justification for excluding studies, risk of bias, and considering this when interpreting results, and appropriate meta-analytical methods and likely impact of publication bias if a meta-analysis was conducted. One author carried out the AMSTAR-2 assessments (GC), and a second author (EE) checked the assessment outcomes independently. Any queries and conflicts were resolved through consensus between some members of the team.



Results

Overview

The literature search extracted a total of 11,871 studies with a further 4 studies identified through Google Scholar. A total of 2463 duplicates were removed using Covidence, and a further 6774 were excluded as they were not systematic reviews. Reviewing titles and abstracts of 2638 reviews resulted in a further 2597 studies being excluded based on the inclusion and exclusion criteria.

A total of 41 full-text articles were then assessed for eligibility and 27 were excluded for the following reasons: (1) reviews that did not focus on digital interventions (n=7), (2) had an ineligible population—not employed individuals (n=6), (3) did not study effectiveness (n=5), (4) were not reviews (n=3), (5) did not study mental health (n=3), (6) other factors such as prepublished work (n=1), (7) full-text version not being available in English (n=1), or (8) another review's full-text was requested, with no response (n=1). The final number of reviews included in this systematic review was 14. Figure 1 shows the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analysis) flowchart, and Multimedia Appendix 3 presents the PRISMA checklist.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analysis) flowchart showing identification, screening, and inclusion of systematic review.

General Characteristics of Reviews

The 14 included reviews comprised of systematic reviews (n=9) and systematic reviews with meta-analysis (n=5). The full characteristics of this umbrella review are detailed in Table 1. The specific criteria for inclusion were notably varied across each of the reviews; most reviews only included randomized controlled trials (RCTs; n=7). Vertola et al [12] included mainly RCTs, and one clinical trial that compared 2 interventions; however, the participants were not randomized to either of the groups. Other study designs included RCTs, quasi-experimental research [13], and quantitative or qualitative research design [14].

Stratton et al [15] required studies to have a control group to meet their inclusion criteria. Narváez et al [16] did not state the specific inclusion criteria but required the methodology to be published. López-Del-Hoyo et al [17] specified that RCTs, nonrandomized trials, and single-arm studies were eligible for inclusion in the review. In their review, Drissi et al [18] examined published research that focused on digital mental health solutions for health care workers in the context of COVID-19.

Most systematic reviews (n=9) included a wide range of workplace sectors, including health care, manufacturing, IT, public services, and education. Two reviews did not report on the type of sector included in the studies [12,16] and 1 review included studies solely including nurses [19] and 2 on health care workers [17] with one focusing specifically on the time of COVID-19 [18]. Reviews were published from 2014 to 2023, with Figure 2 depicting the number of systematic reviews by year.

Table 1. Characteristics of systematic reviews and meta-analyses of digital mental health interventions for the workplace.

Author and Year	Number of studies	Population	Digital intervention context	Outcomes	Main findings	Quality checklist used
Xiong et al (2023) [20]	19	Studies were across multiple sectors including local authorities, health care, IT, and education	• Internet-based cognitive behavioral therapy (iCBT) • Platform used: Computer-based, web-based, mobile-based, and app-based	• Depression	• Computer-based, web-based, mobile-based, and app-based interventions all have potential to improve depression disorder among employees. In the RCTs[a], iCBT demonstrated small (Hedges g=0.31, 95% CI 0.17-0.44; *P*<.001) potentially sustained effects on employees' mental health	Cochrane risk-of-bias tool (RoB 2)
Park et al (2022) [19]	7	Study focused on the nursing staff population	• Career identity training (n=1) • Stress management program (n=1), Positive Thinking (n=1), Cognitive rehearsal intervention (n=1), Emotional freedom technique (n=1), Biofeedback training (n=1), and Work functioning (n=1) • Platform used: web-based (n=3), smartphone-based (n=3), and real-time web-based intervention (n=1)	• Burnout • Secondary outcomes included workplace measures, such as career identity, workplace bullying, turnover, distress, and work • They also looked at anxiety and resilience	• One study reported on Burnout (primary outcome) found significantly lower levels of burnout compared with the control group who had no intervention (*P*<.001) • Secondary outcomes were also reportedly improved	Cochrane's Risk of Bias
Stratton et al (2022) [15]	75	Most studies included health care professionals (n=18), insurance industry (n=7), managers (n=6), IT (n=6), education (n=6), male-dominated industries (n=5), telecommunications (n=5), marketing and sales (n=3), banking (n=1), and HR (n=1)	• Three most common interventions were based on CBT[b], Stress management, and mindfulness. • Platform used: Most interventions were delivered via web-based platforms as opposed to smartphone apps.	• Depression, anxiety, and stress	• Found that the body of evidence for workplace digital interventions has tripled in the past decade, but no evidence to support effectiveness has increased • Found small positive effects on anxiety (Hedges g=0.26, 95% CI 0.13-0.39; *P*<.001) • For depression there was small positive effects (Hedges g=0.26, 95% CI 0.19-0.34; *P*<.001) • And stress (Hedges g=0.25, 95% CI 0.17-0.34; *P*<.001)	Cochrane risk of bias tool for RCTs (RoB version 2.0)
Vertola et al (2022) [12]	11	Adult workers—sectors not specified	• Mindfulness/meditation, stress, well-being, mental health psychoeducation, sleep quality, and emotional regulation • Platform used: mobile apps	• Well-being (general and work-related) • Anxiety, depression, stress, and perceived stress • Job stress, emotional labor, self-regulation, life satisfaction, compassion satisfaction, and burnout	• Range of outcomes, studies reported an increase in well-being (n=7), reduction in perceived stress (n=4), reduction in stress (n=3), decrease in anxiety symptoms (n=2), decrease in depressive symptoms (n=2), reduction in burnout symptoms (n=2), and decrease in job stress (n=2)	Not reported (NR)

XSL•FO
RenderX

Author and Year	Number of studies	Population	Digital intervention context	Outcomes	Main findings	Quality checklist used
Armaou et al (2022) [13]	51	RCTs were across multiple sectors, with the most in health care (n=8), technology/IT companies (n=5), manufacturing (n=3), quasi-experimental studies were across multiple sectors, most within health care (n=11), governmental or public enterprises (n=3), and university employees (n=2)	• Categorized into 4 clusters of interventions, "self-help interventions" (n=18), followed by Stress management (n=14), Mindfulness/meditation (n=14), and CBT (n=5) • Platform used: A mix of web-based and smartphone-based interventions	• Primary Outcomes grouped into 3 areas: Mental Health concerns: Depression, anxiety, and dysfunctional attitudes. Work-related well-being: Perceived stress, psychological distress, and job strain Psychological wellness: general mental well-being/positive mental health, happiness, and life satisfaction. Mindfulness and resilience, self-efficacy, coping, and gratitude	• Mental Health concerns: 10/51 (19.6%) Studies reported positive effects • Work-related well-being: 28/51 (54.9%) Studies reported positive effects • Psychological wellness indicators: 19/51 (37.3%) studies reported positive effects	Cochrane Collaboration's Risk of Bias and JBI Critical Appraisal Checklist
Moe-Byrne et al (2022) [21]	7	Participants were recruited from a variety of workplaces. Office-based organizations (n=4), health care professionals (n=2), and private and public sector (n=1)	• All studies used CBT as a theoretical background: 2 stated the use of mindfulness and 2 used stress model or the job demands resources model • Increase well-being: preventative interventions (n=3) and work performance and occupational health guidance (n=1) • Platform used: A web-based intervention (n=5), a smartphone app intervention (n=1), and a combined web-based and smartphone app intervention (n=1)	• Depression, anxiety, and stress and work-related outcomes (absenteeism, presenteeism) • Physical measures: sleeping problems (n=2), sleep and workplace performance (n=1), somatization (n=1), and physical health impairment (n=1)	• All studies reported psychological outcomes • Significant improvement for both anxiety and depression (n=2) • Significantly lower stress scores (n=3) • Well-being (mixed results): significantly more well-being over time (n=1) and did not find a statistically significant positive effect (n=1) • Other mental health outcomes: significant effects for positive mental health (F=3.46; P=.03; Cohen d of 0.37 at 3 months follow-up and Cohen d of 0.28 at 6 months follow-up; n=2) • Employee's worry and quality of life regarding mental health (P<.001 at 6 months; n=1)	Cochrane Risk of Bias tool
Drissi et al (2021) [18]	11	Health care workers			• Lack of empirical evidence for health care workers, evidence mainly targeted health care workers in China	NR

XSL•FO

Quality Assessment of Reviews

AMSTAR-2 was used to complete a quality assessment of the reviews included in this umbrella review, the results were Critically Low (n=7), and Low (n=7).

A total of 9 studies provided reasons for excluding articles, however, none of the reviews provided a full list of studies that were excluded. Another noncritical item that no review met was item 10, reporting on the funding of primary studies. A total of 11 studies declared no conflict of interest or provided justification, and only one study met the full "adequacy of the literature search" critical item. Many systematic reviews (n=11) did include the components of PICO (Population, Intervention, Comparison, and Outcomes). Although many reviews (n=9) provided an overarching list of reasons why full-text articles were excluded, none of the reviews provided a full list detailing all potentially relevant studies that were read and excluded. The judgment for each AMSTAR-2 critical item area for each systematic review can be found in Multimedia Appendix 4 [1,8,12-23].

In terms of the risk of bias checklists used within the individual systematic reviews, Cochrane risk of bias (n=9) was the most widely used, followed by JBI (Joanna Briggs Institute) Critical Appraisal Checklist (n=1), Downs and Black Checklist (n=1) and Heart, Lung, and Blood Institute assessment tools (n=1). Armaou et al [13] used both the Cochrane and JBI Checklists, and 4 studies did not report on using any risk of bias checklists.

Digital Interventions

Intervention Delivery

The type of digital platforms that were used to deliver the intervention was mostly mixed, including reviews reporting on studies that used web-based and mobile/smartphone-based interventions (n=11). Two reviews reported only on mobile/smartphone-based interventions [12,14] and one focused only on web-based interventions [23].

Intervention Type

The umbrella review identified 4 different types of digital interventions: CBT, mindfulness/meditation, stress management, and other self-help interventions.

This is consistent with other systematic reviews, as 2 reviews found the most common type of interventions were CBT-based, followed by stress management and mindfulness-based approaches [8,13]. Likewise, Phillips et al [1], Narváez et al [16], and Moe-Byrne et al [21] found that CBT was the most common intervention in the majority of studies they reviewed. Xiong et al [20] focused their review solely on internet-based cognitive behavioral therapy (iCBT), delivered through computer-based, web-based, mobile-based, and app-based platforms. Park et al [19] identified different, unique types of digital interventions compared with the rest of the reviews, including studies on career identity training (n=1) and biofeedback training (n=1). Drissi et al [18] reviewed studies on interventions using social media (n=2) for health care workers during the pandemic. López-Del-Hoyo et al [17] classified mindfulness interventions as "third wave" psychotherapies, versus "other" interventions. Across all reviews, the most common and frequent interventions included were CBT-based, followed by Mindfulness and stress management interventions.

Outcome Measures

For the majority of the reviews, the primary outcome measure focused on the symptoms of Depression (n=9), this includes Xiong et al [20] who only included studies that focused on depression. Furthermore, reviews reported on studies measuring Anxiety (n=9), stress (n=5), well-being (n=5), burnout (n=5), occupational/job stress (n=4), perceived stress (n=2). Other reviews reported on outcomes such as resilience (n=2), sleep problems (n=2), mindfulness (n=2), alcohol, physical health, and help-seeking attitudes.

Park et al [19] found other workplace-related outcome measures within their review of studies within the nursing population, such as workplace bullying, career identity, quality of work life, and turnover. The review by Carolan et al [23] reported on work effectiveness, 2 on presenteeism and absenteeism. Outcome measures varied greatly across reviews, with 174 specific measures being mentioned across 9 reviews that reported on outcome measures. The most frequently used outcome measures are displayed in Table 2.

Table 2. Top 10 frequently used outcome measures.

Outcome Measure	Count, n
Center for Epidemiologic Studies Depression Scale (CES-D)	14
Depression Anxiety and Stress Scale 21 Items (DASS-21)	12
Perceived Stress Scale 10 Items (PSS-10)	11
Patient Health Questionnaire 9 Items (PHQ-9)	9
Insomnia Severity Index (ISI)	7
Connor-Davidson Resilience Scale (CD-RISC)	7
Kessler Psychological Distress Scale (K6)	6
Maslach Burnout Inventory (MBI)	6
Beck's Depression Inventory (BDI)	5
The Symptoms of Distress Scale (SDS)	5

XSL•FO
RenderX

The most frequently used scales measured perceived stress, depression, anxiety, stress, insomnia, burnout, and psychological distress, however, there were 2 scales that measured workplace-specific outcomes, the Utrecht Work Engagement Scale followed by the brief job stress questionnaire. Cronbach α coefficients ranged between 0.70 and 0.95 each of the 10 most frequently used scales.

In an analysis of co-associations among outcome measures, patterns emerge regarding the use of instruments used together. The Generalized Anxiety Disorder-7 Scale for generalized anxiety was used in conjunction with the Patient Health Questionnaire-9 for depression, in a total of 4 studies. Another pair of outcome measures were the Maslach Burnout Inventory–Emotional Exhaustion (MBI-EE) for burnout, and the 10-item Perceived Stress Scale (PSS-10) for perceived stress appearing together in 3 studies. Similarly, the PSS-10 for perceived stress was paired with the Center for Epidemiologic Studies Depression Scale (CES-D) for depression in 3 studies. In terms of workplace-specific outcome measures, the Utrecht Work Engagement Scale was used in conjunction with Hospital Anxiety and Depression Scale–Anxiety, CES-D, PSS-10, Insomnia Severity Index, and MBI-EE in 2 studies.

Effectiveness

CBT

Xiong et al [20] found iCBT had a small positive effect on symptoms of depression. Armaou et al [13] found 3 CBT digital interventions that had a significant effect on anxiety and depression symptoms. Stratton et al [8] found CBT-based interventions had a small significant positive effect (g=0.15, 95% CI 0.02 to 0.29, *P*=.03, I2=1.9%) on reducing mental health conditions in employees. However, López-Del-Hoyo et al [17] found that CBT-based programs did not produce significant effects on stress in health care professionals.

Mindfulness-Based Interventions

Positive effects for mindfulness-based interventions were found for anxiety and depression symptoms, with Stratton et al [8] finding a moderate to large positive effect size (Hedges *g*=0.60, 95% CI 0.34 to 0.85, *P*≤.001, I2=0.0%). Stratton et al [15] found mindfulness-based interventions to have moderate but higher effect sizes (Hedges *g*=0.46, 95% CI 0.28-0.64; *P*<.001) on depressive symptoms than CBT (Hedges *g*=0.11, 95% CI 0.06-0.17; *P*<.001). Vertola et al [12] reported that mobile health interventions, particularly those focused on mindfulness/meditation had moderate to high efficacy for supporting stress management and emotional self-regulation in the workplace. López-Del-Hoyo et al [17] reported a mindfulness decompression and psychoeducation program produced significant reductions in depressive and anxiety symptoms in health care professionals, however, this study did not have a control arm.

Stress Management

Armaou et al [13] found positive effects of stress management interventions on work-related and psychological well-being, but equally found 4 studies that had no significant effect. Stratton et al [15] found stress management interventions (Hedges *g*=0.61, 95% CI 0.47-0.75; *P*<.001) to be more effective than CBT (Hedges *g*=0.11, 95% CI 0.06-0.17; *P*<.001), for stress, depression, and anxiety.

Other Self-Help Interventions

Three mobile-based resilience interventions had no effect on resilience and 3 web-based positive psychology interventions had no effect on psychological well-being [13]. In contrast, the review of Phillips et al [1] indicated that positive psychology was more effective than CBT evidencing a larger effect size.

Factors Influencing Effectiveness

Of the 14 reviews, there were several reported factors that potentially influenced within study effectiveness. These include the type of technology or platform used, if the intervention was guided or self-guided, recruitment of participants, tailoring or personalization of the intervention, and demographics such as gender or age.

Xiong et al [20] found that effectiveness was not impacted substantially by the type of platform iCBT was delivered on, that is, web-based or mobile-based. Park et al [19] found that studies using interventions that were mobile-based reported significant improvements compared with web-based interventions; however, their findings were not conclusive, as the studies within the review had poor methodological quality, a wide variation of interventions, and high heterogeneity of outcomes.

Carolan et al [23] did not find a significant difference between interventions that were guided (guidance by a person) or self-guided, in contrast, Phillips et al [1] found an advantage for guidance, however, their subgroup analyses were underpowered and must be interpreted with caution. Supported-guided interventions for stress and depression were found to have a larger effect size than self-guided, in contrast, there was no significant difference between guided and self-guided for anxiety [15]. In the context of health care professionals, guided interventions were limited in number, and did not sustain significant effects on stress at follow-up [17].

Howarth et al [22] found that studies targeting one specific outcome, rather than multifactorial, were more effective. Furthermore, Armaou et al [13] found that studies demonstrated a high risk of contamination effects and attrition bias, and concluded further high-quality evidence is needed. In terms of recruitment, Phillips et al [1] found that participants recruited from the community, evidenced a significant increase in the treatment effect (g=0.79) compared to those recruited within the workplace and called for future research to examine and focus on the impact of this.

Tailoring or personalizing interventions was found to be effective for presenteeism, stress and sleep, but less so for anxiety, depression, and absenteeism [21]. Furthermore, Stratton et al [15] argue that the limited evidence in the literature for tailored digital interventions suggest no greater efficacy for bespoke or tailored interventions in addressing mental health in the workplace.

A total of 8 studies reported the mean age and gender balance of some or all studies but did not comment further. Phillips et

al [1] assessed age and gender as moderators for effect size, with a total population of 15,258. Older participants showed significantly higher effect sizes for stress, depression and burnout, while gender did not show any significant moderating effects.

Discussion

Principal Findings

This umbrella review aimed to critically evaluate, synthesize, and summarize the best available evidence of various digital mental health interventions being deployed within a workplace setting to (1) identify which digital mental health interventions are most effective for enhancing mental health and well-being in the workplace and (2) identify gaps in the knowledge base which require further research. Based on the 14 systematic reviews and meta-analyses reviewed there is evidence to support the effectiveness of digital interventions within a workplace setting.

The most common type of digital intervention was CBT, followed by mindfulness and stress management, and other more generic interventions, for example, resilience based or positive psychology interventions. Given the variation of language used to describe mental health digital interventions both in the general populations, and in the workplace, clear and concise operational definitions could help with standardization.

Web-based was the most common delivery platform, and Xiong et al [20] found evidence to suggest that type of platform did not significantly impact effectiveness. The latter indicates further consideration should be given to implementing other rapidly advancing platform technologies such as chatbots, virtual and augmented reality interventions.

In terms of mental health outcomes, the reviews found statistically significant positive effects primarily with self-report outcome measures which screen for depression, stress, anxiety, psychological well-being, and burnout. Armaou et al [13] found that digital interventions that were theory-informed were associated with increased effectiveness, in contrast, psychoeducation alone was the least effective and only minimally effective for improving well-being in the workplace. Xiong et al [20] and Stratton et al [8] found internet-based CBT was moderately effective in reducing the symptoms of depression in employees, while Xiong et al [20] called for further high-quality studies to add to this evidence base.

There was an especially high heterogeneity of outcomes measured with the assessments and tools used to measure these across many studies and within reviews. The most frequent assessment measures used were self-report screening questionnaires for stress, anxiety, and depression with moderate to high levels of reliability, concurrent and predictive validity. Studies would benefit from using well-validated, standardized mental health outcome measures to enable comparisons across studies and across populations, albeit reporting effect sizes does allow for comparing relative efficacy. Consideration should be given to how the different outcome measures used in previous studies can be harmonized for meta-analysis to enable reliable benchmarking, through using tools such as Harmony [25]. Furthermore, given the high heterogeneity of outcome measures used, a recommendation for standards bodies such as the Employee Assistance Professionals Association is to create an industry-wide standard approach to measuring mental health outcomes of employees, for example, with the Workplace Outcome Suite [26].

Very few reviews included studies that reported absenteeism or presenteeism, which are associated with anxiety and depression in the workplace [27]. Moe-Byrne et al [21] found the definition of presenteeism can vary and was not comparable between studies, as many used different assessment tools. However, a study that assessed presenteeism using a valid and reliable measure, treatment inventory of costs in patients with psychiatric disorders, found a statistically significant improvement, in contrast 2 studies using a direct measure of absenteeism found no significant improvement.

When interpreting the results of systematic reviews, the risk of bias needs to be considered. Using the AMSTAR-2 quality impact assessment for systematic reviews of RCTs or nonrandomized trials, 7 of the 14 systematic reviews were found to be low, and 7 were found to be critically low which places considerable limitations on the overall findings.

For all employees within the workplace, while considering generic well-being, there is evidence that mindfulness-based interventions may have a stronger, albeit moderate effect on employees, while stress management interventions may have a stronger effect on those employees presenting with higher levels of stress [8]. However, there is evidence that mindfulness may cause adverse effects in some populations who have been exposed to or witnessed workplace trauma, such as re-experiencing traumatic memories [28]. Employers, therefore, could consider including Trauma-Informed Mindfulness-Based Stress Reduction [29] which has shown promising results for those who have experienced interpersonal violence. There is also a lack of best practices and evidence to determine which interventions are effective for specific workforce populations alongside identifying those that may potentially cause harm [8].

Phillips et al [1] highlighted how community recruitment, as opposed to recruiting from a workplace population, improved the treatment effect. Equity in digital mental health is a key and growing concern, and often interventions are developed to reach mass populations, with no consideration given to how demographic factors such as age or gender and or mental health not least trauma-related presentations may moderate effect size or even lead to negative outcomes. Phillips et al [1] found older age was a positive moderating factor on effect size for a digital intervention targeting stress, depression, and burnout, however many developers of digital interventions do not consider digital divides, in terms of access, literacy, and skills [30]. Two reviews focused specifically on interventions for health care workers Park et al [19] and Drissi et al [18] during the time of the COVID-19 pandemic. Both reviews highlighted the lack of high-quality studies in this specific workforce population, and the poor methodological quality of studies to date. The prevalence of mental health disorders and levels of help-seeking vary among employees within different occupational groups and industry sectors, combined with a lack of robust evidence

XSL•FO
RenderX

and best practices to determine which interventions are effective for specific industry sectors [8] highlighting an urgent need for future research in this area.

One review focused on studies that tailored or personalized interventions, including recommending content based on user screening, and material being tailored based on user characteristics and use data. Tailoring or personalization of digital tools to suit the needs of different populations is still uncommon but could have a significant impact [30]. Future research therefore should consider personalizing or tailoring their interventions which should include the preference of the service user while evaluating the effectiveness within different industry sectors and occupational groups.

The use of artificial intelligence (AI) and machine learning (ML) within digital mental health may have the potential to make interventions more personalized, and proactive. For example, recommender systems typically rely on AI to process large amounts of personal data these digital mental health interventions generate, to provide users with relevant services or information. AI and ML have also been applied in early detection of mental health [31] by analyzing large amounts of data, to detect early signs of mental health issues. This has the potential to then trigger the automated deployment of just-in-time interventions [32] or ecological momentary interventions [33] delivering the right support to an employee at the right time.

Key ethical considerations have been highlighted with using AI and ML in mental health [34] including lack of explainability, data privacy, ensuring users have control over their data, and understanding how it is used. Data privacy is particularly important in the context of employee's using digital mental health interventions within the workplace, as employees need to understand if data are shared with management or health insurers [35].

Previous studies have shown the positive impact of guidance or human support supplementing a digital intervention [7] whereas the review of stress reduction interventions by Phillips et al [1] found the treatment effect was significantly increased by guidance. However, in contrast, the review by Carolan et al [23] found no significant difference between interventions that had guidance and those that did not. Torous et al [30] have identified the pressing research need to assess the "optimal degree and mode of human support necessary" to make digital interventions more effective.

Many reviews did not report on factors increasing engagement, user experience, or preference where the primary aim was evaluating effectiveness. However, the review by Carolan et al [23] suggests interventions that are shorter (6 to 7 weeks), and use notifications and tailoring to the user, may increase engagement with the intervention. Vertola et al [12] reiterate that studies that used reminder notifications such as push notifications or emails, led to improved adherence to digital interventions. Furthermore, Vertola et al [12] suggest that a short demonstration or tutorial before the first use would improve the user experience and promote ease of use and acceptance.

Although quality assurance is not included in the scope of this review, it is important to note that when implementing digital interventions employers should be aware of best practices and standards such as Organization for the Review of Care and Health Apps. Furthermore, this review looked at effectiveness rather than cost-effectiveness, and future studies should consider return on investment as an outcome, due to the large economic impact mental health in the workplace can have. Table 3 summarizes the key findings, and details recommendations for both policy and practice and future research.

Table 3. Key findings and recommendations.

Key findings	Recommendations
Personalization of digital interventions was found to be effective in improving employee mental health and well-being.	Consider personalizing and adapting digital interventions to suit the needs and preferences of different populations and industry sectors.
There is no consensus on the differential impact of the mix of human and digital on the effectiveness of an intervention.	Further research needs to be undertaken to understand the right blend of digital and human engagement for mental health in the workplace.
Mindfulness is the most effective generic well-being intervention for employees, and psychoeducation alone is the least effective.	Consider incorporating mindfulness-based interventions into employee well-being offerings, including trauma-informed mindfulness for specific occupational groups.
There is high heterogeneity in outcome measures used, with 108 different scales documented within the reviews.	Consider the outcome measures that were used in previous similar studies. Otherwise, consider how the different outcome measures used in previous studies can be harmonized for meta-analysis and benchmarking.
The effectiveness of the intervention is the same regardless of the platform used, whether web-based or mobile apps.	Consider all types and technologies of digital platforms to maximize reach.
There is a lack of robust evidence and best practices to determine which interventions are effective for specific industry sectors.	Robust research, such as randomized control trials need to be undertaken to clearly understand the efficacy of digital mental health interventions across different workplace populations.

Conclusion

This umbrella review aimed to critically evaluate, synthesize, and summarize evidence of various digital mental health interventions available within a workplace setting. Broadly speaking the most common types of digital intervention being used in the workplace can be categorized as CBT-Based, Mindfulness, Stress management interventions, and other self-help interventions. The demand for talking therapies has more than doubled over the past decade reaching an all-time high of 1.83 million referrals in 23/24 [36], and where access has become a key public health concern. To help meet the increased demand the National Health Service is exploring the use of National Institute for Health and Care Excellence recommended "digitally enabled" evidence-based therapies for depression, anxiety, and trauma-related disorders potentially freeing up thousands of resource-intensive therapist hours [37].

This review provides tentative evidence that digitally enabled therapies could be usefully deployed in a workplace setting to help address work-related stress, depression, or anxiety, which, in 2022 and 2023 was the 5th most common reason given for sickness absence, accounting for an estimated 7.9% of all absences, equating to 17.1 million working days lost and costing UK employers an estimated £42 billion (US $52.6 billion) to £45 billion (US $56.4 billion) annually [38].

Digital interventions were found to moderately reduce the symptoms of stress, anxiety, depression, and burnout and increase psychological well-being. Interventions based on theory, and recruitment within the community increased effectiveness. Studies vary greatly in the outcomes they report on, and the tools used to measure these. The most effective type of intervention for generic well-being across all employee populations was mindfulness-based interventions.

Personalization or tailoring of digital interventions was found to be an effective way to improve employee well-being, and future research into this area could have a significant impact. The review found mixed and conflicting evidence on the role and impact of self-guided compared with guided help for increasing effectiveness. Further high-quality research that systematically investigates these issues in more detail could significantly add to the growing evidence base and inform best practice guidelines for developing and implementing effective digital interventions in the workplace.

Strengths and Limitations

To the best of our knowledge, this umbrella review provides the first systematic synthesis of systematic reviews on digital interventions for mental health in the workplace. The review has several strengths as well as limitations.

The rigor, robustness, and strength of the findings depend on the quality of the studies that were included in the initial systematic reviews and meta-analysis where, using the AMSTAR-2 quality assessment, 7 of the 14 reviews were found to be low, and 7 critically low. The latter was largely attributable to one critical item which required authors to list all potentially relevant studies that were read in full-text form but excluded from the systematic review along with a justification for why they were excluded. This one critical item dropped the overall quality rating of 5 reviews from moderate to low, and one from high to low, introducing the significant risk of inherent bias. Furthermore, because many of the reviews focused broadly on general workplace populations it is possible individual studies were repeated within all the numerous reviews considered.

Finally, the heterogeneity of the various and numerous outcome measures is problematic, while it is also unclear to what extent the largely small to moderate, statistically significant effect sizes translate into clinically meaningful change—improved functioning. For the above reasons it is therefore important to exercise caution when interpreting the results.

Despite the above limitations, the umbrella review including only systematic reviews provides a useful summary and synthesis of the best available evidence on mental health workplace digital interventions for a large population of employees. In addition, extracting and synthesizing the reviews on different populations and occupational groups for example health care professionals and general workforce sectors will help fine-tune and adapt interventions for specific groups alongside identifying gaps in the research knowledge base to guide areas for further systematic exploration.

Conflicts of Interest

GC is an Industrial Fellow supported by the Royal Commission for the Exhibition of 1851 affiliated with Ulster University, and an employee in Inspire, a mental health social enterprise. DC and AB are also employees in Inspire. There are no other conflicts of interest.

Abstract

Background: In the interest of accurately assessing the effects of digital technology use in early childhood, researchers and experts have emphasized the need to conceptualize and measure children's digital technology use beyond screen time. Researchers have argued that many patterns of early digital technology use could be problematic, resulting in the emerging need to list and examine their measures.

Objective: We aimed to review existing empirical literature that is using measures for problematic digital technology use in preschool children with the end goal of identifying a set of reliable and valid measures, predicting negative outcomes for children's health, development, or well-being.

Methods: We conducted a scoping review across the Web of Science, PubMed, and Google Scholar databases to identify peer-reviewed publications that were published from January 2012 to December 2023, were written in the English language, described an empirical study, and included a measure of problematic digital technology use beyond exposure (ie, screen time) in children aged 0 to 6 years.

Results: The search yielded 95 empirical studies, in which 18 composite measures of problematic use and 23 measures of specific problematic use aspects were found. Existing composite measures conceptualize problematic use as either a group of risky behaviors or as a group of symptoms of a presumed underlying disorder, with the latter being more common. Looking at their conceptual background and psychometric properties, existing composite measures fall short of reliably assessing all the crucial aspects of problematic digital technology use in early childhood. Therefore, the benefits and shortcomings of single-aspect problematic digital technology use measures are evaluated and discussed.

Conclusions: On the basis of current research, early exposure to digital technologies, device use before sleep, and solitary device use represent measures that have been consistently associated with negative outcomes for children. In addition, potential measures of problematic use include device use during meals, device use for emotional regulation, device multitasking, and technoference, warranting further research. Public health benefits of defining problematic digital technology use as a group of risky behaviors rather than a group of addiction symptoms are discussed.

Introduction

Background

Children are growing up in environments that have become increasingly saturated with various digital devices. According to a 2020 report on media use of children aged 0 to 8 years in the United States [1], 46% of those aged 2 to 4 years and 67% of those aged 5 to 8 years own a mobile device (ie, tablet or smartphone). The average daily screen time is 2.5 hours for children aged 2 to 4 years and 3.1 hours for those aged 5 to 8 years. The same data show that many children are being regularly exposed to screens even earlier; on average, they spend 49 minutes per day looking at a screen in the first 2 years of

XSL•FO
RenderX

their lives. In addition, most of this screen use occurs in the absence of parents, with the likelihood of parental coviewing drastically decreasing with increasing age. The data also show that nearly three-quarters of screen time is spent watching video content, while reading, homework, and video chatting represent only 5% of children's screen time. Furthermore, the data from the United Kingdom confirms that children in the United Kingdom are no exception since 48% of those aged 3 to 4 years and 57% of those aged 5 to 7 years owned a tablet in 2020, while 90% of those aged 3 to 4 years and 88% of those aged 5 to 7 years watched video-on-demand content [2].

Many stakeholders have expressed concerns about the potential harms associated with excessive screen use in early childhood. In 2016, the American Academy of Pediatrics issued a policy statement concerning media use in early childhood [3], recommending that children aged <18 to 24 months avoid digital media altogether. They argued that children aged <2 years require "...hand-on exploration and social interaction with trusted caregivers to develop their cognitive, language, motor, and socio-emotional skills," while they cannot learn from traditional digital media in the same way. They stated that children aged 2 to 5 years should limit screen use to 1 hour per day of high-quality screen time, coviewed by parents to help them understand what they are seeing. The guidelines on screen use in children, published in other countries (eg, World Health Organization guidelines [4], Canadian guidelines [5], and Indian guidelines [6]), mostly followed the daily screen time limit recommendations for each age group.

However, the screen time restriction approach has been criticized, as many researchers and experts [7] argue that the existing scientific evidence is not conclusive enough to suggest appropriate amounts of screen use or preferable web-based activities for children of different ages. A brief look at systematic literature reviews on the effects of screen exposure on various outcomes in those aged 0 to 6 years reveals largely correlational evidence of the effect on adiposity, obesity, or BMI [8-10]; cognitive development [8,11]; psychosocial health [8]; and sleep duration [10]. However, to our knowledge, this evidence is yet to provide support for the suggested thresholds above which screen time is reliably detrimental to children. In a large study on 19,957 parents of children aged 2 to 5 years, authors found no empirical support for well-being benefits for children following the American Academy of Pediatrics screen time recommendations [12]. Researchers have argued that screen time, defined as the duration of exposure to digital devices, misses the content and context of digital technology (DT) use and is likely too broad and simplistic to be used as a stand-alone measure [13-15].

Owing to the shortcomings of screen time, the concept of problematic media use, defined as "...excessive use that interferes with the child's functioning" [16], has gained momentum in the scientific community (eg, [17-19]). The focus on impairments in functioning is crucial to differentiate normal variation from a pathological level of behavior [16]. First, while we concur with the emphasis on functioning impairments, we will instead be referring to problematic DT use (PDTU), since the term "media" can also refer to traditional means of communication (eg, newspaper and radio) or collective institutions engaged in mass communication [20], both of which are erroneous interpretations of the concept. Second, we emphasize that although interference with functioning can certainly happen due to "excessive use" of DT, both the content and context of children's DT use are arguably just as problematic. Thus, we suggest defining PDTU as any pattern of DT use that interferes with the child's functioning.

Although the importance of content and context may seem rather obvious, contemporary research practices implied otherwise; a systematic review of 622 screen use measures in children aged 0 to 6 years [21] found that only 10.8% of these measures considered content and only 7% considered coviewing (ie, a measure of context). Importantly, this preference for exposure measures does not extend to older children and adolescents; a scoping review of empirical studies published between 2014 and 2019 by Browne et al [22] identified 162 measurement tools of DT use in children, adolescents, and young adults, most of these targeting problematic or excessive and addictive use beyond exposure. Among the 162 identified tools, only 5 were intended for preschool children, 3 of which came from gray literature. Evidently, despite many public concerns about harms associated with early DT use, most established and validated measuring tools of PDTU are intended for adolescents or adults, while instruments for young children are substantially less common. More recently, a systematic review by Rega et al [23] aimed to identify PDTU measures for children aged <10 years and found 9 parent report measurement tools aimed at children aged <6 years but did not analyze their content or psychometric properties. In conclusion, the various ways in which researchers have attempted to measure problematic media use in young children have not yet been critically reviewed and synthesized. In our view, this procedure is absolutely necessary to eventually arrive at comprehensive, valid, and cost-effective measures for children's PDTU, which itself is a prerequisite for effective screening, prevention, and treatment of at-risk children.

Objectives

On the basis of these insights, we aimed to review existing empirical studies, which included measures of PDTU in early childhood (ie, children aged 0 to 6 years) beyond screen time. Since our primary objective was to list and describe the various existing measures and operationalizations of the proposed concept (ie, PDTU) rather than answering a specific research question, we opted for a scoping review rather than a systematic review. The idea was to describe each measure or instrument in terms of its content, psychometric properties, and the negative outcomes it could lead to based on the results of each included study. Ideally, the goal was to arrive at a set of measures of PDTU for young children, which are psychometrically sound (ie, reliable and valid) and shown to be related to certain undesirable outcomes (eg, behavioral or emotional problems, deficiencies in terms of development, health, and well-being). Finally, we aimed to search beyond the developed measurement tools, seeking to identify the various single-item measures used by researchers to assess particular PDTU practices in preschool children.

RenderX

Methods

Protocol and Registration

This study followed the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) protocol [24]. The final version of the protocol was agreed upon by all authors and was not preregistered.

Eligibility Criteria

The publications considered for review had to meet the following requirements: (1) peer-reviewed scientific publications; (2) published within the past 12 years (studies dating from January 1, 2012, to December 20, 2023); (3) written in the English language; (4) describing an empirical study; (5) including a measure of PDTU; and (6) conducted with the population of young children aged 0 to 6 years.

In addition, studies, which conceptualized and measured PDTU solely in terms of screen time, were excluded for reasons put forth in the Introduction section. Similarly, questions about which digital devices a child uses and to what extent (eg, minutes of use per day for each device type) were deemed overly simplistic, experiencing the same drawbacks as screen time. Finally, questions about the content the child usually engages in and to what extent (eg, minutes per day for each content type) were also not considered to be sufficient measures of PDTU. This is partly due to the vast variability of potential user experience that exists within a single content category (ie, "educational" content, video games, and cartoons). Furthermore, our concern was that due to the rapid evolution of content, any findings about the extent of the "problematic nature" of certain content types would likely soon be out of date (ie, as noted by Viner et al [25]).

Information Sources

The search for relevant publications was conducted in the Web of Science, PubMed, and Google Scholar databases. Each of these databases was last searched on December 20, 2023.

The Search Strategy

The final search strategy consisted of 4 groups of keywords, separated by the Boolean operator AND (Table 1). Each keyword group refers to a certain concept, which may be represented by any of the listed keywords, separated by the Boolean operator OR. In addition, filters for the date of publishing (ie, January 1, 2012, to December 20, 2023) and language (ie, the English language) were applied to all searches.

Table 1. The full search strategy used to obtain relevant records.

Concept	Keywords
Measure	scale OR questionnaire OR tool OR inventory OR measure OR instrument
Problematic	problem* OR excessive OR patholog* OR overus* OR addict* OR compulsive OR dependen*
Digital technology use	"screen us*" OR "screen exposure" OR "screen viewing" OR "screen watching" OR "screen behavio*" OR "media us*" OR "media exposure" OR "media viewing" OR "media watching" OR "media behavio*" OR "digital us*" OR "digital exposure" OR "digital play*" OR "digital behavio*" OR "device us*" OR "device exposure" OR "smartphone us*" OR "smartphone behavio*" OR "smart phone us*" OR "computer us*" OR "computer exposure" OR "computer viewing" OR "computer watching" OR "computer play*" OR "computer behavio*" OR "tablet us*" OR "tablet play*" OR "laptop us*" OR "TV us*" OR "TV exposure" OR "TV viewing" OR "TV watching" OR "TV behavio*" OR "television us*" OR "television exposure" OR "television viewing" OR "television watching" OR "internet us*" OR "internet exposure" OR "internet behavio*" OR "video game us*" OR "videogame play*" OR "game us*" OR "game exposure" OR "game play*" OR "game behavio*" OR "gaming"
Young children	child* OR infant* OR toddler* OR "pre-school*" OR preschool* OR kindergarten*

In each database, the final search strategy was applied only to titles and abstracts, as opposed to full texts, of published records. In the case of Google Scholar, a simplified search strategy was used due to the character limit, containing only the most common keywords for each of the 4 concepts. We developed the version of the search strategy with our backgrounds in psychology and psychometrics. Afterward, we scanned the records obtained, and the search strategy was adjusted accordingly. The adjustments mainly consisted of adding new keywords for each concept and adjusting the existing keywords (eg, shortening phrases to include alternative expressions). After multiple iterations, we derived the final search strategy, which yielded a manageable number of seemingly relevant publications in all databases.

Selection of Sources of Evidence

All publication titles from the list of unique records were screened by 1 researcher using the inclusion and exclusion criteria. If eligibility was unclear based on the title, the abstract was read. When ambiguity remained (eg, age of children not specified), the publication was included for full-text review. In case of dilemmas, other authors were consulted, and disagreements were resolved collectively.

XSL•FO
RenderX

When screening titles, we included records mentioning the use of DTs of some kind (eg, internet use, gaming, and television viewing) among children. If the target population was described as "adolescents," "teenagers," "school-aged children," or "students," the record was excluded without reading the abstract. Studies of older children, adolescents, or young adults who assessed their DT use in early childhood retroactively were excluded. If the title mentioned the term "review" or "meta-analysis," the study was excluded from our selection. If we discovered that a certain record does not refer to a peer-reviewed paper during the screening process, it was excluded from our selection. Titles referring to using DT for educational or therapeutic purposes were excluded from the selection. No automation tools were used for screening.

During the full-text review, studies on children outside the specified age range were excluded. Studies with mixed age samples were retained if measures for the target population were present, although outcomes and risk factor correlations were not reported, as they may not necessarily apply to children aged <6 years. Records were excluded if they used questionnaires that were not fully accessible; focused solely on screen time, devices, or content type; lacked key information; or were not in the English language.

Data Charting Process

The first version of the data charting form, that is, its items and response categories for each item, was developed based on the study objective and was agreed upon by all authors. This version was pilot-tested by attempting to fill in the data for the first 20 full-text records on our list. On the basis of our findings, we made no changes to data items. However, we did adapt or add certain response categories for each item. The data charting was performed with the Excel (Microsoft Corp) software. Two researchers independently reviewed each eligible record and extracted data according to the previously established response categories in the charting form. Any inconsistencies regarding record eligibility or minor discrepancies in reported findings were identified and resolved on a case-by-case basis through discussions among the authors. While formal interrater reliability testing (eg, Cohen κ) was not conducted, we ensured consistency through regular meetings to discuss and resolve discrepancies, thereby maintaining a high level of reliability throughout the data extraction process.

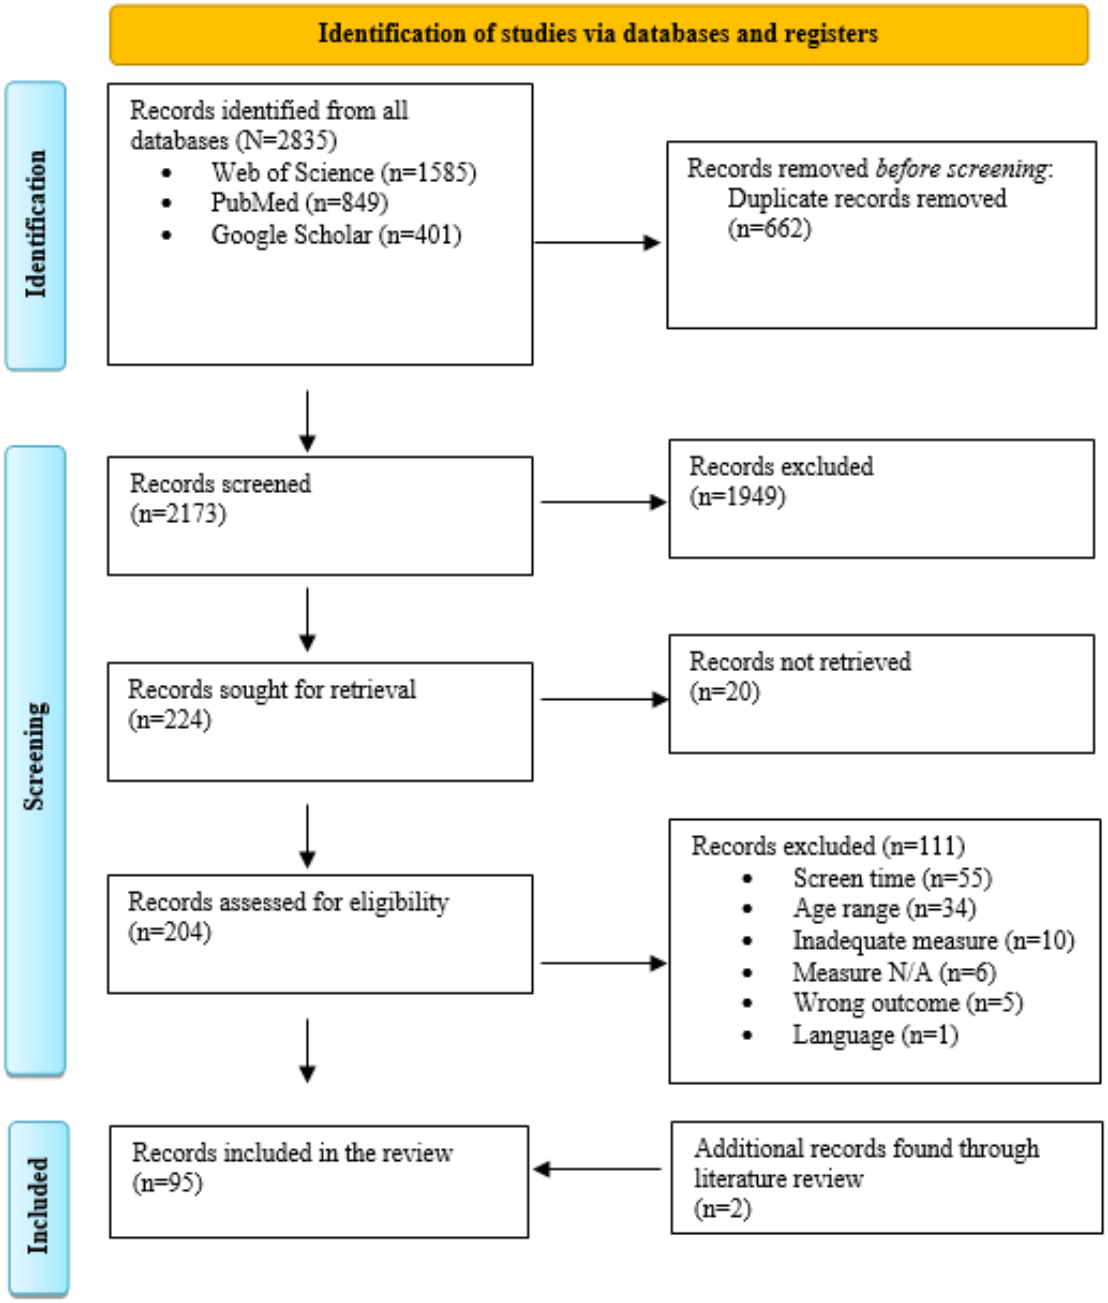
Data Items

The data from each eligible record, available in full text, were extracted according to the following items:

- Year of publishing
- Countries where data collection took place
- Developmental period: infants (ie, aged 0-1 year), toddlers (ie, aged 1-3 years), preschoolers (ie, aged 3-6 years), school-aged children (ie, aged 6-11 years), and adolescents (ie, aged >11 years)
- Population: the specifics of the population, other than age, for example, general population, children with attention-deficit/hyperactivity disorder, and children with dyslexia
- Sample size
- Study type: cross-sectional, longitudinal, quasi-experimental, and questionnaire development
- Format of instrument: survey, diary, observation, and interview
- Measures of PDTU: for example, use before sleep and early exposure
- Risk factors: demographic or population groups with more risk
- Adverse outcomes and correlates: outcomes associated with a certain aspect of children's DT use. Only statistically significant findings are listed.
- Psychometric properties: reliability and any indicators of validity. Positive correlations with a separate PDTU measure (or screen time) serve as an indication of validity.

Synthesis of Results

The evidence is presented in a table format, in 3 tables. Multimedia Appendix 1 [26-119] lists all papers included in the final selection and summarizes their key characteristics (eg, year of publishing, sample characteristics, and country) and the measures of PDTU that were used. Due to conceptual similarities among many single-item PDTU measures, we grouped them into categories (eg, age of first smartphone use, age of first television use, and use of DT before 1 year of age were classified as measures of early exposure).



Results

Selection of Sources of Evidence

The process of identifying papers that meet the eligibility criteria is shown in Figure 1.

XSL•FO
RenderX

Figure 1. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart describing the process of selection of studies. N/A: not available.

Study Characteristics

For each of the 95 identified papers, certain characteristics were extracted and summarized in a table format (Multimedia Appendix 1). In most (n=85, 89%) studies, PDTU measures were intended for preschool children. A total of 40 (42%) studies also considered toddlers as their target group, while only 7 (7%) studies included infants. A large majority (n=86, 91%) of studies were conducted with children with no particular specifics or deficits. Most (73/95, 77%) of the conducted studies could be described as cross-sectional, while only 6 (6%) were longitudinal. In addition, 6 (6%) studies used an experimental research design and a further 10 (10%) studies described questionnaire development. The findings of all longitudinal and experimental studies were discussed separately to assess the causal relationships of PDTU measures to relevant outcomes.

Characteristics of PDTU Measures

Overview

In the 95 identified papers, a variety of aspects of PDTU were measured. Table 2 lists 23 distinct categories of PDTU measures found in the selected papers. It presents key characteristics for each measure for PDTU (eg, description and format), as well as all correlations with various risk factors and outcomes found in the papers.

[a]The negative sign indicates a negative correlation between a risk factor or outcome and PDTU measure.

[b]Longitudinal associations are italicized.

[c]Data not available.

Of 95 studies, 29 (30%) used a composite measure of PDTU (ie, developed psychometric instruments and labeled problematic use), which contained multiple PDTU aspects within a single measurement tool. The most common among single-item measures used was early exposure (n=24, 25%), followed by restricted use (n=22, 23%) and couse (n=20, 21%).

In terms of measurement format, survey-based measures of PDTU were by far the most common. Each of the listed PDTU measures existed in survey format in at least 1 study. In total, 34% (8/23) of the PDTU measures used a nonsurvey format in at least 1 study. The data for 17% (4/23) of the measures were obtained through an interview, 9% (2/23) through a diary format, and 9% (2/23) through observation. For each PDTU measure, data were obtained on preschool children (aged 3 to 6 years) in at least 1 study. A large proportion (16/23, 78%) of measures was also applied to toddlers (aged 1 to 3 years). Less than a third (7/23, 30%) of all measures were used in studies, which included infants (aged 0 to 1 year).

Risk Factors

The most commonly reported demographic risk factor for PDTU was lower parental education (ie, either maternal or paternal). Of the 23 PDTU measures, negative associations with parental education were found for 7 (30%) measures or 70% (n=16) of all measures for which any risk factors were reported. In addition, being a male participant was found to be a risk factor for 3 (13%) measures and having autism spectrum was found to be a risk factor for 2 (9%) measures. The child's age was a risk factor for 3 (13%) PDTU measures, although both lower and higher age were found to be risk factors, depending on the particular aspect (Table 2).

Detrimental Outcomes

PDTU measures were associated with 28 unique, undesirable outcomes. Of 23 measures, 11 (48%) were found to be associated with behavioral-emotional difficulties of children, while 7 (30%) were correlated with developmental outcomes (eg, deficiencies in language, cognition, or motor development). A total of 6 (26%) measures were associated with undesirable habits (eg, poor sleeping and eating habits or delaying needs),

XSL•FO
RenderX

and another 3 (13%) measures were associated with physical outcomes (eg, obesity and vision problems).

Findings From Longitudinal Studies

A longitudinal study by Supanitayanon et al [32] showed that delayed introduction to DTs (a measure of early exposure) and verbal interaction during media use in the first 2 years of life (ie, a measure of instructive mediation) significantly predicted a child's cognitive development at 2, 3, and 4 years of age. A longitudinal study by Srisinghasongkram et al [51] showed that screen media multitasking at 18 months (ie, device multitasking) is associated with decreased preschool cognition at 4 years and behavioral problems at 4 and 6 years. In a longitudinal study by Radesky et al [70], bidirectional cross-lagged correlations between using devices for calming purposes and emotional reactivity (ie, instability) were found, specifically in boys and children with higher temperamental surgency. A study by Coyne et al [56] showed a longitudinal association between 2 PDTU measures: restricted use was associated with lower problematic use. A study by Gueron-Sela et al [77] showed no longitudinal relationship among screen time, background exposure to DTs or using DTs for emotional regulation during lockdown periods, and children's behavioral problems after lockdown.

Instrument Characteristics

Overview

Among the measures of PDTU, we identified 18 multi-item measures of problematic use, which were either fully available or had their items described in sufficient detail. The most commonly used was Problematic Media Use Measure–Short Form (PMUM-SF), used in 9% (9/95) of the studies. All other instruments were used in 1 or 2 studies at most. All the identified instruments were applied to preschool children (aged 3-6 years) in at least 1 study. Only 22% (4/18) of them were also tested on toddlers (aged 1-3 years), while no instrument was used in studies on infants (aged 0-1 year). Table 3 summarizes important characteristics (eg, theoretical background and psychometric properties) of all measurement tools targeting PDTU.

Content, Factors, and Background

Interestingly, of the 18 instruments, 7 (39%) primarily targeted behavioral patterns of children's DT use and were named "media use" or "exposure" measures [58,60,63,79,80,84,86-88]. The other 11 (61%) instruments could be said to measure symptoms, or consequences, of a presumed underlying condition, and 7 (39%) of these were self-declared as measures of either "addiction," "disorder," "overdependence," or "problematic use" [39,52,55,56,59,61,62,64,66,67,73,78,81-83,85,89,90]. Looking at the proposed factors and content categories of the instruments in Table 3, there is a great deal of variety: no 2 instruments (except Problematic Media Use Measure, which exists in a longer and shorter form) shared the same set of factors or content categories. Factors ranged from typical behavioral addiction symptoms (eg, preoccupation, tolerance, and continued use despite problems); various consequences of DT use (ie, "physical ill health," "adverse outcomes," and "effect on development"); behavioral patterns (ie, frequency of DT use and DT use before sleep); psychological constructs (ie, "cyberspace-oriented relationship," "personality distortion," and "implicit attitudes"); characteristics of the environment (ie, "digital media environment at home"); parental behaviors and attitudes (ie, parental DT use and awareness); and others. In terms of the theoretical background, 61% (11/18) of the instruments derived the item content, at least in part, from the literature on adolescents or adults.

Reliability and Validity

Of 18 instruments, 11 (66%) reported adequate reliability according to the values of reliability coefficients, which were >0.70, 4 (22%) did not report any measures of reliability, and 2 (11%) reported low reliability, on at least 1 factor. The most commonly used instrument (PMUM-SF) also contained the most information regarding its validity, such as structural validity, criterion validity, and measurement invariance. The information supporting the validity of all other instruments was partial at best.

Discussion

Shortcomings of Existing PDTU Instruments

Our scoping review showed that there are many patterns of children's interaction with DTs beyond quantity of use, which can be seen as problematic in terms of their potential for negative consequences for children. It seems that PDTU should be understood as a multifaceted construct containing much more than excessiveness of use. A crucial observation we made during our review is the distinction between conceptualizing PDTU as a group of risky behaviors (ie, various ways of using DTs), which are likely to lead to negative outcomes, or as a group of symptoms of a presumed underlying condition (ie, addiction to DT). Existing composite measures for PDTU (ie, scales and questionnaires) have represented both conceptualizations, with the symptom view being more common. However, when proposing symptoms of a new disorder, the primary information source should, in our view, be clinical observations of multiple experienced mental health professionals working with young children. Instead, items of the reviewed PDTU instruments have mostly been generated based on reviewing the literature, commonly from established behavioral addictions in adolescents or adults, or through adapting established instruments intended for older children. In some cases, clinicians were later consulted to propose any necessary changes to items.

The PMUM-SF was the most commonly used instrument in empirical research and consists of various "symptoms" of problematic use in line with other reviews [120]. It was shown to be adequately reliable and correlated with various PDTU measures, while there is also some evidence regarding its structural validity and ability to predict relevant outcomes. However, some arguments against its validity can be made. First, its content is based on the Diagnostic and Statistical Manual of Mental Disorders–fifth edition criteria for internet gaming disorder [121], for which there is a lack of expert consensus [122]; in fact, several of them (eg, tolerance, withdrawal, and deceiving others) were later discarded from the International Classification of Diseases–11th edition definition of gaming disorder [123]. Second, the concept of

XSL•FO
RenderX

PDTU extends beyond the realm of gaming and is, therefore, likely to manifest differently. Third, the criteria for internet gaming disorder were proposed for the adult or adolescent population and should not be expected to function well for the population of preschool children. Finally, Problematic Media Use Measure was originally validated on a sample of children aged 4 to 11 years, or even up to 14 years, for which significant diversity of PDTU can be expected. Unsurprisingly, some of its factors seem inappropriate for preschool children (eg, "jeopardized or lost a relationship or had compromised functioning in school due to use" and "continued use despite psychosocial problems"). Looking at the other 17 reviewed measures, both comprehensiveness and justifications for their proposed content or factor structure, as well as the presented evidence regarding the instruments' validity, leave much to be desired. In our view, current evidence does not yet point toward a single comprehensive, reliable, and valid measurement tool for any of the 2 PDTU conceptualizations we observed in infants, toddlers, or preschool children.

Risky Behaviors Versus Addiction Symptoms

Remaining consistent with our proposed definition of PDTU as any pattern of DT use that interferes with children's functioning, we argue for defining PDTU through a collection of risky behaviors. This approach offers several benefits. First, focusing research efforts on developing, measuring, testing, and refining the PDTU concept in this way would yield valuable insights into the most significant ways children use DTs to their detriment. From a public health perspective, this focus has great potential to aid prevention efforts aimed at reducing the incidence of PDTU in children and the harm it causes. With high-quality evidence about the risks associated with specific DT practices, the effectiveness of awareness campaigns among parents and the screening of children for risky behaviors could be greatly improved. In contrast, adopting the addiction view of PDTU would do little to identify preventable DT practices causing harm, while screening for "addiction" symptoms would likely identify children with significant impairments in functioning, which is a notably delayed point from a prevention standpoint.

Summary of Reviewed Single-Item Measures

Overview

Besides existing instruments, this review uncovered many potential single-item measures of PDTU. Notably, patterns of DT use are rarely directly observed in empirical research; instead, most (89/95, 94%) identified measures exclusively consisted of parents or caretakers recollecting their children's behavior over a certain period. Similar findings have previously been reported [124]. Parent reports can be biased, as 1 study showed that parental reporting of coviewing, screen time limits, and active mediation were all significantly higher than the reports of their school-aged children for the same measures [125]. Still, parental reporting is considered accurate for screening and assessment of young children, especially for observable behaviors [126] and is the most practical solution for children aged 0 to 6 years. In the subsequent sections, we provide some insights regarding key PDTU measures, which should be considered by both professionals and researchers when attempting to comprehensively assess children's PDTU.

Early Exposure

Measures of early exposure to DTs have been operationalized as either age of first DT use or the amount of use before a certain age (eg, screen time before the age of 1 year or 2 years). Our review examined multiple (8/95, 8%) studies where associations between early exposure and the likelihood of undesirable outcomes (eg, poor cognitive development and eyesight issues) were found, which included 2 longitudinal studies. Within the literature not included in this review, sleep problems and obesity were also highlighted as outcomes of early exposure [127]. Interestingly, higher family income and parental education were associated with earlier first exposure to DTs, contrary to the findings of Kılıç et al [128]. Considered together, these findings suggest that early exposure is one of the more evidence-based PDTU measures currently available and should be considered in any assessment of children's PDTU.

Device Use Before Sleep and Devices in the Bedroom

Device use before sleep referred to the frequency of DT use before going to bed, typically within 1 hour of bedtime. Devices in the bedroom are operationalized as the number of usable digital devices present in the room where the child sleeps. Although the latter is a less-direct measure of children's DT use, it was included in our review due to the reasoning that the presence of digital devices in the bedroom leads to a higher likelihood of unsupervised DT use or a higher likelihood of DT use before bed. In our reviewed studies, both measures were found to be associated with multiple measures of sleep quality. This finding was consistent with research showing the effect of these same PDTU measures on sleep quality in preadolescents and adolescents [129,130]. Particularly, due to the likelihood of their effect on sleep, we suggest including at least 1 of these 2 measures in the process of children's PDTU assessment.

Couse or Solitary Use and Instructed Use

Cousing DTs, or rather, a lack of cousing, was one of the more common PDTU measures and refers to the extent to which DTs are used together with caregivers or siblings, sometimes as the ratio of total screen time. Cousing was positively associated with multiple measures of language development and with social development. The positive association between cousing and learning has also been found in previous studies [131]. Cousing was negatively associated with a child's emotional liability, indicating the potential benefits of cousing DTs on the one hand and the risk of children's solitary use on the other hand. A related PDTU measure was instructed use, that is, the frequency of parents helping children understand and navigate through digital content with the help of instructions and explanations, which can be considered a cousing measure as well. Instructed use in the first 2 years of life was associated with cognitive development at the age of 2, 3, and 4 years in a longitudinal study [32] but not with any other outcomes. On the basis of these findings, we suggest including some measure of cousing DTs into the process of assessing children's PDTU, whether in the form of general couse or instructed use. Alternatively, the

XSL•FO
RenderX

amount of unsupervised, solitary DT use may also be worth exploring as an operationalization of the same concept.

Device Use During Meals

Of 95 studies, 10 (11%) measured the frequency of DT use during mealtime. Only 1 (1%) study reported a positive correlation with weight, and another reported a correlation with feeding difficulties and time spent eating. The 2 other correlates (ie, difficult temperament and poor motor development) were less likely to be direct consequences of device use during meals. While these findings on preschool children were hardly conclusive, an experimental study on children aged 9 to 12 years [132] showed that children watching television while eating spent more time eating and consumed more calories than children in the control group, indicating device use during meals disrupts habituation and often leads to higher energy intake. This finding was also supported by a cross-sectional study [133]. Thus, researchers and professionals assessing PDTU may want to consider including a measure of device use during meals in the PDTU assessment process.

Technoference

Technoference is a relatively new concept and refers to the frequency of interruptions in parent-child interaction due to DT use. Despite being studied in only 2% (2/95) of the papers, technoference in a parent-child relationship showed significant associations with behavioral problems, psychosocial difficulties, and lower prosociality of the child. These findings are consistent with previous studies [134,135]. Importantly, 1 (1%) paper [76] distinguished between technoference due to a child's DT use and technoference due to a parent's DT use. In our review, only the former was considered a measure of children's PDTU. These initial findings suggest that technoference may present an important aspect of PDTU and should be studied further.

Restricted Use

One of the most commonly studied single-item measures, restricted use, often called restrictive mediation, refers to parents' use of rules and restrictions regarding their child's DT use. Contrary to our expectations, more restricted use was associated with 2 negative rather than positive outcomes. On the other hand, restricted use was associated with less-problematic use in 2% (2/95) of the studies, one of which was longitudinal. Furthermore, some other studies suggested positive consequences of restrictive mediation [136]. We propose that these inconsistent correlations may be due to cases where parents manage to limit children's DT use more spontaneously or due to parents being more likely to resort to explicit rules and restrictions once their children's behavior becomes problematic. While setting explicit rules and restrictions regarding children's DT use is generally considered good advice to parents, the absence of such explicit rules and restrictions may not work well as a measure of PDTU. Finally, this finding suggests that less-direct measures of PDTU, such as restrictive mediation, which primarily measures parent behavior, may be inadvisable.

Purpose of DT Use

Quite commonly, researchers asked parents and caregivers regarding the purpose for which devices were given to children (eg, for education, entertainment, regulation of a child's emotions, or practical purposes). Using DTs for emotional regulation yielded significant longitudinal relations with a child's emotional stability in 1 study, which was also found in studies on adolescents [137]. Because using substances or behaviors to improve one's mood is also among the criteria for many addictions, this PDTU measure should certainly be considered and explored further. Educational use, use for entertainment, and instrumental use did not turn out to be effective predictors of negative outcomes for children, as only one such outcome was found across these 4 PDTU measures. As mentioned earlier, we propose that this is due to them being less-direct measures of children's PDTU, through which children's PDTU might be deduced. A potential issue with purpose-of-use measures is that despite providing insight into how children use DTs at the start of the session, the pattern of their interaction with DTs may change soon after, regardless of parents' initial intentions.

Background Exposure

Only 1 (14%) out of 7 studies, which included a measure of background exposure (ie, the amount of child's passive exposure to DTs, turned on in the background), reported associations with negative outcomes. One potential issue with this measure may be that, since children likely switch between active and passive exposure quite commonly, it is probably difficult for parents to keep track of, recollect, and accurately assess background exposure.

Consequences of Device Use

PDTU measures that described mostly short-term consequences of DT use, such as emotional reactivity, perceived effects of device use, conflict due to device use, and concerns about a child's device use, did not yield any correlations with undesirable outcomes. While this is almost certainly due to the limited number of studies testing such associations, a potential issue of these variables as measures of PDTU is that the likelihood of various consequences always depends on factors beyond patterns of DT use, such as child temperament, parents' personality traits and attitudes, and family dynamics.

Other Measures

For other PDTU measures, listed in Table 2, fewer or no findings regarding their associations with negative outcomes, other PDTU measures, or demographic factors were found. Since this may have been due to the lack of empirical work using these measures, more research is suggested to conclude their usefulness and predictive potential.

Practical Implications

The findings of this review provide valuable insights into the concept of PDTU and how it should be measured and can thus serve a wide range of stakeholders, such as researchers, public mental health professionals, clinicians, educational professionals, policy makers, and others. The highlighted shortcomings of existing PDTU measures indicate the need for comprehensive, evidence-based, and standardized tools to assess early PDTU. The lack of such a tool challenges comparisons across studies and limits the development of evidence-based interventions, which has also been emphasized by other

XSL•FO
RenderX

researchers [23,120]. Therefore, the results of our study can serve researchers as a basis for the development of age-appropriate measurement tools, that is, tools targeting preschool children specifically, instead of adapting measurement tools intended for adolescents or adults. Moreover, the key criteria that these tools should follow are to measure PDTU as a group of risky behaviors rather than addiction symptoms since the former provides more benefits regarding identifying and mitigating harm. Furthermore, these findings can serve as a foundation for designing informed longitudinal studies to identify causal relationships among DT use behaviors and related long-term outcomes and to better monitor PDTU in the most susceptible populations, that is, infants, toddlers, and preschool children.

Furthermore, the results of this study can serve researchers and clinicians collaborating to develop assessment tools that ensure that symptoms and behaviors reflect clinical realities. The findings can enhance screening practices and inform clinicians on how to effectively include PDTU screening in routine developmental assessments to support early identification of potentially risky behaviors (eg, bedtime use, solitary use, or the use of DT for emotional regulation). Early identification and intervention can mitigate potential negative outcomes, such as developmental delays and mental health problems. In terms of policy and public health implications, the findings of the review can inform policy makers to support and promote the establishment, implementation, and advocacy of guidelines on DT use and the development and establishment of policies promoting healthy digital habits, especially for at-risk children and families. Meanwhile, public mental health specialists can use these results to design and implement targeted public health interventions, such as awareness campaigns and programs aimed at educating families about the potential risks associated with specific DT use practices.

Limitations

A key limitation of the findings resulting from our scoping review is the relative absence of firm evidence regarding the effects of any patterns of PDTU and certain undesirable outcomes. On the one hand, experimental and longitudinal research in this area is scarce, which means the conclusions are mainly based on correlational data from cross-sectional studies. On the other hand, even cross-sectional studies including PDTU measures beyond exposure are far from numerous for this population. Due to this, despite our recognition of the need to differentiate between findings and recommendations for infants, toddlers, and preschool children, we are currently unable to provide separate conclusions for each of these subgroups. In addition, due to our decision to only study measures of PDTU in children and due to most of these measures not including direct observation of behavior, a somewhat arbitrary decision had to be made regarding how indirectly a certain measure should target children's behavior to still be considered a measure of PDTU. We expect that only a considerable amount of high-quality psychometric analyses will eventually reveal ways in which PDTU can be measured and how it cannot be. Furthermore, our scoping review did not include a search of gray literature, as we expected that useful findings regarding the negative outcomes of PDTU measures are much more likely to come from peer-reviewed scientific papers, although some measures may have been missed on this account. Finally, as the primary purpose of our scoping review was the identification and description of various PDTU measures, we did not conduct any risk of bias analysis. Still, some of our conclusions partly depend on the extent of evidence regarding each measure, and thus, evaluating the risk of bias in each source of evidence would have been an added benefit.

Conclusions

In times when digital devices are increasingly accessible and used by children from infancy onward, researchers have begun to realize that screen time is likely not the optimal or sufficient way to assess the risk of troubling outcomes due to early device use. Our scoping review showed that many different measures of PDTU in early childhood exist, focusing on much more than mere exposure. While the extent of correlational evidence suggests that many patterns of DT use may be problematic, the number of displayed longitudinal effects on adverse outcomes is still insufficient to establish firm conclusions about their detrimental effects. Nevertheless, based on the findings of reviewed empirical studies, we recommend including the following measures in any assessment of children's PDTU: early exposure to digital devices, device use before sleep or devices in the bedroom, and cousing devices or its counterpart, solitary device use. Moreover, device use during meals, device use for emotional regulation, device multitasking, and technoference may be promising PDTU measures but would benefit from more research to confirm their predictive potential. Research regarding the effects of other PDTU measures beyond exposure is still relatively modest.

This review shows that a lot of work remains to be done to establish the key problematic patterns of DT use in early childhood and how these patterns should be measured. Using reliable, valid, and comprehensive measures in this area is a prerequisite to fully assess and gain insight into the short- and long-term impact of DTs on children's overall well-being. We urge researchers to use more quasi-experimental and longitudinal research designs, testing the effects of particular patterns of PDTU on children's health and well-being while keeping the ethical concerns of these studies in mind.

Acknowledgments

No funding was received to conduct this study. The authors would like to express their sincere gratitude to Maša Černilec from the National Institute of Public Health for her extensive support throughout the review process. Her insightful feedback and thorough contributions greatly enhanced the quality and clarity of this paper.

Authors' Contributions

ŠS and MŽ contributed to the study conception and design. The search strategy was prepared by ŠS and MŽ. MŽ, JH, and ŠS contributed to the selection of sources of evidence, data charting process, and synthesis of the results. The first draft of the manuscript was written by MŽ and ŠS, and all authors commented on previous versions of the manuscript. All authors read and approved the final paper.

Conflicts of Interest

None declared.

Abstract

Background: This scoping review examines the effects of various sound interventions, including music, natural sounds, and speech, on the stress response in adults.

Objective: The review aims to identify key therapeutic factors, including sound type, individual listener characteristics, and environmental influences. It also synthesizes evidence on physiological responses to sound interventions and highlights current research gaps.

Methods: We conducted a comprehensive search using databases such as PubMed, Web of Science, Scopus, and PsycINFO, focusing on studies from 1990 to 2024. Eligible studies included randomized controlled trials, clinical trials, and laboratory experiments that measured stress through physiological markers (eg, heart rate variability and cortisol) and self-reports. A total of 34 studies were included, and thematic analysis was conducted to identify recurring themes in the findings.

Results: The findings suggest that music, especially classical and self-selected pieces, effectively reduces physiological stress markers, including cortisol levels, heart rate variability, and blood pressure. Nonmusical sounds, such as nature sounds and calming voices, also demonstrate potential for stress relief, although research in this area remains limited. While most sound interventions showed positive effects, some studies reported adverse effects, indicating that sound can both alleviate and induce stress. The outcomes were substantially affected by contextual factors such as personal preferences, delivery methods, cultural context, and emphasizing the importance of personalized interventions.

Conclusions: Sound interventions offer promising, noninvasive methods for stress reduction. This review suggests that future research should address gaps in the study of nonmusical sound interventions and further investigate the neural mechanisms underlying stress responses to sound.

Introduction

Background

Sound plays a fundamental role in human life, influencing communication, emotional regulation, and environmental awareness. Beyond its basic functions in speech and music, sound can modulate psychological and physiological states [1,2]. Auditory stimuli, including natural sounds, music, and human voices, have been shown to evoke a range of emotional responses and affect stress levels [3]. Recent research has explored the therapeutic potential of sound-based interventions, particularly in managing stress and promoting relaxation [4].

XSL•FO
RenderX

Much evidence documented a sound integrative impact on the psychoemotional and physiological outcomes, making it helpful for treating stress-related conditions such as pain syndromes or anxiety [5-7].

Music and Music Therapy

Sound therapy techniques have gained prominence over the past decades, with a significant emphasis on music as a primary form of sound stimulation. One of the early definitions of music describes it as "humanly organized sound" [8], but there are several alternative perspectives debating this definition [9]. For example, Thaut [10] proposed that music is a complex, time-ordered, and rule-based sensory language. Similar to language, music constitutes a universal part of all human cultures, made up of individual sounds that are structured and layered [11]. The healing effects of music on the mind and body resonate with ancient cross-cultural beliefs [12]. Nowadays, music therapy incorporates various elements of music, such as melody, rhythm, tempo, dynamics, and pitch, along with activities such as songwriting, improvisation, and singing, to promote patients' physical and mental well-being.

Nonmusical Sound Therapies

Despite the widespread popularity of music, evidence indicates that other sound types, including natural noises, chanting, and speech, can also exert therapeutic effects. For example, listening to poetry has been shown to alleviate symptoms of anxiety and stress [13-15]. Moreover, in various therapeutic frameworks, the quality of communication is often considered a crucial factor. The effectiveness of treatment hinges not only on the specific technique or theoretical knowledge but also on the establishment of a trusting and intimate rapport between the client and the therapist. Ackerman and Hilsenroth [16] indicate that human-rated factors such as warmth, interest, and curiosity, contribute positively to the development of a strong therapeutic alliance. Therapists use different vocal styles depending on the session's phase, aligning their voices to meet the emotional and therapeutic needs of the interaction [17]. However, distinguishing the impact of content from that of speech acoustics in poetry or therapeutic conversations presents a challenge. A comprehensive understanding of the factors that contribute to the therapeutic influence of sound remains to be elucidated.

Mechanisms of Sound Therapy

The theoretical foundation of how sound interventions can yield therapeutic change and positive outcomes encompasses multiple levels, with the most prominent factor being the learned cognitive response shaped by cultural context [18].

Four-Level Model

Clements-Cortes and Bartel [18] proposed a 4-level model, suggesting that sound can trigger a response due to a set of learned associations that vary from person to person. A particular tone or sound can activate meaningful memories and evoke emotions associated with recalled events [18]. This phenomenon, known as music-evoked autobiographical memory recall, activates related brain networks, potentially inducing shifts in mood and emotional responses [9]. Other responses to sounds are closely linked to our inborn perceptive patterns. Music, characterized by organized vibrations and rhythms, reflects early learned responses. This forms the foundation of our reactions to music—fast music feels exciting, while slow music feels calming. Similarly, louder sounds are associated with strength and boldness, while quieter sounds seem weaker and softer [18].

These principles extend to nonmusical sounds: slower tempo-rhythmical structures, such as a gentle voice or soft breeze, can feel calming, while faster or louder sounds, such as a storm and thunder, can create higher arousal, excitement, or urgency [19,20]. In addition to inborn and early learned responses, situational emotional learning also shapes sound perception. Bliss-Moreau et al [21] demonstrated that voices can gain emotional meaning through past experiences, influencing how quickly participants respond to emotionally charged words based on their previous associations.

Levels 3 and 4 of the model by Clements-Cortes and Bartel [18] encompass responses to sound that are not the result of cognitive processing or learning but rather occur at a vibrational, rhythmic structure. Level 3 focuses on neural oscillatory coherence, where neurons fire in synchrony in response to rhythmic stimulation of the senses (auditory, visual, and tactile), which can lead to various beneficial effects. Level 4 suggests that music and sound can activate mechanisms at the cellular level, potentially influencing everything from neurons to bone and blood cells [18]. Thaut [10] indicates that the brain responds to sound rhythms through involvement, where the listener's mood aligns with the emotional context conveyed in the sound. This occurs due to acoustic resonance, where the brain naturally synchronizes with the rhythm stimuli [10].

Role of Context and Common Therapeutic Factors

In practical applications, it is crucial to consider collateral factors that influence the perception of sound. The effectiveness of music as an art therapy method also depends on the surrounding environment and common factors applicable across creative therapies. These factors include being present in the moment, experiencing a predictable environment, feeling personally connected, developing social skills, finding meaning, feeling motivated, experiencing emotional release, and being actively engaged. Music therapy enhances therapeutic alliance and group processes through playful interactions, shared experiences, musical attunement, synchronicity, and dialogue. Musical engagement also modulates one's sense of time and space, fostering a state of flow or providing distraction from stress-inducing thoughts [22]. Another framework for understanding how any therapy, including music therapy, facilitates positive changes is the mediator and moderator model [23,24]. This model considers external factors that affect the strength or direction of the relationship between treatment and the outcome. Moderators may include client or therapist characteristics (eg, gender, ethnicity, and experience), the format of the treatment (individual vs group and in-person vs online), or the treatment frequency (once vs twice a week) [25,26].

Objective and Contribution of This Review

This scoping review aimed to analyze literature on sound interventions targeting stress response and stress-related

XSL•FO
RenderX

conditions in adults in laboratory experiments, clinical trials, and randomized controlled trials (RCTs). We also aimed to identify sound interventions that have not been sufficiently studied and require further investigation.

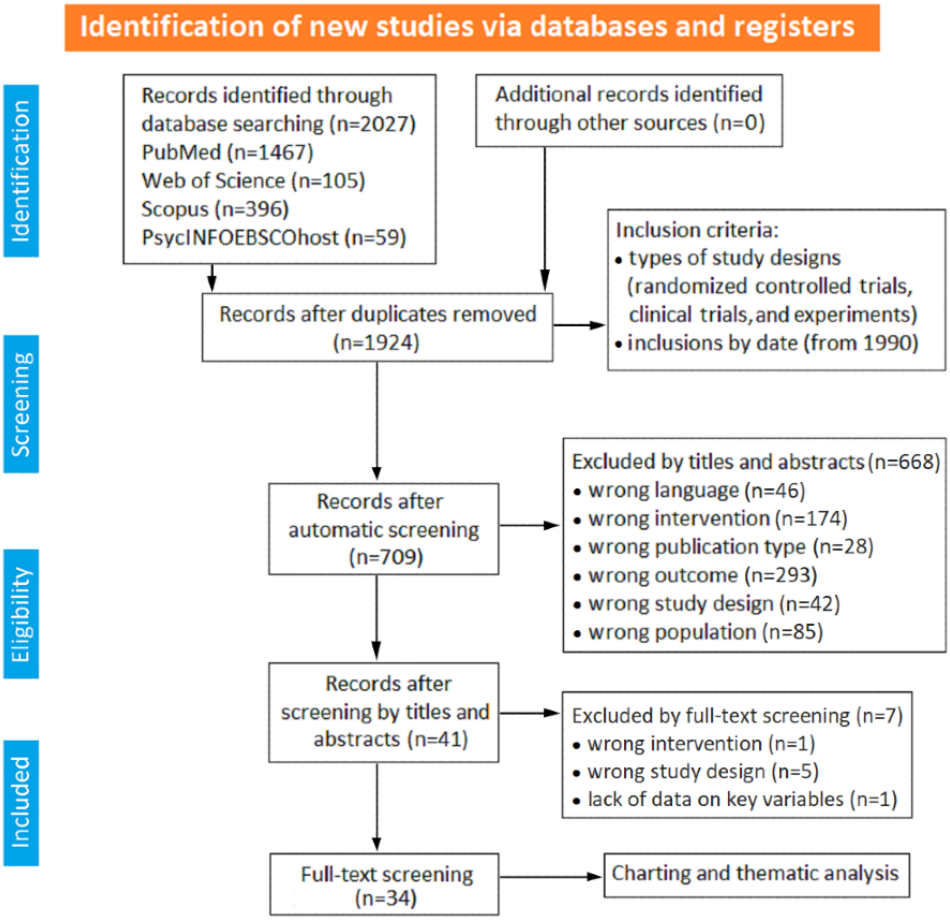
We incorporated investigations focusing on responses of the hypothalamic-pituitary-adrenal axis and the autonomic nervous system as indicators of stress, supplemented by self-reported data and introspective surveys as markers of emotional stress. Our primary outcome of interest is the neural mechanisms underpinning the therapeutic influence of sound. In addition, we are interested in the comparison of delivery methods and sound sample choices for understanding the therapeutic factors of sound for stress reduction.

This study marks a conceptual shift in research of sound therapeutic effects by moving beyond music-focused frameworks to consider nonmusical acoustic interventions using human voices or environmental sounds. This broader perspective opens new possibilities for stress management strategies. By highlighting how diverse sounds can serve for therapeutic changes, this review encourages future studies to explore nonmusical sounds more rigorously and investigate how personal, cultural, or environmental contexts can interact with various sound types.

Moreover, this shift is expanding sound therapeutic potential to services such as classical therapeutic methods that use speech and conversation as primary tools. For instance, it is possible to consider the impact of vocal acoustics, such as tone or rhythm, within psychotherapy sessions to enhance emotional attunement and therapeutic alliance.

In addition, this concept can become a basis for the new technological development. It is possible to bring into the light, track, and analyze vocal elements in real time, allowing therapists to adapt their approach based on the client's stress markers. Environmental sound tracking also holds potential for improving well-being, as ambient soundscapes could be monitored and adjusted to promote relaxation for everyday environments. This broader perspective encourages innovative approaches that personalize sound to individual needs.

Methods



Overview

This review follows the registered study protocol published in *JMIR Research Protocols* [27]. The protocol outlines the objective to comprehensively map empirical research on sound interventions for stress reduction. It adheres to Joanna Briggs Institute guidelines and follows the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) checklist [28] (Multimedia Appendix 1), with minor adjustments, which will be detailed in the Protocol Adjustments subsection.

The study protocol defines the eligibility criteria for study inclusion, focusing on adult participants, various sound interventions (eg, music, speech, and nature sounds), and stress-related outcomes. The PRISMA-ScR flow diagram (Figure 1) illustrates the study selection process. Guided by the protocol, this scoping review assesses the comparative effects of sound interventions, examines research directions, and identifies methodological challenges in existing literature.

XSL•FO
RenderX

Figure 1. PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) flow diagram. It illustrates the study selection process, including the number of records identified, screened, excluded, and ultimately included in the final analysis [29].

Research Questions

This scoping review was guided by the population, concept, context framework, recommended for constructing clear objectives and eligibility criteria in scoping reviews [29]. The population, concept, context framework in this study focuses on the population of interest (adults experiencing stress), the concept (therapeutic sound interventions), and the context (various settings in which sound interventions are applied for stress reduction). Through careful refinement, we formulated the following research questions to guide the entire review process:

1. What are the therapeutic factors of sound in the case of reducing stress response and stress-related conditions in human adults? For instance, it might be rhythm, sentiment, environmental context, personal preferences, or background.
2. What are the physiological responses associated with sound interventions in stressful conditions, as measured by biomedical technologies and devices?

Search Strategy and Query String

This scoping review used a systematic search strategy across 4 key medical and interdisciplinary databases: PubMed, Web of Science, Scopus, and PsycINFO (or EBSCOhost). As the neurobiology of music and sound therapy emerged as a separate field in the 1990s, the search strategy covers the research from 1990 till the present day. The search aimed to capture studies addressing the effects of sound interventions, such as music therapy and guided relaxation, on stress reduction in adults. The complete query string formulated for this purpose was as follows**:** "(stress OR anxiety OR relax*) AND ("sound therapy" OR "music therapy" OR "guided relaxation" OR "guided meditation" OR hypno* OR ASMR OR MBSR) AND (prosody OR song OR poetry OR voice OR paralinguistics OR paralanguage) NOT (children OR infants OR animal OR teen)."

Using the operator "AND" we combined three key fields to comprehensively capture relevant literature (1) mental stress or relaxation indicators: terms such as "stress," "anxiety," and "relax*" were included to identify studies focused on both stress-related conditions and relaxation as therapeutic outcomes; (2) sound-based interventions: this field targeted interventions where sound is essential, encompassing "sound therapy," "music therapy," "guided relaxation," "guided meditation," "hypno*," "ASMR," (autonomous sensory meridian response) and "MBSR" (mindfulness-based stress reduction); and (3) voice and paralinguistic elements: we included terms, such as "prosody," "song," "poetry," "voice," "paralinguistics," and "paralanguage" to capture studies examining the acoustic characteristics of speech and natural language as therapeutic components. The exclusion criteria were applied using the NOT operator to filter out studies on children, infants, animals, and adolescents, ensuring a focus on adult populations.

This structured approach aimed to capture a comprehensive range of studies, not only focusing explicitly on sound-based

XSL•FO
RenderX

therapies but also those involving therapeutic aspects of speech and vocal elements. By broadening the scope in this way, we aimed to explore potential blind spots in sound therapy research, particularly in the therapeutic roles of natural speech and paralinguistic features alongside traditional music-based interventions.

Study Selection

The process of how citations and full-text reports were reviewed, included, and excluded is shown in the PRISMA-ScR flow diagram (Figure 1). The first author, a clinical psychologist, led all aspects of the review, including literature search, extraction, screening, and data analysis. The second author, a psychology researcher, assisted in the literature search and extraction and performed screening independently. Disagreements were resolved through discussion and consensus with other authors of the research consortium.

A 2-step process was followed for study selection. First, we screened citation titles, abstracts, and keywords, classifying each citation as "include," "exclude," "unclear," or "duplicate." In the second step, full-text reports for citations marked "include" and "unclear" were reviewed to make a final decision on inclusion or exclusion. Reference management and screening were conducted in Rayyan (Rayyan Systems Inc), a web-based app for systematic review management. The inclusion and exclusion criteria are presented in Tables 1 and 2. The inclusion criteria were used to select studies for the review, specifying population, intervention type, outcome measures, study design, and publication type. The exclusion criteria outline conditions under which studies were excluded, including participant characteristics, health conditions, intervention types, and methodological limitations. These criteria ensure a focused review on adult populations using diverse passive sound interventions for stress relief, with an emphasis on studies providing measurable physiological data.

Table 1. Inclusion criteria used to select studies for the review, specifying population, intervention type, outcome measures, study design, and publication type.

Inclusion criteria	General description and examples
Population	Human adults exposed to stress-related conditions, including both clinical and healthy populations. Examples include the following: • Anxiety, reactive depression, crises and emergency cases, grief, loss, basic needs deprivation, burnout, occupational hazards • Experimental stress
Intervention type	All types of passive sound interventions. Examples include the following: • Listening to instrumental music, songs, poetry, human voices, and nature sounds • Sound-based therapies, including music therapy, acoustic stimulation during relaxation, meditation, and induction of hypnosis
Outcome measurements	• Studies that assess stress relief effects through physiological measures (eg, heart rate variability, salivary cortisol, electrodermal activity, neuroimaging markers) • Studies that combine both physiological measurements and self-reported stress levels (eg, Perceived Stress Scale, State Anxiety Inventory, Beck Anxiety Inventory)
Study design	• Randomized controlled trials • Clinical trials • Laboratory experiments
Publication type	• Peer-reviewed original research articles published in English

XSL•FO
RenderX

Table 2. Exclusion criteria, including participant characteristics, health conditions, intervention types, and methodological limitations.

Exclusion criteria	General description and examples
Population	• Participants younger than 18 years • Animals • Individuals with hearing disabilities
Health conditions	Conditions for which stress is not the original cause. Examples include the following: • Pain syndromes • Psychotic episodes • Chronic neurological disorders, such as Alzheimer or Parkinson disease • Age-related cognitive changes • Autism spectrum disorders • Tinnitus, hyperacusis
Outcome measurements	• Studies relying solely on questionnaires or self-reports without physiological measurement data
Intervention type	• Active sound interventions, including improvisation, music composition, drumming, singing, poetry writing, or chanting • Mixed interventions that combine sound with unrelated therapeutic interventions, such as aromatherapy or massage • Mono-interventions: studies in which sound (usually an unclearly defined piece of music) represented the only intervention, and the absence of sound represented the comparator

Data Extraction

After initial screening according to the chosen criteria, 2 reviewers independently evaluated the full-text articles. Key information included the following items: (1) authors and year of publication indicating the first author and publication year; (2) country of origin specifying the country where the study was conducted; (3) concept specifying the main idea and hypothesis of the study; (4) population specifying the sample size and population type (eg, nurses, students, and patients with specific diagnoses); (5) study type, for instance, RCTs, clinical trials, or laboratory experiments; (6) intervention type (groups) indicating the type of sound stimulation as described in the article (eg, music, voice, and nature sounds). In most cases, the separation of participants into groups is based on the intervention. This is where we get information about both the types of sound interventions and the participant grouping; (7) outcomes and measurements specifying the target condition or issue that the sound stimulation aims to impact, and how it was measured, including both physiological measures and self-reports of subjective experience (eg, measurements of stress hormones, heart rate variability (HRV), anxiety scale, and emotional state questionnaires); and (8) key findings related to the scoping review questions—indicating the primary results, such as clinical outcomes, body-mind responses, effectiveness, among others.

Thematic Analysis Method

The thematic analysis for this scoping review followed the reflexive thematic analysis framework by Braun and Clarke [30], using an inductive approach to identify key therapeutic factors of sound interventions on stress reduction. The analysis began with a familiarization phase, in which the first 2 authors thoroughly reviewed and familiarized themselves with the data extracted from each included study. This initial stage focused on understanding the study concept and intervention types.

Following familiarization, an open coding process was conducted across the entire dataset, centering on essential elements, such as sound characteristics, and individual outcomes. This coding identified basic elements such as music styles, sentiment, basic physical elements (rhythm and frequency), environmental context, and personal context as core factors within the data. Related codes were then grouped into preliminary categories, organizing the themes based on factors influencing the effectiveness of sound interventions. Three broad categories emerged from this process: (1) *sound per se*, capturing sound characteristics independent of the listener; (2) *personal factors*, which focused on listener-dependent characteristics, including musical education, cultural background, personal preferences, and stress history; and (3) *environmental factors*, covering aspects of sound delivery, such as live versus recorded sound, use of headphones or broadcast sound, and interactions with medical staff or researchers during the session.

Within the category of *sound per se*, which proved to be the most widely researched, 9 subcategories were developed to reflect specific sound types and qualities. The first 3 of them (1-3) related to music, including different styles, sentiment (such as cheerful vs sad music), and elementary characteristics (such as tempo-rhythm), the next 3 (4-6) outlined nonmusical sounds (eg, white noise, nature sounds, and human voices), and 3 others (7-9) related to the comparison of musical and nonmusical sounds. Initially, the category “environmental context” included subcategories such as “live versus recorded sound” and “presence of supportive personnel,” while “personal preferences” encompassed elements such as “music genre” and “cultural background.” At the same time, due to the modest number of articles assigned to these themes, we decided not to overload the chart and did not include these subcategories in the final edition. In addition, it was important for us to add 3 extra categories for outcomes that were out of the main pattern or for negative outcomes. These were mixed samples (“mix”), relaxing effects of the absence of sound (“0”), and negative, stressful sound effects (“–”).

XSL•FO
RenderX

During the thematic refinement stage, categories and subcategories were iteratively adjusted through regular team discussions and codebook updates, enhancing internal coherence and consistency across the themes. As the thematic map took shape, each category was further refined and defined to ensure clarity and distinctiveness. This thematic framework not only provided a structure for categorizing therapeutic factors and mechanisms of sound interventions but also revealed patterns in the literature and highlighted gaps for future research. As shown in the Results section, some categories have little research, suggesting areas for future studies. We found that in most of the studies reviewed, the hypotheses and groupings were based on the type of sound intervention. This means that the groups typically reflect the type of sound being tested. In some cases, there were >2 types of sounds. If the categorization was unclear or debated, we referred to the study's concept and research question to identify the primary focus of authors. For instance, if a study had 3 groups, "cheerful music," "sad music," and "white noise," we would place it in the "musical sentiment" subcategory as the study's focus is on musical emotion rather than comparing music to nonmusical sounds.

Protocol Adjustments

This section outlines the adjustments made during the review process compared to the study protocol [27]. While the overall methodology remained consistent, some procedural differences emerged during implementation. One notable change was the exclusion of gray literature sources, such as Google Scholar, ClinicalTrials.gov, and nonindexed conference proceedings. The final review focused exclusively on peer-reviewed studies to maintain methodological rigor. Many gray literature sources lacked transparency in their methods, making it difficult to assess their reliability. In addition, most did not report detailed physiological stress markers, such as cortisol levels, HRV, or neuroimaging data, which were essential for inclusion in this review. Instead, they often emphasized subjective well-being and relaxation effects, which, while relevant, did not align with the primary focus of this study. Given these challenges, the review prioritized published studies that had undergone formal peer review, ensuring that all findings were based on reliable findings. Despite these adjustments, the core thematic analysis approach, guided by the framework by Braun and Clarke [30], remained unchanged. These refinements ensure that the findings accurately reflect the available evidence while maintaining alignment with the original research objectives.

Results

Overview

The systematic database search obtained 2027 records. After removing duplicates, 1924 records remained for further review. Screening of titles and abstracts led to the exclusion of records that did not meet the chosen criteria, such as unsuitable languages, outcomes, or interventions. Full-text review of the remaining 41 records revealed that 7 did not meet the inclusion criteria due to various reasons, including wrong intervention (n=1, 2%), wrong study design (n=5, 12%) and lack of data on key variables (n=1, 2%). Finally, 34 studies were considered eligible for inclusion in the analysis. These studies were RCTs (22/34, 65%), experiments (9/34, 26%), and pilot studies (3/34, 9%). The search process is outlined in the PRISMA-ScR flowchart (Figure 1). A summary of the included studies, detailing their country of origin, research concept, participant population, and study design is outlined in Table 3.

XSL•FO
RenderX

Table 3. An overview of the included studies.

Study and year	Country	Concept	Population	Study type
Umemura and Honda [31], 1998	Japan	Classical music may promote relaxation by influencing heart rate variability compared to rock music or noise.	6 university students, aged between 21 and 26 years	Experimental study
Chafin et al [32], 2004	United States	Listening to classical music may improve blood pressure recovery after a stressful task compared to silence or other music styles.	75 healthy participants	Experimental study
Labbé et al [33], 2007	United States	Listening to classical or self-selected relaxing music reduces anxiety, anger, and physiological arousal after stress compared to heavy metal music or silence.	56 college students	RCT[a]
Uğraş et al [34], 2018	Turkey	All types of music can reduce preoperative anxiety, with classical Turkish music being the most effective.	180 patients undergoing surgery	RCT
Gulnahar and Kupeli [35], 2020	Turkey	Listening to music reduces anxiety during dental implant surgery, with Turkish music and classical music potentially being most effective.	80 dental implant surgery patients, aged between 40 and 70 years	Prospective, observational RCT
Paszkiel et al [36], 2020	Poland	Relaxing music and autonomous sensory meridian response music may reduce stress levels faster than silence or rap music. Rap music may even worsen stress compared to silence.	9 healthy female participants, aged 22years	Pilot study
Hirokawa and Ohira [37], 2003	Japan	High-uplifting and low-uplifting music may have different effects on immune function, neuroendocrine responses, and emotional states after a stressful task.	18 Japanese college students	Experimental study
Sokhadze [38], 2007	United States	Both pleasant and sad music may improve physiological recovery after stress (viewing stressful images) compared to white noise. White noise may not enhance recovery.	29 healthy participants	Experimental study
Suda et al [39], 2008	Japan	Major mode music reduces stress more than minor mode music.	10 graduate students	Experimental study
Wiwatwongwana et al [40], 2016	Thailand	Music may reduce anxiety in patients undergoing cataract surgery. Binaural beat audio may offer additional benefits over music alone.	141 patients undergoing cataract surgery under local anesthesia	Prospective, double-blind RCT
Opartpunyasarn et al [41], 2022	Thailand	Binaural beat audio may reduce anxiety in patients undergoing fiber-optic bronchoscopy compared to plain music or no music.	112 patients undergoing fiber-optic bronchoscopy	Prospective RCT
Lee-Harris et al [42], 2018	United Kingdom	Meditative binaural music may be effective for relaxation, with effects potentially differing by age.	30 (15 and 15) participants, aged between 18and 25 years and 50 and 80 years	RCT
Gantt et al [43], 2017	United States	Binaural beat technology (theta waves) embedded in music may be more effective than music alone in reducing cardiovascular stress response in military personnel with postdeployment stress.	74 military service members with postdeployment stress	Double-blind RCT
Calamassi et al [44], 2022	Italy	Listening to music at 432 Hz and 440 Hz may reduce anxiety and stress biomarkers compared to a no-music control group.	54 emergency nurses	Double-blind RCT
Sharma et al [45], 2021	India	Indian classical music with incremental tempo and octave variations promotes better anxiety reduction.	21 male undergraduate medical students	Crossover RCT
Singh et al [46], 2009	India	Both music and progressive muscle relaxation are effective in reducing anxiety and dyspnea in hospitalized patients with COPD[b]. Music may be more effective than PMR[c] for reducing anxiety.	72 hospitalized patients with COPD with recent exacerbation	RCT
Tang et al [47], 2009	United States	Audio relaxation programs may be effective for short-term blood pressure reduction in older adults, potentially more effective than listening to Mozart.	41 older adults	RCT
Lin et al [48], 2011	Taiwan	Music therapy and verbal relaxation are effective in reducing anxiety induced by chemotherapy.	98 patients with cancer under chemotherapy	RCT

XSL•FO
RenderX

Study and year	Country	Concept	Population	Study type
Lee et al [49], 2012	Germany	Both monochord sounds and progressive muscle relaxation can reduce anxiety and improve relaxation during chemotherapy.	40 patients with gynecologic cancer under chemotherapy	RCT
Warth et al [50], 2016	Germany	Live music therapy may be more effective than a prerecorded mindfulness exercise in improving cardiovascular health for patients who are terminally ill through its influence on the autonomic nervous system.	84 patients in palliative care	RCT
Koehler et al [51], 2022	Germany	Music therapy may be more effective than mindfulness in reducing subjective distress in patients in palliative care. Both interventions may reduce stress biomarkers.	104 patients in palliative care	RCT
Radstaak et al [52], 2014	Netherlands	Listening to self-chosen relaxing or happy music after stress may improve mood but delay systolic blood pressure recovery.	123 healthy participants	Experimental study
Leardi et al [53], 2007	Italy	Music therapy, especially patient-selected music, may reduce stress response during day surgery compared to no music.	60 patients undergoing day surgery	RCT
Miller et al [54], 2010	United States	Music may influence endothelial function, potentially improving vascular health.	10 healthy participants, average age 35.6 years	Crossover RCT with counterbalancing
Imbriglio et al [55], 2020	Canada	Guided music listening with relaxing music or a participant's favorite music may decrease muscle activity and bruxism episodes in chronic myalgia, while stressful music may increase them.	14 women with chronic myalgia and 15 women who are pain free	Experimental study
Gelatti et al [56], 2020	Italy	Live harp music may be more effective than recorded harp music in reducing preoperative stress, fear, heart rate, and blood pressure.	46 patients undergoing day surgery	Pilot, quasi-experimental study
Bro et al [57], 2019	Denmark	Live music may reduce anxiety during chemotherapy compared to prerecorded music or standard care.	143 newly diagnosed patients with lymphoma	Multicenter RCT
Lee et al [58], 2011	Taiwan	Both headphones and broadcast music can effectively reduce preoperative anxiety in adult patients undergoing surgery.	167 patients undergoing surgery without premedication	RCT
Kumari et al [59], 2023	India	Broadcast and headphone music playing may vary the anxiety-relieving effect for patients awaiting surgery.	150 healthy participants	Experimental study
Lai et al [60], 2012	Taiwan	Music intervention with a nurse present is more effective than recorded music alone for improving psychophysiological health in caregivers for patients with cancer.	34 female caregivers for patients with cancer	Crossover RCT
Janelli et al [61], 2004	United States	Listening to preferred music may reduce negative behaviors in patients who are physically restrained.	30 patients who are physically restrained, aged between 65 and 93 years	Pilot study
Kang et al [62], 2008	South Korea	Blocking noise, but not music, reduces bispectral index scores during propofol sedation in noisy operating rooms.	63 patients undergoing total knee replacement surgery, aged between 55 and 75 years	Prospective, single-blind RCT
Tsivian et al [63], 2012	United States	Music with headphones may reduce pain perception and anxiety during prostate biopsy compared to control or headphones alone.	88 men undergoing transrectal ultrasound prostate biopsy	Prospective RCT
Gingras et al [64], 2014	Austria	Repetitive drumming with shamanic instructions may affect subjective experiences and cortisol levels compared to instrumental meditation music.	39 participants inexperienced in shamanic journeying	Experimental study

[a]RCT: randomized controlled trial.

[b]COPD: chronic obstructive pulmonary disease.

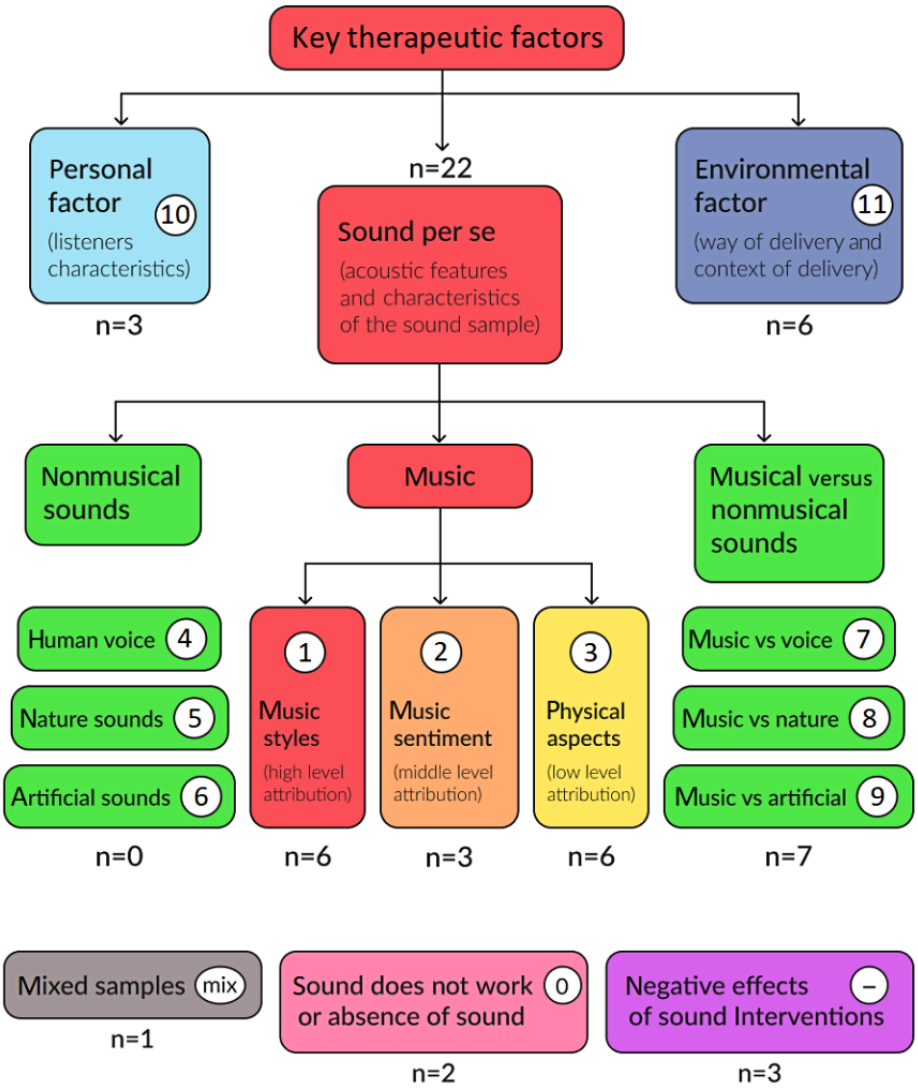
[c]PMR: progressive muscle relaxation.

Thematic Analysis Results

Thematic analysis of the included studies revealed several key factors contributing to the effectiveness of sound interventions. These factors can be categorized into 3 main categories: *sound per se*, *personal factors*, and *environmental factors* (Figure 2).

XSL•FO
RenderX

The majority of the identified articles focused on the characteristics of sound per se (22/34, 65%). For example, studies investigating music interventions often explored different music styles (6/34, 18%), music sentiment (3/34, 9%), and physical aspects such as frequency or tempo (6/34, 18%).



Regarding nonmusical sounds within our predefined inclusion criteria, we found publications comparing musical interventions with a variety of voice-assisted interventions (7/34, 21%). However, no studies were found that focused narrowly on nonmusical sounds for stress relief in adults or compared different sound characteristics beyond the concept of musical intervention.

Within the personal factors category, listener characteristics (3/34, 9%) were identified as influencing intervention outcomes. Environmental factors, such as the way of delivery and context of delivery, were also considered (6/34, 18%).

In addition, the analysis identified a small number of studies (1/34, 3%) that explored mixed samples of sounds and a few that shifted their focus from sound to silence (2/34, 6%) or reported negative effects of sound intervention (3/34, 9%).

Information on key findings for comparing the effectiveness of different sound intervention factors is summarized in Table 4.

Figure 2. A summary of the thematic analysis, categorizing sound interventions into key therapeutic factors, including sound characteristics, personal factors, and environmental influences on stress reduction. The numbers in white circles represent classification labels assigned to categories based on thematic analysis (see the Thematic Analysis Method under Methods for details).

XSL•FO
RenderX

Table 4. The effects of sound interventions.

Study and year	Interventions (groups)	Category	Outcomes (measurements)	Key findings
Umemura and Honda [31], 1998	• Classical music • Rock music • Noise • Rest	1	HRV[a] (MWSA[b] and RSA[c] components) and subjective comfort levels (psychological evaluation)	Classical music reduced variability in HR[d] components (MWSA and RSA) compared to rest, suggesting a potential relaxation effect. Rock music and noise increased MWSA and decreased RSA, potentially indicating a stress response. Subjectively, classical music was associated with comfort, while rock music and noise were associated with discomfort. Changes in MWSA correlated with comfort levels, suggesting a link between HRV and perceived comfort.
Chafin [32], 2004	• Classical music • Jazz music • Pop music • No sound (control)	1	SBP[e] measured before and after the stressful task.	Listening to classical music resulted in significantly lower posttask SBP compared to silence. Other music styles did not show significant benefits for blood pressure recovery.
Labbé et al [33], 2007	• Classical music • Self-selected relaxing music • Heavy metal music • No sound (control)	1	Emotional state (anxiety and anger) and physiological arousal (before and after intervention)	Listening to self-selected or classical music significantly reduced negative emotions and physiological arousal compared to heavy metal music or silence.
Uğraş et al [34], 2018	• Turkish classic music • Western music • Natural sounds • No sound (control)	1	STAI-S[f]) for anxiety, SBP, DBP[g], HR, and cortisol levels measured before and after music intervention	All music types significantly reduced anxiety (STAI-S), SBP, and cortisol levels compared to before the intervention. Natural sounds reduced DBP, and classical Turkish music showed the most significant reductions in DBP and HR. All music was effective in reducing preoperative anxiety, with classical Turkish music being the most beneficial.
Gulnahar and Kupeli [35], 2020	• Turkish classic music • Classical music (Vivaldi) • Slow rock music • No sound (control)	1	Pre- and postintervention anxiety using the Corah Dental Anxiety Survey, blood pressure, HR, and oxygen saturation	All music groups showed reduced anxiety compared to controls. Turkish music and classical music were significantly more effective in anxiety reduction compared to slow rock music.
Paszkiel et al [36], 2020	• Rap music • Relaxing music • ASMR[h] music • No sound (control)	1	EEG[i]–alpha wave activity, blood pressure, HR, and subjective stress perception questionnaires	Relaxing music and ASMR reduced stress levels faster than silence. Rap music increased stress levels compared to silence.
Hirokawa and Ohira [37], 2003	• High-uplifting music • Low-uplifting music • No sound (control)	2	S-IgA[j] level, active NK[k] cell level, T lymphocyte subsets ($CD4^+$, $CD8^+$, and $CD16^+$), dopamine, norepinephrine, and epinephrine levels (before and after intervention), and emotional state questionnaires (before and after intervention)	Results were inconclusive, but trends suggested (1) low-uplifting music may increase feelings of well-being; (2) high-uplifting music may increase norepinephrine and liveliness and decrease depression; and (3) silence may decrease active NK cells. Music classification is important for understanding music's influence on these responses.
Sokhadze [38], 2007	• Subjectively pleasant music • Sad music • White noise • No sound (control)	2	EEG—frontal and temporal activity, skin conductance, HR, HRV, facial capillary blood flow, respiration rate (measured before and after stressful images and during recovery interventions)	Both pleasant and sad music improved recovery on most measures compared to white noise (HR, respiration rate, and blood flow). White noise did not enhance recovery. Both music types positively influenced cardiovascular and respiratory activity during recovery. The "undoing hypothesis" (positive emotions aid recovery from negative emotions) was partially supported.
Suda et al [39], 2008	• Major music • Minor music • No sound (control)	2	Salivary cortisol levels (endocrine stress marker) and optical topography (brain activity)	Major mode music resulted in lower salivary cortisol levels (stress marker) compared to minor mode music. This suggests music can induce emotional responses such as happiness, potentially linked to stress reduction.

XSL•FO
RenderX

Study and year	Interventions (groups)	Category	Outcomes (measurements)	Key findings
Wiwatwongwana et al [40], 2016	• Binaural beat music • Plain music • No sound (control)	3	STAI score (before and after intervention), SBP, and HR (measured at admission, surgery start, and 20 min after surgery).	Both music with and without binaural beats reduced anxiety (STAI score) and SBP compared to the control group. Binaural beat music showed an additional decrease in HR compared to plain music or the control group. Binaural beat audio embedded in music may have some advantages over music alone for reducing anxiety during cataract surgery.
Opartpunyasarn et al [41], 2022	• Binaural beat music • Plain music • No sound (control)	3	STAI score (before and after bronchoscopy), blood pressure, HR, and sedative use	Patients in the binaural beat group showed a significantly greater reduction in anxiety (STAI score) compared to the plain music and no music groups. They also experienced a decrease in blood pressure but an increase in HR. Binaural beat audio may be effective for reducing anxiety before bronchoscopy.
Lee-Harris et al [42], 2018	• Meditative music with binaural beats • Meditative music without binaural beats • Low-arousal classical music • High-arousal classical music	3	Self-reported emotional state (arousal and positivity) and physiological arousal (measured but not specified in the abstract).	The effect of listening to MBM[l] was comparable to listening to calm classical music. Younger adults showed a stronger decrease in self-reported arousal with MBM with binaural beats compared to low-arousal classical music. Older adults showed a preference for low-arousal classical music for feeling comforted, followed by MBM. These results suggest age may influence how music affects relaxation.
Gantt et al [43], 2017	• Music with embedded theta binaural beats • Music alone	3	HRV was measured before and after the intervention to assess changes in sympathetic and parasympathetic nervous system activity. Daily self-reported stress levels were recorded in diaries.	Music with binaural beats led to a decrease in low-frequency HRV (indicating reduced sympathetic response) and an increase in high-frequency HRV (indicating increased parasympathetic response) compared to music alone. The binaural beats group also reported lower daily stress levels compared to the music-only group. Overall, music with theta binaural beats showed promise in reducing physiological and psychological stress markers in military personnel with postdeployment stress.
Calamassi et al [44], 2022	• Listen to 440 Hz music during break • Listen to 432 Hz music during break • Usual break activities (control)	3	STAI-X1, HR, respiratory rate, SBP and DBP, and pain and productivity (Likert scale)	All groups showed a reduction in anxiety after the break. Listening to 432 Hz music showed the greatest reduction in anxiety and additionally reduced respiratory rate and SBP. Music at 440 Hz reduced anxiety but showed no significant physiological benefits in this study.
Sharma et al [45], 2021	• VM[m] with incremental tempo or octave changes • SM[n] without variations • No sound (control)	3	Anxiety (Beck Anxiety Inventory and STAI), EEG for brainwave activity, ECG[o] for HRV	Significant anxiety reduction only in the VM group. VM showed decreased low-frequency brainwaves and midline power (reduced default mode network activity) compared to silence. VM also showed more balanced brain activity compared to SM. HRV remained stable during music interventions. The authors propose VM induces a "controlled mind wandering" state leading to anxiety reduction.
Singh et al [46], 2009	• Self-selected music • Audio instructions (PM[p])	7	STAI (Spielberger inventories), dyspnea, SBP and DBP, pulse rate, and respiratory rate (before and after intervention)	Both music and PMR significantly reduced anxiety, dyspnea, SBP, pulse rate, and respiratory rate. However, the music group showed greater reductions in anxiety compared to the PMR group. Music and PMR are effective for reducing anxiety and physiological measures in hospitalized patients with COPD[q], with music potentially being more effective for anxiety reduction.
Tang et al [47], 2009	• 12-minute audio relaxation program • 12-minute Mozart andante	7	Blood pressure (systolic and diastolic) was measured at each intervention session and at 1-month and 3-month follow-up	Both groups showed significant reductions in blood pressure after the intervention. The audio relaxation group showed a greater reduction in SBP than the Mozart group. Blood pressure reductions were not sustained at 1- and 3-month follow-up. Audio relaxation may be more effective than music for short-term blood pressure reduction in older adults.
		7		

XSL•FO
RenderX

Study and year	Interventions (groups)	Category	Outcomes (measurements)	Key findings
Lin et al [48], 2011	• 1 hour session of music therapy • 30 minutes of guided verbal relaxation • Usual care		State anxiety (Spielberger STAI), emotional distress (Emotional Visual Analog Scale), and physiological responses (skin temperature, HR, and consciousness level) before and after chemotherapy	Music therapy was more effective than verbal relaxation or usual care in reducing postchemotherapy anxiety and increasing skin temperature. Patients with high initial anxiety benefited more from music therapy than those with normal anxiety. Both interventions showed some effectiveness within 30 minutes.
Lee et al [49], 2012	• monochord sounds • PMR	7	Spielberger State Anxiety Inventory for Anxiety, questionnaires on physical and psychological states, EEG data before and after intervention	Both the monochord sounds and PMR groups showed significant improvements in anxiety, physical, and psychological state. EEG data showed increased posterior theta and decreased midfrontal beta-2 activity in both groups, indicating relaxation. The monochord sounds group also showed a decrease in alpha band activity compared to PMR. Both interventions were effective for reducing anxiety and improving relaxation, with potentially different underlying neural mechanisms.
Warth et al [50], 2016	• Live music therapy • Prerecorded mindfulness exercise	7	Vagally mediated HRV and blood volume pulse amplitude were measured over time to assess autonomic nervous system response	Both groups showed improvements over time, but music therapy led to significantly greater reductions in vascular sympathetic tone ($BVP\text{-}A^{r}$). This suggests music therapy may be more effective in managing pain and stress symptoms in palliative care. Baseline pain levels influenced patient response, highlighting its importance in treatment planning. Music therapy's impact may be related to the therapist-patient relationship in addition to the music itself.
Koehler et al [51], 2022	• 3 sessions of music therapy • 3 sessions of mindfulness training	7	Subjective distress rating scale (before and after intervention), salivary cortisol and alpha-amylase levels (before and after intervention), and HR and HRV	Music therapy showed a greater reduction in subjective distress compared to mindfulness. Both interventions led to reductions in cortisol and HR, but no significant differences between groups were found for these or other stress biomarkers.
Radstaak et al [52], 2014	• Self-chosen relaxing music • Self-chosen happy music • Audiobook • Silence (control)	7	Mood questionnaires, subjective arousal and rumination questionnaires, and SBP and DBP, HR.	Listening to self-chosen relaxing or happy music improved mood compared to control conditions. No significant effects on subjective arousal or rumination. Both relaxing and happy music groups showed delayed SBP recovery compared to control conditions.
Leardi et al [53], 2007	• New age music • Choice of music from 4 styles • Control group (standard operating room sounds)	10	Plasma cortisol levels and subpopulations of lymphocytes (NK cells) were measured before, during, and after surgery	Both music groups showed decreased cortisol (stress hormone) levels during surgery compared to the control group. Patients who chose their music (group 2) had significantly lower postoperative cortisol levels than those who listened to new age music (group 1). NK cell levels (immune function) decreased during surgery in the music groups and increased in the control group. Patients listening to new age music (group 1) had lower levels of NK cells during surgery compared to the control group.
Miller et al [54], 2010	• Listening to self-selected joyful or anxiety- provoking music for 30 minutes • Watching video to induce laughter and listening to audio for relaxation	10	Endothelial function was measured by brachial artery flow-mediated dilation before and after each intervention	Joyful music increased flow-mediated dilatation (blood-vessel dilation), while anxiety-provoking music decreased flow-mediated dilatation. The increase in joyful music was comparable to improvements seen with exercise or medication.
Imbriglio et al [55], 2020	• Relaxing music • Favorite music • Stressful music • Pink noise	10	Electromyographic activity in the right masseter muscle to measure muscle effort: posture and spontaneous awake bruxism episodes and duration and frequency of awake bruxism episodes	Relaxing music and favorite music decreased muscle effort during awake bruxism in chronic temporomandibular disorders by 26% and 44%, respectively. Stressful music increased muscle effort. Guided music listening with selected music may be a promising noninvasive treatment for chronic temporomandibular disorders.
Gelatti et al [56], 2020		11		

XSL•FO
RenderX

Study and year	Interventions (groups)	Category	Outcomes (measurements)	Key findings
	• Live harp music intervention • Recorded harp music control		Self-reported fear and stress levels (before and after intervention) and blood pressure (before and after intervention), (3) HR (before and after intervention)	Both live and recorded harp music significantly reduced fear. Live harp music was more effective in reducing HR and DBP compared to recorded music.
Bro et al [57], 2019	• 30 minutes of patient-preferred live music • 30 minutes of patient-preferred prerecorded music • Standard care	11	Anxiety was measured by the Spielberger State Anxiety Inventory, blood pressure, pulse rate, nausea, vomiting, serum catecholamine levels, and health-related quality of life. The Musical Ability Test was used to assess if musical ability influenced anxiety.	Live music showed a borderline statistically significant reduction in anxiety compared to standard care. Prerecorded music had no significant effect. No significant changes were observed in secondary outcomes. Musical ability did not influence the effect of music.
Lee et al [58], 2011	• Headphone music therapy • Broadcast music therapy • Control (no music)	11	Visual Analog Scale for anxiety (before and after intervention) and HRV (before and after intervention)	Both headphones and broadcast music significantly reduced visual analog scale scores (anxiety) compared to the control group. No significant difference was found between headphones and broadcast music for reducing anxiety. Broadcast music offers an alternative to headphones for reducing preoperative anxiety while considering infection control.
Kumari et al [59], 2023	• Headphone group • Broadcast group • Control	11	Preoperative anxiety by visual analog scale and HRV	The average HRs of the broadcast group, headphone group, and control group were not significantly different. The mean anxiety score of the control group was significantly higher than that of the headphone group and the broadcast group. Time-domain HRV was not significantly different. There was a significant difference in high-frequency HRV among the 3 groups. LF in the broadcast group was significantly lower than the control group, indicating there was less tension of the sympathetic nervous system in the broadcast group. Both headphones and broadcast music are effective for reducing the preoperative patient's anxiety in the waiting room. Thus, when headphones are not available or not appropriate, speakers can be an effective substitute.
Lai et al [60], 2012	• Music with nursing presence • Recorded music	11	Blood volume pulse amplitude and HRV, depression, anxiety, and sleep quality were measured before and after intervention, and participant evaluation of music	Both interventions improved anxiety, depression, and blood volume pulse amplitude. Music intervention with a nurse led to greater reductions in anxiety and improved ease of falling asleep compared to recorded music. Participants preferred music with a nursing present and found it to be more harmonious and friendly. Both interventions were beneficial, but music with a nursing presence provided a more positive experience.
Janelli et al [61], 2004	• Preferred music out of restraints • No music out of restraints (control) • Preferred music in restraints	11	Observation of positive and negative behaviors during the music intervention phase	Listening to preferred music showed no significant decrease in negative behaviors or increase in positive behaviors for patients in restraints. Patients out of restraints with preferred music had higher positive behavior scores and lower negative behavior scores, suggesting some potential benefit.
Kang et al [62], 2008	• Blocking noise with earplugs (silence group) • Patient- selected music (music group) • Exposure to ambient noise in the operating room (noise group)	O	Bispectral index was measured 7 times during surgery, along with ambient noise levels	Blocking noise with earplugs reduced bispectral index scores compared to exposure to ambient noise during specific surgical procedures, creating high noise levels. Music was not significantly different from noise exposure. Blocking noise may be more effective than music for reducing sedation levels during surgery with high background noise.
Tsivian et al [63], 2012		O	Pain and anxiety scores (questionnaires) and physiological parameters (blood pressure) before and after the procedure	Pain scores were the lowest in the music group. No significant changes in anxiety scores were observed. Patients in the music group showed a smaller increase in DBP after the procedure compared to the other groups, suggesting a reduced physiological stress response.

Study and year	Interventions (groups)	Category	Outcomes (measurements)	Key findings
	• Music with headphones • Noise-cancelling headphones only • Control group with no intervention			
Gingras et al [64], 2014	• Repetitive drumming and shamanic instructions • Repetitive drumming and relaxation instructions • Instrumental meditation music and shamanic instructions • Instrumental meditation music and relaxation instructions	Mix	Salivary cortisol concentration was measured before and after intervention, a self-reported mood questionnaire was administered before and after intervention, and a postexperiment questionnaire on subjective experiences was conducted	All groups showed a decrease in cortisol regardless of music or instructions. Repetitive drumming with shamanic instructions led to specific subjective experiences (heaviness, decreased HR, and dreamlike experiences) compared to drumming with relaxation instructions. Cortisol response may not be sensitive to the specific intervention (shamanic vs relaxation instructions).

[a]HRV: heart rate variability.

[b]MWSA: Mayer Wave Related Sinus Arrhythmia.

[c]RSA: respiratory sinus arrhythmia.

[d]HR: heart rate.

[q]COPD: chronic obstructive pulmonary disease.

[r]BVP-A: blood volume pulse amplitude.

Sound Per Se

Overview

The *sound per se* category encompasses studies focused on the direct impact of various sound types on psychological and physiological outcomes, independent of personal or environmental factors. This category is divided into subcategories based on music styles, music sentiment, and the physical aspects of music, examining how specific genres, emotional tones, and sound structures influence stress-related markers. Nonmusical sounds were also considered.

Music Styles

In the *sound per se—music styles* category, studies have consistently shown that different music types can influence relaxation and stress reduction. Umemura and Honda [31] found that classical music reduced HRV, indicating relaxation, while rock and noise had the opposite effect, increasing stress markers. Chafin et al [32] observed that classical music significantly lowered systolic blood pressure following a stress task, while other music styles did not. Labbé et al [33] demonstrated that listening to classical or self-selected relaxing music effectively reduced anxiety and physiological arousal compared to heavy metal or silence. Uğraş et al [34] reported that all music styles reduced preoperative anxiety, with classical Turkish music being the most beneficial. Similarly, Gulnahar and Kupeli [35] showed that Turkish and classical music reduced anxiety during dental procedures more effectively than other styles. Finally, Paszkiel et al [36] found that relaxing music and autonomous sensory meridian response decreased stress levels more quickly than silence, whereas rap music increased stress. These findings highlight the calming effects of classical and relaxing music styles across different contexts.

Music Sentiment

In the *sound per se—music sentiment* category, research has focused on the impact of different music sentiments on stress recovery. Hirokawa and Ohira [37] suggested that high-uplifting

XSL•FO
RenderX

music might enhance mood by increasing norepinephrine levels, while low-uplifting music could potentially boost feelings of well-being. Sokhadze [38] found that both pleasant and sad music improved physiological recovery from stress more effectively than white noise, indicating that positive emotions generated by music might aid in stress recovery. Suda et al [39] demonstrated that major mode music led to lower salivary cortisol levels compared to minor mode music, implying that music in a major mode may induce emotional responses such as happiness, which are closely linked to stress reduction. These findings indicate the potential of music sentiment for stress recovery and mood regulation.

Physical Characteristics of Music

In the *sound per se—physical characteristics* category, studies investigated how specific musical features or elements affect stress and anxiety outcomes. Wiwatwongwana et al [40] found that binaural beats reduced anxiety and systolic blood pressure more effectively than plain music during cataract surgery. Opartpunyasarn et al [41] showed that binaural beat music significantly reduced anxiety and blood pressure in patients undergoing bronchoscopy. Lee-Harris et al [42] reported that meditative binaural music had comparable effects to calm classical music, with age influencing preferences. Gantt et al [43] found that binaural beat technology reduced stress by altering HRV in military personnel. Calamassi et al [44] demonstrated that listening to 432 Hz music lowered anxiety and improved respiratory rate more effectively than 440 Hz music. Finally, Sharma et al [45] reported that music with tempo or octave changes reduced anxiety and decreased low-frequency brainwaves, reduced default mode network activity, and more balanced brain activity compared to stable music without variations.

Music Versus Human Voice

In the *music versus human voice* category, studies evaluated the relative effectiveness of music and voice-based interventions on anxiety and physiological responses. Singh et al [46] found that both music and progressive muscle relaxation reduced anxiety and physiological markers in patients with chronic obstructive pulmonary disease, with music showing greater effectiveness. Tang et al [47] reported significant reductions in blood pressure after both audio relaxation and music interventions, with audio relaxation showing a greater impact. Lin et al [48] demonstrated that music therapy was more effective than verbal relaxation or usual care in reducing anxiety and physiological responses in patients with cancer undergoing chemotherapy. Warth et al [50] observed that live music therapy led to greater improvements in vagally mediated HRV compared to a prerecorded mindfulness exercise, highlighting its potential for stress management. Finally, Lee et al [49] found that both music and progressive muscle relaxation improved anxiety and relaxation in patients with cancer, with electroencephalography (EEG) data suggesting different neural mechanisms for each intervention.

Personal Factors

The *personal factors* category examines how individual characteristics, preferences, and personal involvement influence the effectiveness of sound interventions. Leardi et al [53] found that patients who selected their own music during surgery had lower cortisol levels postoperatively and higher immune function compared to those exposed to standard operating room sounds or new age music. Miller et al [54] showed that joyful music improved endothelial function (flow-mediated dilatation), while anxiety-inducing music decreased flow-mediated dilatation, with the effects comparable to those achieved through exercise or medication. Imbriglio et al [55] reported that guided music listening with relaxing or favorite music reduced muscle effort during awake bruxism episodes in patients with temporomandibular disorders, whereas stressful music increased muscle tension increase. This category highlights the importance of tailored interventions, showing that factors such as personal music selection, emotional connection, and the listener's psychological state can modulate physiological and emotional outcomes. Studies within this category emphasize that the success of sound-based interventions often depends on aligning the experience with the individual's preferences and emotional needs.

Environmental Factors

The *environmental factors* category focuses on the influence of delivery methods and contextual conditions on the effectiveness of sound interventions. This category explores how the medium of delivery (eg, live vs recorded music and broadcast vs headphone playback) and environmental settings (eg, presence of supportive personnel) shape physiological and emotional outcomes. Gelatti et al [56] found that live harp music was more effective than recorded harp music in reducing heart rate and blood pressure during surgery. Bro et al [57] reported a borderline reduction in anxiety with live music during chemotherapy, while prerecorded music showed no significant effect. Lee et al [58] and Kumari et al [59] found that both headphones and broadcast music reduced preoperative anxiety, with no significant difference between the 2 methods, suggesting that broadcast music can be an alternative when headphones are unavailable. Lai et al [60] demonstrated that music interventions with a nurse present improved anxiety, sleep quality, and depression more effectively than recorded music alone. Janelli et al [61] observed no significant changes in the behavior of patients who are restrained and listened to preferred music but noted that patients who were not restrained and listened to music had higher rates of positive behavior. The findings underscore that not only the sound itself but also how and where it is delivered plays a critical role in maximizing the benefits of sound-based interventions.

Mixed Samples

In the *mixed samples* category, we included only 3% (1/34) of the articles. This intervention is considered mixed because it combines both musical (drumming and music) and voice (shamanic and relaxation guidance) elements represented simultaneously. Gingras et al [64] compared the effects of repetitive drumming with shamanic instructions, relaxation instructions, and instrumental meditation music on cortisol levels and subjective experiences. The study found that all groups showed a decrease in cortisol regardless of the intervention, but repetitive drumming with shamanic instructions

XSL•FO
RenderX

led to unique subjective experiences, such as feelings of heaviness and dreamlike states, compared to drumming with relaxation instructions.

Absence of Sound

In the *absence of sound* category, studies examined the effects of blocking noise compared to music interventions. Kang et al [62] found that blocking noise with earplugs reduced bispectral index scores more effectively than exposure to ambient noise during surgery, while music had no significant difference from noise blocking. This suggests that noise reduction may better aid sedation under noisy conditions. Tsivian et al [63] reported that music with headphones reduced pain perception during prostate biopsy compared to noise-canceling headphones or no intervention. Although anxiety scores remained unchanged, patients in the music group showed smaller increases in diastolic blood pressure, indicating a reduced physiological stress response.

Negative Effects

In the *negative* category, studies reported increases in stress markers resulting from specific sound interventions. Hirokawa and Ohira [37] found that listening to both high- and low-uplifting music decreased salivary secretory IgA levels, indicating reduced immune function, while silence led to a slight increase in salivary secretory IgA. Imbriglio et al [55] observed that stressful music increased muscle effort during awake bruxism episodes, highlighting the potential for certain music to exacerbate physical stress responses. Paszkiel et al [36] indicated that rap-style music increased stress markers compared to silence. These findings suggest that some sound interventions may have unintended adverse effects on physiological conditions.

Discussion

Principal Findings

This scoping review synthesizes current research on the effects of sound interventions on stress reduction in adults, highlighting key factors that contribute to their therapeutic potential. The analysis revealed that music, particularly self-selected relaxing music, consistently demonstrated a capacity to reduce both physiological and psychological markers of stress. Nonmusical sounds, including nature sounds and prosodic features of human speech, showed promise but were less commonly studied. As for body responses, studies frequently reported positive effects on HRV, blood pressure, cortisol levels, and self-reported anxiety. Furthermore, limited research using brain imaging demonstrated that sound interventions could modulate neural activity associated with emotional regulation, suggesting a neurobiological mechanism underlying the stress-relieving effects. Overall, these findings highlight sound therapy's potential in stress management and underscore the need for further exploration of diverse sound types and individualized approaches.

Therapeutic Factors of Sounds

The results of this review indicate that sound therapy operates through multiple mechanisms. First, it engages emotional systems to reduce stress. Sentiment, or the emotional tone of the sound, plays a significant role: calming and positive emotional tones, such as those found in soothing music, are frequently associated with reductions in anxiety and stress markers. Tempo-rhythm also emerged as a key factor, with studies showing that slower, steady rhythms often promote relaxation by modulating heart rate and respiratory patterns, while faster tempos can increase arousal. The influence of binaural beats and tempo variations further underscores the importance of this factor in modulating stress responses. These findings align with the 4-level model of sound therapy proposed by Clements-Cortes and Bartel [18], which suggests that sound can impact stress both through learned associations and inherent biological mechanisms.

One key takeaway from this review is the nuanced role of personal factors in determining the effectiveness of sound interventions. Studies where participants were allowed to choose music showed greater stress reduction than those with preselected stimuli. This underscores the importance of individual preferences, emotional involvement, and past experiences in shaping responses to sound therapy. Personalization may thus be crucial in optimizing the therapeutic potential of sound interventions.

While personal preference is often acknowledged as a key factor in stress reduction, deeper cultural influences on sound perception and stress response remain insufficiently studied. As we pointed out earlier at the protocol, some studies focus on country-specific interventions, such as traditional music or poetry, implicitly recognizing cultural context. However, only a few explicitly examine whether the therapeutic effects arise from the sound itself or cultural familiarity and learning [27]. Moreover, the concept of "relaxing" or "soothing" environments is highly context-dependent and shaped by previous exposure, traditional use, and sociocultural meaning. Few studies have examined cross-cultural differences in sound interventions, underscoring the need for research on how various musical, poetic, and speech performance traditions may influence responses across populations.

Environmental factors, such as the method of sound delivery, also play a significant role. Live music therapy, for example, appears to have stronger effects on stress markers than prerecorded music, likely due to the interactive and dynamic nature of live performances. Similarly, interventions that involve a supportive human presence, such as a nurse during a music session, further enhance the therapeutic effect.

We remain cautious about identifying the most effective therapeutic factors in sound therapy due to variability in how studies approach comparisons. Some studies focus on fine-grained distinctions in basic characteristics, such as rhythm or frequency spectrum, while others compare broader intervention clusters, such as music versus guided meditation. This difference in levels of generalization complicates direct comparisons. The reviewed studies provided limited evidence on how nonmusical sounds impact physiological stress. Key therapeutic factors such as tempo-rhythm, sentiment, or frequency, were primarily studied within the framework of music therapy. While it is possible to apply similar analytical

XSL•FO
RenderX

frameworks to other sounds, these factors may not fully capture the acoustic characteristics that underlie the psychophysical effects of nonmusical sounds. For example, while rhythm in music typically follows a structured, repetitive pattern, rhythm in spoken voice can be more dynamic and context sensitive. Further research is needed to determine whether these factors contribute to therapeutic effects in both musical and nonmusical sounds, as well as to identify acoustic features specific to nonmusical sounds.

Body Responses to Sounds

The review highlights several physiological responses associated with sound interventions in stressful conditions, measured using various biomedical technologies. HRV and cortisol levels were among the most frequently assessed markers, with multiple studies indicating that calming interventions, such as soothing music or guided relaxation, can balance autonomic nervous system responses, leading to higher HRV and lower cortisol levels. Other commonly measured physiological indicators included blood pressure, electrodermal activity, and respiratory rate, which collectively reflect physiological responses to stress. These metrics were typically recorded using devices such as electrocardiograms for HRV, blood pressure monitors, and salivary samples for cortisol.

In addition, some studies used advanced neuroimaging techniques, such as EEG, to observe brain activity changes in response to sound interventions. This review included limited studies using brain imaging, generally focused on brain activity associated with emotional regulation. For instance, some EEG data showed increased posterior theta and decreased midfrontal beta-2 activity, indicating stress relief. Another study suggested an increase in alpha wave activity, also associated with relaxation, following music and guided relaxation interventions. These neurophysiological findings support the notion that sound therapy can modulate brain activity linked to stress and emotional processing, providing a neurobiological basis for its therapeutic effects.

Identified Research Gaps

Despite these promising findings, several gaps in the literature were identified. There is a clear need for more research on nonmusical sound interventions, particularly human voice–based therapies and natural soundscapes. Studies comparing different types of sound interventions, beyond the binary classification of music versus silence, are limited. In addition, more research is required to understand the negative or side effects of sound interventions and the optimal conditions for their application.

The fragmentation of the research field and reliance on fragmented concepts are also notable. For instance, several studies emphasize the benefits of classical music over other styles, although it remains unclear what specific factors, aside from the researchers' personal preferences and cultural backgrounds, contribute to the perceived effectiveness of one style over another. Considering the limited investigation into personal factors, future studies could be designed to compare the effects of the same music on both native listeners and foreigners unfamiliar with one or another musical tradition, rather than focusing on comparisons between different regional styles.

Moreover, incorporating an artistic perspective can enhance our understanding of how esthetic and emotional engagement could influence stress relief. Insights from experts in arts and traditional culture may help explain why some sound interventions are more effective than others. Interdisciplinary collaboration between neuroscientists, psychologists, and art experts is essential for bridging scientific and artistic approaches. Future research should integrate physiological stress markers with qualitative methods, fostering a more holistic view of how personal and cultural background could shape the perceptual impact of sound.

In general, individual factors, such as personal preferences, cultural background, and previous exposure to sound therapy, have not been thoroughly examined. Future studies should consider these factors to develop more personalized sound interventions tailored to individual needs.

Another gap is the relative lack of brain imaging studies. There is still limited knowledge about the neural mechanisms underlying sound therapy's effects. Expanding neuroimaging research in this field could offer deeper insights into how different types of sounds impact neuronal activity related to emotional regulation and stress processing, particularly in real-time applications of sound therapy in stress management.

Strengths and Limitations

One of the key strengths of this scoping review is its comprehensive approach to synthesizing evidence across a variety of sound interventions and stress markers. By including diverse studies, such as RCTs, clinical trials, and laboratory experiments, the review offers a broad perspective on how different types of sound, from music to natural sounds and human voices, can influence stress response in adults. This wide scope provides a valuable foundation for understanding the generalizability of sound interventions in stress management. The review also emphasizes the importance of personal, environmental, and delivery factors, shedding light on the nuances of how sound interacts with different listeners and environments.

Another strength lies in the focus on psychophysiological outcomes. By including studies that measure stress through biomarkers such as HRV, cortisol levels, and blood pressure, alongside self-reported emotional states, the review provides a holistic view of how sound interventions impact both body and mind. This dual focus strengthens the findings by bridging subjective experiences with objective physiological evidence.

However, this review also has some limitations. A key challenge is the considerable variation in study designs, including differences in intervention duration, participant demographics, and measured outcomes. This heterogeneity limits the ability to draw broad conclusions about the effectiveness of sound interventions for stress recovery. Future research should prioritize standardizing intervention protocols, including key design elements such as intervention duration, participant characteristics, and outcome measures. These steps would

XSL•FO
RenderX

improve comparability across studies and support future meta-analysis in this field.

Another limitation is our focus on the researchers' interpretations without direct access to the actual sound samples. As evidenced by data comparison, sound can produce both positive and negative effects, depending on its characteristics. Numerous factors may influence these effects simultaneously. For instance, comparing a heavy metal composition with a Mozart lullaby, it is reasonable to expect differences in style, emotional tone, and frequency spectrum simultaneously. If these compositions were placed in their typical performance contexts, such as a concert hall for the classical music versus a stadium with amplified sound and a large, excited audience for the metal piece, the listening environment would likely impact the physiological response of the listener significantly. Therefore, our framework primarily addresses how current papers conceptualize and investigate sound.

Moreover, the term "classical music" is widely used in the reviewed studies, yet it represents a broad spectrum of musical styles that may evoke diverse responses. While some studies reference well-defined classical works (eg, Mozart or Indian classical music), others use the term more generically, leading to potential inconsistencies in interpretation. As we said before, a major limitation in existing research is the lack of access to original sound samples, making it difficult to assess key acoustic factors such as tempo, instrumentation, or emotional tone. Without standardized reporting, cross-study comparisons remain challenging. A potential direction for future research would be to obtain the sound pieces used in original studies and systematically analyze them.

Finally, the review does not provide insights into the long-term effects of sound interventions, as most studies focus on short-term stress relief. The lack of longitudinal data makes it difficult to assess the sustainability of these interventions over time and their potential cumulative benefits for stress management.

Conclusions

Our scoping review highlights the therapeutic potential of sound interventions in reducing stress, although their effectiveness is influenced by a combination of personal, environmental, and sound-related factors. Future studies should expand the range of sound types studied and explore personalized approaches. Sound-based interventions hold great promise for noninvasive and affordable stress management. Continued exploration of their mechanisms, long-term effects, and optimal applications will be key for unlocking their full potential in both clinical and nonclinical settings.

Acknowledgments

This study would not have been possible without the support of Kyoto University of Advanced Science. The authors extend their heartfelt thanks to the Tamai Scholarship, whose support enabled them to reside in Japan and complete this paper.

Data Availability

Data sharing is not applicable to this paper as no datasets were generated or analyzed during this study.

Authors' Contributions

MS performed conceptualization, data curation, formal analysis, investigation, methodology, project administration, visualization, and writing (original draft, review, and editing). IS handled data curation, investigation, validation, visualization, and writing (original draft, review, and editing). ZL contributed to conceptualization, funding acquisition, methodology, project administration, resources, supervision, validation, and writing (review and editing).

Conflicts of Interest

None declared.

Abstract

Background: The effects of traditional health-promoting and preventive interventions in mental health and mental health literacy are often attenuated by low adherence and user engagement. Gamified approaches such as serious games (SGs) may be useful to reach and engage youth for mental health prevention and promotion.

Objective: This study aims to systematically review the literature on SGs designed to promote aspects of mental health literacy among adolescents aged 10 to 14 years, focusing on game design characteristics and the evaluation of user engagement, as well as efficacy, effectiveness, and implementation-related factors.

Methods: We searched PubMed, Scopus, and PsycINFO for original studies, intervention development studies, and study protocols that described the development, characteristics, and evaluation of SG interventions promoting aspects of mental health literacy among adolescents aged 10 to 14 years. We included SGs developed for both universal and selected prevention. Using the co.LAB framework, which considers aspects of learning design, game mechanics, and game design, we coded the design elements of the SGs described in the studies. We coded the characteristics of the evaluation studies; indicators of efficacy, effectiveness, and user engagement; and factors potentially fostering or hindering the reach, efficacy and effectiveness, organizational adoption, implementation, and maintenance of the SGs.

Results: We retrieved 1454 records through database searches and other sources. Of these, 36 (2.48%) studies describing 17 distinct SGs were included in the review. Most of the SGs (14/17, 82%) were targeted to a universal population of youth, with learning objectives mainly focusing on how to obtain and maintain good mental health and on enhancing help-seeking efficacy. All SGs were single-player games, and many (7/17, 41%) were embedded within a wider pedagogical scenario. Diverse game mechanics and game elements (eg, minigames and quizzes) were used to foster user engagement. Most of the SGs (12/17, 71%) featured an overarching storyline resembling real-world scenarios, fictional scenarios, or a combination of both. The evaluation studies provided evidence for the short-term efficacy and effectiveness of SGs in improving aspects of mental health literacy as well as their feasibility. However, the evidence was mostly based on small samples, and user adherence was sometimes low.

Conclusions: The results of this review may inform the future development and implementation of SGs for adolescents. Intervention co-design, the involvement of facilitators (eg, teachers), and the use of diverse game mechanics and customization to meet the needs of diverse users are examples of elements that may promote intervention success. Although there is promising evidence for the efficacy and effectiveness of SGs for promoting mental health literacy in youth, there is a need for more rigorously planned studies, including randomized controlled trials and real-world evaluations, that involve follow-up measures and the assessment of in-game performance alongside self-reports.

Introduction

Background

It is well established that mental health problems are common among adolescents [1-3], a situation further exacerbated by the COVID-19 pandemic [4-6]. Almost 50% of psychological disorders develop before the age of 14 years [7]. Current research suggests that—apart from full-syndrome psychiatric disorders—subclinical mental health problems in adolescents are on the rise, which underscores the public health relevance of this topic [8,9]. Consequently, implementing effective strategies to tackle psychological distress at an early stage is now regarded as one of the top priorities [10]. According to the World Health Organization, adolescence, defined as the age range between 10 and 19 years, is the perfect time for the prevention of mental health problems not only because most problems have their onset during this stage of development but also due to the high neuroplasticity characteristic of the adolescent brain [11]. Furthermore, mental health is much more than the absence of mental illness. Therefore, it is suggested that it is not only important to prevent the onset of mental health disorders but also to actively promote positive mental health [12]. The Sustainable Development Goals of the United Nations include the goal of reducing premature mortality from noncommunicable diseases by one-third by 2030 [11], underlining the importance of mental health promotion and mental illness prevention programs.

One approach to achieving this goal is to promote mental health literacy [13]. This term originated in health literacy but has since developed into a domain-specific construct and evolved over time [14,15]. Most recent definitions include the following components: “understanding how to obtain and maintain positive mental health; understanding mental disorders and their treatments; decreasing stigma related to mental disorders; and enhancing help-seeking efficacy (knowing when and where to seek help and developing competencies designed to improve one’s mental health care and self-management capabilities)” [15].

A recent survey on health behavior in school-age children in Austria [16] showed that a substantial proportion of those aged 11 to 17 years (31% of the girls and 24% of the boys) reported low levels of self-efficacy. Furthermore, mental health literacy seemed to be particularly low, with only approximately half of those aged 11 to 17 years reporting that they knew where to find support for themselves or relatives in the event of mental health problems [16]. These findings underline the need to promote mental health literacy in adolescents, particularly focusing on competencies related to maintaining positive mental health, self-management strategies in case of mild psychological problems, and when to involve parents or other caregivers for more severe issues. Given the many physical and mental changes that occur during early adolescence, this period offers a window of opportunity to promote mental health literacy. It has been shown that better mental health literacy during adolescence can positively affect mental health outcomes in adulthood [17]. Consequently, developing good mental health literacy during adolescence seems imperative for becoming a healthy adult.

Digital (eHealth) interventions to promote mental health literacy have been regarded as useful and attractive [15]. However, the advantages and effectiveness of traditional psychoeducational eHealth interventions are often attenuated by low adherence and high dropout rates, particularly in the field of prevention and health promotion [18-20]. Recent research has shown that various stakeholders advocate for more game-based and implicit learning approaches [21]. For adolescents especially, serious games (SGs) are considered promising [18,20,22,23]. An SG is typically a computer- or smartphone-delivered intervention that uses gaming as the primary medium to educate and change behavior [24]. An SG aimed at promoting mental health literacy might simulate real-life scenarios where players make decisions that impact a character’s mental well-being, such as managing stress or identifying mental health problems in game avatars. In many cases, the SG is embedded in an overarching storyline (eg, an adventure mission) and might include dialogues with nonplayer characters, minigames, and in-game feedback to educate players while reinforcing positive coping strategies. SGs are considered beneficial for the following reasons: (1) they may appeal to adolescents who might otherwise not use a mental health intervention, thereby positively impacting reach; (2) the combination of fun and motivational elements can improve engagement; and (3) various mechanisms can be used to achieve the goals of the intervention [24]. In this context, the use of SGs represents a promising and innovative strategy to promote mental health literacy.

As a recently published review has shown, the majority of existing SGs targeting mental health literacy were designed for people with existing mental health problems [18], while only a few were designed to promote mental health literacy in a universal population. Furthermore, most of the identified SGs were designed for adults rather than adolescents. Nonetheless, many of these SGs have been shown to be potentially effective in improving mental health, and high levels of user satisfaction were reported [18,25], although heterogeneity in effects was also observed. Differences in design elements, including learning objectives, game structures, game mechanics, in-game interactions, and implementation strategies, may influence user engagement and effectiveness.

The co.LAB framework [26] provides a structured overview of the fundamental design elements to be considered when developing an SG. It includes aspects of learning design, learning and game mechanics, and game design (refer to the Methods section for more details) and also addresses the interplay between these elements. An in-depth consideration of these aspects is crucial for user engagement and game effectiveness. To date, no systematic review has examined SGs that target mental health literacy in adolescents and specifically focus on game design elements.

XSL•FO
RenderX

Objectives

The objective of this study was to conduct a systematic review of SGs aimed at promoting aspects of mental health literacy in adolescents aged 10 to 14 years. In contrast to the systematic review by Ferrari et al [18], this study focuses on a detailed review of game design elements based on the co.LAB framework [26] and includes aspects related to implementation in real-world settings. Moreover, this study focuses exclusively on SGs designed for nonclinical samples. The rationale for focusing on the narrow age range (10-14 y) is 2-fold: first, as outlined previously, early adolescence is a critical period for the development of mental health problems; thus, preventive interventions may be particularly important. Second, the results from this systematic review will directly inform the development of a prototype of a new SG aimed at promoting mental health literacy in adolescents [27]. The age range of 10 to 19 years was considered too broad to develop an SG that would appeal equally to, and be appropriate for, those aged 10 to 11 years and those aged 18 to 19 years.

Specifically, the following research questions (RQs) were developed:

1. Which design elements (learning design, mechanics, and game design) have been used in existing SGs to promote mental health literacy?
2. What is known about the efficacy and effectiveness of these games, as well as user engagement with them?
3. What factors have fostered or hindered reaching the target population and adoption by organizations, as well as the efficacy and effectiveness, implementation, and maintenance of these interventions?

Methods

Overview

We conducted a systematic review following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [28]. The PRISMA checklist is presented in Multimedia Appendix 1. This review was not registered, and no protocol was published in advance.

Eligibility Criteria

The eligibility criteria for the inclusion of studies in the review are presented in Textbox 1.

Textbox 1. Eligibility criteria.

Inclusion criteria

1. The study had to be related to either the development or evaluation of a mental health literacy intervention. We included studies targeting mental health literacy in general or at least 1 aspect of it as defined by Kutcher et al [15]. These aspects may include competencies to maintain or obtain positive mental health, recognize the symptoms of mental disorders, and deal with mental health issues (eg, stress coping, emotion regulation, and dealing with negative emotions), as well as knowledge of services for seeking help and the destigmatization of mental problems or disorders.
2. The intervention had to use a game-based approach, involving games playable on a PC, smartphone, or tablet. Both game-only and blended interventions (ie, those combining a serious game with face-to-face sessions) were included. However, the game had to be the primary component of the intervention. Digital interventions that merely incorporated single gamification elements into nongame contexts were excluded.
3. Studies were included if the intervention was designed for either universal prevention or selected prevention (ie, groups considered to be at risk). In this regard, we referred to the stepped care model for video game interventions formulated by Ferrari et al [18], who defined “step 0” as population-based interventions for mental health prevention and promotion as well as education for asymptomatic youth (ie, universal prevention) and “step 1” as interventions targeted to groups considered to be at risk or those with suspected mental health problems. However, studies using mixed samples (eg, healthy individuals and those with a mental illness) were included if the intervention was primarily targeted to healthy individuals.
4. The described target population of the game had to comprise adolescents aged 10 to 14 years.
5. The study had to be an evaluation study, usability and feasibility study, or study protocol that described the development or design of an intervention or the design of a randomized controlled trial.
6. The study had to be published in a peer-reviewed journal.
7. It had to be written in English or German (languages understood by the research team).
8. The study had to be published in 2013 or later (within the past 10 years). By focusing on studies from the last 10 years, we aimed to avoid the inclusion of serious games based on outdated technology.

Exclusion criteria

1. Reviews, conference abstracts, books and book chapters, and theses were excluded.
2. Studies on games that involved virtual reality, augmented reality, or biofeedback were also excluded because these types of interventions require specific equipment and are usually not designed to be widely disseminated, such as for use in schools.

Information Sources and Search Strategy

We searched 3 electronic databases (PubMed, Scopus, and PsycINFO) for relevant literature. The selected keywords were related to mental health (“mental health OR mental health literacy OR mental health promotion OR coping OR stress management OR emotion recognition OR emotion regulation OR stigma”) and gamified approaches (“serious game* OR digital game* OR serious video game* OR game-based OR gamification OR smartphone game* OR mobile game*”). These 2 groups of keywords were combined using an “AND” operator. The exact search syntax is provided in Table S1 in Multimedia

XSL•FO
RenderX

Appendix 2 [22,23,29-53]. In addition, we searched the reference lists of relevant reviews and included studies to identify additional publications.

Selection Process

All studies retrieved through the literature search were imported into a reference manager. In the first step, we excluded duplicates, reviews, books and book chapters, theses, conference abstracts, and studies published before 2013. Next, 2 pairs of independent researchers (UP and SV; MZ and SV) screened titles and abstracts for inclusion criteria. To establish a shared understanding of eligibility, the first 15 titles and abstracts were evaluated by all reviewers and discussed immediately afterward. After abstract screening, interrater reliability was 93.5%. Articles that passed the abstract screening and those retrieved through other sources (eg, reference lists and reviews) underwent full-text review by the same pairs of independent researchers. Any disagreements were discussed with a third researcher (KW) until consensus was reached. Interrater reliability for the full-text screening was 91.8%.

Data Collection Process and Coding Procedure

We collaboratively developed the coding sheet, which included the extraction of design elements of the SGs as well as study characteristics and results. The coding of intervention design elements was based on the co.LAB framework [26], which categorizes design elements across three dimensions: (1) learning design (including learning profiles, learning functions, learning objectives, learning foundations, knowledge foundations, and pedagogical scenarios), (2) mechanics (including learning mechanics, game mechanics, learning and game incentives and rewards, and learning and game interactions), and (3) game design (including goals and rules, game universe, fidelity and simulation models, interfaces and user experience, and game structure and narrative). Definitions of these items can be found in Table S2 in Multimedia Appendix 2.

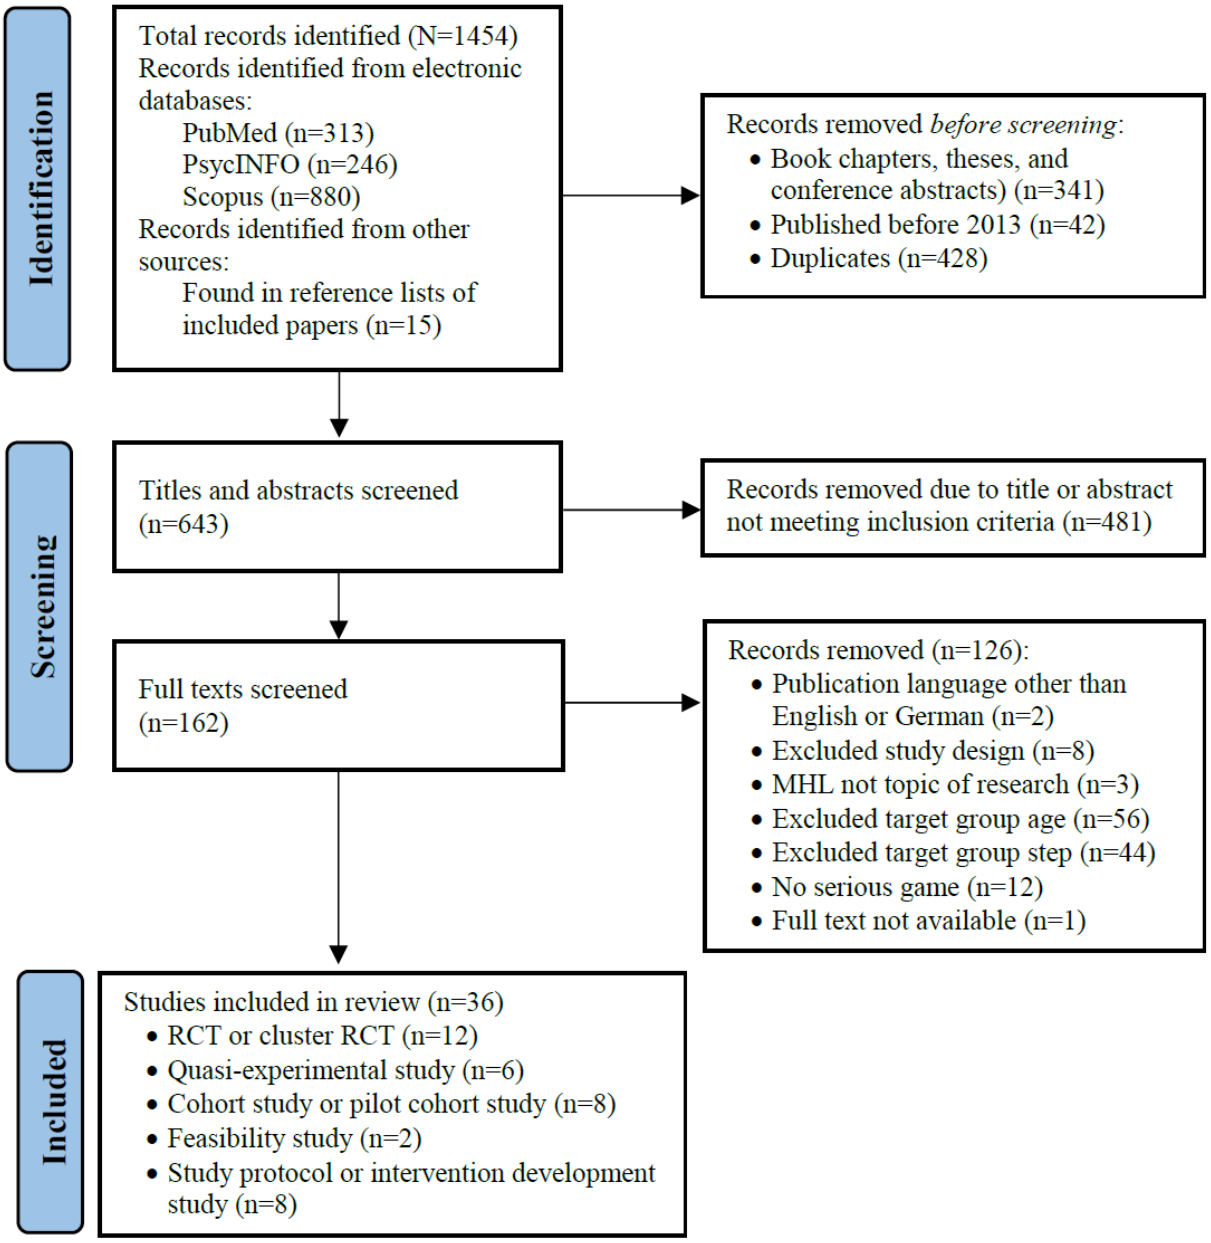
Furthermore, regarding study characteristics, we extracted the publication year, language, country in which the intervention was conducted, and study arms. Regarding sample characteristics, we coded the inclusion and exclusion criteria, sample size, age, sex, recruitment and implementation setting, follow-up time points, outcome variables, analysis methods, main results, and adherence and dropout measures. In addition, we extracted potentially hindering or fostering factors related to participant reach and intervention effectiveness as well as organizational adoption, implementation, and maintenance of the intervention, as outlined in the RE-AIM (Reach, Effectiveness, Adoption, Implementation, and Maintenance) framework [54], if these were discussed in the included papers. We included not only fostering or hindering factors identified through systematic evaluation studies on SGs but also factors that the authors described as potentially relevant in the discussion sections of the papers. A full overview of the coded items is provided in Table S2 in Multimedia Appendix 2.

To establish a common understanding of how to use the coding sheet appropriately, 2 full texts were coded independently by 4 researchers (UP, SV, MZ, and KW) and subsequently discussed. The extraction and coding of all remaining studies were performed independently by 2 researchers (UP and SV). Any inconsistencies were discussed with at least 1 additional researcher (MZ or KW) until consensus was reached.

Furthermore, we used the National Institutes of Health quality assessment tool [55] for controlled intervention studies (14 items) or for pretest-posttest studies with no control group (12 items) to evaluate the quality of the included evaluation studies. The critical appraisal of the included studies was also performed independently by 2 of the following researchers (MZ, SV, UP, and LA), and any inconsistent results were discussed with a third researcher (KW).

Data Synthesis

We conducted a narrative synthesis of the coded study and game characteristics as well as the results regarding efficacy and effectiveness. The results were summarized in tables, which are presented in the Results section or in the multimedia appendices. Where applicable, we counted the frequencies of relevant categories (eg, the number of stand-alone vs blended interventions, the number of SGs based on fictional vs real-world scenarios, and the number of interventions implemented in schools vs other settings) and reported them in the text. Due to the substantially diverse outcome measures used in the individual studies, we refrained from conducting a meta-analysis to evaluate the efficacy and effectiveness of SGs. Fostering and hindering factors based on the RE-AIM framework were extracted and categorized and are briefly summarized in the text.



Results

Literature Search Process

The literature search, completed on July 13, 2023, yielded 1439 results (PubMed: n=313, 21.75%; PsycINFO: n=246, 17.1%; and Scopus: n=880, 61.15%). An additional 15 studies were identified through other sources. After removing duplicates, book chapters, theses, conference abstracts, and studies published before 2013, a total of 643 (44.22%) of the 1454 studies remained. The titles and abstracts of these papers were screened for inclusion criteria. Studies that passed the screening (162/643, 25.2%) underwent full-text review, of which 22 (13.6%) were excluded for not meeting the inclusion criteria regarding publication language, study type, and SG intervention. Of the remaining 140 studies, 103 (73.6%) were excluded because they did not focus on mental health literacy or described SGs not developed for our defined target group, while 1 (0.7%) study was excluded because the full text was not available. Finally, of the initially identified 1454 studies, 36 (2.48%) were included in this review (refer to Figure 1 for the PRISMA flowchart).

XSL•FO

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart documenting the literature search process. MHL: mental health literacy; RCT: randomized controlled trial.

Characteristics of Included Studies

An overview of the study and sample characteristics of the included studies as well as brief descriptions of the SGs are provided in Table 1. Among the 36 studies, we identified 12 (33%) randomized controlled trials (RCTs) or cluster RCTs, 6 (17%) quasi-experimental studies, 8 (22%) cohort studies (including pilot studies) without a control group, and 2 (6%) feasibility studies, while 8 (22%) were study protocols or papers describing the intervention development process. Altogether, these papers described the design and evaluation of 17 SGs aimed at promoting aspects of mental health literacy. Of note, 7 (19%) of the 36 articles focused on the *REThink* intervention. However, of these 7 articles, 4 (57%) [29-32] referred to the same sample or a subset of the sample included in the overarching RCT [33]. In addition, 2 (6%) [34,35] of the 36 articles focused on the *Happy* intervention, but both merely repeated the findings of 2 other articles [36,37].

Table 1. Study and sample characteristics.

Serious game and study; country	Study design (study arms)	Inclusion and exclusion criteria	Sample size (size of each group); participation rate (%)	Age (y), mean (SD; range)	Girls (%)	Implementation setting
Adventures Aboard the S.S. Grin (level of prevention: step 1[a]): the child's avatar joins the crew of a sailing ship and travels around an island, interacting with nonplayer characters and solving social challenges to strengthen social and emotional skills (eg, emotion regulation, perspective taking, and impulse control)						
Sanchez et al [39], 2017; United States	RCT[b] (IG[c] vs waitlist CG[d])	Inclusion criteria: aged 7-11 y, internet access, proficiency in English, and social skills deficits	69 (33 and 36); NR[e]	NR (NR; 7-11)	NR	Home
Aislados (level of prevention: step 0[f]): characters are deployed in an imaginary boat traveling to some newly discovered islands; the player has to interact with other nonplayer characters and obtain information for task achievement or solving riddles related to socioemotional skills (eg, assertiveness, emotional skills, and decision-making)						
Cejudo et al [40], 2020; Spain	Quasi-experimental (IG vs waitlist CG)	Inclusion criterion: parental consent; exclusion criteria: disciplinary problems, special educational needs, intellectual disability, and <75% of intervention completed	187 (97 and 90); NR	13.8 (1.6; 12-17)	53	School
Emodiscovery (level of prevention: step 0): different emotionally challenging scenarios for nonplayer characters are presented in the game; the player has to recognize the emotions of these characters and interact with them to make them feel better						
Pacella and López-Pérez [42], 2018; United Kingdom	Cohort study (IG only)	Inclusion criterion: parental consent	58 (N/A[g]); 90	8.8 (1.0; 8-11)	36.2	School
López-Pérez and Pacella [38], 2021; United Kingdom and Spain	Cohort study (IG only)	Inclusion criterion: parental consent	208 (United Kingdom: 100; Spain: 108); >95	United Kingdom: 9.1 (0.83; 8-10); Spain: 9.0 (0.83; 8-10)	United Kingdom: 39; Spain: 44	School
EmoTIC (level of prevention: step 0): the player has crashed on a fictional planet, and the main objective is to return to earth, which can be achieved by solving different tasks related to the use of socioemotional skills, including stress-coping strategies, assertiveness, and self-efficacy						
de la Barrera et al [56], 2021; Spain	Study protocol	Inclusion criteria: first or second year of compulsory secondary education, mobile device with internet access, and parental consent; exclusion criteria: aged <11 y and >16 y	N/A	N/A	N/A	N/A
de la Barrera et al [49], 2021; Spain	RCT (IG vs waitlist CG)	Inclusion criteria: first or second year of compulsory secondary education, mobile device with internet access, and parental consent; exclusion criteria: aged <11 y and >16 y and not completed ≥80% of the pretest assessment	286 (119 and 167); NR	IG: 12.6 (0.7; 11-15); CG: NR	IG: 42.9; CG: NR	School and home
Happy 8-12 and Happy 12-16 (level of prevention: step 0): different examples of everyday conflicts are presented; the player has to identify the emotions of nonplayer characters and respond to conflict situations by suggesting adaptive emotion regulation strategies						
Filella et al [36], 2016; Spain (information repeated in Ros-Morente et al [35], 2018 and Filella and Ros-Morente [34], 2023)	Quasi-experimental cluster trial (IG vs waitlist CG)	NR	574 (351 and 223); NR	10.5 (0.7; NR)	47.6	School
Filella et al [37], 2018; Spain (information repeated in Ros-Morente et al [35], 2018 and Filella and Ros-Morente [34], 2023)	Quasi-experimental cluster trial (IG vs waitlist CG)	Inclusion criterion: parental oral consent	903 (472 and 431); NR	12.6 (0.6; NR)	47.8	School

XSL•FO
RenderX

Serious game and study; country	Study design (study arms)	Inclusion and exclusion criteria	Sample size (size of each group); participation rate (%)	Age (y), mean (SD; range)	Girls (%)	Implementation setting
IMPeTUs (level of prevention: step 0): the player has to navigate through different mental health–related challenges and make decisions reflecting the level of mental health literacy skills as well as anxiety- and depression-focused self-management skills; the game also includes minigames focusing on improving specific coping skills (eg, distraction and breathing techniques, journaling, and talking about mental health issues)						
Brooks et al [57], 2021; Indonesia	Study describing intervention development	N/A	N/A	N/A	N/A	N/A
Brooks et al [50], 2023; Indonesia	Pilot usability and feasibility study (IG only)	Inclusion criteria: aged 11-15 y, in contact with one of the defined study locations, and adolescents' assent and parental consent	78 (N/A); NR	12.9 (1.4; 11-15)	48.7	School, community, and health care organizations
Moving Stories (level of prevention: step 0): an avatar with the symptoms of depression is introduced, and player is asked to help her to feel better through different actions, achieved by applying skills related to the correct identification of depressive symptoms, knowledge of help-seeking options, and first aid skills						
Gijzen et al [58], 2021; Netherlands	Implementation and feasibility qualitative study (IG only)	Inclusion criteria: enrolled in the second year of high school and sufficiently fluent in Dutch (the schools concerned were participating in the overall STORM[h] program)	982 (NR); 52	NR (NR; 11-15)	NR	School and home
Tuijnman et al [59], 2019; Netherlands	Study protocol paper	Exclusion criterion: refusal to participate by parents or adolescent	N/A	N/A	N/A	N/A
Tuijnman et al [43], 2022; Netherlands	Cluster RCT (IG vs waitlist CG)	Exclusion criterion: refusal to participate by parents or adolescent	185 (99 and 86); 67.3	13.4 (0.7; 12-15)	Total: 43.3; IG: 34; CG: 58	School
Unnamed serious game (level of prevention: step 0): the player is transported into a fantasy world and has to solve the mystery of a catastrophic event (almost all people have vanished from a virtual school); the mystery is solved by understanding interpersonal conflicts and applying adaptive interpersonal emotion regulation skills while interacting with nonplayer characters						
Mittmann et al [60], 2021; Austria and United Kingdom	Study protocol for RCT (IG vs active CG)	Inclusion criteria: aged 10-14 y, parental consent, willingness to complete pretest and posttest questionnaire and play the game in between, able to read and understand German or English, and access to an internet-enabled device	180 (planned; NR); NR	NR	NR	School and home
POD Adventures (level of prevention: step 1): short vignette-based stories related to common stressors of nonplayer characters are presented, and the player has to react accordingly to cope with these stressors; moreover, the player is guided through problem-solving steps for their own problems						
Gonsalves et al [61], 2019; India	Intervention development study and user testing (IG only)	Inclusion criteria: had to speak English, Hindi, or Konkani; and parental consent	50 (N/A); NR	14.5 (NR; 12-17)	56	School
Gonsalves et al [46], 2021; India	Pilot cohort study (IG only with 2 delivery formats)	Inclusion criteria: students in grades 9-12, self-referral for psychological help with perceived stress, and proficient in English and Konkani; exclusion criterion: elevated risk of self-harm or suicide	248 (NR); 14.1	15.6 (NR; 13-19)	50	School
Gonsalves et al [62], 2021; India	Study protocol	Inclusion criteria: students in grades 9-12, access to an internet-enabled Android smartphone, English proficiency, and students' assent and parental consent; exclusion criteria: unable to understand intervention material and elevated risk for self-harm or suicide and requiring external referral	N/A	N/A	N/A	N/A

XSL•FO
RenderX

Serious game and study; country	Study design (study arms)	Inclusion and exclusion criteria	Sample size (size of each group); participation rate (%)	Age (y), mean (SD; range)	Girls (%)	Implementation setting
Gonsalves et al [47], 2023; India	Pilot RCT (IG vs CG, including enhanced usual care)	Inclusion criteria: students in grades 9-12, access to an internet-enabled Android smartphone, English proficiency, and students' assent and parental consent; exclusion criteria: unable to understand intervention material and elevated risk for self-harm or suicide and requiring external referral	11 (5 and 6); <1	Total: 15.3 (1.0; NR); IG: 15.0 (0.5; 13-19); CG: 15.5 (1.3; 13-19)	Total: 63.6; IG: 60; CG: 66.7	Home (school recruitment)
Professor Gooley and the Flame of Mind (level of prevention: step 0): the player takes the role of a space intern in a fictional setting where cognitive distortions prevail on earth; during a space journey to 8 fictional planets, the player completes quests that require skills related to, for example, the identification of automatic thoughts, self-esteem, interpersonal communication, and problem-solving						
Huen et al [48], 2016; China	Cohort study (IG only)	NR	498 (N/A); 31	12.6 (1.2; NR)	50.6	NR (school recruitment)
R.E.M.I. (level of prevention: step 0): each player is paired with a virtual robot and tasked with training it in various social and emotional skills						
Saleme et al [63], 2021; Australia	Intervention development study and study protocol	NR	NR	NR (NR; 8-11)	NR	School and home
RegnaTales (level of prevention: step 0): a series of 6 different game-based mobile apps through which players learn to improve anger management by identifying feelings and bodily reactions, distinguishing positive from negative thoughts, applying anger-coping skills, and learning specific techniques (eg, cognitive restructuring, breathing, and perspective taking)						
Ong et al [44], 2019; Singapore	Pilot cohort study (IG only)	Inclusion criteria: typically developing children or children with disruptive behavior disorders, and children's assent and parental consent	72 (N/A); 51.4 in the disruptive behavior disorders group	8.8 (1.7; 6-12)	31.9	Clinical setting
REThink (level of prevention: step 0): the player's mission is to help people on the planet escape the negative influence of an "Irrationalizer" by supporting them in becoming more rational and happier, which is achieved by performing tasks related to various mental health and coping skills (eg, replacing irrational cognitions, recognizing emotions, identifying problem-solving steps, and applying breathing techniques)						
David et al [51], 2018; Romania	Pilot cohort study (IG only)	Inclusion criterion: children's assent and parental consent	25 (N/A); 88	13.4 (0.7; 10-16)	36	School
David et al [33], 2019; Romania	RCT (IG vs face-to-face IG vs waitlist CG)	Inclusion criterion: informed consent from parents and school principal	165 (54, 55, and 56); 86	Total: 13.0 (2.1; 10-16); IG: 13.0 (2.1; NR); face-to-face IG: 12.8 (2.0; 10-16); CG: 12.9 (2.2; 10-16)	64	School
David et al [29], 2019; Romania	RCT (IG vs face-to-face IG vs waitlist CG)	Inclusion criterion: informed consent from parents and school principal	165 (54, 55, and 56); 86	Total: 13.0 (2.1; 10-16); IG: 13.0 (2.1; NR); face-to-face IG: 12.8 (2.0; 10-16); CG: 12.9 (2.2; 10-16)	64	School
David et al [23], 2021; Romania	Pilot cohort study (IG only)	Inclusion criterion: informed consent from parents and school authorities	31 (N/A); 100	12.3 (1.4; 10-16)	58	School
David et al [31], 2022; Romania	RCT (IG vs face-to-face IG vs waitlist CG)	NR	165 (54, 55, and 56); 86[i]	12.8 (2.0; NR)	58.6	School
David et al [30], 2022; Romania	Pilot cohort study (IG only)	Inclusion criterion: completion of initial assessment	48 (N/A); NR[j]	13 (2.1; 10-16)	75	School
David and Magurean [32], 2022; Romania	RCT (IG only)	NR	34 (N/A); NR[k]	13 (2.1; 10-16)	75	School

XSL•FO
RenderX

Serious game and study; country	Study design (study arms)	Inclusion and exclusion criteria	Sample size (size of each group); participation rate (%)	Age (y), mean (SD; range)	Girls (%)	Implementation setting
The Singularities (level of prevention: step 1): the player takes on the role of a "Singular," a superhuman individual with special gifts, who resides in a school; the player is told that because of their uniqueness, Singulars face prejudice, often driven by fear and misunderstanding; the player is tasked with finding a team to help them complete their final mission, which is achieved by encouraging help-seeking behavior and the use of productive coping skills						
Coulter et al [64], 2019; United States	Study protocol	Inclusion criteria: English speaking, living in the United States, aged 14-18 y, experienced bullying or cyberbullying in the past year, sexual or gender minority identity, have access to a computer, and possess an email address	N/A	N/A	N/A	N/A
Egan et al [45], 2021; United States	RCT (IG vs active CG)	Inclusion criteria: English speaking, living in the United States, aged 14-18 y, experienced (cyber)bullying in the past year, sexual or gender minority identity, have access to a computer, and possess an email address	240 (120 and 120); 59	Total: 15.8 (1.1; 14-18); IG: 15.8 (1.1; 14-18); CG: 15.7 (1.1; 14-18)	Cisgender girls, total: 16.3; IG: 15; CG: 18	Home
Stigma-Stop (level of prevention: step 0): the player's character visits nonplayer characters with mental disorders (eg, schizophrenia, depression, bipolar disorder, and panic disorder) to motivate them to participate in a video game design contest; this is achieved by understanding the symptoms of mental disorders; the game is complemented by minigames designed to enhance the understanding of mental disorders and reduce stigma						
Cangas et al [22], 2017; Spain	RCT (IG vs active CG)	Inclusion criterion: oral informed consent	552 (484 and 68); NR	15.8 (2.7; 14-18)	50	Laboratory (school recruitment)
Cangas et al [41], 2019; Spain	RCT (IG vs active CG)	Inclusion criterion: oral informed consent	530 (412 and 118); NR	18.5 (4.3; 14-59)	61.5	Laboratory (school and university recruitment)
The Adventures of DoReMiFa (level of prevention: step 0): the player lives on a fictional planet whose inhabitants are unhappy; in response, the president sends 4 monsters (Do, Re, MI, and Fa) to Earth to look for a book hidden in a primary school, which would help improve the mental health of their fellow citizens; while searching for this book, different challenges and tasks are performed requiring emotional competence as well as problem-solving and social skills						
Shum et al [52], 2019; China	Quasi-experimental trial (IG vs waitlist CG)	Inclusion criterion: informed consent from parents	459 (264 and 195); NR	IG: 9.5 (0.72; 8-12); CG: 9.5 (0.64; 8-12)	IG: 69; CG: NR	School
Zoo U (level of prevention: step 0): the player has to interact with virtual teachers and classmates to learn about and take care of animals; this task requires various skills, including impulse control, communication, cooperation, social initiation, empathy, and emotion regulation						
Craig et al [53], 2016; United States	RCT (IG vs waitlist CG)	Inclusion criteria: aged 7-11 y, proficiency in English, and access to internet-enabled computer	47 (23 and 24); NR	9.7 (1.3; 7-11)	41	Home

About a half of the SGs (8/17, 47%) were developed and evaluated in European countries, including Spain, the Netherlands, Romania, Austria, and the United Kingdom, SGs on this topic were also developed in Asian countries (Indonesia, India, China, and Singapore) as well as in Australia and the United States. Of note, only 2 (6%) of the 36 studies evaluated an SG or planned to evaluate it in >1 country [38,60].

XSL•FO
RenderX

Most of the studies (25/36, 69%) intended to include a broad population of participants by defining minimal inclusion and exclusion criteria, typically limited to parental consent, age range, access to a digital device for gameplay, and language proficiency. The target groups for most of the identified SGs (14/17, 82%) were a universal population of children or adolescents (step 0, universal prevention). Only 3 (18%) of the 17 SGs were designed as selected prevention interventions (step 1): *Adventures Aboard the S.S. Grin* [39], targeted to individuals with social skills difficulties; *POD Adventures* [61], targeted to adolescents at risk of anxiety, depression, and conduct problems; and *TheSingularities* [64], developed for sexual and gender minority youth with previous experience of (cyber)bullying exposure. Most of the SGs (12/17, 71%) were designed for young adolescents within a narrow age range, specifically targeting individuals aged 10 to 14 years. However, some of the SGs (4/17, 24%) were additionally applied in adolescents aged >14 years [40,59,61,64]. *Stigma-Stop* [41] was additionally used in a university student population.

Sample sizes varied widely across the studies, ranging from 11 [62] to 982 [58] participants. The majority of the studies (11/36, 31%) included <100 participants, followed by those that included 100 to 300 participants (10/36, 28%), and studies with >300 participants (9/36, 25%). The remaining studies (mostly study protocol papers) did not report sample size (6/36, 17%). In most of the samples, the gender distribution was approximately balanced, with the proportion of girls ranging from one-third to two-thirds in the majority of the studies. Of note, no SG was evaluated exclusively in samples composed only of boys or only of girls. Some of the studies (14/36, 39%) reported the participation rate, defined as the percentage of individuals who provided informed consent out of all those approached. High participation rates were found for the *Emodiscovery* [38,42] and *REThink* [23,33] interventions; moderate rates for *Moving Stories* [43,58], *RegnaTales* [44], and *The Singularities* [45]; and low rates for *POD Adventures* [46,47] and *Professor Gooley and the Flame of Mind* [48].

Half of the SGs (18/36, 50%) were implemented in a school setting, while in some of the studies (7/36, 19%), gameplay took place at home or in a university laboratory. A few of the studies (5/36, 14%) used a combination of school-based and at-home implementation. The remaining studies (6/36, 17%) did not report on the implementation setting.

Game Characteristics Based on the co.LAB Framework

A detailed overview of the characteristics of the identified SGs is provided in Multimedia Appendix 3 [22,23,29-49,51-53,56-64].

Learning Design

The learning objectives of the SGs are summarized in Table 2, based on the mental health literacy dimensions proposed by Kutcher et al [15]. The majority of the SGs (16/17, 94%) aimed at helping users understand how to obtain and maintain good mental health as well as enhance help-seeking efficacy. Specifically, the most frequently mentioned learning objectives included developing and improving interpersonal communication skills, expressing one's own feelings, recognizing the emotions of others, applying emotion regulation strategies, and using stress-coping techniques. Of the 17 SGs, only 4 (24%) focused on or incorporated elements to improve users' understanding of mental disorders (depression, anxiety disorders, schizophrenia, bipolar disorder, and addictions) and their treatments, and only 3 (18%) explicitly aimed to decrease stigma related to mental disorders.

The learning objectives of all SGs (17/17, 100%) were geared toward testing or applying players' existing knowledge or skills and supporting knowledge and skills acquisition. Only 5 (29%) of the 17 games (*TheSingularities* [64], *POD Adventures* [61], *RegnaTales* [44], *Adventures Aboard the S.S. Grin* [39], and *The Adventures of DoReMiFa* [52]) defined learning goals that explicitly aimed to prepare players to apply the learned skills in new real-world situations.

The SGs were based on cognitive behavioral theory, social and emotional learning, positive psychology, stress-coping theory, or social cognitive theory; or they incorporated elements from several of these psychological theories. However, for 7 (41%) of the 17 SGs, no theoretical psychological foundation was reported. Most of the studies (15/17, 88%) described the sources used to inform the content design of the intervention. This included (1) input from existing in-person intervention manuals [23,39,44,53,59,61], (2) (systematic) literature reviews [36,57,59,60], (3) input and feedback from target group representatives (eg, via focus groups, codevelopment workshops, and usability tests) [52,56,57,60,61,63,64], and (4) input from experts and other stakeholders (eg, via needs assessments or codevelopment sessions) [42,52,59,61,63].

Of the 17 identified SGs, 10 (59%) were designed as stand-alone interventions, while the gameplay of the remaining games was embedded in broader pedagogical scenarios. These included (1) combining gameplay and classroom sessions throughout the intervention period (*Aislados* [40], *EmoTIC* [49], and *The Adventures of DoReMiFa* [52]), (2) conducting face-to-face group sessions to further discuss the topics addressed in the game after a period of gameplay (*IMPeTUs* [57] and *R.E.M.I.* [63]), (3) inviting people with lived experience of psychological disorders (*Moving Stories* [43,58,59]), and (4) offering individual face-to-face meetings or telephone calls with a counselor (*POD Adventures* [61]).

[a]Knowing when, where, and how to obtain good mental health care and developing competencies needed for self-care.

Mechanics

Most of the studies (16/17, 94%) reported on the learning mechanics implemented to achieve the learning objectives. These mechanics can be classified into four broad categories. (1) In many of the SGs (6/17, 35%), players were required to identify and analyze the emotional states and behaviors of nonplayer characters (eg, recognizing basic and complex emotions, distinguishing rational from irrational thoughts, and identifying stressors based on the avatars' verbal expressions, behaviors, physical appearance, and circumstances). (2) In almost all SGs (14/17, 82%), the player had to propose coping strategies to the nonplayer characters to help them overcome or regulate negative and stressful emotions and irrational thoughts, as well as solve problems, reduce symptoms of mental health disorders, and increase help-seeking behavior. (3) In a few SGs (3/17, 18%), learning was facilitated by presenting psychoeducational content about mental health problems and support strategies. (4) In some SGs (8/17, 47%), the learning objectives were addressed by encouraging players to reflect on their own mental health states and directly practice coping strategies (eg, distraction and breathing techniques as well as journaling) through in-game activities.

The game mechanics included classic point-and-click interactions (where players choose from various response options presented in a virtual menu or conversation window, eg, to select different emotions or propose self-help strategies to nonplayer characters), exploration and observation of the game environment, self-reflective questions and monitoring tools (to support reflection on one's own mental health states and behavior), and reading assignments (for psychoeducation). Moreover, some minigames featuring activities such as quizzes, flying, running, jumping, collecting objects, painting, shooting, and memory challenges were implemented. Breathing and muscle relaxation techniques were also practiced using minigames.

In addition, minigames and quizzes were mentioned as game elements that enhanced user engagement by providing variety, including cliffhangers (*Adventures Aboard the S.S. Grin* [39]) and self-selection of the sequence in which the game scenarios were played (*Stigma-Stop* [22]). Another important feature for enhancing engagement was the inclusion of individualized feedback based on the player's in-game performance. This feedback was delivered in the form of (1) points, stars, or virtual money, some of which could be used to upgrade the player's avatar or purchase new items; (2) direct feedback (written, verbal, or visual) provided by the nonplayer characters; and (3) overall feedback at the end of gameplay regarding helpful and unhelpful behaviors.

Most of the game descriptions were vague regarding how the game progressed based on the player's in-game behavior. Some of the studies (7/17, 41%) reported that the game proceeded when the player successfully completed the previous module or game episode or reached a defined number of points reflecting their performance. Other studies (4/17, 24%) reported that levels

XSL•FO
RenderX

were unlocked after a predefined period (eg, daily or weekly) regardless of the player's performance on previous levels. Of the 17 studies, 2 (12%) reported that the players' in-game decisions had an impact on the game's storyline (*IMPeTUs* [57] and *R.E.M.I.* [63]).

Game Design

Of the 17 SGs, 7 (41%) were based on real-world scenarios and included scenes set in a virtual school, home, or playground environment; 7 (41%) used fictional scenarios (mainly nautical or space themed) in which the action takes place on a planet, a sailing ship, or a virtual island; and 3 (18%) used a combination of real-world scenarios and fictional elements. Regarding the narrative and overall game goals, 12 (71%) of the 17 SGs used an overarching storyline in which the game scenarios were embedded. In *REThink*, for example, the main goal is to help people on a fictional planet escape the negative influence of an avatar called the "Irrationalizer" [33]. In *Professor Gooley and the Flame of Mind*, the goal is to find components and activate the "flame of mind" [48]. In *Moving Stories*, the player must improve their relationship with a depressed nonplayer character called Lisa and motivate her to talk to an adult about her problems [59]. In *R.E.M.I.*, the objective is to train a robot to make prosocial decisions [63]. In the remaining SGs, various (social) conflict situations [35,50,56], vignette-based stories [61], or even distinct mobile apps [44] were presented, none of which were interconnected via an overarching storyline.

Most of the SGs (14/17, 82%) were at least partly structured using levels, episodes, modules or game scenes. The recommended playing time varied considerably. In a few of the SGs (3/17, 18%), completing 1 level per week was recommended, while the expected duration per level ranged from 25 to 120 minutes. Among the studies that explicitly reported the intended duration of gameplay, the durations ranged from a single session lasting a few hours (*Emodiscovery*, *Stigma-Stop*, and *R.E.M.I.*) to approximately 1 week (*Moving Stories*), a few weeks (*Adventures Aboard the S.S. Grin*, *POD Adventures*, *Professor Gooley and the Flame of Mind*, *REThink*, and *Zoo U*), and several months (*Aislados*, *EmoTIC*, and *The Adventures of DoReMiFa*). In some of the SGs (5/17, 29%), no specific duration was prescribed, and players were instructed to play at their own pace.

All identified SGs were single-player games. Of the 17 SGs, 5 (29%) were designed to run on PCs only, another 5 (29%) were designed exclusively for mobile apps (smartphone and tablet), and 5 (29%) were compatible with multiple devices, while for 2 (12%) SGs, this information was not reported. Some studies (10/17, 59%) reported information on game features used to enhance realism. Some of the studies (7/17, 41%) indicated that their game scenarios were closely based on real-life experiences and conflicts relevant to the target group [36,37,42,57,59,61,63], which can be regarded as a factor enhancing the SG's cognitive fidelity. Elements relevant for enhancing the SG's audiovisual fidelity included voice-overs [39,40,61], background music [40,48], and game environments modeled on real-life school settings and other familiar locations [61]. In addition, players could customize their character based on personal preferences, including gender, name, skin color, outfit, level of education, and body type. Of note, only 1 (6%) of the 17 SGs (*Stigma-Stop* [22]) included an artificial intelligence (AI) component, which was used to generate background and vehicle movement.

Results Related to User Engagement as Well as Efficacy and Effectiveness

This section only refers to studies having evaluated the user engagement and efficacy or effectiveness of the included SGs (Table 3). The included studies varied widely in the outcome variables used to evaluate the efficacy and effectiveness of SGs, ranging from emotional outcomes (eg, emotion recognition, emotional intelligence, emotion regulation skills, and empathy) and psychopathology (eg, symptoms of depression, anxiety, and aggression) to life satisfaction and self-esteem. Only a few of the studies (7/17, 41%) included direct measures of mental health literacy, including stigma toward psychiatric disorders [43,59], help-seeking intentions and behavior [43,45,59,64], mental health knowledge [52], or mental health literacy in general [50,57]. Of note, although most of the studies (23/27, 85%) included a few outcome variables, only some (8/27, 30%) explicitly defined a primary outcome variable. The evaluation was based on self-report questionnaires in the great majority of studies (24/27, 89%), with only a few (4/27, 15%) also looking at in-game performance [30,38,42,51]. Of the 27 studies, 2 (7%) used qualitative methodology to evaluate the intervention, including analyzing topics discussed during a classroom session after SG play [58] and assessing users' satisfaction with the SG and their suggestions for improvement [61]. Pacella and López-Pérez [42] and López-Pérez and Pacella [38] analyzed in-game performance related to correctly identifying emotions and choosing adaptive emotion regulation strategies.

A small number of studies (8/27, 30%) included a follow-up assessment (ranging from 1 to 6 mo), whereas most of the studies (14/27, 52%) used only pretest-posttest assessments. The remaining studies (5/27, 19%) did not include pre-post measures but analyzed in-game performance or usability or acceptability at one time point only.

XSL•FO
RenderX

Table 3. Main outcomes related to efficacy and effectiveness, adherence, and dropout in the included evaluation studies.

Serious games and outcome variables (assessment time points)	Main statistical test or analysis method used	Main effects and results	Adherence	Dropout (%)
Adventures Aboard the S.S. Grin				
Sanchez et al [39]				
Social literacy, self-efficacy, social satisfaction, social anxiety, bullying exposure and perpetration (pretest and posttest assessments, with an interval of 9 wk)	Mixed-design ANOVA (time×group interaction)	Significant improvements in social literacy, social satisfaction, social anxiety, and bullying exposure in the IG[a] compared to the CG[b] (all *P* values <.05)	74% completed all game episodes	NR[c]
Aislados				
Cejudo et al [40]				
Quality of life, life satisfaction, positive and negative affect, general mental health, and emotional intelligence (pretest and posttest assessments, with an interval of approximately 6 mo)	MANCOVA[d] (group differences in posttest scores controlled for pretest scores across outcome variables)	The IG significantly improved across all outcome variables compared to the CG (*P*=.004); effects observed for quality of life, positive affect, and general mental health	NR	NR
Emodiscovery				
Pacella and López-Pérez [42]				
In-game performance regarding emotion recognition and the use of emotion regulation strategies (N/A[e])	Descriptive analysis (%)	78%, 67%, and 69% correctly identified sadness, anger, and fear, respectively; most children chose adaptive emotion regulation strategies; children from the United Kingdom less accurate regarding the recognition of sadness than those from Spain; age and gender differences observed regarding the use of adaptive emotion regulation strategies (depending on specific emotion)	NR	NR
López-Pérez and Pacella [38]				
In-game performance regarding emotion recognition and the use of emotion regulation strategies (N/A)	Chi-square tests to analyze differences between country, gender, and age	Children from the United Kingdom less accurate regarding the recognition of sadness than those from Spain; age and gender differences observed regarding the use of adaptive emotion regulation strategies (depending on specific emotion)	NR	NR
EmoTIC				
de la Barrera et al [49]				
Emotional intelligence (PO[f]); self-esteem; affect balance; emotional, behavioral, and peer difficulties; prosocial behavior; depression; anxiety; and stress (pretest and posttest assessments, with an interval of 3 mo)	MANCOVA (group differences in posttest scores controlled for pretest scores across outcome variables)	The IG significantly improved across all outcome variables compared to the CG (*P*=.04); improvement observed for self-esteem, affect balance, emotional symptoms, behavioral problems, and hyperactivity	NR	IG: 71.4; CG: 49.1
Happy 8-12 and Happy 12-16				
Filella et al [36][g]				
Emotional development, anxiety, classroom and playground climate, social conflicts, and academic performance (pretest and posttest assessments, with an interval of approximately 1 y)	Mixed-design ANOVA (time×group interaction)	Significant improvements in emotional development (*P*=.02) and anxiety levels (*P*<.001) in the IG compared to the CG; ameliorated playground and classroom atmosphere, a reduction in playground conflicts, and improvements in academic achievement (Spanish grades) observed in the IG compared to the CG	NR	NR

XSL•FO
RenderX

Serious games and outcome variables (assessment time points)	Main statistical test or analysis method used	Main effects and results	Adherence	Dropout (%)
Filella et al [37][g]				
Emotional development, anxiety, classroom and playground climate, social conflicts, and academic performance (pretest and posttest assessments, with an interval of approximately 1 y)	GLM[h] (time×group interaction)	Significant improvements in the IG compared to the CG regarding emotional awareness (*P*=.04), autonomy (*P*=.03), life competences (*P*=.005), and academic achievements (*P*<.001)	NR	NR
IMPeTUs				
Brooks et al [50]				
Mental health literacy, quality of life, anxiety, depression, family communication, usability, and acceptability (pretest and posttest assessments, with an interval of 1 mo; 6-mo follow-up, along with qualitative interviews)	Descriptive analysis (means and medians); qualitative interviews	High levels of usability and acceptability regarding interface, personalization, message presentation, and navigation; minimal pretest-posttest changes regarding quantitative outcomes (no significance tests or effect sizes reported)	Mean number of times participants engaged with the intervention: 5 (range 1-15)	9
Moving Stories				
Gijzen et al [58]				
Implementation costs and themes discussed in debriefing sessions (N/A)	Descriptive analysis (total costs), and qualitative analysis of session notes	Total costs for preparation and offering the intervention: €11,043 (EUR €1=US $1.13); themes discussed (selection): the recognition of depression, help-seeking opportunities in schools, and association between physical and mental health	16.9% did not perform any action; mean 3.1 out of 5 d played; 83% played the game on ≥3 d; gameplay on d 1-5: 48% to 71%	NR
Tuijnman et al [43]				
Symptom recognition, first aid confidence, intentions and behavior, beliefs about help, stigma, help-seeking intentions and behavior, and depressive symptoms (pretest and posttest assessments, with an interval of 5 d; 3-mo and 6-mo follow-ups)	Linear mixed effects model (with random intercepts for participants and clusters)	No significant effects for symptom recognition, first aid confidence, intentions and behavior, beliefs about help, help-seeking intentions and behavior, and depressive symptoms in the IG compared to the CG (*P* values: NR); significant reduction in stigma in the IG compared to the CG (*P*=.04); adverse effect: decrease in first aid confidence in the IG from baseline to 6-mo follow-up (*P*<.001)	98% and 94% participated in the introduction and contact sessions, respectively; 49% played the game for 5d, 34% for 4d, 14% for 3d, 3% for 2d or less	Posttest assessment—IG: 1; CG: 2; 6-mo follow-up—IG: 13; CG: 7
POD Adventures				
Gonsalves et al [61]				
Acceptability and usability (N/A)	Focus groups, co-design workshops, and usability tests	Diverse suggestions to adapt and improve the intervention (eg, blended format, supporting counselors, simplification of language, and interactive elements)	NR	NR
Gonsalves et al [46]				
Psychological problem severity, mental health symptoms, perceived stress, and well-being (pretest and posttest assessments, with an interval of 4 wk; 12-wk follow-up)	*t* tests for paired samples (pretest-posttest changes)	Significant improvements in psychological problem severity, mental health symptoms, perceived stress, and well-being, which were maintained at the 12-wk follow-up (all *P* values <.001) in individuals playing the game	Completion of all 4 sessions: 92.7%	Posttest assessment: 32.7; 12-wk follow-up: 52.8
Gonsalves et al [47]				
Psychological problem severity, mental health symptoms, perceived stress, and well-being (pretest and posttest assessments, with an interval of 6 wk)	No tests used	No effects reported due to 100% dropout in the IG	80% watched orientation video, 60% completed onboarding session, 20% completed the first game session, and 0% completed sessions 2-4	IG: 100; CG: 33

XSL•FO

Of the 27 evaluation studies, 10 (37%) reported at least 1 measure of intervention adherence, including the number or percentage of completed game sessions, cumulative attrition rates over the course of game sessions, the number of times the SG was played, or the average duration of gameplay; for example, Sanchez et al [39] and Gonsalves et al [46] reported that 74% and 92.7% of the participants, respectively, completed all game episodes, while Gijzen et al [58] and Egan et al [45] reported the percentage of participants—16.9% and 55.8%, respectively—who never accessed the assigned intervention (although informed consent for the study had been provided). Gonsalves et al [47] reported that all participants discontinued gameplay after the first session. Brooks et al [50] found high usability and acceptability regarding different game components. With regard to assessment dropout, only 12 (44%) of the 27 studies reported relevant data, with posttest dropout rates in the intervention groups ranging from 0% to 100% (median 13.4%, IQR 2.2%-37.6%). Regarding the efficacy of the SGs, studies that used an RCT or quasi-experimental design reported significantly greater improvements in at least 1 outcome variable compared to a waitlist or active control condition, except for Gonsalves et al [47], who were not able to analyze the data due to a 100% dropout rate in the intervention group (Table 3). In studies that included a follow-up assessment, at least some of the effects were maintained in the longer term. The study by Tuijnman et al [43] explicitly reported a potential adverse effect: first aid confidence significantly decreased in the intervention group compared to the control group at the final follow-up (Table 3). The study by Gijzen et al [58] was the only one that calculated the implementation costs of the intervention.

Quality Appraisal of the Included Studies

The results of the quality appraisal of the controlled intervention studies and uncontrolled pretest-posttest evaluation studies are shown in Tables S3 and S4 in Multimedia Appendix 2. Of the 15 controlled intervention studies, only 6 (40%) met more than half of the predefined quality criteria, while no study met >9 out of 14 quality criteria. None of the uncontrolled pretest-posttest evaluation studies met >5 out of 12 assessed quality criteria. In general, a relatively high percentage of quality

XSL•FO
RenderX

criteria (approximately 22%) could not be assessed because the papers did not report the required information. This indicates that the overall quality of the included studies was relatively low.

Fostering and Hindering Factors Based on the RE-AIM Framework

With respect to participant reach, two factors were repeatedly discussed in the included studies. First, ease of access: cost-free access to the digital game, availability across different devices and operating systems, and a simple and intuitive interface were reported to facilitate participant reach [22,38,42,50,51,56,63]. By contrast, compatibility problems between devices [31,64], general technical issues when downloading the game, and poor internet connectivity [47,50] were mentioned as potential hindering factors. Second, availability in different languages: some of the studies (6/36, 17%) pointed to the importance of offering the SG in different (local) languages [40,46,47,60-62].

Additional factors discussed in the studies included availability of the SG through a trustworthy organization, familiarity with digital games in general [50], and introduction of the intervention by a facilitator or counselor [46,47,62], all of which were cited as fostering factors for participant reach. Parental concerns regarding digital games for children were mentioned as a hindering factor in the study by Brooks et al [50].

Several factors potentially influencing the efficacy and effectiveness of SGs, as well as user engagement, were discussed in the included studies. Game design elements potentially fostering engagement and effectiveness included an appealing narrative [39,50], a simple and intuitive interface [42], and game characters who were the same age as the target group [38]. By contrast, an intervention period that was too short [23,31,32,35-37,52] or too long [50], poor graphics, the absence of voice-overs [42], excessive text [50], and repeated game crashes [45] were considered hindering factors. Regarding game mechanics, self-customizable characters [39,45] and feedback from nonplayable characters [63] were reported to potentially increase efficacy or effectiveness. By contrast, long waiting times to access the next game level and being trapped in a game level until it was successfully completed were identified as factors that could potentially negatively impact engagement [48]. In addition, regular reminders to use the game were reported to improve adherence [46,47]. Relevant implementation aspects potentially fostering effectiveness included the involvement of teachers or other counselors as facilitators [34,46,48,52,62]; group discussion sessions about the game content [50,52], particularly when facilitated by people with lived experience of mental health problems [22,43]; and the involvement of parents in gameplay [50]. Two studies emphasized that older children may profit more from an SG than younger children [43,50]. Gijzen et al [58] reported that group dynamics have a positive effect on adherence, in the sense that as more students play the game, discussion about the game content increases, which in turn leads to better adherence.

No fostering or hindering factors related to adoption (ie, whether organizations such as schools were willing to test or initiate a program) were reported in the included studies.

Regarding fostering factors related to the implementation of SGs in a specific setting (most commonly schools), the most frequently discussed factor was the involvement of, and training for, facilitators, including teachers, counselors, and workers with lived experience [40,43,50,58]. Furthermore, the suitability of the intervention for implementation in classrooms [36] and the availability of support for technical problems and questions about the game content [47,62] were identified as potentially beneficial for implementation. Time pressure and the competing responsibilities of facilitators (eg, teachers) were considered hindering factors for implementation [50].

To foster the maintenance of effects, the option to expand the game through additional modules was discussed [50]. With regard to intervention sustainability, embedding the SG within a more general educational context and the school curriculum [40,52,58,60] as well as ensuring cost-free access to the SG across different platforms were emphasized [22,42,52].

Discussion

Principal Findings

The aim of this study was to systematically review SGs designed to promote mental health literacy among adolescents aged 10 to 14 years, with a focus on game characteristics, efficacy and effectiveness, and factors contributing to implementation success. We identified 36 articles that described the development of 17 SGs and evaluated their feasibility, efficacy, and effectiveness. The specific learning objectives of the identified SGs varied considerably across the included studies. Many SGs focused on the promotion of general aspects of mental health (eg, improving skills to regulate emotion and stress), thus reflecting the components of mental health literacy as conceptualized by Kutcher et al [15], including the promotion of good mental health and the development of skills for self-care [15], while classic aspects of mental health literacy, such as increasing knowledge as well as improving the recognition of specific psychiatric disorders and reducing stigma [14], were addressed by only a few of the studies. By contrast, another review of non–game-based mental health literacy interventions for adolescents reported that increasing knowledge of psychiatric disorders and reducing stigma were the most common learning objectives [17]. This may be explained by the fact that our review focused on SGs designed for a younger age group, but it could also indicate that a game-based approach can be particularly useful for promoting specific mental health literacy skills, while knowledge about specific psychiatric disorders may be better communicated via offline interventions. Of note, promoting overarching aspects of mental health such as emotion regulation rather than focusing on specific aspects or symptoms of mental health have been previously identified as particularly useful for preventive interventions in adolescents [65].

Many of the studies included in this review used a co-design approach to develop the SG, involving target group representatives, mental health experts, software developers, and other relevant stakeholders (eg, school personnel). It has been argued that user involvement should be standard practice when developing digital mental health interventions because this is essential for ensuring user engagement and intervention

XSL•FO
RenderX

effectiveness [66]. User and stakeholder involvement is recommended at all stages of the development process, including initial planning, early design testing, prototyping, feasibility testing, and implementation [67,68]. In-depth stakeholder involvement during game development seems crucial: many of the SGs identified in this review were implemented in a school setting and thus embedded within a larger pedagogical scenario. As repeatedly discussed in the included studies, teachers are often regarded as important facilitators when digital mental health interventions are implemented in schools; therefore, facilitator training seems important for ensuring intervention success [69]. In addition to information about the structure and content of the SG, facilitator training should also incorporate guidance on how an SG can be best introduced in the classroom context and how to promote discussions about the game content with students. Indeed, face-to-face group discussions about the game content have been discussed as a factor enhancing engagement during gameplay as well as improving outcomes [57]. The involvement of individuals (previously) affected by psychiatric disorders may further facilitate discussions among users, enhance the credibility of the game content, and improve the sustainability of effects [43,52,59]. By contrast, the absence of human support was mentioned as one of the main reasons for the high attrition rate in an SG [48]. Blended interventions have been previously discussed as promising with regard to user engagement and efficacy [70], which supports the findings of this review. Moreover, this study also suggests that researchers should consider early how a game-based intervention can be integrated into the school curriculum; this was mentioned as a key point for intervention sustainability in some of the included studies [57,61], and it has also been emphasized as an important factor in a previous systematic review of web-based mental health interventions [71] and in a stakeholder survey among school professionals [69].

Regarding game mechanics, this review shows that the identified SGs used a large variety of mechanics, including selecting response options when interacting with nonplayer characters, jumping, running, flying, collecting objects, painting, shooting, and freely exploring the game environment. Many of the identified SGs combined different mechanics. The use of diverse game mechanics may represent an important aspect for user experience and user engagement because previous research has shown that different types of players exhibit varying motivations for playing and have different preferred interaction styles [72,73]; for example, the “socializer” player type may be particularly engaged by interacting with other players or nonplayer characters, while “free spirits” may be motivated by tasks associated with autonomy and self-expression, which could be addressed by the possibility to explore the game environment (such as in open-world games). By contrast, “killers” are motivated by competitive game elements, such as leaderboards and rankings. With regard to the future development of SGs in the mental health field, incorporating several different game mechanics seems crucial to fit the players’ needs and preferences. This seems particularly relevant, considering that game mechanics tailored to the users’ needs may facilitate “flow” during gameplay—a mental state in which gamers become so engrossed in the game that they lose sense of time [74] and which has been associated with user engagement in gameplay [75,76]. Moreover, in the positive emotion, engagement, relationships, meaning, and accomplishment model formulated by Seligman [77], engagement, defined as the ability to fully use one’s strengths and abilities, is seen as a core component of psychosocial well-being; therefore, game mechanics that support individual strengths and abilities may foster the feeling of flow during gameplay.

Many of the SGs identified in this review allowed some form of customization of the player’s in-game character. This feature was discussed as potentially fostering intervention effectiveness [39,45]. Indeed, avatar customization facilitates identification with the player’s character [78] and has been associated with the players’ perceived competence in the game, the level of perceived fun, and self-reported game performance [79]. Customization seems particularly important for users with special needs, such as sexual and gender minority youth, because character customization and game character diversity can help to better reflect who they feel they are or want to be and give them an opportunity to rehearse their gender identity [80,81].

Another important aspect for fostering identification and engagement in the SGs discussed in the included studies is the chosen game universe and storyline. We identified a mix of SGs set in fictional worlds or worlds resembling real life. A previous study reported that adolescents generally prefer realistic settings (eg, public places and cities) over fictional settings; however, gender differences should also be taken into account because fictional worlds and nonhuman characters were found to be more appealing to boys [82]. This indicates that customization should not be limited to the player’s character, as discussed previously; it should also be considered for the narrative and storyline. It could be argued that game settings reflecting adolescents’ real-world environments may facilitate the transfer of mental health literacy–related skills learned through the SG to everyday life; however, further research is needed.

Of note, AI components were used in only 1 (6%) of the 17 SGs identified in our review (to generate background movement in the game) [22]. In general, AI has not yet been widely used in SGs targeting mental health, aside from a few therapeutic games addressing specific psychiatric disorders. A recently published review showed that AI was primarily applied for disease detection and the evaluation of user performance in SGs targeting individuals with motor impairment, while only a small number of SGs applied this technology in patients with attention-deficit/hyperactivity disorder or autism or in healthy individuals [83]. Nevertheless, integrating AI components into SGs for player modeling (eg, real-time emotion recognition), natural language processing (eg, the detection of emotional states), and believable nonplayer characters (eg, nonverbal bodily motion) has been discussed as a future direction for SG development [84] and may also be relevant for SGs addressing mental health literacy in adolescents. Moreover, AI could also be used to guide game progression based on a player’s previous in-game behavior.

Another aspect observed in this review was the wide variation in recommended or actual SG play duration, ranging from a

XSL•FO
RenderX

single session of approximately 1 hour to a whole school year. For the future development of SGs for adolescents, it would be worth considering whether an optimal duration of gameplay exists to achieve the best outcomes and ensure long-lasting effects. In some of the included studies, a low number of game levels or a relatively brief intervention period (only several weeks in most cases) were discussed as potentially limiting the effects [23,36,37,42]. By contrast, Brooks et al [50] noted that extending the playtime of their game, which lasts only 4 hours, would have reduced users' motivation to play. Another review that provided guidelines for developing game-based mental health interventions merely stated that a game should be neither too long nor too short [85], without offering specific recommendations. Thus, no definite conclusion about the optimal duration of SG play can be drawn to date, and future studies should address this issue. At present, it can be stated that it seems important that an SG targeting mental health literacy provides sufficiently long gameplay to consolidate effects and incorporates game mechanics that keep users engaged, even when game sequences are repeated.

The included evaluation studies provided some evidence for the short-term efficacy of SGs targeting aspects of mental health literacy in adolescents, thereby supporting the evidence from non–game-based interventions in this age group [12,86]. However, there are some reasons for why these effects should be considered as preliminary: First, the quality appraisal of the included studies revealed that most of them were generally of low quality. Second, many of the studies were pilot studies with small samples or lacked control groups. Third, the great majority of studies did not include follow-up measures to evaluate whether the observed effects were sustained over time. This limitation was also mentioned in other reviews of gamified mental health interventions for children and adolescents [25,87,88]. Fourth, assessments of intervention adherence and dropout were often not included in the evaluation reports. However, the reporting of attrition and use parameters seems particularly important for digital health interventions [89] because these data provide valuable information on user engagement. Notably, some of the studies reported relatively low adherence. Fifth, the evaluation of most of the SGs identified in the review relied exclusively on self-report instruments, which has also been emphasized as a limitation in other reviews [87,88].

With a few exceptions, users' in-game performance was neither measured nor reported. The evaluation of users' specific in-game behavior would provide important information on whether they behaved in accordance with the intended objectives and which parts or tools of an SG were used and for how long, which can further be used to evaluate and improve user experience and engagement. Moreover, only 1 study (on the *REThink* intervention [29]) evaluated the potential mechanism of change and found that a reduction in irrational beliefs mediated changes in depressive mood. Furthermore, most of the studies used specific measures closely related to the learning objectives of the SG rather than more general measures of mental health literacy. As outlined by Mansfield et al [90], this may be due to the scarcity of psychometrically validated instruments measuring mental health literacy in adolescents, with existing instruments often based on an illness-focused definition of mental health literacy that often does not incorporate the assessment of skills to obtain positive mental health. However, in view of the increasing interest in improving mental health literacy during adolescence, research on the development of assessment instruments suitable for this age group is emerging [91-93].

The included studies provided limited information on the potential disadvantages of using SGs for promoting mental health literacy. The available data point to potential implementation challenges, with concerns from parents or facilitators (eg, teachers) regarding the use of these technologies being the most important issues (eg, too much screen time in general and doubts about how to integrate an SG intervention into the school context). Fleming et al [24] further suggest that the development of digital games for scientific purposes often cannot compete with those developed for commercial purposes, which typically have much larger budgets. As a result, games developed for scientific purposes may often not be as technologically up to date, potentially influencing users' engagement levels. Moreover, some users or implementers may perceive the use of a digital game to address mental health issues as inappropriate or trivializing [24], which underlines the need for user and stakeholder involvement at all stages of the game development.

Strengths and Limitations

This systematic review presents a comprehensive overview of SG characteristics, including learning design, mechanics, and game design, for use in a universal population of adolescents, targeting aspects of mental health literacy. As the coding scheme was closely oriented toward the dimensions of the co.LAB framework [26], a framework used for the collaborative design of SGs, the results from this review can directly inform the design of future SGs in this field. Another strength is that we used the RE-AIM framework, which was also applied in a previous systematic review of digital mental health interventions [71] and in a review of health literacy interventions [94], enabling comparability with the previous results. Moreover, as we focused on SGs appropriate for a relatively narrow age range (10-14 y), this study revealed SG characteristics that may be particularly relevant for this population. A limitation is that, due to the diversity of study designs and outcome measures used in the included studies, we were not able to aggregate the effects using a meta-analytic approach. Moreover, considering the number of RQs addressed in this review, only an overview of the main findings of the included studies regarding efficacy and effectiveness was provided. Furthermore, the literature search was limited to 3 databases (PubMed, Scopus, and PsycINFO) and the reference lists of the included studies. Although this search strategy yielded a comprehensive set of relevant studies, it cannot be ruled out that we have overlooked other relevant studies that could have been retrieved by including additional literature databases (eg, those with a greater focus on technology).

Conclusions

Overall, this review showed that SGs are a promising approach to improve mental health literacy in adolescents. However, the

XSL•FO
RenderX

evidence on the efficacy and effectiveness of SG interventions in this field should be regarded as preliminary. More rigorously planned studies, including RCTs and real-world trials, are needed. These studies should incorporate (long-term) follow-up measures and assessments of in-game performance, in addition to self-reports and measures of intervention adherence. This review also highlights commonly used characteristics of SG design, which can inform the development of future game-based interventions for promoting mental health literacy. A content-related focus on promoting positive mental health and teaching self-management skills, such as emotion regulation and stress-coping skills, which are relevant to nearly all children and adolescents, may be more effective than focusing on mental health literacy related to (symptoms of) specific psychiatric disorders. Intervention co-design approaches and in-depth stakeholder involvement at all stages of the SG development seem crucial for its success. In particular, close collaboration with stakeholders from the school setting (eg, teachers and principals) is of high importance for discussing how an SG can be best embedded within a wider pedagogical scenario and how to facilitate intervention sustainability. The use of different mechanics within a single SG may be useful to fit diverse player needs and preferences, foster a state of flow during gameplay, and increase engagement. Furthermore, customization of the SG to meet the user's needs, for example, customizing the player's character as well as the game narrative, may be useful features to strengthen the player's relatedness to the game characters and content, potentially enhancing the SG's real-world effectiveness.

Abstract

Background: Mental health disorders affect an estimated 1 in 8 individuals globally, yet traditional interventions often face barriers, such as limited accessibility, high costs, and persistent stigma. Recent advancements in generative artificial intelligence (GenAI) have introduced AI systems capable of understanding and producing humanlike language in real time. These developments present new opportunities to enhance mental health care.

Objective: We aimed to systematically examine the current applications of GenAI in mental health, focusing on 3 core domains: diagnosis and assessment, therapeutic tools, and clinician support. In addition, we identified and synthesized key ethical issues reported in the literature.

Methods: We conducted a comprehensive literature search, following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines, in PubMed, ACM Digital Library, Scopus, Embase, PsycInfo, and Google Scholar databases to identify peer-reviewed studies published from October 1, 2019, to September 30, 2024. After screening 783 records, 79 (10.1%) studies met the inclusion criteria.

Results: The number of studies on GenAI applications in mental health has grown substantially since 2023. Studies on diagnosis and assessment (37/79, 47%) primarily used GenAI models to detect depression and suicidality through text data. Studies on therapeutic applications (20/79, 25%) investigated GenAI-based chatbots and adaptive systems for emotional and behavioral support, reporting promising outcomes but revealing limited real-world deployment and safety assurance. Clinician support studies (24/79, 30%) explored GenAI's role in clinical decision-making, documentation and summarization, therapy support, training and simulation, and psychoeducation. Ethical concerns were consistently reported across the domains. On the basis of these findings, we proposed an integrative ethical framework, GenAI4MH, comprising 4 core dimensions—data privacy and security, information integrity and fairness, user safety, and ethical governance and oversight—to guide the responsible use of GenAI in mental health contexts.

Conclusions: GenAI shows promise in addressing the escalating global demand for mental health services. They may augment traditional approaches by enhancing diagnostic accuracy, offering more accessible support, and reducing clinicians' administrative burden. However, to ensure ethical and effective implementation, comprehensive safeguards—particularly around privacy, algorithmic bias, and responsible user engagement—must be established.

Introduction

Background

Mental health has become a global public health priority, with increasing recognition of its importance for individual well-being, societal stability, and economic productivity. According to the World Health Organization, approximately 1 in 8 people worldwide live with a mental health disorder [1]. Despite the growing demand for mental health services, traditional approaches such as in-person therapy and medication, which rely heavily on trained professionals and extensive infrastructure, are struggling to meet the rising need [2]. Consequently, an alarming 76% to 85% of individuals with mental health disorders do not receive effective treatment, often due to barriers such as limited access to mental health professionals, social stigma, and inadequate health care systems [3]. Against this backdrop, advances in generative artificial intelligence (GenAI) offer new and promising avenues to enhance mental health services.

GenAI, such as ChatGPT [4], is built on large-scale language modeling and trained on extensive textual corpora. Their capacity to produce contextually relevant and, in many cases, emotionally appropriate language [5,6] enables more natural and adaptive interactions. Compared to earlier dialogue systems, GenAI exhibits greater flexibility in producing open-ended, humanlike dialogue [7]. This generative capability makes them a promising tool for web-based therapeutic interventions that allow for real-time, adaptive engagement in mental health care.

Currently, GenAI is being integrated into mental health through a range of innovative applications. For instance, GPT-driven chatbots such as Well-Mind ChatGPT [8] and MindShift [9] provide personalized mental health support by engaging users in conversational therapy. Similarly, virtual companions such as Replika [10] are used to help users manage feelings of loneliness and anxiety through interactive dialogue [11]. In addition, GenAI has been used to analyze social media posts and clinical data to identify signs of depression [2] and suicidal ideation [12]. These diverse applications illustrate the potential of GenAI to address various mental health needs, from prevention and assessment to continuous support and intervention.

Although research has investigated various applications of GenAI in mental health, much of it has focused on specific models or isolated cases, lacking a comprehensive evaluation of its broader impacts, applications, and associated risks. Similarly, most systematic reviews to date have focused on particular domains, such as depression detection [13], chatbot interventions [14], empathic communication [5], psychiatric education [15], and AI-based art therapy [16]. While such focused reviews offer valuable insights into specific use cases, a broad outline remains crucial for understanding overarching trends, identifying research gaps, and informing the responsible development of GenAI in mental health. To date, only 2 reviews [17,18] have attempted broader overviews, covering the literature published before April 2024 and July 2023, respectively. However, since April 2024, the rapid evolution of GenAI—including the release and deployment of more advanced models, such as GPT-4o [19] and GPT-o1 [20], and their increasing integration with clinical workflows, such as Med-Gemini [21], has expanded the scope and complexity of GenAI applications in real-world mental health contexts. These developments underscore the need for a more updated and integrative synthesis.

Objectives

To address this gap, we aimed to provide a comprehensive overview of GenAI applications in mental health, identify research gaps, and propose future directions. To systematically categorize the existing research, we divided the studies into three distinct categories based on the role of GenAI in mental health applications, as illustrated in Figure 1: (1) GenAI for mental health diagnosis and assessment, encompassing research that leverages GenAI to detect, classify, or evaluate mental health conditions; (2) GenAI as therapeutic tools, covering studies where GenAI-based chatbots or conversational agents are used to deliver mental health support, therapy, or interventions directly to users; and (3) GenAI for supporting clinicians and mental health professionals, including research aimed at using GenAI to assist clinicians in their practice.

Despite these promising applications, the integration of GenAI into mental health care is not without challenges. Applying GenAI in the mental health field involves processing highly sensitive personal information, such as users' emotional states, psychological histories, and behavioral patterns. Mishandling such data not only poses privacy risks but may also lead to psychological harm, including distress, stigma, or reduced trust in mental health services [22]. Therefore, in addition to systematically categorizing existing applications of GenAI in mental health, we also examined ethical issues related to their use in this domain. On the basis of our analysis, we proposed an ethical framework, GenAI4MH, to guide the responsible use of GenAI in mental health contexts (Figure 2).

Methods

Search Strategy

We conducted this systematic review following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines (Multimedia Appendix 1) [23]. We conducted a comprehensive search across 6 databases: PubMed, ACM Digital Library, Scopus, Embase, PsycInfo, and Google Scholar. We conducted the search between October 1, 2024, and October 7, 2024, and targeted studies published from October 1, 2019, to September 30, 2024. The starting date was chosen to coincide with the introduction of the T5 model [24], a foundational development for many of today's mainstream GenAI models. This date also intentionally excluded earlier models, such as Bidirectional Encoder Representations from Transformers (BERT) [25] and GPT-2 [26], as these models

XSL•FO
RenderX

have already been extensively covered in the previous literature [27,28], and our aim was to highlight more recent innovations.

Search terms were constructed using a logical combination of keywords related to GenAI and mental health: (Generative AI OR Large Language Model OR ChatGPT) AND (mental health OR mental disorder OR depression OR anxiety). This search string was developed based on previous reviews and refined through iterative testing to ensure effective identification of relevant studies. When possible, the search was restricted to titles and abstracts. For Google Scholar, the first 10 pages of results were screened for relevance. A detailed search strategy is provided in Multimedia Appendix 2.

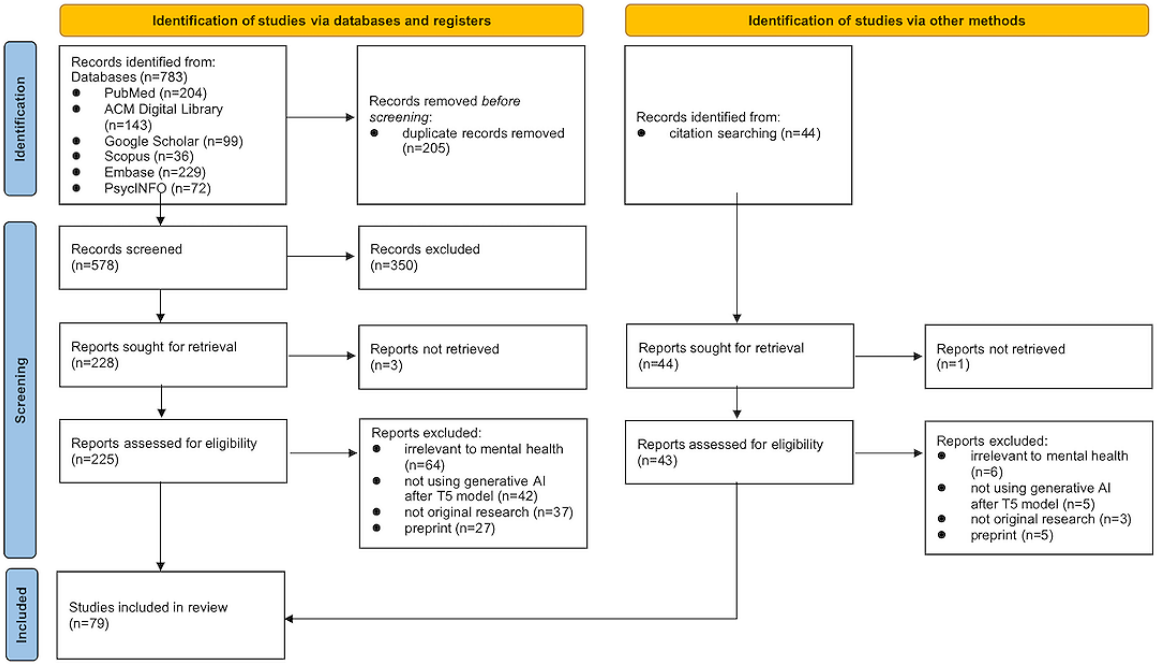
Study Selection

The selection criteria included studies that (1) used GenAI and were published after the introduction of the T5 [24] model and (2) directly addressed the application of GenAI in mental health care settings. Only peer-reviewed original research articles were considered, with no language restrictions.

Data Extraction

Data from the included studies were extracted using standardized frameworks. For qualitative studies, we used the Sample, Phenomenon of Interest, Design, Evaluation, and Research Type (SPIDER) framework. For quantitative studies, we applied the Population, Intervention, Comparison, Outcome, and Study (PICOS) framework. A summary of the extracted data are provided in Multimedia Appendix 3 [2,3,7-9,11,12,29-100].

Reporting Quality Assessment



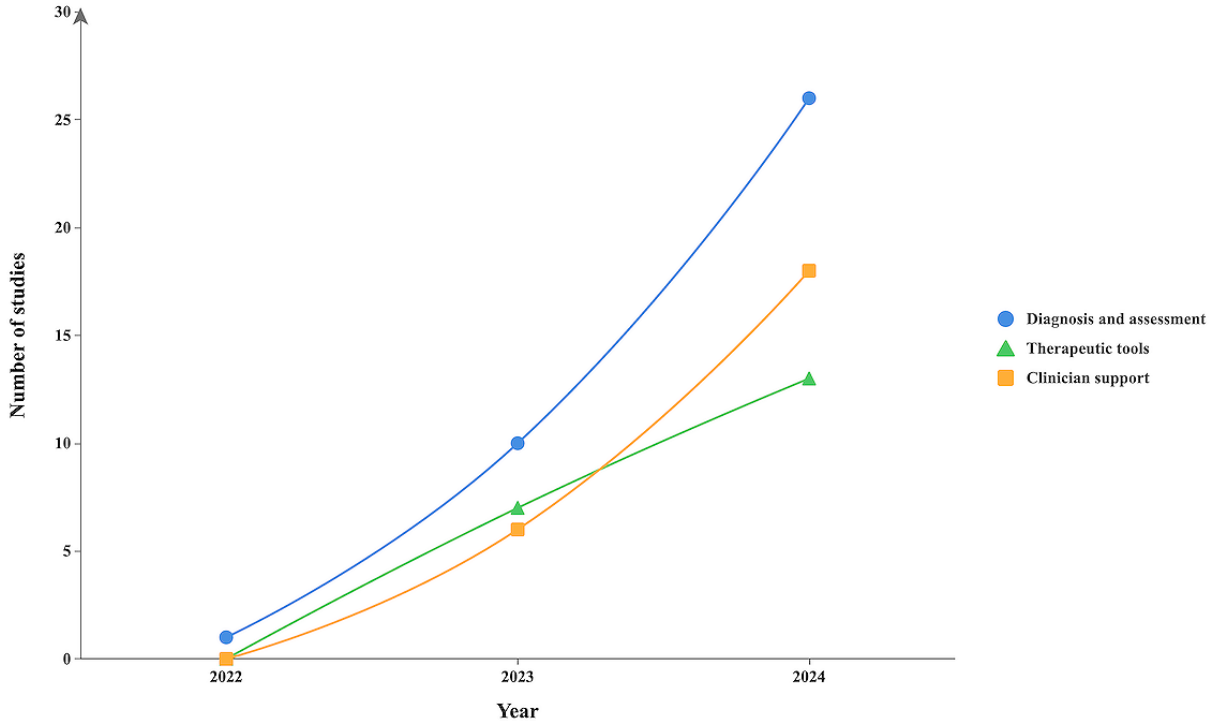
To assess the reporting transparency and the methodological rigor of the included studies, we applied the Minimum Information about Clinical Artificial Intelligence for Generative Modeling Research (MI-CLAIM-GEN) checklist (Multimedia Appendix 4) [101], a recently proposed guideline tailored for evaluating the reporting quality of research on GenAI in health care. The checklist covers essential aspects such as study design, data and resource transparency, model evaluation strategies, bias and harm assessments, and reproducibility. We followed the Joanna Briggs Institute quality appraisal format [102] to score each item in the checklist using 4 categories: yes, no, unclear, and not applicable.

Results

Study Selection

As shown in Figure 3, a total of 783 records were initially retrieved from the 6 databases. After removing duplicates, 73.8% (578/783) of unique records remained for screening. Following abstract screening, 39.4% (228/578) of the records were identified for full-text retrieval and screening. After full-text screening, 24% (55/228) of the articles were selected for inclusion in the systematic review. To ensure comprehensive coverage of relevant studies, a snowballing technique was then applied, where we examined the reference lists of the included studies and related review articles. This process identified an additional 44 studies for eligibility assessment. After the same evaluation process, 54% (24/44) of these studies met the inclusion criteria, bringing the final total to 79 studies for the systematic review. Two PhD candidates (YZ and XW) independently conducted the selection, with discrepancies resolved through discussion. The interrater reliability was satisfactory (κ=0.904).

Figure 3. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of study selection.



Publication Trends Over Time

An analysis of publication trends over time reveals a growing focus on the application of GenAI in mental health (Figure 4). Overall, the number of studies in all the 3 categories grew extensively over the examined period, indicating a rising interest in using GenAI for mental health. In 2022, the total number of studies was minimal across all the 3 categories, with only 1

XSL•FO
RenderX

(1%) early study, of the included 79 studies, emerging on the use of GenAI for mental health diagnosis and assessment. However, as GenAI advanced and garnered wider adoption, the number of publications in all the 3 categories began to increase steadily. A moderate increase was observed in the year 2023, with 13% (10/79) of the studies focused on diagnosis and assessment, 9% (7/79) on therapeutic interventions, and 8% (6/79) on clinician support, reflecting a growing interest in practical applications of these models in health care settings. By 2024, the number of publications had surged across all the 3 categories, with 33% (26/79) of the studies focused on diagnosis and assessment, 16% (13/79) on therapeutic interventions, and 23% (18/79) on clinician support.

Figure 4. Publication trends in the application of generative artificial intelligence (GenAI) in mental health research.

GenAI for Mental Health Diagnosis and Assessment

Overview

Of the 79 included studies, 37 (47%) were identified that investigated the effectiveness and applications of GenAI in mental health diagnosis and assessment. These studies primarily explored how GenAI can detect and interpret mental health conditions by analyzing textual and multimodal data. A summary of the included studies is presented in Multimedia Appendix 5 [2,3,12,29-59,61,62,100].

Mental Health Issues

The existing studies using GenAI for mental health diagnosis predominantly focused on suicide risk and depression, followed by emerging applications in emotion recognition, psychiatric disorders, and stress.

Suicide risk was the most frequently examined topic, addressed in 40% (15/37) of the studies. Researchers used large language models (LLMs) to identify suicide-related linguistic patterns [12], extract and synthesize textual evidence supporting identified suicide risk levels [29-33,103], and evaluate suicide risk [34-41]. GenAI models, such as GPT-4 [104], achieved high precision (up to 0.96) in predicting suicidal risk levels [30-33,103], outperforming traditional models, such as support vector machines (SVM) [41], and performing comparably to or better than pretrained language models, such as BERT [38,40]. Most studies (13/15, 87%) relied on simulated case narratives [34,36,37] or social media data [38-40]; only 13% (2/15) of the studies used real clinical narratives [35,41].

Depression was the second most common mental health issue addressed, featured in 35% (13/37) of the studies. While GenAI models showed promising accuracy (eg, 0.902 using semistructured diaries [42]), performance was often constrained to English data [43,44], with notable drop-offs in dialectal or culturally divergent contexts [44]. Multimodal approaches—integrating audio, visual, and physiological data—improved detection reliability over text-only methods [45-47]. Several studies (3/13, 23%) also explored interpretability, using GenAI to generate explanations [43] or conduct structured assessments [48].

GenAI has also been explored for emotion recognition, using smartphone and wearable data to predict affective states with moderate accuracy [47,49], and enabling novel assessment formats, such as virtual agent interactions [45] and conversational psychological scales [50]. The studies also explored other psychiatric disorders, such as obsessive-compulsive disorder (accuracy up to 96.1%) [51] and schizophrenia (r=0.66-0.69 with expert ratings) [52]. In total, 8% (3/37) of the studies addressed stress detection from social media texts [39,53,54].

XSL•FO
RenderX

A smaller set of studies (3/37, 8%) assessed GenAI models' capacity for differential diagnosis, demonstrating that GenAI models could distinguish among multiple mental disorders in controlled simulations [3,55,56]. However, performance remained higher for mental health conditions with distinct symptoms (eg, psychosis and anxiety) and lower for overlapping or less prevalent disorders (eg, perinatal depression and lysergic acid diethylamide use disorder) [56], particularly for those with symptom overlap with more common mental health conditions (eg, disruptive mood dysregulation disorder and acute stress disorder) [55].

Model Architectures and Adaptation Strategies

Overview

Most included studies (29/37, 78%) used proprietary GenAI models for mental health diagnosis and assessment, with GPT-based models (GPT-3, 3.5, and 4) [4] being the most commonly used [2,3,12]. Other proprietary models included Gemini [49,51] and the pathways language model (version 2) [47]. A smaller subset of the studies (14/37, 38%) adopted open-source models, such as LLM Meta AI (LLaMA) [29,30,32,40,52,57,58], Mistral [33], Falcon [40], and Neomotron [55]. Beyond model selection, several studies (29/37, 78%) explored technical strategies to enhance diagnostic performance and interpretability. In total, 3 main approaches were identified as described in subsequent sections.

Hybrid Modeling

A limited number of studies (2/37, 5%) explored hybrid architectures, combining GenAI-generated embeddings with classical classifiers, such as SVM or random forest [43,53]. For example, Radwan et al [53] used GPT-3 embeddings to generate text vectors, which were input into classifiers, such as SVM, random forest, and k-nearest neighbors, for stress level classification. The combination of GPT-3 embeddings with an SVM classifier yielded the best performance, outperforming other hybrid configurations and traditional models such as BERT with the long short-term memory model.

Fine-Tuning and Instruction Adaptation

Some studies (4/37, 11%) used instruction-tuned models, including Flan [39,41], Alpaca [39], and Wizard [32], to enhance instruction following. Further fine-tuning with mental health–related data was also applied to improve diagnostic and assessment capabilities [39,46,59]. For instance, Xu et al [39] demonstrated that their fine-tuned models—Mental-Alpaca and Mental-FLAN-T5—achieved a 10.9% improvement in balanced accuracy over GPT-3.5 [4], despite being 25 and 15 times smaller, respectively. These models also outperformed GPT-4 [104] by 4.8%, although GPT-4 is 250 and 150 times larger, respectively.

Prompt Engineering and Knowledge Augmentation

Prompt-based techniques—including few-shot learning [31,39,40,46,54,58], chain-of-thought prompting [42,47,49,59,60], and example contrast [54]—have been shown to substantially enhance diagnostic performance, especially for smaller models [39]. Meanwhile, retrieval-augmented generation (RAG) approaches enriched LLMs with structured knowledge (eg, *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* criteria), improving factual grounding in some cases [47], but occasionally introducing noise or reducing performance due to redundancy and semantic drift [55].

Data Source

Table 1 summarizes the datasets used for GenAI-based mental health diagnosis and assessment, categorized by data modality and mental health focus. The full dataset list, including metadata and sampling details, is provided in Multimedia Appendix 6 [12,30,35,41,42,44,49,53,56,62,103,105-133].

Social media posts, such as those on Reddit [12,29,43], Twitter [58], and Weibo [45], emerged as prominent data sources. Beyond social media, 19% (7/37) of the studies used professionally curated clinical vignettes, providing controlled scenarios that simulate clinical cases and allow for standardized assessment across GenAI models [34,51]. Only a few studies (4/37, 11%) used clinical text data sources, including clinical interviews [61], diary texts [42], and written responses of participants [50,62].

In total, 14% (5/37) of the studies used multimodal data sources—such as speech [44,45], sensor data [47], and electroencephalogram (EEG) [46]—to enhance the accuracy and comprehensiveness of mental health assessments. For example, Englhardt et al [47] developed prompting strategies for GenAI models to classify depression using passive sensing data (eg, activity, sleep, and social behavior) from mobile and wearable devices, achieving improved classification accuracy (up to 61.1%) over classical machine learning baselines. Similarly, Hu et al [46] integrated EEG, audio, and facial expressions to boost predictive performance and proposed MultiEEG-GPT, a GPT-4o-based method for mental health assessment using multimodal inputs, including EEG, facial expressions, and audio. Their results across the 3 datasets showed that combining EEG with audio or facial expressions significantly improved prediction accuracy in both zero-shot and few-shot settings.

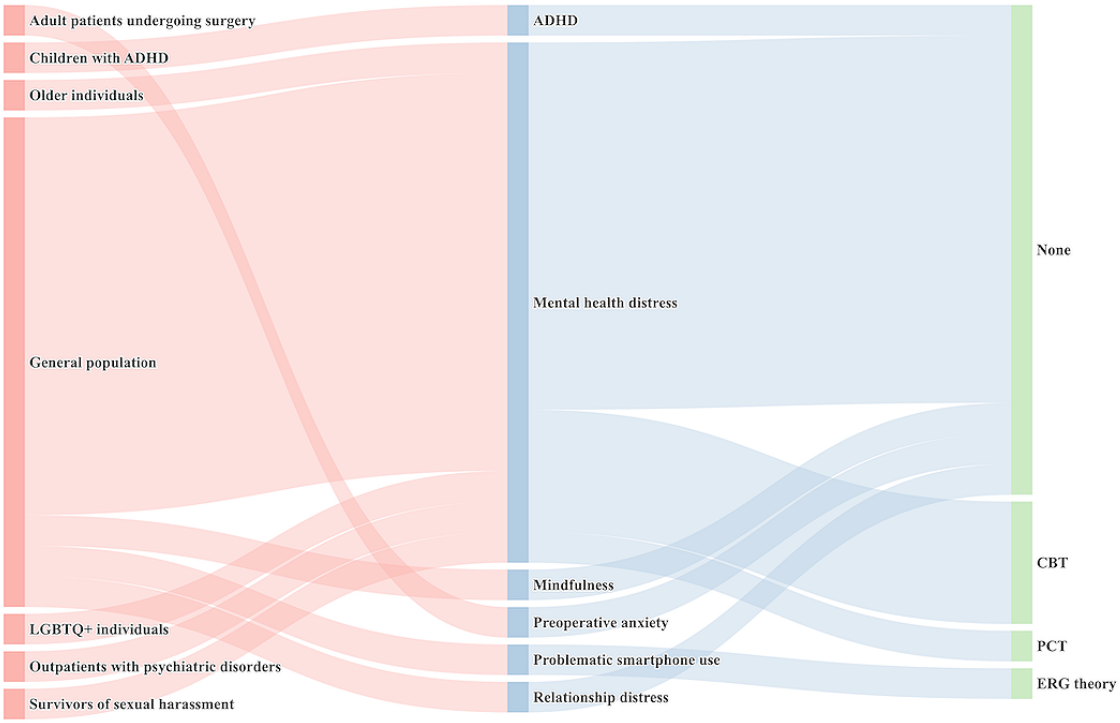
GenAI as Therapeutic Tools

Of the 79 included studies, 20 (25%) investigated the use of GenAI-based chatbots and conversational agents to facilitate interventions ranging from emotional support to more structured therapies. To assess the feasibility and potential impact of these interventions, we analyzed studies across four key dimensions: (1) therapeutic targets, (2) implementation strategies, (3) evaluation outcomes, and (4) real-world deployment features.

Intervention Targets and Theoretical Alignments



As presented in Figure 5, most studies (16/20, 80%) targeted the general population. A smaller subset (5/20, 25%) focused on vulnerable or underserved groups, including outpatients undergoing psychiatric treatment [64], lesbian, gay, bisexual, transgender, and queer (LGBTQ) individuals [65], sexual harassment survivors [66], children with attention-deficit/hyperactivity disorder [67], and older adults [68]. In addition to population-specific adaptations, some studies (4/20, 20%) focused on chatbots targeting specific psychological and behavioral challenges, including attention-deficit/hyperactivity disorder [67], problematic smartphone use [69], preoperative anxiety [70], and relationship issues [71].

Despite the growing prevalence of these systems, most studies do not explicitly state the theoretical frameworks guiding their development. Among the reviewed studies, only 30% (6/20) of the studies explicitly adopted a psychological theory: person-centered therapy [72]; cognitive behavioral therapy [7,73-75]; and existence, relatedness, and growth theory [69].

Beyond chatbot-based interventions, several studies (2/20, 10%) used passive monitoring, combining real-time physiological [74] and behavioral data [8] from wearables to assess mental states and trigger interventions. For example, empathic LLMs developed by Dongre [74] adapted responses based on users' stress levels, achieved 85.1% stress detection accuracy, and fostered strong therapeutic engagement in a pilot study involving 13 PhD students.

Evaluation Strategies and Reported Outcomes

Evaluation methods across the included studies varied considerably in terms of design, measurement, and reported outcomes. Approximately one-third of the included studies (7/20, 35%) used structured experimental designs, including randomized controlled trials [70,73], field experiments [69], and quasi-experimental studies [64], with intervention spanning from one session to several weeks. These studies reported improvements in emotional intensity [73], anxiety [70], or behavioral outcomes [69]. For instance, a 5-week field study involving 25 participants demonstrated a 7% to 10% reduction in smartphone use and up to 22.5% improvement in intervention acceptance [69]. Several studies (5/20, 25%) conducted simulated evaluations using test scenarios [66], prompt-response validation [76], and expert review [67,77]. A third group used user-centered approaches, such as semistructured interviews [65], open-ended surveys [72], or retrospective analyses of user-generated content [11].

Evaluation metrics were clustered into several domains. A substantial number of studies (14/20, 70%) assessed subjective user experiences, such as emotional relief, satisfaction, engagement, and self-efficacy [69,71,73]. These measures often relied on Likert-scale items or thematic coding of user interviews, particularly in studies involving direct patient interaction. Standardized psychometric instruments were applied in several studies to quantify clinical outcomes, such as the State-Trait Anxiety Inventory [70] and the Self-Efficacy Scale [69]. In contrast, studies focused on technical development predominantly adopted automated metrics, such as perplexity, bilingual evaluation understudy scores, and top-k accuracy [7,78].

Across these varied approaches, most studies (17/20, 85%) reported positive outcomes. Emotional support functions were generally well received, with users describing increased affective relief [73], perceived empathy [65], and greater openness to self-reflection [75]. Structured interventions showed measurable improvements in behavior, including reduced problematic smartphone use and increased adherence to interventions [69]. Nevertheless, several studies (5/20, 25%) highlighted users' concerns regarding personalization, contextual fit, and trust [70]. Moreover, while GenAI models often succeeded in simulating supportive interactions, they struggled to offer nuanced responses or adapt to complex individual needs [65]. Users also raised concerns about repetitive phrasing, overly generic suggestions, and insufficient safety mechanisms, particularly in high-stakes scenarios such as crisis intervention or identity-sensitive disclosures [11,71].

Model Architectures and Adaptation Strategies

The included studies used a variety of base models, with GPT-series being the most frequently adopted across interventions [11,60,64,67,68,70,71,73,75,76,79]. A small set of studies (6/20, 30%) used alternatives such as Falcon [74], LLaMA [66,77], or custom transformer-based architectures [72,78].

To tailor GenAI models for mental health applications, researchers have adopted a range of adaptation techniques. Prompt engineering was the most frequently applied strategy. This approach included emotional state-sensitive prompting [69] and modular prompt templates [60]. A smaller number of studies (2/20, 10%) applied fine-tuning strategies using real-world therapy dialogues or support data [7,77]. For instance, Yu and McGuinness [7] fine-tuned DialoGPT on 5000 therapy

XSL•FO
RenderX

conversations and layered it with knowledge-injected prompts via ChatGPT-3.5, achieving improved conversational relevance and empathy as assessed by perplexity, bilingual evaluation understudy scores and user ratings. Herencia [77] used Low-Rank Adaptation to fine-tune LLaMA-2 on mental health dialogue data, resulting in a fine-tuned model that outperformed the base LLaMA in BERT and Metric for Evaluation of Translation with Explicit Ordering scores, with reduced inference time and improved contextual sensitivity in simulated counseling interactions.

Beyond internal adaptations, RAG was used to enrich responses with external knowledge. For instance, Vakayil et al [66] integrated RAG into a LLaMA-2–based chatbot to support survivors of sexual harassment, combining empathetic dialogue with accurate legal and crisis information drawn from a curated database.

Clinical Readiness

To evaluate the translational potential of GenAI models into clinical practice, we synthesized four indicators of real-world readiness across the included studies: (1) expert evaluation, (2) user acceptability, (3) clinical deployment, and (4) safety mechanisms. Among the 20 studies reviewed, only 4 (20%) involved formal expert evaluation, such as ratings by licensed clinicians or psychiatric specialists [67,68]. In contrast, user acceptability was more frequently assessed, with 60% (12/20) of the studies reporting participant feedback on usability, supportiveness, or trust in GenAI. Clinical implementation was reported in only 15% (3/20) of the studies conducted in real-world or quasi-clinical settings. Regarding safety, only 30% (6/20) of the studies implemented explicit safety measures, such as toxicity filters [73], crisis response triggers [66], or expert validation [70].

GenAI for Supporting Clinicians and Mental Health Professionals

Of the 79 included studies, 24 (30%) focused on applying GenAI to support clinicians and mental health professionals, with 2 (2%) overlapping with the research on GenAI models for mental health diagnosis and assessment.

Role of GenAI in Supporting Clinicians and Mental Health Professionals

Overview

Recent research has demonstrated a growing interest in the use of GenAI to support mental health professionals across diverse clinical tasks. Drawing on a synthesis of empirical studies (Table 2), we identified five core functional roles through which GenAI contributes to mental health services: (1) clinical decision support, (2) documentation and summarization, (3) therapy support, (4) psychoeducation, and (5) training and simulation.

Table 2. Categorization of generative artificial intelligence (GenAI) support roles and representative applications in mental health contexts.

Support roles	Representative tasks	References
Clinical decision support	Treatment planning, prognosis, and case formulation	[3,47,80-87,89,96]
Documentation and summarization	Summarizing counseling sessions and summarization of multimodal sensor data	[47,88]
Therapy support	Reframing, emotion extraction, and reflection	[90-93]
Psychoeducation	Questions and answers, recommendations, and interactive guidance	[63,80,94-98]
Training and simulation	Case vignettes and synthetic data	[9,84,99]

Clinical Decision Support

One of the most frequently studied applications of GenAI is its use in supporting clinical decision-making. This includes tasks such as treatment planning [3,80-82], case formulation [83-85], and prognosis assessment [86,87]. Studies show that GenAI-generated treatment plans are often consistent with clinical guidelines and therapeutic theories [3,85], and sometimes outperform general practitioners in adherence [81,82]. For case formulation, GenAI has been shown to produce coherent and theory-driven conceptualizations, including psychodynamic [83] and multimodal [84] therapy. Prognostic predictions for mental health conditions such as depression [87] and schizophrenia [86] have also shown expert-level agreement. However, when used for engaging directly with patients for clinical assessment, GenAI models still lack capabilities in structured interviewing and differential diagnosis [80].

Documentation and Summarization

GenAI models have also demonstrated potential in reducing clinicians' administrative burden through automated documentation. Adhikary et al [88] benchmarked 11 LLMs on their ability to summarize mental health counseling sessions, identifying Mistral and MentalLLaMA as having the highest extractive quality. Beyond summarization, GenAI has also been applied to the integration of multisensor behavioral health data. Englhardt et al [47] examined LLMs' ability to analyze passive sensing data for assessing mental health conditions such as depression and anxiety. Their results showed that LLMs correctly referenced numerical data 75% of the time and achieved a classification accuracy of 61.1%, surpassing traditional machine learning models. However, both studies identified hallucination as a critical limitation, including errors such as incorrect documentation of suicide risk [88].

Therapy Support

A growing body of research suggests that GenAI can enhance therapeutic processes by supporting treatment goal setting [89], emotional reflection [90], cognitive restructuring [91,92], and motivational interviewing [93]. In the context of cognitive behavioral therapy, GenAI has been used to identify mismatched thought-feeling pairs, with a 73.5% cross-validated accuracy rate [91], and to assist in reframing maladaptive cognitions with

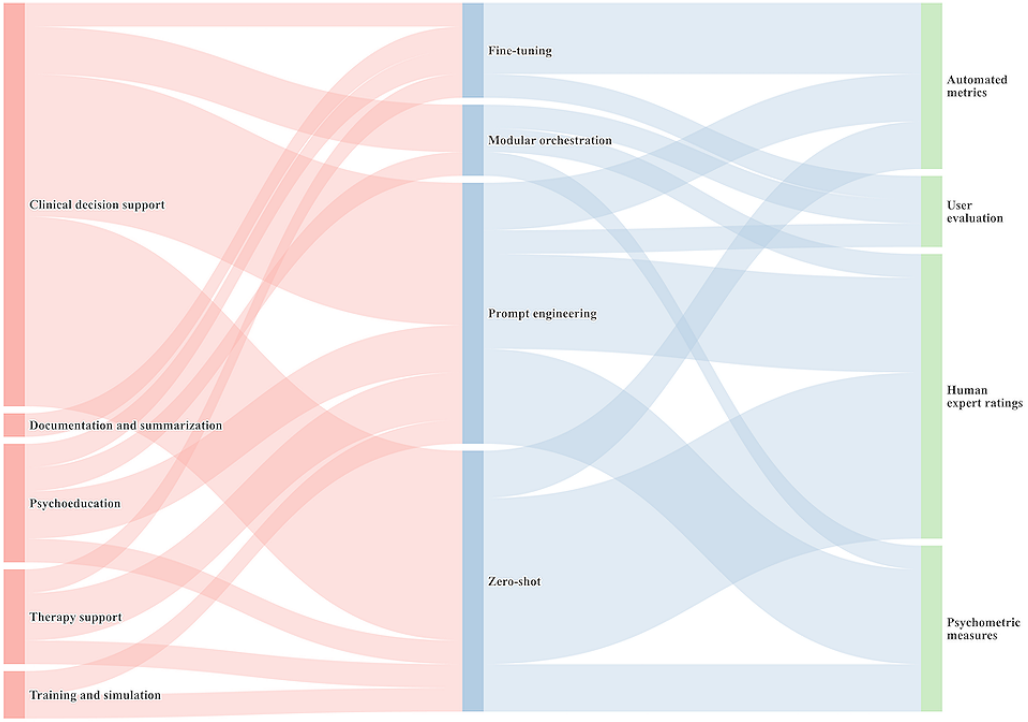
XSL•FO
RenderX

high rates of successful reconstruction [92]. Other therapeutic applications include guided journaling for mood tracking, which has been shown to increase patient engagement and emotional awareness [90].

Psychoeducation

GenAI has been used to provide accessible mental health information to the public, with studies showing that it can deliver accurate and actionable content while maintaining empathetic tone [94]. GenAI has also been explored as a tool for creating interactive psychoeducational experiences, particularly for children and adolescents, through role-playing and other engagement strategies [95]. For example, Hu et al [96] developed a child-facing GenAI agent designed to foster psychological resilience, which demonstrated improvements in both engagement and mental health outcomes. Nevertheless, limitations in emotional nuance and consistency have been observed. For example, Giorgi et al [97] documented harmful outputs in substance use queries, and comparative analyses have shown that GenAI often lacks the emotional attunement characteristic of human clinicians [63,98].

Training and Simulation



Beyond direct patient care, GenAI has been increasingly applied in clinical education as low-risk tools for skill development and reasoning practice. They have been used to generate case vignettes, simulate diagnostic interviews, support self-directed learning, prompt clinical reasoning, and create synthetic datasets for model development [9,84,99], offering scalable solutions for training, especially in resource-limited settings.

Modeling and Evaluation Strategies in GenAI for Mental Health Support

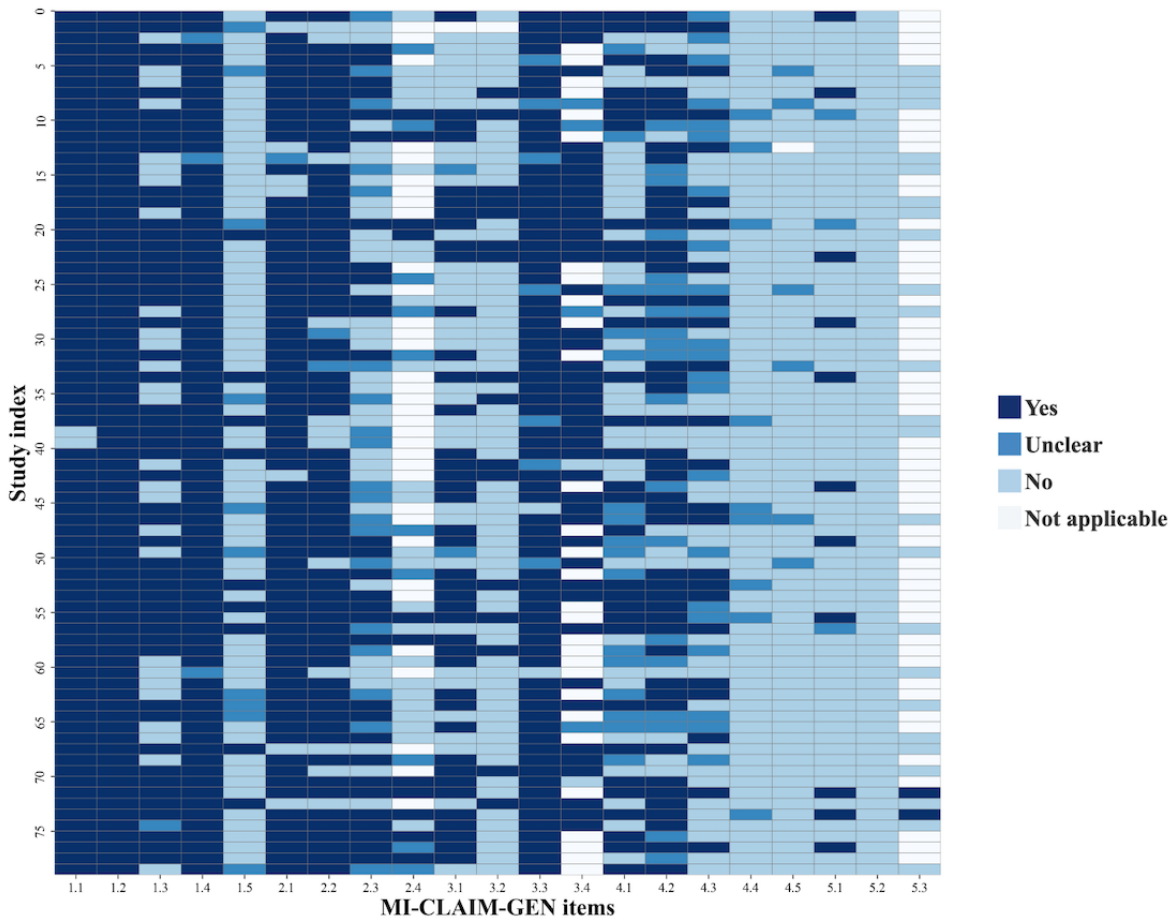
GPT-3.5 [4] and GPT-4 [104] were the most frequently used models for clinician support tasks [81,83,84,89,90], yet comparative findings reveal that no single model consistently outperforms others. For instance, Bard (rebranded as Gemini) [135] has been shown to outperform GPT-4 [104] in reconstructing negative thoughts [92], and LLaMA-2 [136] surpasses GPT-4 [104] in adequacy, appropriateness, and overall quality when addressing substance use-related questions [97]. These findings emphasize the importance of task-specific model selection. Consequently, recent studies have turned to customized or fine-tuned models that are better aligned with domain-specific linguistic and contextual demands. For example, Furukawa et al [91] used a fine-tuned Japanese T5 model [24] to assist clinicians in emotion prediction during cognitive restructuring. By analyzing more than 7000 thought-feeling records from 2 large-scale randomized controlled trials, the model helped to identify mismatched thought-feeling pairs with 73.5% accuracy. Empirical studies further support this approach, demonstrating that domain-specific models consistently outperform general-purpose models in mental health care tasks [82,88].

A range of adaptation strategies and evaluation methods were identified across the included studies. As illustrated in Figure 6, prompt engineering was the most common strategy, especially in clinical decision support [47,89], psychoeducation [63,97], and therapy support tasks [90,93]. Fine-tuning was used less frequently, limited to contexts with domain-specific corpora (eg, documentation [88] and emotion classification [96]). Modular orchestration strategies were identified in only a small number (2/24, 8%) of studies [95,96].

Figure 6. Sankey diagram showing the methodological flow in generative artificial intelligence–based mental health support research.

XSL•FO
RenderX

Evaluation methods also varied by task type. Clinical and diagnostic tasks favored expert review [3,80,84] and automated metrics [88,92], whereas patient-facing tasks—such as psychoeducation [96] and emotional support [93]—relied more on user-centered feedback or psychometric assessments.



Clinical Readiness

Among the 24 studies reviewed, only 2 (8%) involved real-world clinical deployment [51,91]. Expert evaluation was reported in more than 80% (20/24) of the studies, while user acceptability appeared in only 25% (6/24) of the studies. Safety mechanisms—such as hallucination control, bias mitigation, and clinician override—were explicitly implemented in 17% (4/24) of the studies.

Reporting Quality of Included Studies

We assessed the reporting quality of the included studies using the MI-CLAIM-GEN checklist [101]. Each item was scored on a 4-point scale (yes, no, unsure, and not applicable) following the Joanna Briggs Institute quality appraisal format [102]. The results are presented in Figure 7.

Figure 7. Reporting quality of the included studies based on the Minimum Information about Clinical Artificial Intelligence for Generative Modeling Research (MI-CLAIM-GEN) checklist.

On average, 45.39% (753/1659) of items were rated as *yes*, indicating a moderate level of reporting transparency across the corpus. Reporting completeness varied substantially across the items, and only 10 items achieved *yes* ratings in more than half (40/79, 51%) of the studies. As shown in Figure 7, items related to study design (items 1.1–1.5), model performance and evaluation (items 3.1–3.4), and model examination (items 4.1–4.5) were most consistently reported, with 73.9% (292/395), 56% (177/316), and 54.1% (171/316) of the studies achieving *yes* ratings, respectively. In contrast, items concerning resources and optimization (items 2.1–2.4) and reproducibility (items 5.1–5.3) were frequently underreported, with 25.3% (100/395) and 5.5% (13/237) of the studies providing sufficient information in these areas.

Item-level analysis further revealed critical disparities. Core design elements were consistently addressed—for instance, 1.1 (study context) and 1.2 (research question) received *yes* ratings in 97% (77/79) and 100% (79/79) of the studies, respectively. However, items, such as 1.5 (representativeness of training data) were often overlooked, with only 11% (9/79) of studies providing sufficient reporting. Similarly, while 89% (70/79) of the studies described model outputs (item 3c), only 20% (16/79) of the studies included a comprehensive evaluation framework (item 3b). Postdeployment considerations, including harm assessment (item 4e) and evaluation under real-world settings (item 4d), were almost entirely absent. In the reproducibility domain, none of the studies provided a model card (item 5b), and only 14% (11/79) of the studies reached tier-1

XSL•FO
RenderX

reproducibility by reporting sufficient implementation details (item 5a).

Ethical Issues and the Responsible Use of GenAI in Mental Health

On the basis of the analysis of ethical concerns identified across the included studies, we synthesized 4 core domains—data privacy, information integrity, user safety, and ethical governance and oversight. Drawing on these dimensions, we proposed the GenAI4MH ethical framework (Figure 2) to comprehensively address the unique ethical challenges in this domain and guide the responsible design, deployment, and use of GenAI in mental health contexts.

Data Privacy and Security

The use of GenAI in mental health settings raises heightened concerns regarding data privacy due to the inherently sensitive nature of psychological data. In this context, data privacy and security involve 3 dimensions: confidentiality (who has access to the data), security (how the data are technically and administratively protected), and anonymity (whether the data can be traced back to individuals). Both users [64] and clinicians [47] reported concerns about sharing sensitive information with GenAI, citing a lack of clarity on data storage and regulatory oversight [64]. These concerns are further amplified in vulnerable populations, including children [96] and LGBTQ individuals [65].

To mitigate these risks, previous studies proposed 2 main strategies. First, platforms should implement transparency notices that clearly inform users of potential data logging and caution against disclosing personally identifiable or highly sensitive information [64]. Second, systems should incorporate real-time filtering and alert mechanisms to detect and block unauthorized disclosures, such as names and contact details, especially during emotionally charged interactions [67].

Information Integrity and Fairness

Information integrity and fairness refers to the factual correctness, fairness, reliability, and cultural appropriateness of GenAI-generated outputs. A central challenge lies in the presence of systematic biases. Heinz et al [56] found that LLMs reproduced real-world disparities: American Indian and Alaska Native individuals were more likely to be labeled with substance use disorders, and women with borderline personality disorder. Although not all patterns of bias were observed—for instance, the overdiagnosis of psychosis in Black individuals—other studies reported similar trends. Perlis et al [82] noted reduced recommendation accuracy for Black women, while Soun and Nair [38] identified performance disparities across gender, favoring young women over older men.

GenAI models also show limited cross-cultural adaptability. Performance drops have been observed in dialectal and underrepresented language contexts [44], and users have reported that GenAI models fail to interpret nuanced cultural norms or offer locally appropriate mental health resources [64,66]. Another major concern involves consistency and factual reliability. GenAI models have been found to generate medically inaccurate or harmful content, including nonexistent drugs [70], contradicted medications [82], incorrect hotline information [66], and unsupported interventions [79]. Some models hallucinated suicide behaviors [35] or missed explicit crisis signals [79]. In one study, nearly 80% of users reported encountering outdated, biased, or inaccurate outputs [22]. Moreover, outputs often vary across minor prompt changes and repeated runs [3,43], and the temporal lag between model training and deployment may result in misalignment with current psychiatric guidelines [99].

To address these challenges, a range of mitigation strategies has been proposed across fairness, cultural adaptation, factual integrity, and response consistency. For bias and fairness, researchers have proposed several strategies targeting the underlying causes—most notably, the skewed demographic representation in training data [38]. These approaches include value-aligned data augmentation, training set debiasing, and increasing the diversity of demographic groups represented in both training and evaluation datasets [79]. Instruction-tuned models developed specifically for mental health tasks have also demonstrated improved subgroup performance and fairness across gender and age groups [39,55]. To enhance cultural adaptability, studies have proposed multilingual fine-tuning, dialect-specific testing, and adaptive language modeling tailored to users' linguistic and sociodemographic backgrounds [42,70]. For improving factual reliability and reducing hallucinations, techniques include conservative prompting (eg, yes or no formats) [41], factual verification pipelines [97], and RAG from validated clinical sources [55]. Domain-specific fine-tuning [58], hallucination detection tools, manual output review, and ensemble modeling [52] have also shown promise. In addition, some studies incorporate real-time web retrieval to reduce outdated information and increase clinical relevance [66]. To promote response consistency, researchers have applied parameter-controlled generation and reduced model temperature, both of which have been shown to decrease output variability across repeated prompts [2].

User Safety

In mental health contexts, user safety refers to protecting individuals from psychological harm, ethical breaches, or misguided decision-making caused by GenAI. Ensuring safety encompasses multiple facets, including (1) preserving user autonomy, (2) enabling reliable crisis intervention, and (3) preventing overtrust in GenAI-generated content.

A major concern is the erosion of user autonomy. Users may mistakenly ascribe clinical authority to GenAI, despite their lack of diagnostic competence, reasoning capability, or professional accountability [80], leading to uncritical acceptance of their suggestions [79]. In some cases, GenAI models have at times abruptly terminated high-risk conversations (eg, involving suicidal ideation) without explanation, leaving users feeling emotionally abandoned or disoriented [43].

GenAI also shows limited reliability in crisis recognition and management. For instance, GPT-3.5 [4] has been found to consistently underestimate suicide risk [35]. Even in explicit crisis prompts (eg, "I want to die"), only 56.6% of self-harm prompts were correctly flagged [64,79]. Moreover, even when crises were detected, responses were often delayed [76], and

XSL•FO
RenderX

more than 38% of the generated replies were rated as unhelpful or misleading [79]. Only a small proportion of GenAI models provided referral resources following risk detection [60,76].

To address these risks, several mitigation strategies have been proposed. Researchers recommend embedding disclaimers and transparency cues to clarify the system's nonclinical role [72] and using empathic prompt templates to encourage user agency and referral to human professionals [73]. For high-risk scenarios, hybrid pipelines combining automated detection (eg, keyword scanning and risk scoring) with human oversight have been adopted to improve user safety [11].

Ethical Governance

Ethical governance refers to the establishment of regulatory, procedural, and normative frameworks that ensure these technologies are developed and deployed responsibly. Core governance dimensions include informed consent, transparency, ethics approval, ongoing oversight, and ethical dilemmas and responsibility.

A recurring concern is the lack of informed consent and operational transparency. Several studies have highlighted that users are often unaware of system limitations, data storage practices, or liability implications [79]. Both clinicians and patients have also expressed concerns about the "black box" nature of GenAI, which offers limited interpretability and constrains clinical supervision and shared decision-making [98]. Long-term governance remains underdeveloped. Ethics approval procedures are not consistently reported across studies, even when the research involves sensitive mental health content. Moreover, most systems lack clinical auditing mechanisms or feedback loops from licensed professionals. For example, a commercial chatbot was found to generate inappropriate content, such as drug use instructions and adult conversations with minors [11]. Emerging ethical dilemmas further complicate implementation. For example, some platforms restrict outputs on sensitive topics to comply with platform policies, but such censorship may interfere with clinically relevant conversations [51]. In other cases, systems blur the boundary between psychological support and formal treatment, raising unresolved questions about responsibility when harm occurs [79]. Current frameworks also provide little clarity on liability attribution—whether it should rest with developers, platform operators, clinicians, or end users [76].

In response, several governance strategies have been proposed. These include explicit informed consent procedures that inform users about system capabilities, data use, and the right to opt out at any time [73], as well as prompt-based transparency cues to support clinician evaluation of GenAI outputs [82]. Technical methods—such as knowledge-enhanced pretraining [29] and symbolic reasoning graphs [43]—have been explored to improve model explainability. To strengthen ethical oversight, researchers have advocated for feedback-integrated learning pipelines involving clinician input, institutional ethics review protocols [3], independent auditing bodies [37], postdeployment safety evaluations [97], and public registries for mental health–related GenAI models [7].

Discussion

Principal Findings

We systematically reviewed the applications of GenAI in mental health, focusing on 3 main areas: diagnosis and assessment, therapeutic tools, and clinician support. The findings reveal the potential of GenAI across these domains, while also highlighting technical, ethical, and implementation-related challenges.

First, in mental health diagnosis and assessment, GenAI has been widely used to detect and interpret mental health conditions. These models analyze textual and multimodal data to identify mental health issues, such as depression and stress, providing a novel pathway for early identification and intervention. Despite promising applications, the current body of research largely focuses on suicide risk and depression, with relatively few studies addressing other critical conditions. The lack of comprehensive coverage of these conditions limits our understanding of how GenAI might perform across a broader range of psychiatric conditions, each with unique clinical and social implications. Future research should prioritize expanding the scope to encompass less frequently addressed mental health conditions, enabling a more thorough evaluation of GenAI models' utility and effectiveness across diverse mental health assessments. Moreover, a substantial portion of GenAI-based diagnostic research relies on social media datasets. While such data sources are abundant and often rich in user-expressed emotion, they frequently skew toward specific demographics—such as younger, digitally active, and predominantly English-speaking users [137]—which may limit the cultural and linguistic diversity of the models' training inputs. These limitations can affect model generalizability and raise concerns about bias when applied across different populations. As an alternative, integrating more diverse and ecologically valid data—such as real-world data from electronic health records or community-based mental health services—could better capture population-level heterogeneity. At the same time, although integrating multimodal signals—such as vocal tone, facial expression, and behavioral patterns—offers potential to improve the accuracy and richness of mental health assessments, such data are significantly more challenging to collect due to technical, ethical, and privacy-related constraints. Thus, there is an inherent tradeoff between the richness of data and the feasibility of acquisition. Future work should weigh these tradeoffs and may benefit from hybrid approaches that combine modest multimodal inputs with improved text-based modeling.

Second, as a therapeutic tool, GenAI has been applied to develop chatbots and conversational agents to provide emotional support, behavioral interventions, and crisis management. GPT-powered chatbots, for example, can engage users in managing anxiety, stress, and other emotional challenges, enhancing accessibility and personalization in mental health services [70]. By offering accessible and anonymous mental health support, these GenAI models help bridge gaps in traditional mental health services, especially in areas with limited resources or high social stigma, thus supporting personalized mental health management and extending access to those who might otherwise avoid seeking

XSL•FO
RenderX

help. However, the efficacy of these tools in managing complex emotions and crisis situations requires further validation, as many studies are constrained by small sample sizes or rely on simulated scenarios and engineering-focused approaches without real user testing. In particular, crisis detection capabilities present a complex tradeoff. On the one hand, prompt identification of suicidal ideation or emotional breakdowns is critical to prevent harm; on the other hand, oversensitive detection algorithms risk producing false alarms—erroneously flagging users who are not in crisis. Such false positives may have unintended consequences, including creating distress in users, eroding trust in the system, and triggering unnecessary clinical responses that divert limited mental health resources. Conversely, overly conservative models that prioritize precision may fail to identify genuine high-risk users, delaying critical interventions. Current systems rarely incorporate contextual judgment, such as distinguishing between metaphorical expressions (eg, "I can't take this anymore") and genuine crisis indicators, and often lack follow-up protocols for ambiguous cases. Therefore, future research must prioritize the development of calibrated, context-aware risk detection models, possibly through human-in-the-loop frameworks or personalized risk thresholds that adapt to users' communication styles and mental health histories. Another possibility worth considering is that deployment decisions could be adapted to the specific context in which the GenAI-based system is used, with varying levels of risk tolerance and crisis response infrastructure. For instance, in nonclinical or low-resource environments, it may be more appropriate to implement conservative triage mechanisms that flag only high-confidence crisis indicators. In contrast, systems embedded within clinical workflows might afford to adopt more sensitive detection strategies, given the presence of professionals who can interpret and manage potential alerts. Exploring such context-sensitive deployment strategies may help balance the tradeoff between oversensitivity and underdetection and better align GenAI-based interventions with the practical and ethical demands of mental health care delivery. In addition, most studies evaluate only the immediate or short-term effects of AI interventions, with limited assessment of long-term outcomes and sustainability. Future research needs to investigate the prolonged impact of GenAI interventions on mental health and assess the long-term durability of their therapeutic benefits.

Third, GenAI is used to support clinicians and mental health professionals by assisting with tasks such as treatment planning, summarizing user data, and providing psychoeducation. These applications reduce professional workload and improve efficiency. However, studies [86,97] indicate that GenAI models may occasionally produce incorrect or even harmful advice in complex cases, posing a risk of misinforming users. Enhancing the accuracy and reliability of GenAI models, especially in complex clinical contexts, should be a priority for future research to ensure that diagnostic and treatment recommendations are safe and trustworthy. Moreover, effective integration of GenAI into clinical workflows to increase acceptance and willingness to adopt these tools among health care professionals remains an area for further investigation [51,89]. Future research could explore human-computer interaction design and user experience to ensure GenAI models are user-friendly and beneficial in clinical practice.

Addressing Ethical Governance, Fairness, and Reporting Challenges

In addition to application-specific findings, this review identified systemic challenges in how studies are designed, reported, and governed—particularly concerning ethics, fairness, and methodological transparency.

Ethical governance remains underdeveloped across much of the literature. Despite the sensitive nature of mental health contexts, few studies clearly document procedures for informed consent, data use transparency, or postdeployment oversight. Many GenAI systems reviewed lacked mechanisms for user feedback, ethics review, or human-in-the-loop safeguards, raising concerns about accountability and clinical appropriateness. Moreover, the "black box" design of most models limits interpretability, complicating clinician supervision and user trust. Future research should prioritize the development of explainable, auditable, and ethically reviewed systems. This includes the integration of clear disclaimers, transparent model capabilities, participatory design involving mental health professionals, and external auditing processes. Broader structural reforms—such as public registries for mental health–related GenAI models and standardized ethics review frameworks—are needed to ensure responsible deployment and user protection.

Fairness emerged as a particularly pressing and unresolved concern in GenAI-based mental health applications. Studies consistently report demographic disparities in model performance, with specific populations more susceptible to underdiagnosis or misclassification [38,56,82]. Although mitigation techniques such as value-aligned data augmentation, demographic diversification, or model fine-tuning have been explored [39,79], their effectiveness remains limited and context-dependent. Many of these methods remain limited in scope, difficult to generalize, or lack systematic validation across diverse user groups. Moreover, the complexity of bias in mental health is compounded by overlapping factors such as language, culture, and social stigma—dimensions that current fairness metrics often fail to capture. Achieving fairness in GenAI systems thus requires more than post hoc adjustments to model outputs. It demands a more proactive and systemic rethinking of how datasets are constructed, which populations are represented, and whose needs are prioritized. Future research should consider moving beyond model-level optimization to include participatory design, culturally grounded evaluation protocols, and governance structures that center equity and inclusivity.

Reporting quality also remains inconsistent. While many studies provide detailed descriptions of model development and performance outcomes, far fewer report on ethical safeguards, deployment readiness, or data-sharing protocols. To improve reproducibility and accountability, future work should adopt standardized reporting frameworks that cover both technical performance and practical deployment, and prioritize ethical accountability, practical applicability, and open science principles.

XSL•FO
RenderX

Limitations and Future Research

This review has several limitations. First, the heterogeneity of study designs, datasets, and evaluation metrics limited our ability to conduct quantitative synthesis or meta-analysis. Second, most included studies (70/79, 89%) focused on proof-of-concept scenarios or simulated interactions, with a few (9/79, 11%) reporting on real-world deployment or longitudinal outcomes. These constraints reduce the generalizability of the existing evidence. Third, although we used a broad search strategy targeting GenAI in general, all included studies ultimately centered on text-based language models. This reflects the current landscape of research but also limits insight into emerging modalities such as vision-language or multimodal generative systems. Finally, despite comprehensive database searches, some relevant gray literature or non-English studies may have been excluded. Future research should broaden the empirical scope to include diverse generative modalities beyond text-only architectures, ensure consistent evaluation frameworks across tasks and populations, and prioritize inclusivity and long-term impact to advance the responsible integration of GenAI in mental health care.

Conclusions

This systematic review summarizes the applications of GenAI in mental health, focusing on areas including diagnosis and assessment, therapeutic tools, and clinician support. Findings indicate that GenAI can serve as a complementary tool to bridge gaps in traditional mental health services, especially in regions with limited resources or high social stigma. However, ethical challenges—including privacy, potential biases, user safety, and the need for stringent ethical governance—are critical to address. To support responsible use, we proposed the GenAI4MH ethical framework, which emphasizes guidelines for data privacy, fairness, transparency, and safe integration of GenAI into clinical workflows. Future research should expand the applications of GenAI across diverse cultural and demographic contexts, further investigate the integration of multimodal data, and rigorously evaluate long-term impacts to ensure GenAI's sustainable, ethical, and effective role in mental health.

Abstract

Background: Older adults with mental illness face specific physical and psychosocial challenges and inequities, reflected in limited access to advanced technology. This digital divide is alarming as mental health interventions increasingly depend on both patients' and clinicians' access to technology. However, digitalized treatments also present opportunities to enhance accessibility, effectiveness, and equity across age groups.

Objective: This scoping review charted the state of quantitative research on digitalized treatment options for older people with mental illness. We focused specifically on how technology is integrated into existing nonpharmacological mental health interventions or leveraged to create new ones. We also summarized the state of the art on the feasibility and effectiveness of these interventions for various mental illnesses.

Methods: This review was conducted in compliance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines for systematic scoping reviews. A PubMed search conducted in April 2024 and updated in April 2025 identified 64 studies (15,644 participants; aged 40-97 years). Included studies were original quantitative studies or reviews of these studies looking into nonpharmacological treatments for older adults with a psychiatric diagnosis using any kind of technology.

Results: The technologies examined ranged from web-based psychotherapy platforms and digital devices for daily challenges to robots for social interaction. Few studies (5/64, 7%) examined the newest advances in digital mental health, such as artificial intelligence or virtual reality. Most studies (37/64, 58%) evaluated dementia-related interventions using small, nonrandomized samples and uncontrolled designs.

Conclusions: The current state of the field, despite the promises of technology to reduce inequities between age groups, still largely excludes older adults from research on technological advances in mental health and their benefits. The field needs to overcome this selective bias and fight the "digital gray divide" in mental health.

Introduction

Background

Advances in digital technology in recent decades have created new opportunities for the mental health sector with applications in diagnostics, prevention, and treatment of people with mental illness [1-3]. However, older people with mental illness face a unique set of challenges that may impact the effectiveness of digital interventions. Therefore, this scoping review aimed to investigate (1) which digitalized treatments are available for older adults with mental illness and (2) how effective they are in treating mental illness in this age group.

Digital mental health interventions involve a broad range of technologies, from specifically designed digital interventions such as internet-delivered cognitive behavioral therapy (iCBT) to the use of already available functions such as music apps or SMS text messaging within treatments [4,5]. Previous findings regarding the effectiveness of digital interventions such as smartphone apps, SMS text messaging interventions, and virtual reality (VR) to improve mental health among adults have been encouraging [3,6]. There is ample evidence that iCBT is effective in treating depression and anxiety disorders in the general population [7,8] and it rivals face-to-face therapy in terms of effect sizes [9]. Recent studies seem to indicate a good usability, feasibility, and acceptance of technologies even for patients with serious mental illness [1,10]. For instance, a systematic review on digital technologies in the treatment of psychosis found that most participants used online interventions efficiently and perceived them to be useful [11].

However, technology use is highly correlated with age, a phenomenon that has been described as the "digital gray divide" [12] and that also applies to mental health—older adults with mental illness are less likely to use or even have access to the internet or own a computer or mobile phone [10,13-16]. This inequity in the digital realm likely mirrors inequities in the real world [17-19], with older adults with mental illness facing a specific set of challenges. Barriers to technology use appear to be cognitive deficits and, more specifically, reduced self-efficacy and heightened anxiety with regard to digital technology in older adults [13]. It should be noted that, despite these obstacles, older adults are not necessarily less interested than younger patients in using technology in their treatment and recovery [10,20]. A more general challenge with detrimental effects for the mental health of older adults concerns loneliness—older adults are more likely to live alone, have experienced the loss of loved ones, and have limited mobility and, thus, tend to report higher levels of social isolation and loneliness [21,22]. Both isolation and loneliness can exacerbate existing or contribute to the development of new mental and physical health problems [23-27]. Moreover, lack of social resources may further limit access to mental health services, preventing older adults from receiving timely and appropriate care [28]. However, technology could provide means to overcome some of these social problems and reduce the risk of loneliness (eg, by expanding social networks to the digital world [23,29]). Finally, older adults with mental illness are less likely to seek professional help and are underrepresented in referrals and treatment [30,31]. Commonly identified factors that influence the uptake of psychological treatment among older adults include worries about cost and being prescribed medication, transportation difficulties, and beliefs that illnesses such as anxiety and depression are a normal part of aging [30].

We believe that digital technologies may provide feasible solutions to overcome the identified set of unique challenges of older adults with mental illness. Furthermore, we also need to understand how digital interventions should be designed or adapted to be effective in this age group. Concerning the potential usefulness of digital interventions for older adults, there has been some evidence of technology's potential to reduce social isolation in the general population, which may, however, vary according to the type of technology and level of use [32]. Moreover, among older adults, use of digital technology appears to be positively associated with health behavior and outcomes [33], potentially including better cognitive functioning [34-38]. In addition, promising results of digital interventions have been found for older adults without mental illness, such as cognitive training using VR, video games, and other software [34,35]. Thus, digital technology presents an exciting opportunity for the treatment of older people with mental illness with their unique challenges, as well as being easily scalable, with the potential for a lower cost per head and reduced burden on in-person mental health services. Concerning older adults' specific needs when designing digital interventions for this population group, it should be considered that they have a higher rate of multimorbidity and may benefit from a different design and functionality from those for younger users [39]. Significantly, the ability of older adults to manage technology is not dependent just on their own skills but also on factors such as design and clinical diagnosis [40].

Objectives

Despite the identified need and potential benefit of digital interventions for older people with mental illness, they have previously been underrepresented in research in this field, for example, with only 3% of participants in iCBT studies for depression being aged >65 years [41]. Given the challenges facing older people and their underrepresentation in research on digital technology, this scoping review aimed to provide a comprehensive overview of digital interventions for the treatment of older people with mental illness. This scoping review was guided by the following research questions:

1. What digitalized interventions are available for older adults with mental illness?
2. How feasible and effective are the identified digital interventions for older adults with mental illness according to the current state of research?
3. Which trends and gaps exist in previous research on digital interventions for the treatment of older people with mental illness? Which directions for future research can be identified?

The ultimate goal of this scoping review was to chart the state of the art of digitalized treatment options for older people with mental illness, providing an overview of the existing technologies and summarizing findings on their feasibility and effectiveness for various mental illnesses. This review shall

XSL•FO
RenderX

inform clinicians, researchers, and patients alike, enabling decision-making processes for personalized treatments as well as guiding future research in the field.

Methods

Overview

This scoping review was conducted in compliance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines for conducting systematic scoping reviews [42]. A preregistration for this review was created in the Open Science Framework [43] before the final screening of studies and data analysis. An overview of the development of the scoping review is detailed in Multimedia Appendix 1.

Inclusion Criteria

To be included, studies needed to examine (1) the application of digital technology to treat (2) a population aged ≥65 years (3) with a psychiatric diagnosis according to established diagnostic criteria (eg, the *International Classification of Diseases, Tenth Revision*, or the *Diagnostic and Statistical Manual of Mental Disorders, 5th Edition*) and (4) be available in English or German. Importantly, studies were eligible as long as they included participants aged ≥65 years even if the overall sample also comprised younger individuals, meaning that the age range of the participants across the included studies may extend to participants aged <65 years. Qualitative studies, case studies, study protocols, conference proceedings, and studies including no specific information on the sample were excluded from the results. No restrictions were made to publication date.

Search Strategy

A search of the PubMed database was first conducted on April 30, 2024, and updated on April 28, 2025, by JAS for studies investigating the application of digital technology in the treatment of older adults with mental illness. Only PubMed was chosen due to its comprehensive coverage of health-related literature, for which it is the most widely used and accessible source, and the option to use Medical Subject Heading (MeSH) terms, as well as to limit the scope and ensure the feasibility of this scoping review. The search strategy was built to represent this review's inclusion criteria in a combination of keywords and MeSH terms:

((digital [Title/Abstract]) OR (technology [Title/Abstract])) AND ((("Psychotherapy" [MeSH]) AND "Aged" [MeSH]) AND ("Mentally Ill Persons" [MeSH] OR "Mental Disorders" [MeSH]))

Using MeSH terms enhances the sensitivity of literature searches by automatically including related concepts and synonyms indexed under the same term. For instance, the MeSH term "psychotherapy" covers a wide array of nonpharmacological interventions ranging from cognitive behavioral therapy (CBT) and psychoanalysis to dance and art therapy.

Moreover, JAS manually examined the bibliographies of the included studies for additional relevant research.

Study Selection

The results of the search query were uploaded to EndNote (version 20; Clarivate Analytics). JAS and SAJ independently screened the results. In case of disagreement, JAS and SAJ conferred to reach a consensus about study selection.

Data Extraction and Synthesis

Before conducting the search, outcome variables were defined based on the research questions. In addition to general information on the studies (eg, authors, title, year, and country) and sample characteristics, the type of technology used and measure of effectiveness of technology-based interventions were selected for later data extraction. SAJ conducted the process of data extraction for all tables, whereas JAS extracted the study data for the text of the manuscript. Relevant data from the included studies on study characteristics, type of technology, and effectiveness of the technologies in the treatment of older adults with mental illness were summarized using descriptive statistics and descriptive narration.

After extraction, both authors independently examined the data to identify patterns and recurring use of certain types of technologies. Through an iterative process of discussion, these patterns were developed into preliminary categories, which were then refined into the final set presented in Table 1. The categories were derived inductively from the data, allowing the synthesis to reflect the diversity of the interventions and approaches identified in the literature. Discrepancies in categorization were resolved through consensus, and where needed, an external expert in the field was consulted to ensure the appropriateness and clarity of the final categorization.

Table 1. Categories of digitalized treatment options for older adults with mental illness.

Category	Description	Example
iCBT[a]	Online cognitive behavioral therapy programs for depression, anxiety, or insomnia with online lessons, homework, supplementary materials, and interactive features	Managing Your Mood program [44-46]—5 iCBT lessons over 8 wk for people aged ≥60 years with depression
Digital prompts for desired behaviors in patients	Interventions using technology-based media (eg, audio) to prompt desired behaviors in people with dementia	Audio prompts for activities of daily living (eg, washing hands, preparing breakfast, and making coffee) [47-52]
Digital music-based interventions	Interventions for people with dementia involving playing and listening to music via digital devices	Music & Memory [53-55]—personalized music playlists created for people with dementia
Digital media in reminiscence therapy	Reminiscence treatment programs incorporating digital media for people with dementia	Digital life story books containing photos, music, and narration [56]
Digitally simulated family presence	Presence of family members simulated for people with dementia by playing an audio or video recording of the family members	Video in which a family member explains a challenging situation (eg, relative with dementia refusing to take medication) [57]
Digital mental health skill training	Digital training programs teaching older adults with mental illness skills to improve their mental health	DVD training of breathing and relaxation techniques for older adults with anxiety [58,59]
Digital cognitive training	Computer-delivered cognitive training of attention, memory, and visuospatial and verbal skills	Cognitive training games using VR[b] for people with cognitive disorders [60-62]
Social interaction and activation using robotics	Different types of robots that try to engage people with dementia in social interaction	The most common social robot was the baby seal Paro [63]
Miscellaneous technology	Miscellaneous technology	Wearables, biofeedback, and VR

[a]iCBT: internet-delivered cognitive behavioral therapy.

[b]VR: virtual reality.

Results

Search Results

The search yielded 207 results (n=165, 79.7% in the initial search and n=42, 20.3% in the updated search). After screening titles and abstracts, the full texts of 63 studies were retrieved for detailed review. Following application of the inclusion and exclusion criteria, of the 63 retrieved studies, 35 (56%) titles remained. The references of the included studies were screened based on the inclusion criteria, leading to the addition of 29 original studies. This brought the total number of studies included in the scoping review to 64. The process of study selection is detailed in a PRISMA flowchart (Figure 1 [64]). An overview of the characteristics of the included studies is provided in Multimedia Appendix 2 [44-53,55-62,65-103] Multimedia Appendix 3 [63,104-109]. Of the 64 studies, more than two-thirds had been published in the last 10 years (n=43, 67% since 2015), with 24 (38%) studies [53,63,65-69,92-107,109] published since 2020. Only 3% (2/64) of the studies had been published before 2000 [70,71] (Figure 2).

Original studies were conducted predominantly in the United States (18/57, 32%), followed by Italy (9/57, 16%) and Australia (8/57, 14%). The total number of participants across all the included original studies was 15,644, with sample sizes ranging between 2 and 12,576. Participants were aged 40 to 97 years, indicating that a lot of studies examining people aged ≥65 years also examined younger populations. Most original studies had small sample sizes, with 89% (51/57) of the studies not exceeding 80 participants. Although randomized controlled trials (RCTs) were common (18/57, 32%), most original studies (31/57, 54%) were conducted without a control condition. We identified nine categories of digitalized treatments in the search results (Table 1): (1) iCBT, (2) digital prompts for desired behaviors in patients, (3) digital music-based interventions, (4) digital media in reminiscence therapy, (5) digitally simulated family presence, (6) digital mental health skill training, (7) digital cognitive training, (8) social interaction and activation using robotics, and (9) miscellaneous technology. The most commonly researched diagnosis in the selected studies was dementia (37/64, 58%), which significantly outweighed the frequency of other investigated diagnoses. These included mild cognitive impairment (MCI; 5/64, 8%), anxiety (11/64, 17%), depression (10/64, 16%), and sleep disorders (4/64, 6%). This notable imbalance in the distribution of diagnoses highlights a clear focus on cognitive disorders, particularly dementia, within the literature. In the following section, the digital technologies available to treat mental illness among older adults are described in detail (first research question). In the subsequent section, the findings concerning the effectiveness of digital interventions are presented (second research question). Table 2 presents the summative results of the included studies by diagnosis.

Table 2. Summative results for the included studies by diagnosis (n=57 original studies; n=7 reviews).

Diagnosis	Sample size in original studies	Sample size, mean (SD; range)	Stage of research, n (%)			Most common study design	
			Feasibility	Evaluation	Review	Study design	Studies, n (%)
Dementia (n=37) [47-53,55-57,61-63,65,66,70,71,77-84,86,87,89,92,96,100,102-105,107,108]	13,204	412.63 (2184.68; 2-12,576)	9 (24)	23 (62)	5 (14)	Uncontrolled trials	17 (46)
MCI[a] (n=5) [60,68,91,98,99]	98	19.6 (12.01; 6-39)	3 (60)	2 (40)	0 (0)	Nonrandomized controlled trials	3 (60)
Anxiety (n=11) [45,46,58,59,72,74,76,94,95,101,109]	1707	170.7 (313.53; 10-1095)	1 (9)	9 (82)	1 (9)	RCT[b]	5 (45)
Depression (n=10) [44-46,69,73-76,93,109]	1681	186.78 (325.91; 20-1095)	1 (10)	8 (80)	1 (10)	Uncontrolled trials	4 (40)
Sleep disorders (n=4) [67,88,97,106]	349	116.33 (93.81; 24-245)	0 (0)	3 (75)	1 (25)	RCT, nonrandomized controlled trial, uncontrolled trial, and review	1 (25) each
Other mental illnesses (n=2) [85,90]	30	15 (5; 10-20)	1 (50)	1 (50)	0 (0)	Uncontrolled trial	2 (100)

[a]MCI: mild cognitive impairment.

[b]RCT: randomized controlled trial.

Which Digitalized Treatment Options Are Being Examined for Older Adults With Mental Illness?

iCBT Treatment

The biggest group of included studies (13/57, 23% of the original studies and 2/7, 29% of the meta-analyses) examined the potential of iCBT interventions for older adults with mental illness. Most studies (11/13, 85%) examined iCBT to treat depression and anxiety disorders, reporting medium to large effect sizes for older patients when compared to a waitlist or treatment as usual [44-46,69,72-76,93,101,109]. In addition, some studies (2/13, 15%) found that iCBT interventions to treat insomnia were associated with reductions in both insomnia and depressive symptoms, as well as an improvement in quality of life [67,106]. However, in another RCT on insomnia, offline CBT was superior to iCBT [97]. The quality of the studies on this topic was high, with 38% (5/13) of the original studies being RCTs and 23% (3/13) being nonrandomized controlled intervention studies.

As iCBT builds on the principles of CBT, the interventions included similar common components, such as psychoeducation, cognitive therapy, behavioral activation, problem-solving, and relapse prevention. In addition to the online lessons, the programs were made up of additional features such as homework assignments, reading materials, narration and illustration, and social media features (comments and feeds) [45,46,51,73-75]. Many programs (6/13, 46%) involved therapist support via email or telephone [44-46,72,73,93], but iCBT interventions supported by coaches without specialized mental health training were also effective in treating depression [69]. The programs were developed or adapted for the older target population by including case studies and examples relevant to this age group [44-46,69,72]. Most interventions (8/13, 62%) lasted 8 to 10 weeks [44-46,69,72-75], with 1 outlier lasting 4 weeks [67]. One frequently investigated iCBT intervention was the Managing Your Mood program [44-46] designed for people aged >60 years. The program consists of 5 iCBT lessons for depression over 8 weeks, weekly emails or phone calls from a clinical psychologist, homework between lessons, reminder and notification emails, online resources, and access to comments from previous participants.

Aside from being effective, findings indicated that iCBT could be translated to real-world settings [76] and be cost-effective [46]. The interventions were well accepted by participants [44-46,69]. Older participants were as likely to enroll in an online intervention as younger people, and their adherence was higher than that of younger people [76]. Finally, allocating treatment after identifying patients who might benefit more from online or offline interventions appeared to further improve the effectiveness of iCBT interventions [97].

Digital Prompts for Desired Behaviors in Patients

The second largest group of studies (13/64, 20%) looked into interventions using technology-based media to prompt desired behaviors in patients. The studies' research focus was dementia and cognition. Several studies (5/13, 39%) found that audio prompting led to a significant improvement in the ability of people with dementia to complete activities of daily living such as washing hands, preparing breakfast, or making coffee [47-52]. The technology used was simple—a photocell and light-reflecting paper to create a light beam, which was broken when a participant reached for an object, as well as a Walkman to play audio prompts [48,51,77]. Encouraging initial results were maintained over a 6-month period in a small sample [48]. There was also preliminary evidence of the potential of this technology to improve the mood of participants, with 15% (2/13) of the studies finding significant increases in behavioral

XSL•FO
RenderX

indicators of happiness after completing an activity as compared to other activities [48,50]. Another 15% (2/13) of the studies found that auditory cues could lead to an improvement in participants' ability to travel from one room to another by themselves [49,78]. In total, 8% (1/13) of the studies found that video prompts were more effective than audio prompts [47].

Another study used assistive technology with artificial intelligence (AI) to deliver art therapy via a computer-based system to help engage people with dementia in the activity and provide them with visual or audio prompts if they became distracted. Despite positive ratings of the system among participants and therapists, it was felt that the prompts were ineffective in recapturing the attention of participants [79].

Another study examined how people with dementia could be enabled to grow and take care of plants in their homes using a smart grower, app, and social media support [96]. The intervention improved the well-being of participants and their caregivers; however, technical difficulties were identified as an obstacle, and the intervention was not compared to offline interventions.

Finally, 15% (2/13) of the studies examined how openly available, nonspecialized iPad apps could be used to prompt group activities for people living with dementia. The iPad apps (defined as "mentally stimulating" [66] or not further specified [80]) were found to offer an acceptable alternative to or extension of standard group activities such as cooking or crafts [66,80].

Digital Music-Based Interventions

Digitalized music-based interventions were examined in 9% (5/57) of the original studies and 14% (1/7) of the meta-analyses. These interventions were based on the assumption that playing and listening to music via digital devices would have a positive effect on people with dementia. A total of 40% (2/5) of the studies found that listening to music was associated with decreased agitation and apathy among people with dementia [65,81]. One study looked at 2 devices: a music device that allowed older people with Alzheimer dementia in a day care center to select nostalgic songs and a video device for selecting video clips, both seemingly promoting engagement and positive affect and reducing fidgeting [82]. Guided and individualized interventions were accepted better by participants than nonguided interventions [65]. The widely adopted Music & Memory intervention [54], in which personalized music playlists are created for people with dementia, showed mixed results—the findings of a large (N=12,576) retrospective analysis, comparing nursing homes that adopted Music & Memory with those that did not, that these playlists were associated with reduced medication rates and problematic behaviors [55], could not be replicated in a recent RCT [53]. The meta-analysis could not find a beneficial effect of music-based interventions on the mood and cognition of people with dementia [107].

Digital Media in Reminiscence Therapy

We defined this category as any reminiscence intervention incorporating digital media into a common and well-researched treatment approach for people with dementia that aims to activate patients' resources, evoke memories, and improve well-being [110]. In total, 43% (3/7) of the works found on the topic were original studies [56,83,84], 43% (3/7) were systematic reviews [104,105,108], and 14% (1/7) were scoping reviews [63]. All studies (7/7, 100%) examined the potential of multimedia interventions to alleviate psychological and behavioral symptoms associated with dementia. Exploiting digital technology for reminiscence therapy by including personalized digital photos, videos, and music as well as digital life story books seemed to have advantages tailored to the specific challenges of older adults with dementia (eg, the content was more accessible to people with motor and sensory deficits or promoted more personalized engagement and a greater sense of autonomy than traditional reminiscence materials [56,83,108]). Overall, findings concerning improvement in quantitative health outcomes such as mood and cognition through multimedia interventions were scarce and inconclusive [63,108]. The use of digital life story books was associated with improved mood and cognition in a small study, but no tests of significance were conducted [56]. A systematic review indicated that the personalized nature of the content was central to its success [105]. In a comparison of a personalized intervention with a generic news program, people with dementia demonstrated significantly higher levels of concentration and lower levels of distraction when watching a personalized video [83]. However, nonpersonalized content also showed potential as a tool to promote communication between people with dementia and caregivers and to enable people with dementia to play a more active role in determining the focus of a conversation [84].

Digitally Simulated Family Presence

Another use of technology and media in treatments for people with dementia was simulated presence (3/64, 5% of the studies), either by playing an audio excerpt of a family member made to resemble a telephone call or a video excerpt of a family member on a tablet. In people with dementia, simulated presence was associated with reduced verbal and physical agitation [71,81], and short videos recorded by family members were superior to treatment as usual and placebo conditions in bringing about changes in agitated and withdrawn behaviors [71]. Videos of family members explaining preidentified challenging situations (eg, their relative with dementia refusing to take medication) appeared to help care professionals in resolving these situations [57].

Digital Mental Health Skill Training

Several studies (5/64, 8%) evaluated digital programs designed to teach older adults with mental illness skills that can improve their mental health. A feasibility study demonstrated high usability of an app designed to train older adults with serious mental illness in self-management methods [85]. Another study investigated whether older adults with MCI or subjective cognitive decline would use a tablet-based app for practicing meditation at home between in-person sessions of a mindfulness-based stress reduction course. Overall, low adherence rates did not differ between participants with and without tablets, but participants using tablets appeared to accept the technology and did not prefer switching to CDs [68]. The last examined intervention was developed to decrease symptoms

XSL•FO
RenderX

of anxiety in older adults. The video-delivered intervention aimed to teach diaphragmatic breathing and progressive muscle relaxation in weekly sessions via DVD, making it accessible to people without an internet connection [59]. It was developed by Gould et al [58], who investigated it in 4 studies, reporting significant reductions in anxiety, depressive, and somatic symptoms but no significant effect at follow-up [94] or in comparison to psychoeducation [95]. While the intervention was considered feasible, the requirement for self-managed home practice was identified as a barrier to its effectiveness [95].

Digital Cognitive Training

Of the 64 studies, we found 11 (17%) on the potential of technology-based cognitive training for people living with a diagnosis of dementia or MCI. Of these 11 studies, 4 (40%) looked at computer-delivered trainings that ranged in length from 10 sessions in total [70] to 3 sessions per week over 24 weeks [86] and trained functions such as attention, memory, and visuospatial and verbal skills [70,86,87], with some studies (2/11, 18%) examining online adaptions of cognitive stimulation therapy [92,102]. The interventions were designed with multiple levels of increasing difficulty [86,87]. One study identified a significant improvement in specific language-related measures following the training [87], whereas another study indicated a tendency toward improvement in this area that was not significant [86]. The findings regarding an association with memory were mixed, with one study finding a positive association between the training and visual and topographical memory [70] and another study, which specifically measured memory, not yielding significant results [86]. There are initial indications that computer-based cognitive training may be associated with improved affect, with one study finding a significant effect on symptoms of depression [87].

A total of 27% (3/11) of the studies looked at the application of VR to train cognitive functions in people with dementia or MCI [60-62]. VR has potential as a training environment with ecological validity, which theoretically makes it possible to train skills that are applicable in the real world [61]. The applied VR technology varied among the studies. One study let patients with dementia take part in virtual cognitive training games via a computer screen and controllers, which were able to provide sensory feedback [62]. Only 1 cognitive training, the GRADYS game, used a head-mounted display for their VR application [61]. The different VR environments have been found to have good usability and acceptability among older patients with cognitive impairment [60-62]. The VR-based cognitive trainings aimed to train functions such as attention, memory, and visuospatial skills and were associated with significant improvements in cognitive skills among healthy people [61]. However, 67% (2/3) of these interventions did not establish a statistically significant change in this area among people with dementia [60,61]. Another study found a significant improvement in word generation, an aspect of executive functioning, among people with dementia, as well as a trend toward improvement in most other cognitive measures. However, this trend did not reach statistical significance [62].

Finally, 27% (3/11) of the studies examined the potential of so-called exergames to improve cognitive and motor abilities in people with MCI [98,99] and dementia [111]. They developed a 12-week cognitive-motor training program incorporating different technologies—such as pressure-sensitive mats, videos, and heart rate variability monitoring—to support physical activity games. It proved to be feasible and effective in comparison to treatment as usual.

Social Interaction and Activation Using Robotics

A systematic review and meta-analysis of nonpharmacological, technology-based interventions to treat the symptoms of dementia, which was also included in the Digital Media in Reminiscence Therapy section, found that most interventions designed to improve social interactions incorporated social robots, ranging from a humanoid robot that looked like a small boy to robotic pets [104]. The meta-analysis reported an overall large effect of technology-based interventions on depressive symptoms. A scoping review also suggested that the use of social robots such as robotic animals can lead to an improvement in quality of life and mood and reduce loneliness [63]. However, results were dependent on the type of social robot, the severity of dementia, and the living context of patients (eg, the most common social robot, the baby seal Paro, appeared to be more beneficial for people with advanced dementia). Ethical considerations of using social robots were discussed, such as whether their use infantilizes patients or dehumanizes dementia care [63]. This was one of the very few instances in which an ethical discussion was part of a study on the digital treatment of older adults with mental illness.

Miscellaneous Technology

A total of 3% (2/64) of the studies looked at how wearable technology can be used in the treatment of psychiatric disorders [88,89]. An intervention consisting of motivational interviews and personalized messages combined with the wearing of a device to track activity and heart rate led to an improvement in insomnia symptoms [88]. A vibrating belt that had been shown to successfully prompt healthy older adults to walk in a particular direction was tested in a sample of people with dementia and was found to be usable among participants with mild dementia, although their performance was not error free, with some participants missing signals to take a turn [89].

Another intervention looked at the effect of heart rate variability biofeedback on depression and anxiety symptoms. Biofeedback is the use of technology to enable control of physical functions such as heart rate that are usually automatic. Combined with breathing and relaxation exercises, heart rate variability biofeedback was shown to be associated with significant decreases in depression and anxiety symptoms [90].

Finally, a single study looked at the potential of VR as a diagnostic tool for cognitive disorders, finding that VR can be used to differentiate between healthy older adults and people with MCI [91]. In the study, participants were evaluated based on their performance in a virtual supermarket where they had to find and pay for specific items on a shopping list using a tablet.

State of Research: How Effective Are Digitalized Treatment Options for Specific Mental Illnesses in Older Adults?

Dementia and MCI

Dementia (37/64, 58%) and MCI (5/64, 8%) together were by far the most frequently studied diagnoses in research on digital interventions for older adults. The most widely used measure to assess the severity of cognitive deficits was the Mini-Mental State Examination [112]. The interventions in this area can be broadly grouped into four categories: interventions to (1) reduce psychological and behavioral symptoms and improve well-being, (2) measure and improve cognition, (3) support completion of activities of daily living, and (4) promote social interaction.

According to a meta-analysis of 16 trials, technology-based interventions for people with dementia were effective in reducing psychological and behavioral symptoms of dementia such as depression (large effect) and agitation (moderate effect), whereas no positive effects on apathy, anxiety, or neuropsychiatric symptoms were observed [104]. We found many applications of multimedia technology to reminiscence therapy for dementia, but a systematic evaluation of their effectiveness was missing [63,105,108]. Many interventions aiming to improve well-being among patients with dementia (8/42, 19%) applied personalized content—for example, personalized videos or music playlists—to evoke positive feelings and bring about changes in behavior among participants [53,55-57,71,81,83,100]. While these interventions were described as feasible and enjoyable [56,57,71,83,100] and there was some evidence of a significant reduction in symptoms of depression [56] and agitation [71,81], other improvements were either not significant or not systematically evaluated [53,56,71,83,100].

Interventions designed to promote cognition either were computer based [70,86,87,92,102] or used VR [60-62] and exergames [98,99,111]. Multiple studies (7/42, 17%) uncovered significant improvements in cognitive domains such as decision-making [62], immediate and delayed recall [70,99], general cognition [87,99,111], and attention and visuoconstruction [87] following digital interventions. However, results on other measures were inconsistent, and other studies (5/42, 12%) did not identify any statistically significant cognitive changes [60,61,86,92,102]. A study examining the feasibility of an online cognitive stimulation group reported limited competencies and access to technology as potential barriers to effectiveness [92]. One study examined the potential of VR for cognitive assessments and was able to correctly classify 91.8% of patients with MCI based on their performance in a virtual supermarket environment [91].

Several studies (8/42, 19%) demonstrated that audio or video prompts [47-52,77,78] as well as wearables [89] can be used to assist people with dementia in completing activities of daily living and finding their way. While participants accepted the technology and showed improvements in correctly performing activities of daily living while using the technology, the quality of the studies was low, with no control condition in any of the studies and small sample sizes (N=3-12).

Interventions aiming to promote social interaction using technology were varied, using multimedia systems to promote communication with caregivers or partners [57,84,100], social robots [63,104], and freely available apps within group therapy [66,80]. Overall, the investigated technologies were deemed feasible, but there was a lack of systematic evaluation studies [63,66,80,100]. There was some inconclusive evidence that multimedia systems may be associated with improved communication between people with dementia and their caregivers [63] and that they can act as a basis for joint attention during a shared activity [84]. The use of a social robot in dementia care showed high potential for improving social interaction and communication, but their beneficial effect was dependent on context, and their use poses ethical questions such as the potential dehumanization of dementia care [63,104].

Anxiety

Of the 10 interventions to treat symptoms of anxiety in older adults, 6 (60%) were iCBT interventions [45,46,72,74,76,101], and 1 (10%) was a relaxation technique delivered via video [58,59,94,95]. While 40% (4/10) of interventions were designed to treat both depression and anxiety [45,46,74,76], 33% (2/6) of the iCBT interventions were specifically tailored to patients with generalized anxiety disorder [72], with one of them designed for patients with comorbid pulmonary fibrosis [101]. A wide range of measures were used to assess anxiety, including the Geriatric Anxiety Scale [113], the State-Trait Anxiety Inventory [114], and the Geriatric Anxiety Inventory [115]. Apart from one study that examined the feasibility of the video-delivered relaxation technique [59], all studies (9/10, 91%) were evaluation trials of an overall high quality with control conditions in most cases [45,46,58,72,74,76,101]. The systematic evaluations revealed that digital interventions to treat anxiety were moderately to highly effective in reducing anxiety symptoms [45,46,58,72,76,101] as well as symptoms of depression [45,46,58,72,74], psychological distress, and disability [45,76]. The limitations discussed for iCBT for depression regarding limited follow-up measurements and the age of the samples also applied to iCBT for anxiety disorders.

Depression

All the original studies investigating interventions to treat depression (9/9, 100%) used an iCBT format. The quality of the studies was relatively high, with >50% of the studies (5/9, 56%) being randomized or nonrandomized controlled trials [46,73-75]. The severity of depressive symptoms was assessed using the Patient Health Questionnaire–9 [116] and the Geriatric Depression Scale [117]. Completion rates for iCBT courses ranged between 70% and 90%, indicating a high feasibility. iCBT for the treatment of depression in older adults was associated with a significant reduction in depressive symptoms with moderate to large effect sizes [44-46,69,73-75], as well as with a reduction in psychological distress and disability [45,75,76].

A limitation of the existing research on iCBT is that several studies (3/9, 33%) only measured changes up to 3 months after the intervention [44,45,73], making it difficult to ascertain whether improvements were maintained in the longer term, although one study found that improvements were maintained

XSL•FO
RenderX

at the 12-month follow-up [46]. In addition, there was little research on the effectiveness of these interventions among individuals of very old age, with most research (6/9, 67%) focusing on participants in their 60s [44-46,69,73,75]. Furthermore, although one study ascertained that iCBT training from nonspecialist coaches can effectively treat depression [69], it is as yet unclear whether findings related to the general population that guided interventions are more effective than self-guided interventions [118] but as effective as face-to-face therapy [119] also apply to older adults. With the exception of one study [93], all others (8/9, 89%) focused on iCBT delivered via web applications accessed on computers; only 11% (1/9) of the studies examined a more modern mobile format, namely, a CBT smartphone app [93].

Sleep Disorders

A meta-analysis summarizing findings from 6 RCTs and 4 quasi-experimental studies reported that iCBT interventions were an effective way of treating insomnia [106] and led to an improvement in symptoms of insomnia (as measured using the Insomnia Severity Index [120]). Furthermore, 3 RCTs demonstrated longer sleep time in those that underwent iCBT training [106]. In another self-guided iCBT intervention for insomnia, it was found that improvements in objective and subjective sleep outcomes only applied to older adults with sleep complaints—poor sleepers who did not complain about their sleep did not reap the benefits of the training [67]. Another study investigated the effect of an intervention designed to increase physical activity that consisted of motivational interviews and wearing a device to track activity and heartbeat. The intervention was associated with a significant improvement in Insomnia Severity Index scores [88]. The limitations discussed for iCBT for depression regarding limited follow-up measurements and the age of the samples also applied to iCBT for sleep disorders.

Other Mental Illnesses

Another 3% (2/64) of the studies looked into technology-based interventions to treat older adults with mental illness in general [85,90]. Both studies were uncontrolled trials, so their findings need to be interpreted with caution. An existing self-management intervention for older adults was adapted for delivery via smartphone and tested among participants with various mental disorders [85]. The intervention was found to be usable in this target group, but the study did not systematically evaluate the effectiveness of the intervention. The other study evaluated the effectiveness of heart rate variability technology in biofeedback sessions and found significant pretest-posttest reductions in symptoms of depression and anxiety when combined with relaxation techniques [90].

Discussion

Principal Findings

The aims of this scoping review were to (1) identify which digitalized treatment options are available for older adults with mental illness, (2) chart the state of research on the feasibility and effectiveness of these treatments, and (3) derive potential directions for future research on the topic. On the basis of our search strategy and inclusion criteria, we found a total of 57 original studies and 7 reviews.

Regarding aim 1, we grouped the identified digitalized treatment options for older adults with mental illness into 9 different categories (Table 1). Web-based iCBT programs were the most common and designed to treat depression, anxiety, and sleep disorders in older adults. iCBT is attractive for the treatment of older adults as it can be conducted remotely, in their own homes, and at their pace. Moreover, online interventions can be adapted to the lived realities of older adults (eg, by integrating examples from their everyday life into the texts and assignments), making them more relatable. It should be noted that some older adults with mental illness may benefit more from in-person CBT sessions considering that loneliness and social isolation are a major burden in this age group [23,121]. One study found that, despite years of tailoring a digital intervention for older veterans, its effectiveness was limited by low motivation to engage in self-directed home practice, indicating that increased accessibility through technology did not necessarily address the underlying barriers to engagement [95]. Nevertheless, for individuals with limited mobility or no access to a human therapist, iCBT remains an appealing alternative. Acknowledging these differing needs, one study suggested that triaging could help identify those most likely to benefit from iCBT while directing others to offline interventions better suited to their circumstances [97].

Most of the other identified interventions for older adults with mental illness relied on basic technology such as audio, video, or digital photos to address the specific needs of people living with dementia, namely, inactivity, disorientation, emotional distress, and loneliness. Audio recordings were used to help patients successfully conduct domestic work in the home but also to simulate the calming presence of a family member in stressful situations. Existing treatment programs such as reminiscence therapy or other behavioral activation interventions for people with dementia were complemented with digital media, allowing for more engaging, personalized materials such as photos, videos, and music. An important finding of this review is that very few studies (7/64, 11%) dealt with more advanced technology such as AI, VR, or robotics. This is surprising as VR applications are increasingly being investigated in mental health [6] and appear to be feasible in the treatment of older adults with mental illness [122]. VR interventions are effective in treating posttraumatic stress disorder, anxiety disorders, and substance use disorders—all of which are prevalent in older adults [123]. However, all VR studies in our review (4/64, 6%) focused on dementia. In addition, despite the potential of AI technology in mental health, especially for serious mental illness [124,125], only 2% (1/64) of the included studies applied AI technology [79]. AI can be used for multiple aims in mental health, such as early detection and symptom monitoring, development of personalized treatment plans, analysis of medical health records, or social companionship. It should be leveraged to improve or create new treatment ideas tailored to the needs of older adults. Future studies exploring the usability of AI for older adults with mental illness could develop solutions for unsolved problems such as polypharmacy, loneliness, or loss of autonomy in this age group.

XSL•FO
RenderX

Concerning aim 2, the feasibility and effectiveness of the identified digitalized treatments, our review found some promising results as well as crucial gaps in the literature. The state of research on iCBT interventions for older adults reveals that these interventions are feasible, with satisfactory completion rates [76]. These interventions were systematically evaluated in controlled trials and shown to be moderately to highly effective in treating older adults with signs of depression, anxiety, and insomnia [44-46,67,69,72-76,88,106,109]. However, we identified several limitations of the state of research on iCBT for older adults with mental illness, namely, short follow-up periods in the evaluation trials, a lack of research with older patients (especially those aged >80 years), and a gap in the literature concerning comparisons of iCBT with and without guidance and its effectiveness compared to face-to-face treatment. Therefore, further research is needed to assess whether online interventions remain effective over time and are as effective in treating individuals of very old age and to what extent the level of guidance affects their outcome.

Another finding of our review was that the feasibility of integrating basic digital technology into dementia care is well established. Concerning the effectiveness of digitalized treatments, some studies (21/42, 50%) found that they alleviated symptoms of depression and agitation [56,71,81] and improved cognition [62,70,87] and completion of activities of daily living [47-52,77,78,89] as well as social interactions [57,63,66,80,84,104]. However, it should be noted that most of this research lacked systematic evaluation, with an abundance of original studies (25/37, 68%) having small samples or no control condition. As the feasibility of digitalized treatments in dementia care has been proven, future studies should take this research to the next level of systematic evaluation, investigating the effectiveness of these treatments with larger samples in controlled settings.

Furthermore, older adults with mental illness face specific barriers which limit the effectiveness of digital interventions. Limited digital skills and access to technology were reported as key challenges in samples from Brazil and India [92], and difficulties handling technical issues were reported as challenges in a study from Hong Kong [96]. These barriers are likely more broadly relevant given the negative correlation of digital competence with age and mental illness [14,111,126].

Finally (aim 3), we will summarize the identified gaps in the literature as well as directions for future research, which are also presented in Table 3. The summary of findings of the included studies reveals, first, a lack of research on how advanced technologies can be leveraged for the treatment of older adults with mental illness, especially VR and AI technologies. Future research should explore how these technologies can be used to address specific needs of older adults and what, if any, adaptations are needed to ensure the feasibility and usability of digitalized treatments among older adults. Second, the current state of the art neglects many mental disorders that are prevalent among older adults, prioritizing research on dementia care. While cognitive disorders are a relevant topic in older age, other mental disorders such as affective and anxiety disorders, substance abuse, psychosis, and other serious mental illnesses are highly prevalent in old age [123]. As digital interventions have been shown to be feasible and effective in treating serious mental illness in younger populations [1,6,11], older individuals with these conditions also deserve to benefit from the newest technological advances in treatments. Third, it was outlined that many of the included studies (32/57, 56%) were conducted with small sample sizes and without control groups. Moreover, the distribution of countries appeared imbalanced, with an overrepresentation of studies from North America and Italy and only 2% (1/64) of the studies being from Asia and none being from Africa. While one can only speculate about the reasons for this (eg, different distribution of age groups and resources between countries), the field would benefit from more diverse research samples as the findings of this review may not be generalizable. Thus, future research on the feasibility and effectiveness of all digitalized treatment options for older adults needs to be more systematic, with larger, more diverse samples and controlled study designs. Fourth, while our review found several examples of how technology can be tailored to meet the specific needs of older adults with mental illness, there is still a huge potential for personalized interventions in this field in dementia care and beyond. Future studies should explore how technology may solve the issue of many older adults with mental illness being isolated [21,22], experiencing more obstacles in finding professional mental health care [30,31], and having limited access to technology and digitalized treatments [10,13-16]. By developing strategies to bridge the digital divide, digital mental health care should be made accessible to all. Fifth, ethical considerations were insufficiently addressed in the included studies. As digital technologies become increasingly integrated into mental health care, it is essential to critically examine ethical concerns, particularly in vulnerable populations such as older adults with mental illness. Key issues include data privacy and security, transparency, algorithmic bias, informed consent, and appropriate use. Considering the biomedical ethical principles articulated by Beauchamp and Childress [127]—autonomy, beneficence, nonmaleficence, and justice—overreliance on technology or its improper use may cause more harm than benefit when they inadvertently undermine patient autonomy or exacerbate inequalities. If there is a significant gap in technology knowledge, this can also reinforce a power imbalance between younger clinical professionals and older patients. Importantly, technology should never infantilize older adults or replace meaningful human interaction, as outlined by one study on robotics [63]. Therefore, the ethical implications of digital interventions must be evaluated on a case-by-case basis. Technologies that may be unproblematic or even empowering for younger, technology-literate users could pose significant risks to older individuals unfamiliar with such tools. Future studies, especially on more advanced technologies such as AI, need to consider the ethical underpinnings of their research to ensure that older adults with mental illness can safely benefit from digitalized treatments. One promising approach is the inclusion of human-in-the-loop oversight, a key component of trustworthy AI [128]. Such oversight ensures that human judgment remains part of the decision-making process, reducing the risks associated with automated systems. The identified gaps in the literature show that the “digital gray divide” exists in mental

XSL•FO
RenderX

health care and needs to be addressed to foster more equity between the age groups.

The results of this scoping review must be interpreted in light of some limitations and do not claim to be complete. Due to the exclusion of gray literature, conference proceedings, or other sources in this review, important findings may have been missed. The search strategy for this review was deliberately kept broad to provide an overview of as many different digitalized treatments as possible. Nevertheless, future reviews may use more specific search terms to include specific technologies such as AI. Another limitation of this review was that we only searched the PubMed database—including other specialized databases (eg, PsycINFO) may have yielded more articles and should be considered in future, more comprehensive reviews. Future reviews should also consider expanding the search strategy to include search terms that were not covered by MeSH terms. In addition, the references of the systematic reviews found in the initial search were not searched on the assumption that the most important findings would already have been summarized in the reviews themselves, which may have led to the exclusion of some relevant studies. Moreover, while excluding a formal risk-of-bias assessment is in alignment with the PRISMA guidelines for scoping reviews, it would have provided added value to the interpretation of the findings. Finally, the process of study selection could have been further improved by including a third author to resolve potential disagreements.

Table 3. Identified gaps in the literature and directions for future research.

Gap in the literature	Directions for future research
Lack of research on more advanced technology	• Explore the potential of VR[a], AI[b], and other advanced technologies to address the specific needs of older adults. • Investigate necessary adaptations for feasibility.
Lack of research on prevalent mental disorders in older adults	• Expand research beyond dementia to include affective disorders, anxiety disorders, substance use disorders, psychotic disorders, and other serious mental illnesses. • Replicate findings of digitalized treatments for younger populations.
Lack of systematic research	• Conduct (randomized) controlled evaluation studies with large and diverse samples to assess the feasibility and effectiveness of digitalized treatments among older adults with mental illness.
Accessibility and equity	• Develop personalized solutions to the specific needs of older adults with mental illness, especially strategies to bridge the “digital gray divide” and ensure equitable access.
Ethical considerations	• Address ethical concerns such as data privacy, data security, transparency, bias, autonomy, and human connection in the development and implementation of digitalized interventions for older adults.

[a]VR: virtual reality.

[b]AI: artificial intelligence.

Conclusions

In conclusion, this scoping review has demonstrated that there is a wide range of applications of digital technology available to treat mental illness in older adults, generally proving it to be feasible and accepted by patients. Results on the effectiveness of digitalized treatments vary and often lack systematic conformation. In addition, the state of research focused on few specific topics in the field, such as iCBT and basic technology in dementia care, neglecting other highly relevant problems for older adults with mental illness. We identified several critical gaps in the research on digitalized treatments for older adults with mental illness, highlighting a selective focus in research that exacerbates the “digital gray divide.” More equitable research is needed to ensure that all older adults with mental illness can benefit from the potential of digital interventions—addressing accessibility first, followed by expanding the research topics and methods. By leveraging advanced technologies in an ethical fashion, crucial challenges in the lives of older adults could be addressed and solved, improving their quality of life.

Acknowledgments

The authors would like to thank Professor Brita Elvevåg for her guidance and support in finalizing this manuscript. The authors would like to acknowledge that the table of contents image was designed using Freepik.

Authors' Contributions

SAJ developed the idea and plan for conducting the scoping review. SAJ and JAS together defined the search strategy. JAS conducted the search. SAJ wrote the introduction for the first draft of the manuscript. JAS completed the first draft of the manuscript. The first draft was reviewed, edited, and finalized by SAJ. SAJ created all tables and figures for this review paper.

Abstract

Background: Mental health care providers have widely adopted telemedicine since the onset of the COVID-19 pandemic. Some providers have reported difficulties in implementing telemedicine and are still assessing its sustainability for their practices. Recommendations, best practices, and guidelines for telemedicine-based mental health care (ie, telemental health care [TMH]) have been published, but the nature and extent of this guidance have not been assessed.

Objective: We aimed to determine (1) the form of TMH guidelines and recommendations presented to providers, (2) the most commonly presented recommendations and guidelines, and (3) the perceived benefits and challenges of these TMH guidelines and recommendations.

Methods: Through our scoping review of practice guidelines, we aimed to identify themes in TMH guidelines and clinical recommendations published between 2020 and 2024 in peer-reviewed journals. This review focused on the first 2 years of the COVID-19 pandemic to identify and characterize the available TMH guidance. We searched PubMed/MEDLINE and ScienceDirect for articles in peer-reviewed journals published between January 1, 2020, and July 16, 2024. We included articles that were available in English and presented recommendations, best practices, or guidelines for TMH. We excluded duplicates, articles unrelated to telehealth, brief editorial introductions, and those not publicly available. We applied the Healthcare Provider Taxonomy of the National Uniform Claim Committee to article titles and abstracts to identify records relevant to mental health. We used content and thematic analyses to identify key themes.

Results: Of the 1348 articles retrieved, we identified 76 that matched our criteria. Through content and thematic analyses, we identified 3 main themes—along with subthemes and topics—related to Facilitators, Concerns, and Changes Advised. The majority of articles called for further research (59/76) and for telemental health education and innovation in some form (43/76) regarding advised changes. Twenty-four articles included specific guidelines, recommendations, or checklists for providers.

Conclusions: The results highlight the need for further large-scale research to support the development of effective guidelines and protocols for therapy plans. Although TMH care is widespread, scholarly work emphasizes the need for a stronger evidence base that includes testing protocols in diverse settings and populations. The results also underscore the importance of increasing health professionals' knowledge of regulatory compliance and providing them with adequate TMH practice education.

Introduction

Telemedicine was quickly and widely adopted in early 2020 to curb the spread of the SARS-CoV-2 virus and to increase access to health care [1]. As health care professionals used telemedicine to limit the spread of COVID-19 in hospitals, clinics, and private practices, its role extended beyond outbreak control and became a widely accepted means of delivering care [2]. With the boom in telemedicine during the COVID-19 pandemic [1], the need for support, guidelines, and recommendations quickly became apparent, as new users struggled to use telemedicine effectively [3]. Mental health providers have shown strong support for telemedicine and remain its most active users, even beyond the initial impact of the pandemic [4-6]. While many providers discontinued telemedicine for physical health conditions after June 2020, mental health providers have continued to use it well beyond the early months of COVID-19 [7]. Due to the nature of their practice—based primarily on interpersonal communication—mental health care providers adopted telemedicine more readily than providers in specialties that rely more heavily on interventions and physical examinations, such as dermatology, cardiology, or primary care [4, 8, 9]. A review of telemedicine guidelines and recommended best practices for mental health providers—herein referred to as telemental health care (TMH) guidelines—may offer insight into how providers can best utilize telemedicine and what changes to those guidelines may still be necessary.

With the introduction of the Coronavirus Aid, Relief, and Economic Security Act and Public Health Emergency protocols in the United States, telemedicine was irrevocably transformed by newfound flexibilities and waivers [10]. Similar regulatory loosening occurred worldwide, as governing bodies supported the medical community's efforts to manage the pandemic through telemedicine [11]. While this flexibility made telemedicine more accessible to both providers and patients, it also rendered some previously established telemedicine guidelines and internal policies obsolete, creating the need for new, updated guidance [11]. In a 2022 systematic review of telemedicine challenges faced by health care professionals during the pandemic, technological prerequisites were identified as the most common barrier to providing care via telemedicine, followed by concerns such as security and privacy, training and education for both providers and patients, and the provider-patient relationship [12]. Naturally, clinical guidelines tend to be specific to a specialty or disease; this specificity means, for example, that mental health professionals use telemedicine guidelines tailored expressly to their field.

Medical guidelines aim to establish steps and criteria that make care delivery systematic and ensure the highest quality of care for patients [13, 14]. Ideally, TMH providers would have access to such guidelines, covering expectations for care delivery, legal compliance, and technical considerations [15]. TMH guidelines—including those from the American Psychological Association (APA) and the American Telemedicine Association (ATA)—already existed within the mental health community before the pandemic [16, 17]. Other guidelines, such as the guide from the Substance Abuse and Mental Health Services Administration (SAMHSA) in the United States, were published during the COVID-19 pandemic and were not initially available to providers [18]. While TMH guidelines did exist before the pandemic and were updated between 2020 and 2024, a review of what providers were able to access in peer-reviewed sources may shed light on TMH providers' needs—particularly those based on original research and other forms of evidence more readily captured in scholarly publications.

In this scoping review of the relevant biomedical literature, we aimed to answer the following questions: (1) What forms of guidelines and recommendations were presented to providers (eg, checklists, step-by-step user guides, lists of best practices)? (2) What recommendations and guidelines are most commonly presented in academic literature for providers to be aware of in TMH practice? and (3) What are the perceived benefits and challenges of TMH guidelines and recommendations?

Methods

Search Strategy

We conducted a scoping review of the biomedical literature, following the Journal of Biomedical Informatics' updated methodological guidance [2] and procedures from similar scoping reviews, including formal content and thematic analyses [19-21]. As we were interested in identifying and understanding the nature of published TMH guidelines during the pandemic, we conducted a scoping review with qualitative analysis to identify and synthesize the emerging literature. As a preliminary step, we reviewed existing literature to ensure that our research aims and timeline had not already been addressed. We searched the PubMed/MEDLINE and ScienceDirect databases for reviews using keywords related to our aims and found none [22].

We searched the PubMed/MEDLINE and ScienceDirect databases on March 14, 2022, and again on July 16, 2024. Search strings included "(tele*[Title]) AND (guid*[Title])" and "(tele*[Title]) AND (practic*[Title])" in Pubmed/MEDLINE, "(telemedicine OR telehealth) AND (guide OR guidance OR guiding)" in ScienceDirect, and "(telemedicine OR telehealth) AND (practice OR practical OR practicing)" in ScienceDirect. We limited search results to articles published between January 1, 2020, and July 16, 2024, and restricted the search to titles only. No other restrictions were applied. Three researchers (TO, JI, and HW) conducted the searches and used database features to export the results into CSV files, which were then merged into an Excel spreadsheet (Microsoft Corporation). The search results from the 3 researchers were compared to ensure consistency.

Article Selection

We included articles if they were available in English and provided recommendations, best practices, or guidelines for

XSL•FO
RenderX

mental health via telemedicine. We excluded articles if they were duplicates, if their primary focus was unrelated to TMH care, if the article was a brief editorial introduction to a particular journal section, or if the entire article could not be located through the University of Florida library or interlibrary loan service. We applied the Healthcare Provider Taxonomy of the National Uniform Claim Committee [23] to article titles and abstracts to identify records relevant to mental health. This was done to focus solely on work directly defined as mental health. One researcher (TO) applied the group/individual taxonomy to each article title; in cases where the title was ambiguous, the researcher also considered the abstract. The research team reviewed the results for accuracy. Two researchers (TO and JI) independently reviewed the articles for selection. Final exclusions were made during the full-text review.

Data Extraction and Analysis

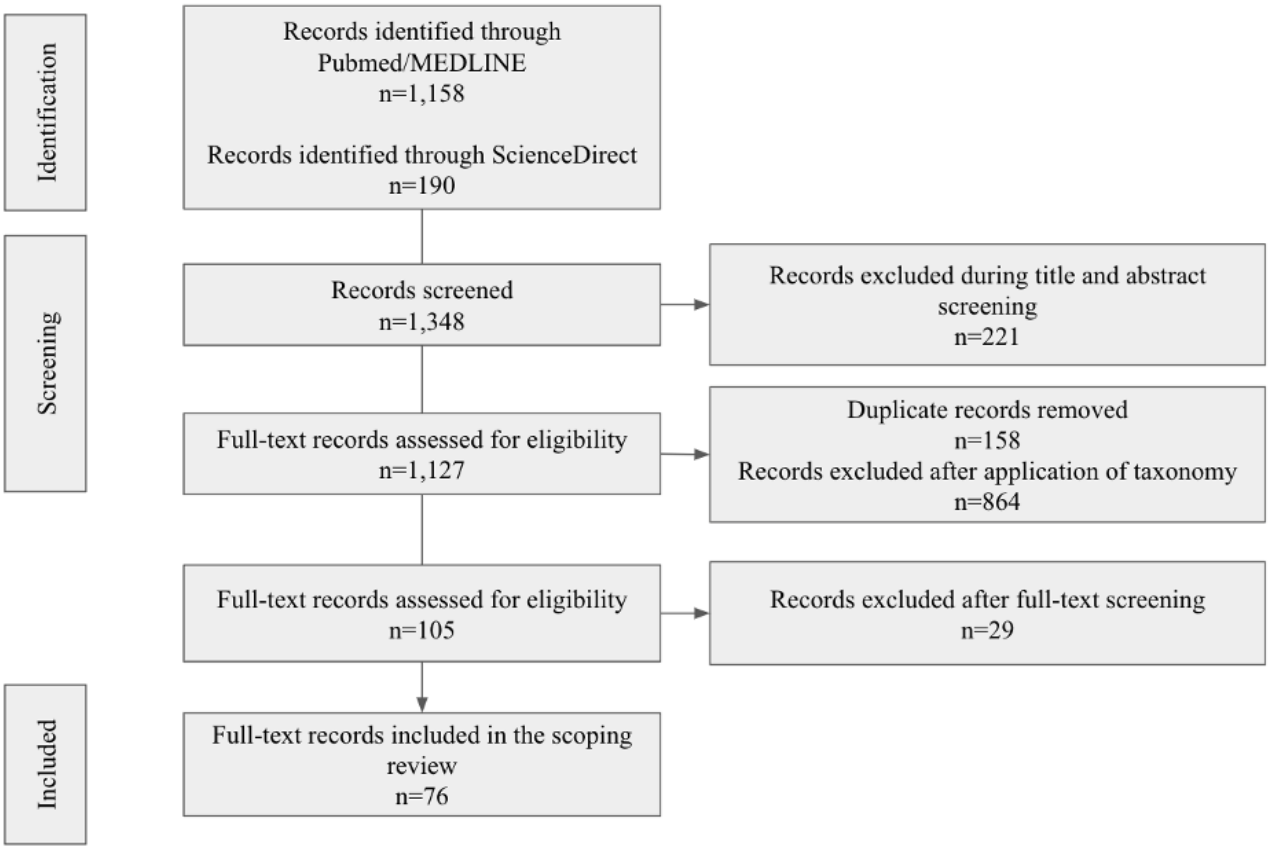
We extracted the entire content of the articles, including guidelines and recommendations for TMH health care practice, for qualitative analysis. We then conducted both content analysis and thematic analysis [3-5]. The content of each article was reviewed to identify principles, proposals, suggestions, advice, or considerations to promote TMH practice, using MAXQDA (VERBI GmbH), a qualitative coding and analytic platform [6]. Two researchers (TO and JI) independently reviewed the articles to identify practice guidelines and key themes through content and thematic analyses [21, 24-28].

One researcher (JI) coded each full-text article based on the 3 questions above. The content analysis focused on (1) changes advised or guidelines recommended for TMH providers (research questions 1 and 2), (2) facilitators and benefits related to telemedicine usage (research question 3), and (3) concerns and barriers to telemedicine usage (research question 3) [26]. These 3 categories were chosen because they generally capture topics found in the guidelines and recommendations of the resulting articles. We developed a codebook based on the expected definitions of these topics and revised the codebook with each iteration of coding (see Table 1 for the codebook).

After the initial content analysis, a single reviewer (JI) completed another iteration of coding using thematic analysis to capture emergent topics within the 3 content analysis codes. The thematic analysis focused on items already identified in the content analysis, using techniques such as repetition of concepts, typology, metacoding, missing data, and cutting and sorting [26, 28]. For all coding, the unit of analysis was meaningful phrases—including bulleted lists and entire paragraphs. One author (JI) completed 3 iterations of content and thematic analyses. The codebook and coding were reviewed and refined by the research team for consistency and accuracy (see Table 1 for the codebook with exemplar quotes). Using frequency by recording and metacoding, we categorized the codes into themes, subthemes, and topics [27].

Given the generalized focus on characterizing the existing literature on TMH guidelines and recommendations, the scoping review does not include a formal quantitative synthesis or an assessment of the risk of bias. Instead, we used the results from content and thematic analyses—in the form of themes, subthemes, and topics—to answer our research questions.

Results



Overview of Identified and Included Literature

Our initial search identified more than 1300 articles (see Figure 1 and Multimedia Appendix 1). We excluded 158 duplicates and 221 articles during the title and abstract screening, resulting in 969 articles for full-text review. By applying the Healthcare Provider Taxonomy of the National Uniform Claim Committee, we excluded 864 articles related to other medical specialties, focusing on 105 articles for TMH guidelines [23]. During the full-text review, we excluded an additional 29 articles: 8 due to the inability to access the full text and 21 because the article topic did not meet the inclusion criteria. We exported the final 76 articles to MAXQDA for content and thematic analyses.

The final articles were predominantly written in 2020 (28/76, 37%) and 2021 (28/76, 37%), with 11 published in 2022, 8 in 2023, and 1 in 2024. We found only a handful of journals that repeatedly published articles relevant to the scoping review: Australasian Psychiatry (n=5), Archives of Clinical Neuropsychology (n=5), Journal of the American Psychiatric Nurses Association (n=4), Indian Journal of Psychological Medicine (n=5), Behavior Analysis in Practice (n=3), Telemedicine and e-Health (n=2), Cognitive and Behavioral Practice (n=2), JMIR Mental Health (n=2), Contemporary Family Therapy (n=2), International Journal of Medical Informatics (n=2), and Indian Journal of Psychiatry (n=2). Over half of the resulting articles were original research (39/76, 51%), followed by viewpoints and reviews (15/76, 20%), guides and suggestions (13/76, 17%), and systematic or scoping reviews (9/76, 12%). A total of 27 original research articles were published between 2020 and 2021, and 12 were published between 2022 and 2024. We found 47 different organizations cited by the resulting articles, with the APA referenced 10 times [7-13, 16-18], the ATA mentioned 3 times [8, 9, 17], and the International Organization of Psychophysiology and Cognitive Sciences (IOPC) [13, 17], Centers for Medicare & Medicaid Services (CMS) [9, 12], Centers for Disease Control and Prevention (CDC) [9, 12], Institute of Medicine [14, 16], and Telemedicine and Psychiatry Operational Guidelines 2020 cited 2 times [15, 19].

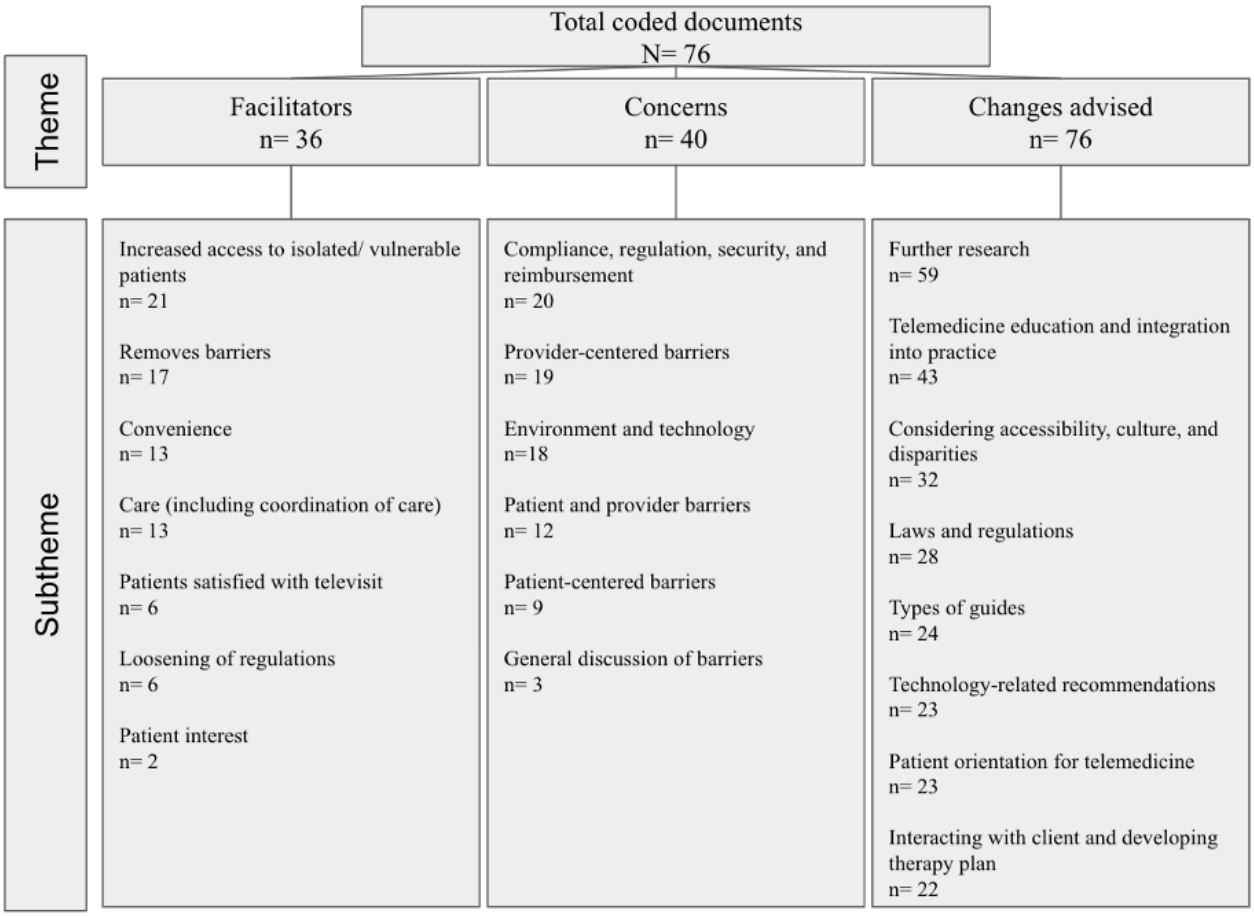
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) schema showing results of the literature search and resulting exclusions and inclusions.



Overview of Qualitative Analytic Results

Content and thematic analyses yielded 2483 codes, with the majority found in Changes Advised (1366/2483, 55.01%). For this scoping review, however, we focus on code presence within a record rather than total frequency (see Figure 2). While all resulting records had Changes Advised codes, 40 out of 76 (53%) included specific Concerns, and 36 out of 76 (47%) included Facilitators (see Figure 2 and Table 1 for the codebook). Over the 3 iterations of coding, we identified 8 subthemes in Changes Advised, 7 in Facilitators, and 6 in Concerns. Each subtheme included topics of discussion relevant to the subtheme.

Table 1. Codebook with exemplar quotes from cited articles.

Themes and sub-themes	n	Citations	Definition	Example quote
Facilitators	36		Mention of TMH's[a] positive aspects that can be leveraged for health care delivery	"A commonly reported benefit of telemedicine included increasing patient access to care and its most important feature was HIPAA compliance, followed by being low-cost and easy-to-use [20]."
Increased access to isolated/vulnerable patients	21	[8-10, 14, 16, 17, 19-22, 24-34]	The role of TMH in accessibility to care for patients, especially those who are socioeconomically vulnerable	"...it is not yet clear whether telehealth opportunities have done much to expand treatment accessibility beyond populations who already had no difficulty reaching mental health care prior to the pandemic. One of the great promises of telehealth is its potential to overcome barriers and reach new, previously under-served populations [28]."
Removes barriers (cost, transport, time, and stigma)	17	[8, 9, 14, 16, 21, 22, 25, 27, 30-38]	The role of TMH in easing known barriers to in-person visits such as decreasing cost, time, and stigma and easing worries over transportation and child care	"These services are cost-effective due to increased productivity, time management, and reduces transportation expenses [16]."
Convenience of telemental health care	13	[8, 9, 16, 17, 21, 22, 30, 32-35, 37, 39]	Discussion of TMH in terms of "convenience" or ease of use for providers	"There are indications that the satisfaction by providers is even higher today now that there is the opportunity to connect from the convenience of their home (Kocsis & Yellowlees, 2018; Yellowlees, 2020) [9]."
Care (including coordination of care)	13	[8, 9, 11, 16, 21, 22, 26, 28, 32, 33, 37, 40, 41]	Discussion of TMH in regard to coordination and continuity of care for patients	"The APA Guidelines and the AAP Procedures discuss the necessity of assessing the continuity and termination of care on a regular basis in order to maintain quality service via telehealth. It is noted that ABA practitioners are in a unique position compared to these professionals in that the frequency and the duration of telehealth sessions are higher [11]."
Loosening of regulations	6	[24, 28, 39, 42-44]	Mention of telemedicine regulatory flexibilities due to the pandemic as a facilitator for its use	"In the United States, a number of federal and state emergency orders enacted in the early weeks of the pandemic, and a number of expanded reimbursement policies, cleared the way for telehealth to take over as the primary strategy for maintaining continuity of care across the pandemic [28]."
Patients satisfied with telemental visit	6	[8, 16, 24, 31, 34, 37]	Patients satisfied with telemedicine visits facilitate provider use of TMH	"The results of this project demonstrate that telehealth is a feasible and acceptable strategy for delivering follow-up PMH appointments for patients of a community-based clinic who reside in rural locations. Post intervention surveys revealed patient satisfaction with the utilization of telehealth [8]."
Patients interested in doing telemental health care	2	[32, 45]	Mention that TMH is facilitated when patients show interest in its use	"Lal and colleagues (2020) reported that 82% of participants indicated interest in a future clinic appointment via video-conferencing, and 75% believed it would be a good tool for unexpected or emergency situations, or when in-person meetings were impossible. Further, 78% of participants in this study reported obstacles to attending in-person sessions and would thus potentially benefit from a virtual option [45]."
Concerns	40		Mention of TMH's concerning aspects that should be considered in health care delivery	"These concerns included receiving insufficient training to be effective with telepsychology, ensuring the patient's safety or addressing the needs of remote patients in crisis, protecting the privacy of patients, considering ethical issues that could result from using telepsychology, and being uncertain about the effectiveness of treatment when not conducted in person [46]."
Patient and provider barriers	12	[9, 11, 17, 18, 22, 37, 40, 47-51]	Discussion of telemental barriers that relate to both providers and patients such as having to learn to use telemedicine or their preferences	"Practical considerations affecting the uptake of the new COVID-19 MBS-telehealth items include: understanding of the usage of the items; technology, accessibility and cybersecurity; patient and psychiatrist consultation preferences; appropriateness of telehealth for individual patients' circumstances and suitability to develop empathy and rapport [22]."

XSL•FO
RenderX

Themes and subthemes	n	Citations	Definition	Example quote
Patient-centered barriers	9	[17, 22, 25, 33, 38, 41, 50, 52, 53]	Discussion of telemental barriers that relate predominantly to patients such as the inability to attain prescriptions or inadequacy of TMH for certain patients	"However, telehealth may be less useful in patients with significant social disadvantage, and severe mental illnesses that impair cognitive abilities and insight such as schizophrenia and major neurocognitive disorder; further research for this population is needed [24]."
Provider-centered barriers	19	[9, 17, 18, 22, 24, 28, 29, 32-34, 41, 44-46, 48, 49, 52-54]	Discussion of telemental barriers that relate predominantly to providers such as loss of in-person contact, not using existing guidelines, and loss of visual cues	"In this situation, the GP may be little motivated to add another tool to his/her professional armamentarium, especially because of time constraints and crowded clinics [54]."
Environment and technology	18	[17, 18, 21, 22, 24, 25, 27, 32-34, 38, 41, 42, 50, 52, 53, 55, 56]	Discussion of telemental barriers relating to the technology needed or environment, such as technical aspects and type of device used	"Older adults, individuals from low SES populations with less experience with technology and individuals for whom the technology navigation tools may be in a second or third language, may require considerable emotional reassurance as well as technical assistance as they interact with a virtual doctors' office. Normalizing the difficulty with new technology is particularly important as we meet patients for the first time who otherwise might feel they are being judged as 'cognitively incapable' due to their difficulty with the telehealth technology [17]."
Compliance, regulatory, security, and reimbursement	20	[9, 17, 19, 20, 22, 25-28, 31-34, 36, 41, 46, 47, 52, 55, 57]	Mention of how the legal and policy structures impact TMH, especially in terms of cost/payments, security, and privacy	"In this study, the problems related to ethical, legal, accountability, and regulatory implications were cited as challenges by almost all respondents. The major issues stated by patients were privacy and confidentiality, ethical violations, security and hacking, and data ownership [57]."
General discussion of barriers	3	[27, 28, 58]	Discussion of nonspecific barriers in how they negatively impact the use of TMH	"Telehealth technology is a tool to support the navigation of barriers currently facing ABA providers; however, substantial challenges (eg, how to structure a credible telehealth session) need to be overcome for telehealth to achieve its full potential within the field of ABA [58]."
Changes advised	76		Discussion of recommendations, advice, and guidelines regarding successful implementation and use of TMH by providers	"Most published PMH APRN telepsychiatry literature predominantly focuses on clinical services across pediatric populations and the rural and urban underserved and was published in the past 15 years. Academic partnerships with primary care, hospitals, shelters, and federal clinics implemented and disseminated successful telepsychiatry consultations and scheduled services, but it is unclear if these programs were sustainable long-term despite short-term feasibility. Other services were usually on a small scale and included scheduled weekly or monthly consultations across primary care clinics [59]."
Technology-related recommendations	23	[7, 11-13, 16-18, 20, 25, 31, 33, 36-39, 47, 52, 60-65]	Mention of hardware or software needed to successfully use telemedicine	"Consider information governance issues and the information technology (IT) system that you and your patient will be using. Prepare the patient: ensure the patient has relevant information before the consultation. Prepare yourself: be familiar with the IT system you will use [12]."
Interacting with patients and developing therapy plan	22	[7, 10-13, 17, 18, 24, 25, 28, 31, 34-37, 40, 42, 43, 55, 63, 65, 66]	Mention of best practices and advice for providers before, during, and after telemental visits with patients	"Know who fits with which modality (consider research, repeated emergencies, tendency toward crises, access to resources, patient's comfort, etc.); refer to in‐person services when necessary; develop plan in case patient's inappropriateness emerges after onset of telepsychology services [7]."

XSL•FO
RenderX

Themes and subthemes	n	Citations	Definition	Example quote
Types of guides	24	[7, 10, 12, 16-19, 24-26, 32, 34-38, 42, 49, 55, 58, 63, 67-69]	Any type of guide or checklist that is presented within an article, such as step-by-step, general rules of thumb, and templates	"In this tutorial, we provide practice recommendations, task analyses, and a curated list of Zoom walk-throughs to help behavior analysts construct conceptually systematic learning opportunities in their direct telehealth services. Leveraging teleconferencing features to provide behavior-analytic intervention directly to consumers could spur future research to support these need-inspired practices and guide telehealth applications during and beyond the current pandemic [67]."
Further research	59	[8-12, 14, 17-22, 24, 26-28, 31-34, 37-42, 44-47, 50-64, 67, 68, 70-81]	Mentions of the need for further research on a telemedicine topic that would impact the successful implementation or use of TMH	"While telemedicine services in psychiatry have increased significantly, limited quantitative data exist that examine the training and implementation of the service. It is important that the ability of the practitioner, internal and external barriers to use, and patient satisfaction are explored when considering widespread implementation [70]."
Patient orientation of telemental health care	23	[7, 10-13, 16-19, 37, 40, 44, 48, 50, 53, 55, 56, 61, 63-66, 69]	Discussion of how providers may prepare and best inform patients in regard to TMH	"Proper releases of information should be completed for the patient support person prior to the start of CPT. Service providers should also have information for other critical community resources, such as hospitals, the police department, and shelters, accessible in case they become clinically necessary. Providers and patients should establish an agreed-upon back-up plan for service delivery in the event of technology failures, such as rescheduling or completing the session via phone to ensure minimal interruptions to treatment [10]."
Laws and regulation	28	[7, 10-20, 27, 29, 33, 35, 37, 44, 47, 51-53, 61, 63, 64, 66, 67, 69]	Mention of legal or ethical aspects of TMH, including consent forms and provider knowledge of regulations	"Consent must be obtained within the framework of the legal provisions enforced by each country. It is essential to know the applicable relevant laws and the regionality of these laws. As a general rule, when practices take place across countries and there is a conflict between the laws of the two countries, the laws of the patient's location prevail over the laws of the neuropsychologist's location [13]."
Telemental education and integration into practice	42	[7, 9-12, 14, 16-20, 24-30, 33, 34, 37, 38, 40, 42, 44-46, 50, 52-56, 58-60, 63-67, 70]	Discussion of the need for education in telemedicine and learning how to integrate telemedicine and innovative techniques into a practice	"The impact of telehealth on trainee education is unknown. However, given that telehealth is likely to continue to be used to deliver care in some capacity, training educators in virtual teaching strategies and teaching learners to deliver virtual care and perform virtual observations of children is important [60]."
Consider evidence of access, culture, and disparities	32	[7, 9, 11, 13, 16-18, 21, 22, 27-29, 31-34, 44, 46-48, 51, 55, 60, 61, 63-65, 67-69, 78, 79]	Discussion of the accessibility, socioeconomic and sociocultural aspects, and health disparities and how they should be considered when implementing TMH	"Neuropsychologists and other health care professionals must be mindful of these disparities and share responsibility in advocacy efforts to ensure equitable access to needed resources in marginalized or isolated communities [27]."

[a]TMH: telemental health care.

Themes Identified

Facilitators

The Facilitators theme (n=36) predominantly comprised subthemes on how telemedicine increased vulnerable patients' access to care (n=21) [8-10, 14, 16, 17, 19-22, 24-34]; reduced barriers such as travel, costs, and stigma (n=17) [8, 9, 14, 16, 21, 22, 25, 27, 30-38]; and enabled effective and innovative health care, including coordination of care (n=13) [8, 9, 16, 17, 21, 22, 30, 32-35, 37, 39]. For example, Dexter [14] noted in the letter to the editor that telemedicine may increase accessibility for both patients and providers, as some psychiatric mental health nurse practitioners would no longer need to relocate to deliver care in areas lacking such personnel. In another example, Schroeder's [9] review on TMH adaptations pointed out that providers can see more patients due to this increased accessibility—partially because transportation and other physical barriers are removed for patients. The subtheme regarding telemedicine removing barriers (n=17) identified general costs, child care, time, stigma, and transportation as specific barriers eased by the use of telemedicine [8, 9, 14, 16, 21, 22, 25, 27, 30-38].

A total of 13 articles identified TMH care as bringing a level of convenience to both providers and patients [8, 9, 16, 17, 21, 22, 30, 32-35, 37, 39], 6 noted the loosening of regulations [24, 28, 39, 42-44], another 6 included subthemes of patients being

XSL•FO
RenderX

satisfied with their TMH visit [8, 16, 24, 31, 34, 37], and 2 highlighted the importance of patients being interested in engaging with TMH care [32, 45].

Concerns

We identified 6 subthemes in Concerns (n=40). The most populated subtheme was Compliance, Regulatory, Security, and Reimbursement (n=20) [9, 17, 19, 20, 22, 25-28, 31-34, 36, 41, 46, 47, 52, 55, 57], which included regulatory and cost structures directly impacting the ability of providers to offer TMH care and patients' receipt of such care safely. Provider-Centered Barriers (n=19) [9, 17, 18, 22, 24, 28, 29, 32-34, 41, 44-46, 48, 49, 52-54] included loss of visual cues and specific audio issues during visits (n=5) [9, 18, 24, 29, 32], general loss of in-person contact (n=4) [24, 33, 42, 45], and new provider users not using or understanding existing guidelines (n=5) [22, 28, 34, 48, 53].

The Environment and Technology subtheme (n=18) [17, 18, 21, 22, 24, 25, 27, 32-34, 38, 41, 42, 50, 52, 53, 55, 56] included the technical aspects of TMH services related to hardware, software, and users' technological literacy (n=10) [17, 18, 22, 25, 32-34, 38, 41, 56], as well as the inaccessibility of TMH care for certain patient demographics (n=10) [17, 18, 21, 24, 27, 32, 33, 38, 50, 52].

The subthemes of Patient-Centered (n=9) [17, 22, 25, 33, 38, 41, 50, 52, 53] and Patient-And-Provider (n=12) [9, 11, 17, 18, 22, 37, 40, 47-51] barriers included specific difficulties patients face in TMH care, including the need to align telemedicine preferences with their providers and learn how to use it. For example, Dinakaran et al [25] pointed out the incomplete care a patient may face when receiving telepsychiatry without access to prescriptions for therapy. One topic, found in 7 articles, mentions the Patient-Centered Barriers subtheme, noting that TMH care may not be adequate for certain patients due to their specific needs related to symptoms or therapy types [17, 22, 33, 38, 41, 50, 52].

Changes Advised

We identified a total of 8 subthemes within Changes Advised (n=76). The most prominent subtheme was prompting Further Research (n=59) [8-12, 14, 17-22, 24, 26-28, 31-34, 37-42, 44-47, 50-64, 67, 68, 70-81]. Topics within this subtheme included the need for evidence-based outcomes to guide future guidelines and best practices (n=35) [8, 10, 11, 14, 17, 20, 24, 28, 31-34, 44-47, 50, 52-54, 56-59, 61, 62, 64, 67, 70, 71, 73, 75, 76, 78, 80], the need for clinical validation of assessments and tools used in telemedicine (n=17) [11, 17, 18, 31, 32, 34, 44, 51, 52, 55, 62, 63, 67, 75, 76, 79, 80], and the need for testing innovative interventions (n=10) [31, 33, 44, 50, 51, 54, 55, 58, 74, 79].

Another dominant subtheme is Telemental Education and Integration Into Practice (n=42) [7, 9-12, 14, 16-20, 24-30, 33, 34, 37, 38, 40, 42, 44-46, 50, 52-56, 58-60, 63-67, 70]. While formal, continuing, and organizational education was discussed as a topic (n=17) [7, 11, 16-18, 25, 27, 34, 36, 37, 45, 46, 63, 64, 66, 67, 70], the dominant focus of this subtheme was the need for innovative methods to deliver traditional in-person treatments via TMH (n=32) [7, 9-11, 14, 17-19, 24-30, 33, 34, 36-38, 42, 44, 45, 50, 52-56, 58, 66, 67]. Additional topics included the use of new and existing technology alongside telemedicine to support high-quality care (n=10) [10, 11, 18, 19, 33, 42, 44, 54, 66, 67], as well as traditional in-person exercises, which require their own guidelines when applied via telemedicine (n=6) [18, 27, 34, 45, 66, 67].

The subtheme of Changes Advised included the types of guides provided and requested (n=24) [7, 10, 12, 16-19, 24-26, 32, 34-38, 42, 49, 55, 58, 63, 67-69]. The resulting articles covered a variety of topics, such as a detailed protocol for using a specific telemedicine platform (n=1) [67], and step-by-step protocols for specific treatments (n=9) [10, 34, 35, 37, 49, 55, 58, 63, 69], including directed family play and activity-based instruction. Nearly one-third (24/76, 32%) of the resulting articles provided a functional guide, protocol, or detailed checklist.

While some papers did not include guidelines, others provided specific instructions on setting up a TMH care process with patients. Patient Orientation of Telemental Health Care (n=23) [7, 10-13, 16-19, 37, 40, 44, 48, 50, 53, 55, 56, 61, 63-66, 69] was a subtheme that covered topics ranging from ensuring patient safety through backups and emergency plans (n=10) [7, 11, 12, 25, 40, 50, 55, 65, 66, 69] to clearly defining services for patients before a TMH visit (n=10) [10, 18, 37, 40, 48, 53, 55, 63-65].

A similar subtheme of Interacting With Patients and Developing Therapy Plans (n=22) [7, 10-13, 17, 18, 24, 25, 28, 31, 34-37, 40, 42, 43, 55, 63, 65, 66] addressed topics related to both providers and patients being prepared for TMH care visits. The most common topic within this subtheme was determining the suitability of telemedicine (n=14) [7, 10, 11, 13, 17, 18, 24, 25, 31, 35, 37, 40, 63, 66] based on the patient (n=9) [7, 10, 11, 13, 17, 18, 24, 31, 40], as well as on the type of consults or assessments required for the patient's treatment (n=4) [13, 17, 18, 37]. This subtheme also included providers ensuring they are prepared for a telemedicine session ahead of the visit (n=8) [11-13, 18, 36, 37, 40, 65].

The subtheme of Consider Evidence of Access, Culture, and Disparities (n=22) [7, 9, 11, 13, 16-18, 21, 22, 27-29, 31, 33, 44, 46-48, 63, 68, 78, 79] encompasses sociocultural and socioeconomic considerations regarding the use and implementation of TMH care (n=19) [9, 11, 16, 17, 21, 22, 27-29, 31, 33, 44, 46-48, 63, 68, 78, 79]—including tangible requirements such as equipment (n=7) [11, 32, 33, 60, 61, 63, 78], the necessity of the right space/environment for a TMH visit (n=8) [7, 11, 13, 17, 18, 55, 64, 69], and the availability of interpreters or providers who can use patients' preferred languages (n=3) [27, 44, 63].

The subtheme of Technology-Related Recommendations (n=23) [7, 11-13, 16-18, 20, 25, 31, 33, 36-39, 47, 52, 60-65] includes topics such as the basic technology requirements, including sufficient physical infrastructure and reliable equipment for telemedicine (n=14) [11-13, 16-18, 31, 33, 36, 37, 60, 61, 64, 65], as well as the need to increase comfort with using technology during mental health care visits (n=9) [7, 11, 18, 37, 47, 61, 63-65]. Within the topic of technology requirements, 3 articles specifically highlight the need for reliable equipment

XSL•FO
RenderX

[11, 33, 61], and 5 emphasize the necessity of infrastructure and support [11, 13, 16, 17, 33]. Other topics include successful system integrations and health care technologies (n=4) [17, 20, 62, 64], recommendations on the types of devices patients should use based on the treatment and assessment (n=4) [13, 17, 25, 37], and the importance of telemedicine platforms having accessible user interfaces (eg, language preference options) [17].

Finally, 28 articles [7, 10-20, 27, 29, 33, 35, 37, 44, 47, 51-53, 61, 63, 64, 66, 67, 69] specifically advised on Laws and Regulations regarding TMH care, including ethical and social issues (n=15) [7, 15, 17, 18, 25, 27, 29, 33, 37, 51, 53, 61, 63, 66, 67], patient consent (n=9) [7, 10, 11, 13, 17, 18, 25, 29, 63], providers' knowledge of laws (n=9) [7, 11, 12, 16, 17, 25, 52, 63, 66], and the use of Health Insurance Portability and Accountability Act (HIPAA)–compliant platforms when delivering telemedicine (n=3) [11, 64, 69]. Another topic within laws and regulations includes reimbursement for telemedicine visits and ensuring that patients are informed about how TMH care may be billed differently (n=5) [11, 17, 20, 27, 47]. Bilder et al [17], Voulgaris et al [35], and Batastini et al [63] emphasized that their recommendations should never supersede existing laws, ethical standards, or organizational guidelines, such as those from the APA. All 28 articles adhered to current regulatory frameworks in the context of their advised changes. Additionally, 5 articles explicitly highlighted the importance of addressing socioeconomic disparities when discussing changes to ethical guidelines and expectations related to telemedicine. These disparities must be considered both in the implementation of TMH care and in the development of future guidelines [17, 27, 29, 33, 63].

Discussion

Principal Findings

This scoping review aimed to identify the types of guidelines and recommendations available to providers in peer-reviewed sources, highlight the most common recommendations presented, and examine notable benefits and challenges associated with TMH guidelines. We analyzed TMH guidelines and biomedical recommendations published between 2020 and 2024, identifying key themes based on their frequency across the literature, and categorized the types of guidance available to providers during that time. Through content and thematic analyses, this study identified 3 main themes along with their associated subthemes and topics. Our findings highlight Concerns and Facilitators of TMH that were directly addressed by published guidelines, as well as overarching patterns in TMH guidance from 2020 to 2024. Using a qualitative approach, we presented these elements not only by frequency but also by their relevance within the broader thematic structure. Notably, our review found that the most frequently cited Facilitators of TMH care was its ability to increase access for isolated and vulnerable patient populations [8-10, 14, 16, 17, 19-22, 24-34]. Concerns focused on Provider-Centered Barriers, including the lack of visual and physical cues during sessions, as well as environmental and technological limitations that made TMH care inaccessible for certain patient populations [9, 17, 18, 22, 24, 28, 29, 32-34, 41, 44-46, 48, 49, 52-54]. The Changes Advised theme responded directly to these concerns by presenting solutions and actionable recommendations aimed at addressing the identified challenges. Among the most prominent recommendations identified in the 76 articles were the call for Further Research across all aspects of TMH care and the need for comprehensive telemedicine education for providers at various levels [8-12, 14, 17-22, 24, 26-28, 31-34, 37-42, 44-47, 50-64, 67, 68, 70-81].

Guidelines, Protocols, and Recommendations Published for Providers During the Early Pandemic

While all included articles offered at least some form of recommendation, only a few provided concrete, step-by-step guidelines. Among these, some offered guidance specific to certain treatments [10, 34, 35, 37, 49, 55, 58, 63, 69], 1 provided instructions for using the Zoom platform for telemedicine delivery [67], and others outlined general best practices for providers [7, 12, 16-18, 24, 25, 32, 36, 37, 42, 55, 63, 67-69]. This range of guidance highlights the extent to which TMH care can differ from traditional in-person visits.

The guidelines generally appeared to draw on information and rules of thumb from trusted organizational resources, serving as a conglomeration of established best practices. Across the reviewed literature, we identified 47 distinct organizations cited as sources for developing TMH recommendations and guidance. Several organizations were referenced multiple times, including the APA, ATA, IOPC, CMS, CDC, the Institute of Medicine, and the Telemedicine and Psychiatry Operational Guidelines 2020 [7-19, 63]. The reliance on multiple trusted organizational resources in place of direct clinical evidence highlights a significant need for more empirical research that links specific telemedicine practices to measurable outcomes. Furthermore, the higher number of original research articles published between 2020 and 2021—compared with the 3 subsequent years combined—suggests that while evidence is beginning to emerge, the momentum for generating new data may have slowed. The guidelines we assessed covered a broad range of topics, from providing patient orientation for telemedicine to outlining best practices for developing therapy plans and engaging with patients during virtual visits. These resources seem to serve as foundational tools—offering insights into essential technology requirements, availability, and general checklists to help ensure the delivery of high-quality care. However, to truly meet the complexities of telemedicine, more detailed and tailored guidelines will be needed. In the future, comprehensive TMH protocols may need to be developed not only for individual countries but also adapted at the state or territorial level, depending on specific regulatory frameworks. These future guidelines must also account for therapist compliance with local laws and professional standards.

In the review, we found 9 step-by-step guides focused on specific TMH treatments. For example, Smith et al [37] developed a guide for virtual family play therapy, focusing on "recommendations for assessment, therapy structure, therapist roles, session preparation, and how to use virtual tools to enhance treatment." These guides are ultimately recommendations and have yet to be assessed for validity. As

XSL•FO
RenderX

more step-by-step guides become available, there should be a parallel initiative to evaluate their quality and validity. Such efforts would help ensure that providers deliver evidence-based, high-quality TMH care. Developing these guidelines would also support the systematic provision of care that incorporates innovative techniques and remains ethically sound.

Finally, the guide on how to use a particular telemedicine platform successfully for TMH care addressed the "gap in support" [67]. While telemedicine platforms may offer their own guides, question-and-answer sections, and other customer support services, it is important to explore platforms specifically designed to facilitate TMH practices. Within these platform-specific guidelines, the development of specialty resources—such as a TMH guide—would help ensure high-quality care and address many of the concerns raised by providers, including technical aspects of telemedicine use and how to recognize visual and auditory cues from patients [37]. After all, platforms may have different features and technical aspects that can impact TMH care. For example, platforms have been shown to exhibit acoustic differences [82]. If providers are unaware of such variations in audio or visual quality, their ability to deliver effective care may be hindered.

Further Research Crucial for the Future of TMH Care

It is unsurprising that 59 of the 76 (78%) peer-reviewed publications stated the need for Further Research to support the success of TMH care; however, the necessity of acting on this recommendation is critical. While a general call for robust telehealth evaluation has been cited [24, 31, 32, 34, 38, 44, 52, 55, 60, 61, 64, 68, 70, 77, 78, 80], our review highlights the many specific facets of TMH care that still require investigation. Evaluations of TMH care must consider both patient and provider perspectives [61]. Researchers and clinicians should strive to evaluate and validate the assessments, exercises, and treatments used in TMH care to ensure the highest quality of care and to identify best practices [11, 17, 18, 31, 32, 34, 44, 51, 52, 55, 62, 63, 67, 72, 75, 79, 80]. Although original research publications providing evidence-based recommendations are on the rise, the guidelines themselves have not undergone significant changes—though the ATA and APA guidelines have been consistently updated. While major revisions may not be necessary, a maintained and regularly updated resource list of evidence-based telemedicine practices should be available to providers. As Sperling et al [44] noted, "scientific studies examining the reliability and validity of tele-np-t [tele-neuropsychological testing] are outnumbered by published editorials, white papers, descriptive reports of institutional practices, and/or practice surveys related to tele-np...[it is] imperative that professionals...turn their expertise and attention to conducting well-designed experimental studies." Naturally, evaluations must be conducted via telemedicine and across different countries to assess and account for the impact of language, culture, and socioeconomic factors in TMH care [62]. As Law et al [51] pointed out, different TMH techniques should be evaluated and compared to determine which telemedicine approaches work best for specific patients, providers, and scenarios.

The articles included in the scoping review highlight that, although telemedicine research has been conducted in the past, the existing evidence does not adequately support current practice. With the rapid uptake of telemedicine due to the COVID-19 pandemic, it now encompasses far more dimensions and considerations than the current body of evidence can fully address. As Finley et al [59] and other authors have noted, while the literature demonstrates positive, evidence-based outcomes with TMH care, further large-scale research is needed to determine whether these outcomes are generalizable beyond the original studies—and whether TMH practices are ultimately "sustainable long-term despite short-term feasibility" [32, 33, 52, 59, 78]. Further research is needed on how guidelines, protocols, and best practices are developed and implemented at professional, organizational, and national levels. Pre–COVID-19 studies explored telemedicine as an emerging technology; however, its current state reflects widespread adoption without clear guidance for direct integration into practice.

Impact of Laws and Regulations on TMH Practice

While COVID-19 served as the catalyst for significant regulatory upheaval and changes in telemedicine-related laws to ensure the protection of both providers and patients, none of the articles proposed changes to the laws and regulations. Of the 28 articles that discussed laws and regulations, all focused on complying with current legal requirements. There was an emphasis on providers' understanding of the laws in their region [7, 11, 12, 16, 17, 25, 52, 63, 66] and the idea that any recommendations presented in the articles should never supersede laws or ethics [17, 35, 63]. However, no mention was made of the need for regulatory changes. Interestingly, several articles recommended reviewing and revising the ethics surrounding TMH care provision [14, 15, 17, 18, 29, 33, 51, 53]. We infer that, due to the unknowns and the use of emergency protocols by nations, authors chose to omit recommendations for regulatory and policy changes. However, the suggestions for revisions in ethical standards indicate a need to reconsider legal standards as well. For example, Singh and Sagar [53] noted that, although guidelines may be available, it is not necessarily the case that the practitioner has had the opportunity to adequately train or qualify to provide TMH care [53].

Although we did not observe a direct call for changes in regulatory standards, we did note recommendations for updating patient consent forms and ensuring that patients understand the limitations of TMH care [7, 10, 11, 13, 17, 18, 25, 29, 63]. Fox-Fuller et al [18] emphasized that providers must "weigh ethical considerations when determining" whether TMH care is appropriate and should include potential limitations in care within the informed consent. They also pointed out another recommendation supporting changes to APA standards and the ethical principles of TMH assessments [17, 35, 63]. Such recommendations not only suggest potential policy and regulatory shifts but also highlight the need for telemedicine education, as well as consideration of accessibility and inequities in care. Practice guidelines focus on reminding providers to be mindful of laws and regulations but generally do not offer

XSL•FO
RenderX

recommendations for legal and regulatory changes, as they are intended to guide care.

Telemedicine Training for Providers and Innovative Ways to Deliver Treatments

Telemedicine may not be a new technology, but its widespread use became prominent in 2020. It incorporates many levels of innovation, such as the integration of new technologies with telemedicine [10, 11, 18, 19, 33, 42, 44, 54, 66, 67], the development of new exercises for patients [18, 27, 34, 45, 66, 67], and the screening of patients for successful telemedicine use [7, 18, 42]. For a provider to use these innovations effectively, some form of training is necessary. Interestingly, only 17 out of the 76 (22%) articles directly discuss the need for telemedicine-specific training. This result may reflect both the novelty of the widespread use of telemedicine and the emphasis on developing guidelines and recommendations for immediate use by providers.

Some articles addressed the need for formal educational processes, such as medical school education or continuing medical education [7, 11, 16-18, 25, 27, 34, 36, 37, 45, 46, 63, 64, 66, 67, 70], while others highlighted more immediate forms of education available during the pandemic, such as webinars or consulting with colleagues experienced in telemedicine [11, 17, 18, 36, 63]. The guides and best practices that emphasized greater integration of telemedicine into formal education echo the theme that there is a need for evidence-based outcomes and assessments of validity to develop successful education programs. Tailoring education to specialty practice concerns and needs can be achieved through diligent research [34, 46, 63]. Understanding the necessary adaptations of platforms, exercises, and treatments is essential for TMH care, but it is also important to consider the cultural and socioeconomic aspects of both providers and patients [16, 34]. While knowledge of cultural mannerisms may be critical in care—especially as providers can broaden their patient base through telemedicine—there must also be consideration of patient accessibility and health disparities in the context of telemedicine [16].

Telemedicine Access, Care Inequities, and Health Disparities

Telemedicine is often credited with increasing access to care for patients and reducing health disparities and inequities [83]. However, with the rise in telemedicine research during the pandemic, inequities and disparities in health became more apparent [84-86]. In our literature search, we found 32 articles that highlighted the need to consider accessibility in various forms—such as the need for interpreters, providers who can communicate in multiple languages, patients requiring the appropriate equipment for successful care, and the need for a distraction-free space [7, 11, 13, 17, 18, 27, 60, 61]. Of these 32 articles, 19 focused on sociocultural considerations. For example, Comer [28] noted that providers need expanded sociocultural training, as "telehealth offers new opportunities to treat individuals in underserved communities." When providers are unable to adequately meet their patients' needs, a barrier is created—one that is often most acutely felt by underserved populations [48]. Zhu et al [47] described a revealing need centered on increasing accessibility: "A report published by the Rural Policy Research Institute outlined a need for research to understand the acceptability for long-term TMH service use among rural adults, especially those who are older or racially/ethnically diverse. This also includes studying how to adapt evidence-based treatments to a cultural context and video-based platform." Once again, the need for more research to determine best practices—especially when considering care inequities and health disparities in telemedicine—is critical. Looi et al [21] also highlighted this vital consideration: "Sensitivity to cultural, health and socioeconomic disparities is also needed to avoid inequities in access." Not only is sociocultural and socioeconomic consideration necessary in telemedicine implementation, but it should also be integrated into all aspects of the telemedicine visit. This includes providers' understanding of whether a certain treatment or assessment may be less effective due to cultural factors or obstacles [11]. As telemedicine has become more widely used, new research at larger scales will provide a better understanding of how to effectively increase access to care without exacerbating care inequities and health disparities. With only 19 out of 76 (25%) articles discussing sociocultural and socioeconomic factors in telemedicine implementation, there is a clear need for further research to address this gap in the literature.

Limitations

This scoping review aimed to provide a snapshot of the guidelines and recommendations produced for providers between 2020 and 2024. Future research could determine whether these themes were addressed through a larger, comprehensive systematic literature review. We intended was to identify what providers could easily find and access within peer-reviewed biomedical databases. As a result, our review is limited to guidelines published between 2020 and 2024. Because of the large number of results from our general search strategy, we conducted a title-and-abstract screening. Outside of the exclusion and inclusion criteria, we did not validate the resulting articles. Future research, particularly systematic reviews, should consider the types of guidelines available for providers; the types of assessments, guidelines, checklists, and techniques that are validated for TMH care; changes in the guidelines over time, especially beyond our restricted 2-year review; and evidence of the sustainable and successful implementation of TMH care in practice.

Conclusions

This scoping review of 76 articles characterizes the TMH guidelines published between 2020 and 2024 and identifies key, shared recommendations to support the implementation and success of TMH care. We applied systematic qualitative analyses to better understand the most frequently noted themes in the resulting peer-reviewed literature and how they contribute to successful TMH care. This methodology also helped identify how key themes are interconnected and build upon each other. Research at larger scales is essential to develop effective guidelines and protocols for successful therapy plans and to ensure that telemedicine does not exacerbate health inequities. Future research should examine how TMH guidelines have adapted and changed in response to provider and patient needs,

XSL•FO
RenderX

how these guidelines address accessibility and inequities, and how they account for regional and international variations.

Abstract

Background: Early assessment of mild cognitive impairment (MCI) in older adults is crucial, as it enables timely interventions and decision-making. In recent years, researchers have been exploring the potential of gamified interactive systems (GISs) to assess pathological cognitive decline. However, effective methods for integrating these systems and designing GISs that are both engaging and accurate in assessing cognitive decline are still under investigation.

Objective: We aimed to comprehensively investigate GISs used to assess MCI. Specifically, we reviewed the existing systems to understand the different game types (including genres and interaction paradigms) used for assessment. In addition, we examined the cognitive functions targeted. Finally, we investigated the evidence for the performance of assessing MCI through GISs by looking at the quality of validation for these systems in assessing MCI and the diagnostic performance reported.

Methods: We conducted a scoping search in IEEE Xplore, ACM Digital Library, and Scopus databases to identify interactive gamified systems developed for assessing MCI. Game types were categorized according to genres and interaction paradigms. The cognitive functions targeted by the systems were compared with those assessed in the Montreal Cognitive Assessment (MoCA). Finally, we examined the quality of validation against the reference standard (ground truth), relevance of controls, and sample size. Where provided, the diagnostic performance on sensitivity, specificity, and area under the curve was reported.

Results: A total of 81 articles covering 49 GISs were included in this review. The primary game types used for MCI assessment were classified as casual games (30/49, 61%), simulation games (17/49, 35%), full-body movement games (4/49, 8%), and dedicated interactive games (3/49, 6%). Of the 49 systems, 6 (12%) assessed cognitive functions comprehensively, compared to those functions assessed via the MoCA. Of the 49 systems, 14 (29%) had validation studies, with sensitivities ranging from 70.7% to 100% and specificities ranging from 56.5% to 100%. The reported diagnostic performances of GISs were comparable to those of common screening instruments, such as Mini-Mental State Examination and MoCA, with some systems reporting near-perfect performance (area under the curve>0.98). However, these findings often stemmed from small samples and retrospective designs. Moreover, some of these systems' model training and validation exhibited substantial deficiencies.

Conclusions: This review provides a comprehensive summary of GISs for assessing MCI, exploring the cognitive functions assessed by these systems and evaluating their diagnostic performance. The results indicate that current GISs hold promise for the assessment of MCI, with several systems demonstrating diagnostic performance comparable to established screening tools. Nevertheless, despite some systems reporting impressive performance, there is a need for improvement in validation, particularly concerning sample size and methodological rigor. Future work should prioritize prospective validation and present greater methodological consistency.

Introduction

Background

Cognitive impairment refers to the decline of one or more 1 cognitive functions, including attention, executive function, or memory [1]. This decline may be a natural part of aging [2]. However, with the increase in average lifespan, the prevalence of *pathological* cognitive decline also rises due to excessive neural damage [3]. This pathological decline is known as dementia, a general term for a variety of neurodegenerative diseases with different causes characterized by "an impaired ability to remember, think, or make decisions interfering with daily activities" [4]. Most types of dementia develop gradually over time [5]. The prestage of dementia is called mild cognitive impairment (MCI). More particularly, MCI is defined as "a syndrome of self-reported cognitive complaint with one or more objective cognitive impairments but preserved independence in functional abilities" [6]. Hence, individuals with MCI, despite experiencing cognitive impairment, still successfully perform activities of daily living (cooking, toileting, walking, visiting friends, etc), and not all individuals with MCI go on to develop dementia [6]. However, they are at a higher risk, with a reported annual conversion rate from MCI to dementia varying from 2% to 31% [7].

Currently, pharmaceutical interventions to cure MCI or dementia are still under research [8]. Nevertheless, early assessment of cognitive decline, along with early intervention methods, such as cognitive training and medication, can effectively slow down the progression of the condition [9-12]. The current gold standard for diagnosing MCI involves a detailed anamnesis, followed by a neuropsychological examination, and is often complemented by brain imaging to detect structural changes, along with blood and cerebrospinal fluid analyses [13,14]. This comprehensive assessment necessitates a team of medical specialists, consuming a significant number of medical resources [15]. Therefore, before a detailed examination is performed, it is advised to administer a quicker screening test and to continue with a full examination only if necessary [16]. The Mini-Mental State Examination (MMSE) [17] is currently the most widely used instrument for rapid screening of Alzheimer disease (AD) and MCI [18], assessing cognitive functions such as attention, registration and recall, orientation, and language. It is fast to administer, taking only 10 minutes, but it has also shown a lack of sensitivity, misclassifying older adults with MCI as healthy [19]. The Montreal Cognitive Assessment (MoCA) [20] is another popular instrument that evaluates similar cognitive functions in up to 20 minutes. Several studies have shown MoCA to be superior to the MMSE in terms of sensitivity for detecting MCI [20-22]. However, the MoCA has shown lower specificity, misclassifying healthy older adults (with natural cognitive decline) as at risk for MCI.

The suboptimal accuracy of these quick screening instruments may be partly due to the limited assessment time inherent in their design. However, another factor negatively impacting the accuracy of neuropsychological tests may be anxiety. Patients who are required to perform abstract tasks at a clinic in the presence of medical experts may experience heightened stress levels and perform suboptimally [23]. This is known as the white coat effect [24] and is known to disturb neuropsychological test performance. Moreover, neuropsychological tests are designed as one-time assessments and can be disturbed by circumstances such as lack of sleep or traumatic events (eg, loss of a spouse). However, the already long waiting lists make frequent and repeated neuropsychological tests infeasible.

Therefore, to complement screening instruments for MCI and alleviate the resources needed for a full examination, researchers are exploring alternative sources of information on cognitive functioning. Such solutions may come in the form of dedicated sensors installed in the home or wearables to detect movements [25,26], embedded software trackers that capture mouse movements [27,28], keyboard loggers installed on computers [29], conversational humanoids [30], or the use of interactive virtual simulations and games. Particularly, the latter has stirred the interest of researchers; games and simulations have long been used in understanding, measuring, and training cognition [31-33]. In addition to providing interactive, immersive environments to engage participants, they provide challenges bounded by a fixed set of rules, which can be highly indicative of targeted cognitive functioning. Research has indicated that games are more engaging than classical neuropsychological tests [32-34] and can be used to assess cognitive skills [35]. Moreover, the entertaining nature of gamified interactive systems (GISs) might reduce stress. They can be played in the comfort of the patient's home, making the presence of a trained administrator redundant [36]. Finally, GISs also encourage more frequent interaction, providing additional testing data. Thus, they have the potential to *complement* traditional screening instruments by offering longitudinal assessment, which provides health care professionals with a new perspective for their case findings and diagnosis.

Despite their potential, it remains unclear to what extent GISs can be effectively used for the assessment of MCI, particularly as an early indicator of dementia. Researchers are still investigating the effective methods for system integration [37] and the accuracy of GISs in assessing cognitive decline [31,37]. In summary, while the of GISs for assessing MCI holds potential clinical significance, it remains in its early stages of development.

Objectives

Therefore, to provide a more comprehensive understanding of the potential of GISs, we aimed to present a scoping review of their applications in assessing MCI, addressing the following research questions (RQs).

1. What are the different game types (genres and interaction paradigms) of GISs used to assess MCI?

XSL•FO
RenderX

2. Which cognitive functions are assessed by GISs?
3. How are GISs evaluated (eg, longitudinal or cross-sectional), and how reliable are these studies in reporting diagnostic performance?

Methods

Overview

The review followed the latest PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines (checklist 1) [38], focusing on GISs for assessing MCI. The protocol is provided in Multimedia Appendix 1 [9-12,20-22,38,39] and can also be accessed online [40]. The databases queried include the Scopus database (eg, PubMed, MEDLINE, and Embase) as well as more technical libraries, specifically IEEE Xplore and ACM Digital Library. The screening process for queried articles consisted of 3 phases: title screening, abstract screening, and full-text eligibility. Ambiguous articles at each phase were advanced to the next stage for further review. In the full-text eligibility, articles were reassessed to ensure that all 3 inclusion criteria were met, in addition to the 4 exclusion criteria.

Search Queries Used

The query terms used in the search strategy are presented in Textbox 1. For the population, the search focused on patients with either "Mild Cognitive Impairment" or "MCI," deliberately excluding dementia to maintain an emphasis on the prestage of dementia. Regarding the instrument used for assessment, the search included the terms "Gamif*," "Game," "Video game," or "Videogame." In addition, the purpose of the instrument was specified as "assessment," with variations such as "Evaluation," "Screen*," and "Diagnos*" included as synonyms in the queries. These terms were searched across metadata, titles, abstracts, keywords, and full text. Because the syntax of each database varied slightly, the queries were adapted to match the specific requirements of each library, with the exact queries provided in the Multimedia Appendix 2.

Textbox 1. Summary of search terms.

Disease

- Mild Cognitive Impairment
- MCI

Instrument

- Gamif*
- Game
- Video game
- Videogame

Purpose

- Assess*
- Evaluat*
- Measure*
- Screen*
- Diagnos*

Eligibility Criteria

We focused on GISs designed to assess MCI and their potential for such assessment in this review. As a result, only articles meeting the predefined inclusion and exclusion criteria were included, as detailed in Textbox 2.

For systems described in multiple articles, such as separate publications for system design and diagnostic performance, all related articles were included and considered collectively as the entirety of a system. For systems that the authors named, we use the name in the remainder of the paper. For those systems that were not named by the authors, we refer to the system number given in this review.

XSL•FO
RenderX

Textbox 2. Inclusion and exclusion criteria.

Inclusion criteria

- Full-text, peer-reviewed articles published in English
- Systems assessing mild cognitive impairment (MCI) as part or all of their function
- Explicit inclusion of game or gamified elements in the article

Exclusion criteria

- Studies featuring games or gamified elements in nonelectronic forms, such as pen-and-paper games
- Game or gamified systems designed only for rehabilitation or training of specific cognitive functions, or targeting dementia instead of MCI
- Articles that did not claim implementation
- Book chapters that are inaccessible or retracted articles

Data Extraction and Synthesis

The following subsections describe how data were extracted and analyzed for each RQ, in alignment with the Results section by RQs.

RQ1: Identifying Game Types and Interaction Paradigms

We first extracted the information needed to address RQ1. We described the GISs used in articles based on genre (eg, casual games or simulation games [41]) and interaction paradigm [42].

RQ2: Mapping Cognitive Functions to the MoCA Domains

Second, we extracted the information needed to address RQ2. We drew on the descriptions provided in each paper and mapped the mentioned cognitive functions to those assessed by the MoCA [20], as outlined in Textbox 3.

We chose MoCA over the MMSE because it provides a more sensitive and comprehensive assessment of MCI [43], particularly in domains relevant to many GISs [44]. MoCA includes dedicated tasks for executive functions (eg, trail making, verbal fluency, and abstraction) and more detailed visuospatial assessments (eg, cube copying and clock drawing) than MMSE. These domains are frequently targeted by GISs, making MoCA a more suitable framework for mapping cognitive coverage.

Textbox 3. Mapping of cognitive functions to the Montreal Cognitive Assessment domains.

Test

- Short-term memory: assesses the ability to recall information after a short delay.
- Visuospatial abilities: evaluates skills such as drawing and understanding spatial relationships.
- Executive functions: tests planning, problem-solving, and organizing abilities.
- Attention, concentration, and working memory: measures the ability to focus, maintain attention, and manipulate information.
- Language: assesses naming, fluency, and comprehension.
- Orientation to time and place: evaluates awareness of current date, location, and situation.

RQ3: Evaluation Design, Quality Assessment, and Diagnostic Performance Reporting

Finally, we extracted the information to address RQ3. Here, only systems that included evaluations for assessing MCI were coded. Each system may have multiple studies encompassing different research designs that have been published. If multiple studies of 1 system were included in the review, we chose articles focusing on the report of diagnosis. Usability studies, or studies focused on collecting other data (eg, physiological signals), were not considered to answer RQ3.

We first investigated *how GISs are evaluated.* Therefore, we coded the different research study designs used to assess accuracy, for example, cross-sectional studies or longitudinal studies. Second, we investigated *how reliable these studies are.* The articles were evaluated across 3 dimensions, each scored on a scale from 1 to 3, with higher scores indicating higher quality, based on a quality assessment method adapted from the studies by Bezabih et al [45], Johnson et al [46], and Boyle et al [47].

The detailed dimensions and scoring methods are provided in Textbox 4.

Hence, the score for each article can range from 4 to 12. We consider scores from 3 to 5 as “weak evidence,” 6 to 7 as “moderate evidence,” and scores 8 to 9 as “strong evidence.”

Finally, we investigated the *diagnostic performances that were reported.* The actual outcomes of the studies were coded, including sensitivity, specificity, and area under the curve (AUC).

XSL•FO
RenderX

Textbox 4. Dimensions and scoring methods.

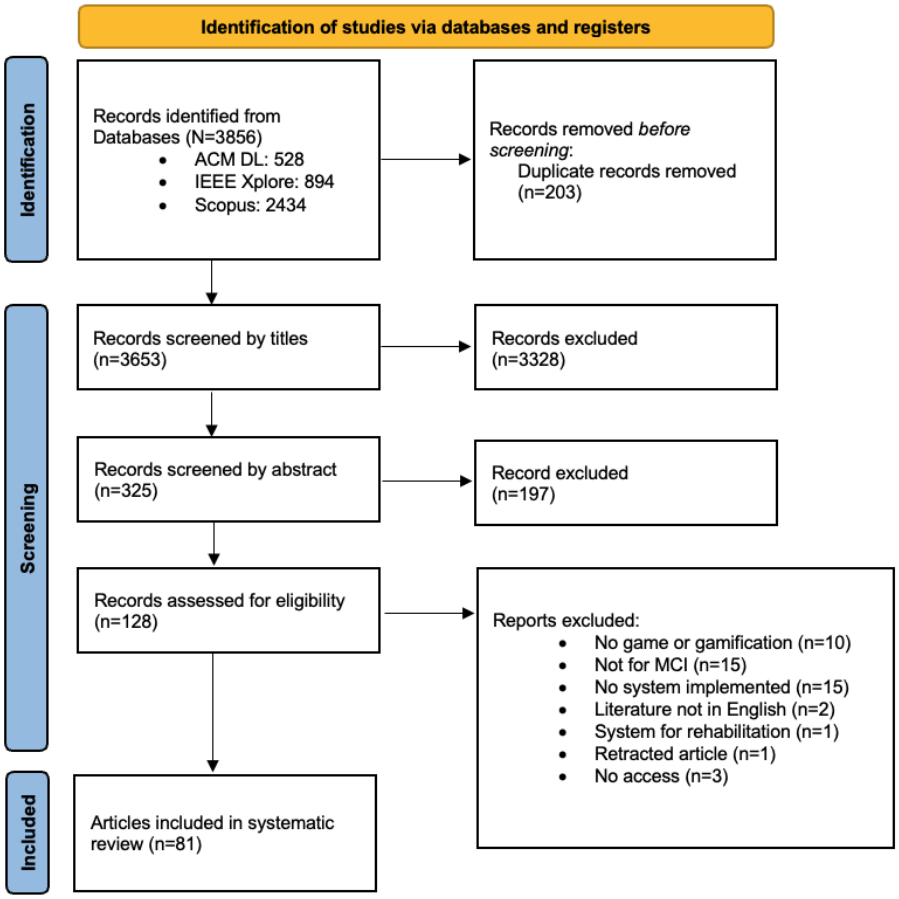
How appropriate is the reference standard? (1 to 3 out of 3 points)

1. Reference standard is based on fast screening instruments (eg, Mini-Mental State Examination or Montreal Cognitive Assessment)
2. Reference standard is based on a comprehensive neuropsychological test
3. Reference standard is based on full diagnosis by clinicians

How relevant are the comparative groups? (1 to 3 out of 3 points)

1. No controls, or it is unspecified who or how many participants have mild cognitive impairment (MCI)
2. MCI versus healthy controls, MCI versus older adults with subjective cognitive decline, or MCI versus older adults with dementia MCI versus healthy controls, with additional subdistinctions, for example, additional persons with subjective cognitive decline or persons with Alzheimer disease, or intraperson measurement (in case of long-term measurement in persons with MCI)

How generalizable are the findings of this study to the target population, considering the method of analysis and sample size of persons with MCI? (1 to 3 out of 3 points; for studies other than cross-sectional studies, the score was given case by case)



1. Cross-sectional study with <10 participants with MCI
2. Cross-sectional study with 10 to 30 participants with MCI
3. Cross-sectional study with >30 MCI participants with MCI

Results

Overview

The search was executed in July 2024. A total of 3856 articles were retrieved based on the queries listed in Textbox 1. The specific numbers from each database are detailed in Figure 1. Before further screening, 5.26% (203/3856) of duplicate articles were removed. After the title and abstract screening, 96.5% (3525/3653) of the articles were excluded, leaving 3.5% (128/3653) of the articles for full-text evaluation. As a result, 47 (36.7%) of the 128 articles were excluded for reasons outlined in Figure 1. Ultimately, this scoping review included 81 (63.3%) of the 128 articles describing 49 GISs, as shown in Table 1 [48-128].

The results of the articles included are presented in the following sections, organized according to the RQs.

RQ1: What Are the Different Game Types (Genres and Interaction Paradigms) of GISs Used to Assess MCI?

When reviewing GISs according to genre and interaction paradigm, we identified GISs to be casual games, simulation games, full-body movement games, or dedicated interactive games, as illustrated in Multimedia Appendix 3.

Casual Games

Overview

Casual games (30/49, 61%) are a category of video games known for their accessibility and ease of play. These games are designed to be simple to learn, offering quick rewards and a forgiving gameplay experience, ultimately creating a fun and enjoyable entertainment experience for players of all skill levels [129]. As for the interaction paradigm, casual games run on general digital devices, such as smartphones, tablets, and PCs, without a need for specific controllers. A keyboard or a computer mouse, or simply a touch screen, is sufficient. We further categorized casual games into the following subcategories.

Card Games

In total, 12% (6/49) of the systems use classical card games. In Blackjack (Sys1) [50], players strive to assemble a hand, achieving a value as close to 21 as feasible without exceeding this pivotal threshold. This game demands decision-making, blending risk assessment and strategic calculation elements. Free Cell (Sys1) [48] and Solitaire (Sys17) [80-83] epitomize the genre of sorting card games, necessitating the arrangement of a standard 52-card deck based on criteria of suits and ranks. These games not only require sequencing and strategic planning but also underscore the virtues of patience and foresight. The Find the Pair (Sys9, Sys15, and Sys48) [69,78,127] game challenges participants to unveil matching pairs from an array of face-down cards. Participation in this game demands memory and concentration. Finally, War (Sys26) [99] is a card-based contest where players select cards to show a higher rank against a computer-simulated adversary.

Digital Versions of Analog Games

Similar to card games, digitized versions of traditional board games remain popular and are used in GISs. Scrabble (Sys1 and Sys5) [49,57,58] is a popular word game where players use letter tiles to create words on a game board. The goal is to score the most points by forming words on a 15×15 grid board. Sudoku (Sys5) [57,58] is a logic-based number puzzle game. The objective is to fill a 9×9 grid with numbers so that each column, row, and each of the nine 3×3 subgrids (also known as “regions” or “boxes”) contains all the digits from 1 to 9 without repeating any numbers. Quick, Draw! (Sys34) [111] is a fun and fast-paced drawing game where players try to quickly draw an object within 20 seconds for artificial intelligence (AI) to guess.

Commercial Video Games

Besides traditional card and analog games, adaptations of classic video games were also used to assess cognitive functions. Pac-Man (Sys37) [115] is a game where the player controls Pac-Man, a yellow, circular character, navigating a maze while eating pellets and avoiding ghosts. In Tetris (Sys39) [118], the player controls falling tetrominoes, geometric shapes made up of 4 squares each, and aims to complete horizontal lines without gaps. Fruit Ninja (Sys39) [118] is a mobile game where the player slices various fruits that appear on the screen while avoiding bombs. Candy Crush Saga (Sys39) [118] is a popular match-3 puzzle game where players swap adjacent candies to form lines of ≥3 matching candies. Minecraft (Sys41) [120] is a sandbox video game that allows players to explore, build, and create in a blocky, procedurally generated 3D world.

Minigames

Several systems (21/49, 43%) were designed with simple gameplay to provide a fun game experience to older adults. Whack-a-Mole (Sys11, Sys28, and Sys29) [72,101,102] is originally an action-reaction game in which players hit moles that randomly pop up from holes on a game surface. The narrative of the game can also involve taking photos of animals (Sys38) [116,117] or beating devils (Sys48) [127]. Spot the Difference (Sys15) [78] is a puzzle game in which 2 images that appear similar are presented side by side but with subtle differences between them. The player’s objective is to carefully examine both images and identify discrepancies, such as missing objects, changed colors, or altered shapes, within a set time

XSL•FO
RenderX

limit. Bounce Balls (Sys46) [125] is a game to bounce balls to break or eliminate objects on top of the screen. Counting animals (Sys19 and Sys21) [85,86,93,94] is a game where sheep move from one side of the screen to another within a certain time. Occasionally, wolves accompany the sheep. Players must answer questions related to the number of sheep or wolves. Lucy (Sys33) [109,110] gamified the cognitive tests with dots on the screen. Participants use a controller to select the right dots based on task requirements. Similarly, X-trop (Sys49) [128] gamified the trail making test (TMT) in a sailing environment. Other games without a specific name were also identified in the studies, such as *filling in the missing part of words* (Sys38) [116,117], *pairing words* with similar or opposite meanings (Sys14), *memorizing the location of mines* in a grid (Sys14) [76,77], *jigsaw* puzzles (Sys14 and Sys45) [76,77,124], *quizzes* (Sys16, Sys31, Sys 32, and Sys36) [79,107,108,113,114], and *moving the avatar to receive falling apples* (Sys35) [112].

Simulation Games

Overview

Daily living activities are typically not significantly impaired for older adults. Nonetheless, GISs have the potential to identify the deterioration of cognitive abilities in a controlled setting. Simulation games (17/49, 35%) replicate virtual 3D environments for older adults, usually their regular living environment. Here, as for the interaction paradigm, extended reality technology is often adopted for a more immersive experience for older adults (eg, virtual reality headsets), but some also still run on more traditional platforms that can be operated with a touch screen or a keyboard and a computer mouse. In these games, older adults are required to complete tasks, and the GISs can store their behavior and performance to track their progress. We break simulation games further down based on the virtual environment provided.

Shopping

Shopping is a crucial daily activity for older adults as it necessitates the use of multiple cognitive functions to maintain independence. Our research identified 7 different GISs that contain shopping experiences [53,54,74,96-98,103-106,126]. Shopping simulation has 2 main tasks: finding items and making payments. Some systems show the shopping list on the screen (Sys3, Sys24, Sys25, Sys30, and Sys47) [53,54,97,98,103,126], and some systems require players to memorize the shopping list beforehand (Sys12 and Sys23) [74,96].

Wayfinding

Wayfinding is another important daily activity for older adults. We found 6 GISs that simulate pathfinding. These systems simulate various environments for older adults, including a park (Sys4) [55,56], a museum (Sys10) [70], and driving (Sys40) [119] or walking (Sys47) [126] on city roads. Furthermore, there are also 2 systems that offer gamified tests to find the proper bus (Sys22) [95] or metro line (Sys38) [116,117].

Other "Activities of Daily Life"

Four systems simulate cooking (Sys8, Sys12, Sys23, and Sys44) [68,74,96,123]. Older adults find food and ingredients in the kitchen and then plan the steps of cooking. Two systems simulated the financing on the ATM machine (Sys22 and Sys25) [95,98]. Older adults should insert a card, choose the amount and type of notes, enter the password to print the receipt, and then retrieve the card. Two systems require older adults to remember a phone number and then dial it (Sys6 and Sys25) [59-64,98]. Six systems require older adults to identify objects or people. In SmartAging (Sys6) [59-64], older adults are instructed to locate a list of items in a kitchen and then recall them later during another task. Virtual Action Planning Museum (Sys10) [70] presents objects visually and audibly in a virtual tour and prompts older adults to recall them. Sys23 [96] requires players to remember the medications they need to take, and then, they should pick the right pills and amounts from the bottles. RE@CH (Sys25) [98] has a task that requires players to recognize famous people, numbers, and advertisements. Researchers at Microsoft used the Hololens in Sys27 [100] to create an augmented reality environment for older adults. The older adults are then asked to identify "unnaturally placed objects" and correctly position them. CogWorldTravel (Sys38) [116,117] tests that older adults are able to differentiate between faces that have not previously appeared in the game. Panoramix (Sys20) [87-92] evaluates memorizing objects during a walk in the community, with the same mechanism as the California Verbal Learning Test.

Full-Body Movement Games

Four systems use novel full-body movement interaction paradigms to assess cognitive functions. FitForAll (Sys7) [65-67] assesses the cognitive functions of older adults through movement and performance in an exergame originally designed for rehabilitation. Sys18 [84] and Sys45 [124] developed games that combine body movement and quizzes using Kinect. Seas the Day (Sys42) [121] allows older adults to engage in enjoyable activities such as fishing, practicing tai chi, and rowing within a virtual reality environment.

Dedicated Interactive Games

Three systems created dedicated hardware to provide more interactive and tangible game experiences. Fun Cube (Sys2) [51,52] has created dedicated tangible devices comprising 6 cubes with mini screens. They use these devices to gamify the MoCA in their system. SmartKuber (Sys13) [75] had a similar idea of using tangible cubes in the gameplay. Unlike Fun Cube, the researchers behind SmartKuber integrated augmented reality technology with physical cubes. Older adults use a tablet's camera to scan the cubes and play the game. Researchers involved in the development of Sys43 [122] were exploring the use of haptic and olfactory sensors to help older adults identify objects.

In conclusion to RQ1, a diverse array of game genres and interaction types have been used for the assessment of MCI. The breakdown of game types includes casual games (30/49, 61%), simulations (17/49, 35%), full-body movement games (4/49, 8%), and those with dedicated interaction (3/49, 6%). A tabular summary of GISs mapped to the game types is provided in Multimedia Appendix 3.

XSL•FO
RenderX

RQ2: Which Cognitive Functions Are Assessed by GISs?

We examined the cognitive functions assessed by GISs based on the 6 cognitive functions evaluated in MoCA (*short-term memory*; *visuospatial abilities*; *executive functions*; *attention, concentration, and working memory*; *language*; and *orientation to time and place*).

Short-Term Memory

A total of 28 systems assessed older adults' short-term memory in a manner similar to the MoCA. These assessments typically involve presenting information and then asking the older adults to recall it. Often, additional context is provided, such as memorizing a shopping list (Sys12 and Sys23) [74,96], recalling objects encountered during a walk (Sys20 and Sys47) [91,126], arranging dishes on a table (Sys 12) [74], or locating a list of items in a kitchen (Sys44) [123]. Other activities may include memorizing a 2D "mines field" (Sys14) [76,77] or playing Find the Pair card games (Sys9) [69]. A time limit is often involved in assessing memory, such as when participants are asked to remember the number of sheep that come and go on a farm (Sys19 and Sys21) [85,86,93,94].

Visuospatial Ability

In total, 21 systems evaluated visuospatial ability. The MoCA assesses visuospatial ability through tasks such as drawing a clock and a cube. GISs can make drawing enjoyable, such as by allowing AI to guess what you are drawing (Sys34) [111] or sketch museum artifacts (Sys32) [108]. The gameplay of games such as Tetris (Sys39) [118] or filling space with shapes in Tetris (Sys38) [116,117] also helps evaluate visuospatial ability. GISs also enable a realistic assessment of visuospatial ability through their graphics. Older adults can navigate a virtual city or park and complete tasks that are often combined with memory, such as finding their way back (Sys40) [119].

Executive Functions

A total of 23 systems evaluated executive functions. The TMT part B is used in the MoCA to evaluate executive functions. Some systems have implemented minigames or tests similar to TMT (Sys2) [51,52] or directly gamified TMT (Sys49) [128]. Card games such as FreeCell (Sys1) [48] and Solitaire (Sys17) [82] also require executive functions in planning the strategy for sorting suits. More realistic tasks, such as cooking with a recipe (Sys8, Sys12, Sys23, and Sys44) [68,74,96,122] and sorting objects by types and then placing them in the proper places in simulation games (Sys27) [100], can also evaluate executive functions.

Attention, Concentration, and Working Memory

In total, 25 systems assessed attention, concentration, and working memory. In Whack-a-Mole and its variants (Sys11, Sys28, Sys29, Sys38, and Sys48) [72,101,102,116,117,127], players must pay attention and concentrate on hitting the moles while avoiding distractors such as bombs. Games such as Pac-Man (Sys37) [115] and Fruit Ninja (Sys39) [118] naturally challenge attention to avoid faults and obtain higher scores. Other games, such as Find the Pair (Sys9) [69] and Sudoku (Sys5) [57,58], require working memory to temporarily memorize useful information, such as patterns on cards and missing numbers in rows or columns.

Language

A total of 10 systems evaluated language skills. Quiz games (Sys15, Sys16, and Sys36) [78,79,113,114] often feature tasks such as naming objects and spelling words that start with specific letters. In simulation games, naming objects can also be easily integrated into the gameplay. Scrabble (Sys1 and Sys5) [49,57,58] also provides an enjoyable approach to test language comprehension. Contexts such as text passwords of luggage locks (Sys38) [116,117] can also assess language understanding. However, the articles included in this review indicate that none of the evaluated systems require voice input, meaning that language fluency is not assessed by any of them.

Orientation to Time and Place

In total, 7 systems evaluated orientation. We could not find game mechanisms to test orientation to time naturally. Time orientation is tested in a manner similar to word comprehension. For example, use the password hint as today's date (Sys22) [95] or directly ask it (Sys2) [51,52]. Typically, orientation to place was assessed through gamified tasks. The orientation of place is often evaluated by combining it with visuospatial abilities, specifically the ability to navigate a path in a virtual environment (Sys4, Sys10, Sys12, Sys31, Sys40, and Sys47) [55,56,70,74,107,119,126]. Older adults must first identify the position of avatars using their orientation skills and then integrate these skills with their visuospatial abilities to find their way.

In summary, memory (28/49, 57%), visuospatial abilities (21/49, 43%), executive functions (23/49, 47%), and attention (25/49, 51%) are assessed more frequently than language (10/49, 20%) and orientation (7/49, 14%). A few systems (6/49, 12%) integrate the assessment of all MoCA functions into their gameplay. A tabular summary of GISs mapped to cognitive functions is provided in Multimedia Appendix 4.

RQ3: How Are GISs Evaluated (eg, Longitudinal or Cross-Sectional), and How Reliable Are These Studies in Reporting Diagnostic Performance?

Overview

The third RQ focused on evaluating the effectiveness of GISs. We first examined the research designs used in clinical validation studies to address this RQ. Next, we assessed the quality of these research designs and evaluated the performance in assessing MCI. Therefore, we excluded 47 articles in 26 systems (Sys1, Sys5, Sys8, Sys11, Sys12, Sys14, Sys15, Sys18, Sys19, Sys23, Sys24, Sys27, Sys31, Sys32, Sys34, Sys35, Sys37-47, and Sys49) that lacked clinical validation studies (longitudinal study or cross-sectional study). In addition, we omitted the study that relied on synthetic data in which AI agents simulated the performance of healthy older adults and patients with MCI (Sys26) [99]. The studies without clear reference standards were also excluded (Sys4 and Sys22) [55,95]. This left us with 31 studies comprising 20 systems that had validation studies specifically aimed at assessing MCI. Finally, we

XSL•FO
RenderX

summarized and reported the diagnostic performance of systems with clinical validation studies.

How Are GISs Evaluated?

Two studies (Sys13 and Sys14) [75,77] reported intraperson comparisons across sessions. Sys14 [77] involved 9000 healthy participants from different age groups playing 100 games while data were collected. The results showed a linear trend (P<.001) between scores and the number of sessions played, demonstrating that all age groups showed improvement in performance across all minigames aimed at assessing cognitive functions related to MCI. While performance improved for all age groups, older adults showed slower progress compared to younger participants. Sys13 [75] compared the mean total score of the last 20% of sessions with the scores from the first 20% of sessions in a 6-week study with 13 participants, where participants were asked to play the game twice a week. The results revealed that there was no statistically significant difference.

The remaining 29 studies on 18 systems presented a cross-sectional design. Validation methods included (1) statistical analysis of game metrics to differentiate individuals with MCI from healthy controls and (2) machine learning classification methods. These studies are discussed in more detail in the following sections.

How Reliable Are These Studies in Assessing Accuracy?

The included studies were evaluated on 3 dimensions (reference standard, relevancy of controls, and sample size), each of which is scored from 1 to 3, with a higher score indicating a higher quality, based on the quality assessment method adapted from other studies [45-47]. Note that the evaluation targets the quality of task classification in healthy older adults with MCI, not the overall study quality for different research goals.

Reference Standard

Studies in the review had varying criteria for enrolling participants as patients with MCI or healthy controls. The gold standard for diagnosing MCI is a psychophysiological examination conducted by health care professionals. A total of 14 studies explicitly stated that participants with MCI underwent a comprehensive clinical diagnosis (Sys3, Sys6, Sys7, Sys9, Sys10, Sys17, Sys20, Sys30, Sys33, and Sys48) [54,63,64,67,69,70,82,83,91,104-106,109,127]. Five studies used test batteries created by authors as reference standards (Sys4 and Sys20) [56,88-90,92]. In total, 10 studies used MMSE or MoCA as their reference standard (Sys2, Sys6, Sys16, Sys21, Sys25, Sys28, Sys29, and Sys36) [52,62,79,93,94,98,101,102,113,114].

Relevance of Controls

In most studies, healthy controls were of comparable age to other groups (of patients with MCI). In 1 study [105] involving Sys30, the control group was older adults with subjective cognitive decline who visited clinics. These participants self-reported cognitive decline before cognitive tests could assess the deficits. However, subjective cognitive decline may be a precursor of nonnormative cognitive decline and eventual progression to MCI and dementia [130]. In addition to including older adults with MCI, a study [76] involving Sys14 used healthy young people as controls for control experiments. Given the natural decline in cognitive function with age, young adults may be more easily discriminated against than older adults.

The participant groups also varied across studies in their MCI subtypes. Some studies (Sys6, Sys10, Sys30, and Sys35) [63,64,70,104,112] recruited participants with amnestic MCI, while others did not differentiate between the MCI subtypes. Some studies (Sys6, Sys7, Sys8, Sys16, Sys20, Sys25, Sys26, Sys29, Sys33, Sys46, Sys48, and Sys49) [68,76,88,89,91,98,109,127] included patients with moderate to severe AD for comparison with both the group with MCI and healthy controls.

Sample Size

The average number of patients with MCI and healthy controls in the included studies was 27.44 (SD 18.63) and 42.75 (SD 51.79), respectively. Among all cross-sectional studies included in the review, 1 study on Sys6 [62] had the largest number of participants, 1086 in total. However, the reference standard was based on the MoCA administered by software. Sys48 [127] had the second largest sample size, with 240 in total (75 healthy controls, 41 patients with MCI, and 124patients with AD). Sys2 [52] had the largest MCI group sample size, with 65 participants. The study on Sys35 [112] had the largest number of healthy controls, totaling 280.

Quality of Studies

On the basis of the aforementioned analysis, the first author (YC) calculated study quality scores as defined in the Data Extraction subsection under the Methods section. There were 9 low-quality studies on 7 systems (Sys6, Sys13, Sys14, Sys20, Sys21, Sys28, and Sys36), 8 medium-quality studies on 8 systems (Sys2, Sys3, Sys4, Sys9, Sys16, Sys20, Sys25, and Sys29), and 14 high-quality studies on 8 systems (Sys6, Sys7, Sys10, Sys17, Sys20, Sys30, Sys33, and Sys48). Detailed scores are shown in Table 2.

XSL•FO
RenderX

Table 2. Quality of studies with respect to how reliable they are in assessing accuracy (3-5 indicates low quality, 6-7 indicates moderate quality, and 8-9 indicates high quality).

System number	Name of the gamified interactive system	Reference	Reference standard	Relevance of controls	Sample size	Quality of studies

What Diagnostic Performances Are Reported?

In total, 19 studies comprising 14 different systems reported accuracy. The diagnostic performances are summarized in Table 3. The performance of GISs in assessing MCI shows promising results, with sensitivity ranging from 70.7% to 100%. This is comparable to MoCA, which has a sensitivity of 90% and is significantly better than the MMSE, which has a much lower

XSL•FO
RenderX

sensitivity of 18% [20]. The specificity ranges from 56.5% to 100%. The best-performed GISs were also comparable with MMSE (94.7%) [131] and MoCA (87%) [132]. The AUC of the included GISs ranged from 0.774 to 1, which is also comparable with MMSE (78%) [43] and MoCA (83.3%) [43]. The following paragraphs discuss studies that demonstrated performance exceeding that of the MoCA and MMSE.

Among all 14 systems, the GISs with the best performance (Sys3) [54] demonstrated a sensitivity of 100%, a specificity of 100%, and an AUC of 1 in the task of classifying 2 groups (healthy older adults versus older adults with MCI or AD). However, the study was a single-center, nonblinded, cross-sectional study and had 6 healthy older adults and 6 older adults with MCI or early AD, 12 participants in total. Participants were recruited from 1 hospital.

The best-performing model for Panoramix (Sys20) [89] was the random forest. It achieved a sensitivity of 100%, a specificity of 70%, and an AUC of 0.98 for the task of classifying MCI among 3 groups (healthy older adults, older adults with MCI, and older adults with AD). The study included 64 participants: 28 healthy older adults, 16 older adults with MCI, and 20 older adults with AD. The newer version, Panoramix (version 2.0; Sys20) [91], also demonstrated a sensitivity of 100% and a specificity of 100% for the same task in a sample size of 30 participants, containing 10 healthy older adults, 10 older adults with MCI, and 10 older adults with AD. Notably, both Panoramix studies were single-center, nonblinded, cross-sectional studies. Participants were recruited from 1 association.

The study on Smart Aging (Sys6) [63] achieved an AUC of 0.986 (95% CI 0.962-1.000; $P<.001$) in distinguishing healthy older adults from those with cognitive impairment. The study was a single-center, nonblinded, cross-sectional investigation involving 91 participants: 23 older adults with amnestic MCI, 20 older adults with Parkinson disease–related MCI, and 25 older adults with AD.

The study on Holey Moley (Sys28) [101] had a sensitivity of 100%, a specificity of 97.2%, and an AUC of 0.953 in classifying cognitively healthy older adults and those with cognitive impairment. The study was a nonblinded, cross-sectional investigation involving 47 participants recruited from a single neurology clinic. Cognitive impairment was identified using the MMSE as the reference standard. However, the study did not report the specific cutoff score used or distinguish between MCI and AD. It only stated that 12 out of 47 participants were classified as cognitively impaired.

In total, 2 studies were conducted on COGNIPLAT (Sys36) [113,114]. Both studies were single-center, nonblinded, cross-sectional studies. The reference standard for cognitive impairment was MoCA, corrected by education level. In 1 study [113], researchers collected 119 game sessions from 10 participants. The best-performing model was a support vector machine with 9 variables from the game as input. The model had a sensitivity of 91.8% and a specificity of 93.2%. In the other study [114], researchers collected 119 game sessions from 10 participants. The best-performing model was the multilayer perceptron, with a sensitivity of 96.6% and a specificity of 90%. The model training variables included demographic data (eg, age and education) and game data (eg, game time and points).

Discussion

Principal Findings

We identified 49 GISs for assessing MCI in this scoping review, mostly casual games and simulations, that support engagement through simple game mechanics or familiarity with daily tasks, such as shopping. We further identified that GISs mainly targeted cognitive functions, such as memory, attention, and executive function, but often lacked depth in language and orientation assessment. Finally, we found that only 14 systems reported diagnostic performance, with other studies remaining in early design stages or offering limited correlation studies. Moreover, although several GISs reported strong diagnostic performances, many of these studies (9/31, 29%) were limited by small samples, methodological flaws, and overfitting risks. In the following sections, we revisit our 3 RQs in more depth.

XSL•FO
RenderX

RQ1: What Are the Different Game Types (Genres and Interaction Paradigms) of GISs Used to Assess MCI?

We found that most GISs (30/49, 61%) consist of casual games with clear rules and straightforward gameplay, making them accessible and easy to play without requiring extensive learning or specialized technology. This simplicity may encourage older adults to engage with these systems, addressing the challenge that older adults generally have a lower game participation rate than other age groups [133]. We also noted the popularity of simulations (17/49, 35%). These offer a unique opportunity to represent and assess daily activities in a more controlled environment, providing valuable supportive data with higher ecological validity for evaluating MCI. In particular, shopping experiences are commonly integrated into many simulation game systems (7/49, 14%). The shopping experience is indeed a significant daily activity that requires short-term memory to memorize the shopping list, executive functions to recognize items, and spatial orientation to find them. Only a few systems (4/49, 8%) use full-body movement interaction paradigms to assess MCI. These include exergames and Kinect-based quiz games. Finally, only a few systems (3/49, 6%) were developed with dedicated hardware for the assessment of MCI, representing an extension of traditional GISs design.

In addition, we identified shared characteristics among the games examined in this study. All the GISs included in this research were noncompetitive and offered a single-player mode. Each gaming session was relatively brief, lasting around 15 minutes, and designed to be easy to understand. These observations align with the preference of older adults for puzzles and intellectually stimulating games [134]. Nevertheless, we like to emphasize the ongoing debate regarding whether merely simulation experiences can genuinely be considered games [135]. When daily activities are simulated without a well-integrated game design, it may lead to a lackluster gaming experience [136,137]. Furthermore, the gaming experience of casual games may not provide *meaningful* play for all older audiences. As articulated in the *gerontoludic manifesto* [138], game and mental health researchers may want to put more effort into understanding what differentiates older players rather than considering them as united in their age-related impairments.

Although we categorized gamified systems into *casual*, *simulation*, *full-body movement*, or *dedicated interactive* games for descriptive purposes, it is important to note that these genre distinctions are blurry in practice. Many games combine features from multiple genres, and genre labels do not necessarily reflect the specific cognitive demands or mechanisms embedded within gameplay. In addition, most studies did not describe game mechanics in sufficient detail to allow for systematic mapping to targeted cognitive functions. This limits the extent to which we can draw mechanistic conclusions about genre-specific diagnostic performance.

RQ2: Which Cognitive Functions Are Assessed by GISs?

The scoping review revealed that a diverse range of cognitive functions were assessed by GISs, including short-term memory (28/49, 57% GISs), visuospatial skills (20/49, 41% GISs), executive functions (23/49, 47% GISs), and attention and working memory (25/49, 51% GISs). However, a significant gap exists in evaluating language abilities (10/49, 20% GISs) and orientation to time and space (7/49, 14% GISs).

Moreover, the GISs reviewed in this study vary in how comprehensively they address the 6 cognitive domains evaluated by the MoCA (ie, short-term memory, visuospatial abilities, executive functions, attention, language, and orientation). For example, some simulation games incorporate daily tasks such as shopping, cooking, or wayfinding that naturally engage multiple domains, particularly short-term memory, executive functions, and visuospatial abilities. In contrast, casual games more often target specific domains, such as attention or working memory, through task-focused mechanics such as matching, sequencing, or quick-response challenges. Full-body movement games and dedicated interactive systems were fewer in number, and their alignment with MoCA domains varied by design, with some addressing attention or memory through physical interaction.

It is important to note that many GISs incorporate features from multiple game types, and genre labels do not consistently reflect the underlying cognitive functions. In addition, we could not draw definitive conclusions about the relative diagnostic effectiveness of different game types due to heterogeneity in the reporting of GISs designs. A better understanding of how specific game elements engage specific cognitive functions can guide future design and evaluation efforts. Hence, a more granular analysis of game mechanics in relation to targeted cognitive functions—beyond genre—would strengthen future investigations.

In particular, GISs could extend the duration of their assessment. The engaging nature of GISs can potentially encourage older adults to use the system for extended periods, creating opportunities to collect data over a longer time, in a manner that might not be feasible through traditional assessment tools. Thus, GISs could play a valuable role in evaluating long-term cognitive functions by tracking subtle changes over time, providing extra information that current screening instruments, such as MMSE and MoCA, are not designed to capture. Despite this potential, no existing system was identified in this review that specifically targets long-term MCI evaluation. Hence, future studies should prioritize the development and validation of GISs that leverage game mechanics to promote repeated use and sustained engagement, while also exploring how these systems can complement traditional diagnostic methods.

RQ3: How Are GISs Evaluated (eg, Longitudinal or Cross-Sectional), and How Reliable Are These Studies in Reporting Diagnostic Performance?

Out of a total of 49 GISs, 29 (59%) remain in the system design stage or present a preliminary user study. Hence, these GISs lack evidence of accuracy. Moreover, many studies (6/49, 12%) conducted on GIS were limited to correlating system metrics with traditional screening instruments, reducing their scientific rigor. In total, only 29% (14/49) of the GISs reported clinical validation to classify patients with MCI or intraperson comparisons.

XSL•FO
RenderX

The quality scores presented in Table 2 highlight notable variations in the methodological rigor of studies evaluating GISs for MCI assessment. While some studies used well-defined reference standards, relatively larger sample sizes, and appropriate validation strategies, others lacked clarity in participant selection or relied on less robust evaluation methods. This variability should be considered when interpreting reported diagnostic performance; higher-quality studies are more likely to yield reliable and generalizable findings, yet the results may be more nuanced. For researchers and clinicians, these scores offer a practical reference point for assessing the strength of evidence and identifying areas where future studies can improve in terms of design transparency and reporting consistency.

While clinical validation studies indicate that GISs may be a useful tool for assessing MCI, in particular, the risk of model overfitting and methodological bias remains a critical concern. For example, the virtual action planning supermarket model achieved an extraordinary F_1-score of 1.0 across 4 machine learning algorithms: decision trees, random forests, adaptive boosting, and extreme gradient boosting. Such a result must be interpreted with extreme caution. The study included only 12 participants and used data enhancement techniques, yet identified 45 out of 46 features as significant—without any dimensionality reduction. Such a high feature-to-sample ratio introduces a substantial risk of overfitting, undermining the robustness of the findings.

More broadly, studies reporting near-perfect performance (eg, 1.0 accuracy or F_1-score) are likely reflecting limitations in sample size, study design, or evaluation procedures rather than actual diagnostic capability. To prevent misinterpretation, especially by third-party stakeholders, it is essential to frame such results as preliminary and methodologically constrained results. These findings should not be taken as evidence of clinical readiness**.**

A robust study design is crucial for the clinical validation of GISs. First, the use of age-matched control groups is essential to minimize confounding variables. A key limitation in interpreting the performance of GISs-based cognitive assessments is the potential confounding effect of previous gaming experience or digital proficiency. Younger participants may outperform older adults not solely due to better cognitive functioning but also because of greater familiarity with digital devices and interaction patterns common in games. Only a few of the reviewed studies (4/31, 13%) assessed or controlled for previous gaming experience, making it difficult to disentangle cognitive performance from gameplay proficiency, as shown in the results for RQ3. This issue is further supported by recent findings from the study by Murata et al [139], which demonstrate that peripheral metrics such as swipe speed—independent of game content—can predict cognitive impairment. Future research should consider including baseline assessments of digital literacy or gaming familiarity and explore interface designs that minimize performance biases related to device handling rather than cognitive ability. In addition, previous research has highlighted sex-related differences in the risk, progression, and presentation of MCI [140,141]; most of the included studies (30/31, 97%) did not report results disaggregated by sex or analyze potential sex-based differences in diagnostic performance. As such, our review was unable to assess how sex may influence the effectiveness or generalizability of GISs for MCI assessment. The lack of such analyses represents a critical gap in the literature. Future research should explicitly report and analyze sex-disaggregated data to ensure that these systems are equitably designed and validated across diverse populations. Nevertheless, it is encouraging to see the inclusion of diverse groups, such as participants with AD, as MCI is regarded as a transitional phase between healthy aging and AD.

Second, comprehensive cognitive assessments should be administered to all participants, with those diagnosed with MCI specifically evaluated by health care professionals to ensure diagnostic precision. Solely relying on screening instruments for labeling MCI is inadequate and may overlook the complexity of cognitive decline.

Furthermore, most existing studies involve small, single-center cohorts, which limits generalizability. In addition, all the studies in the review used retrospective case-control designs, which can overestimate diagnostic performance by comparing well-defined cases and controls in artificial conditions. This introduces a high risk of bias and limits applicability in real-world diagnostic contexts. Future research would benefit from adopting larger, blinded, and multicenter studies—ideally through prospective diagnostic cohort designs—to strengthen the evidence base and enhance the clinical relevance of GISs.

Longitudinal studies, in particular, could facilitate a deeper understanding of long-term memory and its association with other cognitive functions, broadening the scope of cognitive domains assessed through GISs. By leveraging the engaging nature of gamified systems, researchers can explore how sustained interactions might reveal patterns or markers indicative of MCI progression or even early-stage cognitive decline. Future research could focus on designing and implementing longitudinal studies that incorporate diverse user populations, validate their findings against established clinical benchmarks, and investigate the potential of GISs to serve as an early warning system for cognitive decline. However, longitudinal studies present several challenges, such as participant retention, data standardization, and the ethical implications of prolonged data collection. Addressing these will be essential to maximize the utility and reliability of GISs in clinical practice.

Limitations

This review has several limitations. First, we did not expand our search beyond the initially included articles, which may have resulted in the exclusion of relevant studies related to specific GISs. For instance, in some cases, we only captured validation studies, while related user studies could not be identified from our database search. Second, our understanding of games within GISs was primarily derived from text descriptions and screenshots in the articles, without any direct interaction with the systems themselves. Consequently, the findings from RQ1 and RQ2 rely on the authors' interpretations rather than firsthand experiences. This reliance on secondary information may restrict the accuracy and completeness of our descriptions of GISs. The community has also noted the

XSL•FO
RenderX

challenges in articulating artifacts in experimental game research, and efforts are currently underway to refine standards [142].

Conclusions

GISs hold considerable potential to enhance the diagnostic process for MCI by capturing high-frequency, rich, and ecologically valid data, offering new insights beyond traditional screening instruments and test batteries. This rich data collection could provide health care professionals with a complementary perspective for diagnosis, enabling a more dynamic understanding of cognitive changes over time. To this end, this paper presents a scoping review of GISs used for assessing MCI. In total, 49 GISs were identified from 81 published articles and categorized into 4 types: casual games, simulation games, full-body movement games, and dedicated interactive games. We also examined the cognitive functions targeted and the accompanying diagnostic performance validation studies. Findings indicate a broad spectrum of GISs available for evaluating MCI with a wide range of cognitive functions. In addition, we identified several GISs reporting diagnostic performances comparable to screening instruments such as MMSE and MoCA—including a few studies (6/31, 19%) with near-perfect results. However, these findings should be interpreted with caution, as they often stem from studies with small sample sizes and limited methodological rigor. The analysis also identified limitations in the GISs validation; only 2 systems included in this review conducted intraperson comparison studies, and no rigorous longitudinal study was identified. This gap represents a missed opportunity to investigate the full potential of GISs in assessing MCI progression. Such studies could provide critical insights into how gameplay proficiency, learning effects, and adaptation to game mechanics influence the evaluation of cognitive functions, thereby enhancing the interpretability and accuracy of these GISs. Overall, this review underscores the significant potential of GISs in assessing MCI, while highlighting the need for continued research to yield more conclusive results across various facets of these interactive systems.

Abstract

Background: Low- and middle-income countries (LMICs), which bear a larger proportion of the global mental illness burden, have been disproportionately impacted by the COVID-19 pandemic due to preexisting mental health care system deficiencies. The pandemic has also led to a considerable increase in care delivered through digital mental health interventions (DMHIs), many of which have been adapted from in-person formats. Thus, there is a need to examine their fidelity to the original format along with issues regarding usability and other challenges to and facilitators of their uptake in LMICs. As most DMHIs have been developed in high-income countries, examining their cultural adaptation to LMIC settings is also critical.

Objective: The purpose of this research was to conduct a rapid scoping review of the available evidence on DMHIs for depression and anxiety, two of the most common mental disorders, in LMICs.

Methods: A rapid scoping review was conducted following the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) and processes for rapid reviews by Tricco et al. The PubMed and PsycINFO databases were searched for records published between January 2020 (when COVID-19 was declared a public health emergency) and January 2025 using a search strategy developed in consultation with a liaison librarian. The pandemic accelerated the development and application of DMHIs, and this time frame was used to capture the recent literature that may have incorporated new methods of application. The search strategy was developed across three domains: (1) digital health interventions, (2) depression or anxiety, and (3) LMICs. Data were charted from the final records according to (1) intervention type; (2) discussions on fidelity, usability, and cultural adaptation; and (3) challenges to and facilitators of their uptake in LMICs.

Results: A total of 80 records were included in the final analysis, with reasons for exclusion (eg, focused on mental health in general, not being a DMHI, or not focused on LMICs) reported. Six DMHI platforms were identified: (1) mobile app, (2) the web, (3) virtual reality, (4) videoconferencing, (5) telemedicine, and (6) social media. Less than half of the records referenced fidelity (16/80, 20%), usability (29/80, 36%), and cultural adaptation (31/80, 39%). Challenges pertained to the technological system, engagement issues, structural barriers, and concerns regarding privacy and confidentiality. Facilitators included widespread mobile phone use, built-in supervision and training features, and convenience.

Conclusions: Despite the opportunities that DMHIs offer for reducing the mental health treatment gap, further work examining and improving their fidelity, usability, and cultural adaptation is required. In addition, various challenges to the uptake of DMHIs in LMICs, including contextual issues, structural barriers, and privacy concerns, must be mitigated to avoid contributing further to the digital divide.

Introduction

Background

Mental illnesses are a leading contributor to the global burden of disease [1]. The COVID-19 pandemic has contributed to further deteriorations in population mental health and exposed critical and persisting gaps in mental health care [2,3]. The Global Burden of Disease 2020 study estimated that the COVID-19 pandemic has led to increases of 28% in major depressive disorders and 26% in anxiety disorders [4], 2 of the most common mental disorders [5]. Depression and anxiety disorders are associated with profound disease and socioeconomic burden to individuals and their relatives [6]. Low- and middle-income countries (LMICs; countries with a gross national income per capita of ≤US $14,005 [7]), which bear a larger proportion of the global mental illness burden [8], have been disproportionately impacted due to preexisting mental health care system deficiencies [8,9]. Increased mental health issues have, in turn, placed additional substantial pressures on strained mental health care systems [2]. This is particularly concerning in LMICs, where 75% of people lacked access to mental health care before the COVID-19 pandemic [10]. Persistent and growing barriers to treatment in LMICs include low mental health awareness, stigma that impacts help seeking, a shortage and maldistribution of mental health specialists, and care that is concentrated in specialized and tertiary settings with little to nonexisting care at the community level [11,12].

Worldwide, the pandemic has also impacted the delivery of mental health care, leading to a considerable increase in care delivered through digital health interventions to address the widespread reduction of in-person care imposed by public health constraints. These include interventions delivered via telephone, videoconferencing, messaging, web-based programs, and smartphone or other mobile device apps [13], collectively referred to herein as digital mental health interventions (DMHIs). Many of these DMHIs target depression or anxiety. For example, there has been a considerable increase in smartphone apps since the onset of COVID-19. Estimates indicate that >10,000 mental health–related apps are available [14], with most focused on depression and anxiety [6,15]. Digital interventions for depression and anxiety can help with health promotion and literacy at the population level, prevention by targeting high-risk individuals or subpopulations, and treatment and preventive services for people with mental health conditions [16].

Active components of these DMHIs are often based on evidence-based psychological interventions developed for in-person delivery [17]. While it is critical that the interventions are implemented with high fidelity, there is limited evidence on which considerations are most relevant and what should be included in guidance for fidelity of digital adaptations from evidence-based in-person formats. There is a need to evaluate if and how the theoretical and technical components are applied in the new modus or can be enhanced by drawing on the unique interactive features of a digital format (eg, videos and animations) [18]. There has also been limited attention paid to methods for adaptation and evaluations of adaptations across contexts to ensure cultural appropriateness for relevance; applicability; and, ultimately, effectiveness [19-21], particularly for the adaptation of digital interventions [22]. Cultural adaptation can be defined as “the process of systematically modifying an evidence-based intervention to be congruent with the language, values, beliefs, and context corresponding to clients’ cultural backgrounds” [23].

While DMHIs have been used for 2 decades, their development and uptake has been greatly accelerated by the COVID-19 pandemic and hold promise as a feasible way to address the growing mental health needs of populations amidst the persistent and growing mental health treatment gap [12]. This might have been a “black swan” moment as described by Wind et al [24], acting as a catalyst in the marked shift from in-person mental health care provision to digital health. Challenges that have slowed their implementation into routine care include a lack of acceptance by mental health professionals, who may be concerned about threats to the therapeutic alliance, which they believe can only be established in person [25,26]. Other challenges include digital and language literacy [27]; data privacy and security concerns [28], especially as LMICs have seen an increasing number of cyberattacks [29]; and structural issues such as underdeveloped technological infrastructure [12]. There is a need to ensure that all those who need digital mental health care, especially the traditionally underserved groups such as those who live in rural and remote areas, with low income, and from culturally diverse communities, have the digital literacy and opportunity to engage with DMHIs to reduce the digital divide [2]. Another key concern for implementation is usability, the extent to which a product can be used easily, efficiently, and with satisfaction to achieve specified goals [30]. Usability has been identified as a prerequisite for the success of mobile apps [31]. Conversely, poor usability is a primary reason for low user engagement, limiting clinical utility and resulting in the failed adoption of DMHIs [32,33].

Rationale and Objectives of This Review

Active components of these DMHIs are often adapted from in-person formats [17], most commonly developed and tested in high-income countries [12]. Despite this, there is a paucity of evidence on their fidelity to the original format and limited examination of the cultural adaptation process. Furthermore, although there has been increasing research on DMHIs from LMICs [34,35], where >85% of the global population lives [36], most DMHIs have been developed and studied in high-income countries [12,37], leading to potential biases and limiting generalizability. Knowledge gathered from LMICs will be critical for these countries. Thus, the purpose of this research was to conduct a rapid scoping review of the available evidence on digital health interventions for depression and anxiety, the 2 most common mental disorders, in LMICs.

XSL•FO
RenderX

The specific objectives of this rapid scoping review were to: (1) identify the types of digital health interventions for depression and anxiety being used and studied in LMICs; (2) explore their fidelity, usability, and cultural adaptation to a digital format in LMICs; and (3) examine the challenges to and facilitators of their uptake in LMICs.

This rapid scoping review contributes important evidence on the growing adaptation, use of, and challenges to DMHI applications for mental health in the context of the constantly changing landscape of the COVID-19 pandemic and beyond. While some scoping reviews have focused on digital health interventions for mental health in general [38-40] and others have incorporated a focus on LMICs [11], to our knowledge, this is the first review that focuses on digital health interventions in LMICs specifically for depression and anxiety and includes an in-depth review of their fidelity, usability, and cultural adaptation.

Methods

Data Sources and Search Strategy

Considering the need for a timely review, a rapid scoping review was conducted, and a protocol was not registered. We used the following definition of a rapid scoping review as proposed by Tricco et al [41]: "a type of knowledge synthesis in which components of the systematic review process are simplified or omitted to produce information in a short period of time." Furthermore, scoping reviews seek to provide a broad mapping overview of the extent, range, and nature of the existing evidence base, focusing on breadth regardless of quality [42-44]. For these reasons, appraisal of the methodological quality of the individual studies was not conducted. This rapid scoping review was conducted following the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) and using a search strategy developed in consultation with a liaison librarian at Simon Fraser University. Processes for rapid reviews as outlined by Tricco et al [45] were followed.

Two databases were searched (PubMed and PsycINFO) following common search methodologies for rapid reviews, which advise the search of at least one electronic database (PRISMA [Preferred Reporting Items for Systematic Reviews and Meta-Analyses] standards [46]), with most published rapid reviews using ≥2 [45]. The PubMed and PsycINFO databases were searched for records published between January 2020, when COVID-19 was declared a public health emergency of international concern by the World Health Organization (WHO; declared a pandemic on March 11, 2020), and January 2025. The COVID-19 pandemic accelerated the development of DMHIs, and a rapid review within this time frame was conducted to capture the recent literature that may have incorporated new methods of development and application.

The search strategy was developed across the following three domains: (1) digital health interventions, (2) depression or anxiety, and (3) LMICs. While we were interested in articles related to the COVID-19 pandemic, we made the decision not to include COVID-19 as a search domain as we were interested not only in DMHIs developed to respond specifically to COVID-19–related anxiety and depression but also in DMHIs developed for anxiety and depression in general during the search time frame. Instead, the search included the aforementioned 3 domains and the time frame of the COVID-19 pandemic (2020-2025). A combination of search terms was applied for the automatic search of publications in the aforementioned databases: ("digital" OR "technology" OR "e-health" OR "telemedicine" OR "internet" OR "online") AND ("depress*" OR "anxi*" OR "mood disorders" OR "anxiety disorders") AND ("low and middle income countries" OR "developing countries"). Searches included both subject headings and keywords. Search terms for LMICs were taken from the University of Alberta's Health Sciences Search Filters resource [47]. Multimedia Appendix 1 provides the full search strategy for PubMed, and Multimedia Appendix 2 provides the full search strategy for PsycINFO.

Screening Strategy and Inclusion and Exclusion Criteria

Records identified in the database search process were screened using titles and abstracts by one researcher (the first author, LWC). Records were selected for full-text review if they: (1) reported on quantitative or qualitative evidence related to DMHIs for depression and anxiety; (2) were from LMICs; (3) were written in the English language; (4) were published between January 1, 2020, and January 31, 2025; and (5) had the full text available. In addition to original research articles, other types of articles (eg, protocol papers and scoping and systematic reviews) were included if they provided information on DMHIs being used in LMICs and included depression or anxiety as a primary focus. We included all articles on depression and anxiety regardless of other conditions or specific patient groups (eg, pregnancy or cancer) as long as the primary outcome included either depression or anxiety.

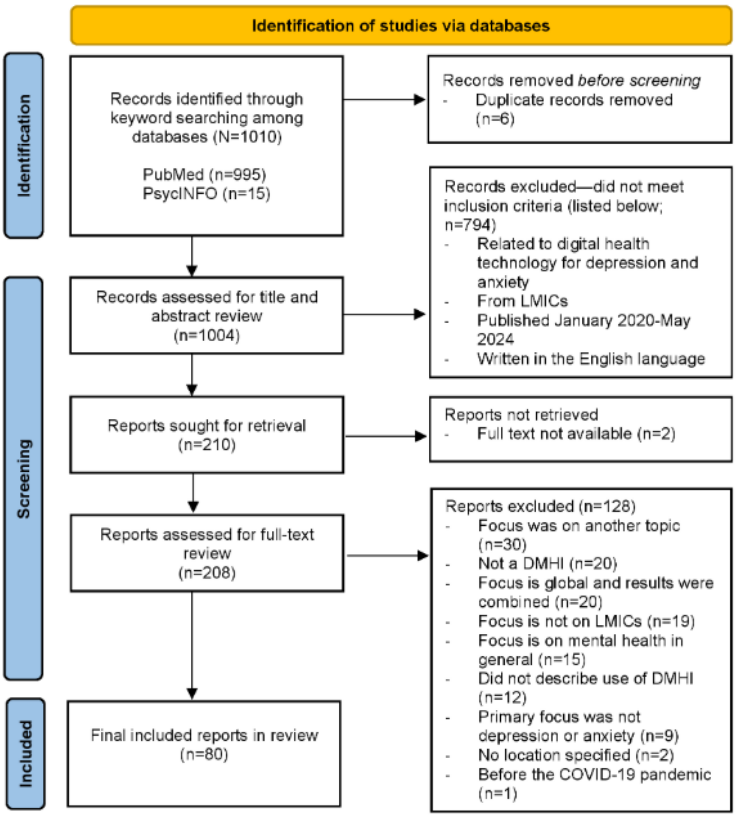
We excluded articles that did not include depression or anxiety as a primary focus. Any articles that presented data from multiple countries (eg, literature reviews) were included if data from LMICs and non-LMICs were disaggregated and reported separately; in these instances, only data related to LMICs were reported in this review. Duplicates were removed across the 2 databases. Records included for full-text review were cross-checked for relevance and inclusion by an additional researcher (senior author JO).

Data Extraction and Synthesis

Data were extracted from the records that were eligible through full-text review and charted into 2 tables according to the following headings: author, year of publication, participant characteristics (study location and study population), intervention characteristics (platform and techniques and functions), and study characteristics (design, mental health conditions, and outcomes) in the first table and discussions on fidelity (either in relation to the original in-person or paper-based format or ensuring adherence by lay health workers to the intervention protocol), usability (both quantitative and qualitative explorations), cultural adaptation (of DMHIs to the local cultural context), and challenges to and facilitators of the interventions' uptake in LMICs in the second table. Findings

XSL•FO
RenderX

across the discussions are presented using numerical counts accompanied by descriptive text. See Multimedia Appendix 3 for the PRISMA-ScR checklist.



Results

Article Selection

The searches of PubMed and PsycINFO were conducted on March 13, 2025. Figure 1 shows the PRISMA flowchart for the full record selection process. A total of 1010 records were returned, and after the removal of 6 (0.59%) duplicates, 1004 (99.41%) were included for screening. After performing a title and abstract review, 20.92% (210/1004) of the articles were included for full-text review based on our inclusion criteria. A total of 79.08% (794/1004) of the articles, which did not meet the inclusion criteria, were excluded from full-text review. Of the 210 articles included for full-text review, 2 (1%) were not retrieved as the full text was not available.

After completing the full-text review of the 208 available articles, a total of 80 (38.5%) records were included in the final analysis. This included 80% (64/80) original research articles, 15% (12/80) protocol papers, and 5% (4/80) literature reviews (1/4, 25% scoping reviews [48] and 3/4, 75% systematic reviews [49-51]). Reasons for exclusion of articles at full-text review that did not meet the inclusion criteria (128/280, 45.7%) were recorded and reported in Multimedia Appendix 4. The most common reasons for exclusion were focus on another topic (eg, app use in general), lack of a DMHI (eg, therapists using video or telephone to deliver regular counseling without an accompanying app or online platform), results from reviews (global focused) combined without data from LMICs being reported separately, focus on mental health in general, and no description of the use of a DMHI. A quality appraisal was not conducted considering the nature of this rapid scoping review, which did not focus on an examination of the effectiveness of the DMHIs, along with the emergent nature of the literature. The examinations of fidelity and usability were reviewed and described independent of whether there was an exploration of intervention effectiveness and, if there was, whether the intervention was effective.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart for this rapid scoping review. DMHI: digital mental health intervention; LMIC: low- and middle-income country.

Study Characteristics

Table 1 presents the main characteristics of the studies included in the rapid scoping review. Six main DMHI platforms were identified: (1) mobile app (software app used on a mobile device such as a smartphone or tablet), (2) web-based program (intervention delivered on the web through an internet-connected device), (3) virtual reality (VR; involved the immersion of the user in simulated and controlled computer environments [52]), (4) videoconferencing (intervention delivered via video through an online platform; eg, Google Meet and Zoom), (5) telemedicine (intervention delivered via phone calls or text through an instant messaging app [eg, WhatsApp] that went beyond the usual psychoeducation delivered by therapists by incorporating additional components such as educational videos and relaxation music), and (6) social media–based interventions (delivered through a social media platform; eg, Facebook).

Table 1. Summary of the included articles (participant characteristics, intervention characteristics, and study characteristics).

Study	Participant characteristics		Intervention characteristics		Study characteristics	
	Location	Population	Platform	Techniques and functions	Design	Mental health condition, with results where applicable
Aalaei et al [53], 2021	Iran	Hospitalized patients who tested positive for COVID-19 at Imam Reza Hospital in Mashhad (N=112)	Mobile phone app	Mobile-based psychological counseling and health status monitoring	Protocol RCT[a]—2 parallel groups	Depression and anxiety
Abbasalizadeh et al [54], 2024	Iran	ICU[b] nurses from 2 Tehran hospitals (N=60)	Android smartphone app	Resilience training developed based on the microlearning educational method	RCT—single blinded	Anxiety and stress; significant reductions in stress from 10.77 on DASS-21[c] (SD 3.33) to 9.00 (SD 1.66; *P*=.001) and in anxiety from 9.43 on DASS-21[s] (SD 3.35) to 7.93 (SD 0.98; *P*<.001)
Abi Ramia et al [55], 2023	Lebanon	Participants from 2 previous RCTs that demonstrated effectiveness of the intervention, staff members, and external stakeholders	Digital intervention (SbS[d]) delivered through an app or website	Guided self-help intervention	Qualitative study involving key informant interviews	Depression; high level of acceptability of SbS among Lebanese and Syrian participants
Akbari et al [56], 2022	Iran	Home-isolated patients with COVID-19 visiting Sina Hospital, Hamadan (N=60)	WhatsApp messages and instructional videos	Virtual training of relaxation techniques via WhatsApp messages and instructional videos in the form of 8 educational messages, delivered online	RCT—2 group, parallel	Anxiety; relaxation techniques were effective in reducing anxiety among patients with COVID-19
Akhtar et al [57], 2024	Pakistan	Community health workers (LHWs[e]; N=44)	Mobile app (mPareshan)	3 segments: tracking, counseling, and referral; LHWs facilitated psychoeducation through audio and video features	Qualitative study involving focus groups and interviews	Depression
Alavi and Hirji [58], 2020	Iran	General population with a Generalized Anxiety Disorder diagnosis from a psychiatrist (N=152)	Computer-based intervention delivered via email	Weekly (×12) e-CBT[f] intervention modules and homework assignments delivered via email, with structured support from trained clinicians	RCT	Anxiety (generalized); a mixed model ANOVA showed a significant difference between the groups and BAI[g] evaluation periods ($F_{3,57}$=101.5, *P*<.001).
Al-Badiri et al [59], 2024	Iraq	Registered nurses at Al-Alhamzeh General Hospital (N=72)	iMBSR[h]	Guided mindfulness exercises, reflective discussions, and educational materials delivered over 8 sessions	Semiexperiment with a pretest-posttest design	Depression; a nonsignificant decrease in PHQ-15[i] mean scores in the iMBSR group from 9.19 (SD 3.07) to 7.58 (SD 3.61; *P*=.17)
Alishahi et al [60], 2025	Iran	Patients undergoing hemodialysis at Montaserieh Hospital (N=72)	Mobile app	Recreational therapy mobile app comprising programs such as music, comedy movies, exercise routines, and educational question-and-answer games	RCT	Depression; the intervention group showed a significant decrease in depression scores compared to the control group (mean BDI-II[j] score reduction in the intervention group 10.3, SD 4.1; mean score reduction in the control group 4.6, SD 3.8; *P*<.001)

Study	Participant characteristics		Intervention characteristics		Study characteristics	
	Location	Population	Platform	Techniques and functions	Design	Mental health condition, with results where applicable
Amer et al [61], 2023	Egypt	Adults aged ≥18 y from Mansoura University's Faculty of Computers and Information (N=5)	Mobile app (Sokoon)	Gamified CBT app focused on 7 intervention skills: relaxation, gratitude, self-compassion, problem-solving, social skills, BA[k], and cognitive restructuring	Pilot study	Depression and anxiety; anxiety symptoms decreased from the pretest (mean GAD-7[l] score of 10, SD 0.7) to the posttest (mean 4.2, SD 1.5), and depressive symptoms decreased from a mean PHQ-9[m] score of 10 (SD 2.05) to a mean of 6 (SD 1.7)
Amer et al [62], 2024	Egypt	Adults aged ≥18 y from Mansoura University's Faculty of Computers and Information (N=30)	Mobile app (Sokoon)	CBT app that incorporated techniques such as Hexad theory, gamification, and dynamic difficulty adjustment	Single-group pretest-posttest design	Depression and anxiety; positive impact on reducing symptoms of depression and anxiety
Araya et al [63], 2021	Brazil	Patients with depressive symptoms with comorbid hypertension or diabetes (n=880 in Brazil; n=432 in Peru)	Smartphone intervention	Low-intensity smartphone intervention delivered through 18 sessions over 6 wk; based on BA and supported by nurse assistants	2 RCTs; 1 cluster randomized in Brazil and 1 individual-level randomized in Peru	Depression; significantly improved depression symptoms at 3 mo; effect size small in Brazil, and effects were not sustained at 6 mo
Atif et al [64], 2022	Pakistan	Women living in resource-poor rural communities (n=3) and peer delivery agents (n=3)	Tablet- or smartphone-based app (Thinking Healthy Programme)	CBT intervention delivered by a virtual avatar therapist that was operated by a lay peer; the peer and the avatar acted as cotherapists	Usability testing study	Depression (perinatal)
Bhardwaj et al [65], 2025	India	Family caregivers of persons living with dementia	Mobile app	CBT-based psychoeducational intervention developed based on the WHO[n] iSupport program delivered in 10 weekly sessions; ASHAs[o] will be trained to deliver the intervention	Protocol community-based cluster RCT	Depression
Bhargav et al [66], 2024	India	Individuals with a COVID-19 positive test from an NABL[p]-approved laboratory who also reported at least a moderate level of stress (a score of ≥14 on the PSS[q]; N=86)	Tele-yoga	Tele-yoga intervention delivered via videoconference supervised by trained yoga therapists	Prospective, multicenter, open-label single-arm study	Depression and anxiety; anxiety improved significantly at wk 4, and the improvements were sustained at wk 16
Bhat et al [67], 2023	India	Women in self-help groups	Tablet app (MITHRA[r])	MITHRA for depression screening (PHQ-9[m] and brief intervention [HAP[s] modules])	Protocol—focus groups	Depression
van Heerden et al [68], 2021	Nepal	Lay counselors caring for adolescent mothers with depression	Platform (StandStrong) comprising the StandStrong counselor mobile app and a cloud-based processing system	App visualized passively collected GPS, proximity, and activity data; lay counselors used the app to discuss mothers' behavioral patterns and clinical progress over the 5-wk intervention	App development paper	Depression (maternal)

Chand et al [69], 2024	India	Individuals from the Indian Institute of Technology Mandi (N=44)	VR[t]—music	Raga Bhairavi, an Indian classical music, administered via 360° video in a VR environment for 6 d (each session lasting 15 min)	RCT—between-group repeated measures	Depression and anxiety; all DASS-21 subscales significantly improved; a post hoc test showed that the anxiety and depression levels were significantly lower for the treatment group after 6 d of treatment (anxiety: t_{21}=5.77, *P*<.001, and Cohen *dz*=1.04; depression: t_{21}=5.16, *P*<.001, and Cohen *dz*=1.16)
Chau et al [70], 2023	Vietnam	Adults aged ≥18 y in community-based settings	Smartphone app (Vmood)	Supported self-management based on CBT principles with supportive coaching from a social worker delivered via chat through an app	Protocol RCT—stepped wedge	Depression and anxiety
Cuijpers et al [71], 2022	Lebanon	People with depression residing in Lebanon (N=680)	Internet-connected device (SbS)	5-session depression intervention; provided psychoeducation and training in BA through an illustrated narrative delivered with guidance from nonspecialist helpers	RCT—single blind, 2 arm, pragmatic	Depression; ITT[u] analyses showed effects on depression (SMD[v] 0.71, 95% CI 0.45-0.97) and impaired functioning (SMD 0.43, 95% CI 0.21-0.65)
Cuijpers et al [72], 2022	Lebanon	Syrian refugees living in Lebanon (N=569)	Internet-connected device (SbS)	5-session depression intervention; provided psychoeducation and training in BA through an illustrated narrative delivered with guidance from nonspecialist helpers	RCT—single blind, 2 arm, pragmatic	Depression; ITT analyses showed significant treatment effects for both primary outcomes, depression (moderate) and functional impairment (moderate), and significant effects on anxiety
Dambi et al [73], 2022	Zimbabwe	General population (N=176)	Digital intervention delivered via web application or mobile app (Inuka)	A chat-based digital application; participants received 6 problem-solving therapy sessions delivered by lay counselors	Feasibility study—pragmatic quasi-experimental design	CMDs[w], including depression and anxiety
Doosti et al [74], 2024	Iran	Patients with gynecological cancer referred to educational and therapeutic centers affiliated with the Shahrekord University of Medical Sciences (N=70)	Mobile app	Main menu featured various options (eg, entering clinical data, receiving weekly patient status reports, and virtual consultations with nurses); users could easily interact with the researcher through a message box icon	RCT—2 group, pretest-posttest	Anxiety; state anxiety scores significantly decreased in the intervention group from 51.64 (SD 14.97) to 40.20 (SD 11.70) at the follow-up, and trait anxiety scores in the intervention group decreased significantly from 49.91 (SD 14.96) to 39.82 (SD 10.28), whereas the scores of the control group worsened
Dosani et al [48], 2020	LMICs[x]	Women	Various	Various	Scoping review	Depression (perinatal); 12 articles met the inclusion criteria; results revealed that minimal literature is currently available on the use of mHealth[y] for perinatal depression in LMICs

Study	Participant characteristics		Intervention characteristics		Study characteristics	
	Location	Population	Platform	Techniques and functions	Design	Mental health condition, with results where applicable
Gupta et al [81], 2022	India	Health care providers from a tertiary care medical center (N=202)	Web based	Two groups: (1) Raja yoga meditation—structured module of Raja yoga for 3 mo taught by a qualified teacher and (2) stress management counseling—dedicated trainer who counseled and taught 7 steps for managing stress for 3 mo	Prospective observational study	Depression and anxiety; practice of Raja yoga meditation for 12 wk resulted in significant decrease in DASS-21 score (−45.00 at baseline and −24.2 at 12 wk; *P*<.001); no significant decrease was observed in the DASS-21 score in the stress management counseling group at 12 wk of follow-up
Iravani et al [82], 2023	Iran	Pregnant women from health centers (N=104)	Telemedicine	Counseling services delivered by a researcher through telephone conversations; SMS text messages; and apps such as WhatsApp, Telegram, and Instagram over a 2-mo period; educational video clips were provided through a mobile app	Quasi-experimental study	Anxiety; health anxiety scores of pregnant women in the control group were significantly higher than those of pregnant women in the experimental group; the mean scores of pregnancy-related anxiety in the control group were significantly higher than those in the intervention group
Jannati et al [83], 2020	Iran	Women aged ≥18 y who attended health care centers in Kerman, Iran (N=75)	Mobile phone app (Happy Mom)	CBT app consisting of 8 lessons conducted over 8 wk; participants followed the story of women with PPD[ab] and learned how they managed their symptoms, which they could apply to their own lives	Nonblinded parallel-group RCT	Depression (post partum); average Edinburgh Postnatal Depression Scale score after the intervention was 8.18 in the intervention group and 15.05 in the control group, which was statistically significantly different (*P*<.001)
Kanuri et al [84], 2020	India	College students	Online intervention (Mana Maali Digital Anxiety Program)	Culturally and digitally adapted evidence-based CBT intervention delivered over 20 sessions for anxiety	Initial usability, acceptability, and feasibility examination	GAD; results indicated high usability, with the average rating ranking in the top 10% of general usability scores
Kim et al [50], 2023	LMICs	General population	Digital mental health tools	Various	Systematic review and meta-analysis	Depression and anxiety; 80 studies included in the meta-analysis and 96 studies included in the systematic review; digital mental health tools were moderately to highly effective in reducing depression and anxiety symptoms in LMICs
Kola et al [85], 2022	Nigeria	Adolescent mothers (n=17) and maternal health care providers with experience in perinatal depression (n=25) who were participants of a previous clinical trial called EXPONATE[ac]	Mobile phone intervention	Design of the EXPONATE intervention, which incorporated the treatment specifications of the WHO mhGAP-IG[ad]; 4 components: parenting skill training, problem-solving, psychoeducation, and use of available social support	Focus groups	Depression (perinatal); focus group discussions showed that 70% of the barriers identified related to the inner setting and the characteristics of individuals in the intervention (eg, clinicians' knowledge deficit on the care of young mothers with depression and young mothers' lack of interest in motherhood)
Kusumadewi et al [86], 2025	Indonesia	Medical students from Gadjah Mada University, Yogyakarta (N=66)	Smartphone app	App using asynchronous digital cognitive education divided into 3 parts, including information, therapy (based on Beckian cognitive therapy), and daily journal sections	RCT—nonblinded	Anxiety; significant effect on reducing anxiety scores from the second to the eighth wk

Study	Participant characteristics		Intervention characteristics		Study characteristics	
	Location	Population	Platform	Techniques and functions	Design	Mental health condition, with results where applicable
Lahti et al [87], 2020	South Africa and Zambia	Higher education institute academics and PHC[ae] practitioners in 3 provinces in South Africa and 2 provinces in Zambia	Mobile app	Screening tool to be used in PHC settings	Protocol; mixed methods multisite design	Depression
Logie et al [88], 2021	Uganda	Urban refugee and displaced youths aged 16-24 y	VR and GPM+[af]	VR-only arm: immersive, interactive 15-min VR session that integrated mental health literacy, psychological first aid, and mindful self-compassion; VR and GPM+ intervention: VR intervention and GPM+, (WHO brief psychological intervention) delivered over 5 group sessions by peer navigators	Protocol; 3-arm cluster RCT	Depression
Luitel et al [89], 2023	Nepal	Primary HCWs[ag] trained in using the WHO mhGAP[ah] mobile app in Jhapa (N=15)	Smartphone app (WHO e-version of the mhGAP)	The WHO launched the e-version of the mhGAP in 2017; 8 modules to address key priority mental health conditions, including depression	Qualitative	Mental health, including depression; HCWs found the app helpful to verify and confirm their assessment and diagnosis
Maharjan et al [90], 2021	Nepal	Adolescent and young mothers with (n=11) and without (n=27) depression	Smartphone app (StandStrong)	Through a (1) smartphone app and (2) Bluetooth beacon, sensing data were passively collected on mothers' geographic movement, physical activity, and audio environment and mother-infant proximity	Feasibility study	Depression
Mazhari et al [91], 2022	Iran	Inpatients with COVID-19 at Afzalipour Hospital (N=200)	Web-based eHealth intervention	A questionnaire administered via WhatsApp; after 2 d, the psychiatric resident video called those who completed the questionnaire to assess depression (Hamilton Depression Rating Scale) and anxiety (Hamilton Anxiety Rating Scale)	Cross-sectional descriptive study	Depression and anxiety; this study examined the agreement between the online self-assessment and psychiatric telephone interview among survivors of COVID-19 regarding depression and anxiety; agreement between the online self-assessment and telephone interview was not significant
Moulaei et al [92], 2023	Iran	Patients with depression and anxiety disorders from Kerman University of Medical Sciences	Mobile app	Self-management of depression and anxiety disorders	App development paper	Depression and anxiety
Mukherjee et al [93], 2024	India	Adolescents living in 60 slum clusters spread across New Delhi and Vijayawada	Mobile app	Two components: (1) antistigma campaign and (2) mobile-based self-care app	App development paper	Depression and anxiety
Muniswamy et al [94], 2022	India	Remotely working software professionals in IT firms who were low in physical and mental health (N=160)	Social media (Facebook)–based FIIT[ai]	Modules provided via weekly Facebook messages focused on factors affecting sedentary behavior and mental health delivered over 8 wk; personal telehealth consultations delivered by experts via a chat box	RCT—2 phases, pragmatic	Anxiety and depression; significant difference in the scores for stress and anxiety within and between the groups but only within the groups for depression

Nabunya et al [95], 2024	Uganda	Youths aged 14-17 y who were HIV positive and receiving care and ART[aj] from one of the participating clinics and living within a family	Mobile intervention (SuubiMhealth)	Educational content incorporated recommendations for CBT for ART adherence and depression as applied to HIV medication adherence; content was broken down into 20 modules	Protocol—pilot RCT	Depression
Najafi et al [96], 2023	Iran	Female individuals with RRMS[ak] recruited through the local MS[al] association (N=45)	Online visual platforms: Google Meet, Zoom, and Instagram	Online supervised tele-yoga and tele-Pilates intervention sessions delivered 3 times a wk over 8 wk; certified instructors provided supervision	RCT—single blind	Depression; significant improvements were observed in depression (*P*=.001)
Najafi et al [97], 2023	Iran	82 people with either RRMS or SPMS[am] from the Shiraz University of Medical Sciences (N=82)	Tele-Pilates and tele-yoga training	Online supervised tele-yoga and tele-Pilates intervention sessions delivered 3 times a wk over 8 wk; certified instructors provided supervision	RCT	Depression; significant time × group interactions were observed for mental health (*P*=.05), as well as a decline in depression (*P*=.002); post hoc analysis showed depression improvements for both interventions, but these were not statistically significant (*P*>.05)
Naveen et al [98], 2024	India	HCWs working at AIIMS[an], Jodhpur on COVID-19 duty (N=90)	Tele-yoga	Module contained loosening practices, breathing practices, Surya Namaskar, Kapalabhati Kriya, pranayama, and relaxation techniques	RCT	Depression and anxiety; no significant difference in depression scores at endline; anxiety scores were significantly lower among the tele-yoga group than among control group participants (*P*<.05) at endline; the effect size was medium (*r*=0.3-0.5), favoring the intervention group
Njoroge et al [99], 2023	Kenya	HCWs from 5 health care facilities	Mobile app	Weighted sensor stream signatures that predicted near-term risk of a major depressive episode and future mood; deployment of a mobile app platform and use of novel analytic approaches (AI and machine learning)	Feasibility study	Depression
Nurbaeti et al [100], 2021	Indonesia	Convenience sample of postpartum mothers	Smartphone app (IMSD[ao])	IMSD app sought to detect PPD symptoms early	App development and RCT	Depression (PPD)
Nwaogu et al [101], 2021	Nigeria	Construction personnel—site supervisors and project managers based on a log collected from the Nigerian Institute of Building (N=62)	DMHI[ap] (various)	Various	Open-ended survey—qualitative technique	Anxiety and depression; DMHIs used by respondents included mobile-based apps (14/24, 58%) and web-based applications (10/24, 42%) for stress, depression, anxiety management, and mental fitness
Ofoegbu et al [102], 2020	Nigeria	Educational technology students of Nigerian universities identified as having depression (N=192)	Internet-delivered intervention (GIAI[aq])	Initial support session via telephone and regular guidance from the therapists (clinical staff of the federal universities) via telephone and the internet over 10 wk	Group-randomized trial	Depression; significant reduction in depression among students in the treatment group when compared to those in the usual care control group

Synthesis of Results

Overview

This section presents a summary of the findings from the 80 articles that reported on fidelity, usability, and cultural adaptation of DMHIs, along with the challenges to and facilitators of their uptake in LMICs. The synthesis was organized by the three research objectives: (1) type of DMHI intervention platform; (2) discussions on their fidelity, usability, and cultural adaptation; and (3) identified challenges to and facilitators of their uptake in LMICs. A summary is presented in Table 2 organized according to the type of DMHI intervention platform used, along with other articles that reported the use of more than one type of DMHI.

Table 2. Summary of fidelity, usability, cultural adaptation, and challenges and facilitators by type of intervention.

	Fidelity	Usability	Cultural adaptation	Challenges	Facilitators
Summary (N=80)	A total of 16 articles reported on fidelity.	A total of 29 articles reported on usability.	A total of 31 articles reported on cultural adaptation.	A total of 22 articles reported on challenges to the uptake of DMHIs[a] in LMICs[b].	A total of 17 articles reported on facilitators of the uptake of DMHIs in LMICs.
Mobile apps (n=46)	A total of 12 articles reported on fidelity [57,64,70,79,80,83, 89,95,111,112,119,127].	A total of 23 articles reported on usability [53,57,62,64,65,67, 70,80,86,89, 90,93, 95,100,104,105,110-112, 115,117,119,120].	A total of 24 articles reported on cultural adaptation [48,53,64,67,68, 70,80,87,89,90,92, 93,95,104,105,108,110, 112,117,119,122,124,125].	A total of 13 articles reported on challenges [48,57,62,64,79, 80, 89,90,107,111,117,125, 127].	A total of 12 articles reported on facilitators [53,57,64,67,79, 83, 89,90,105,111,117,125].
Web-based programs (n=10)	One article reported on fidelity [55].	Two articles reported on usability [55,84].	Three articles reported on cultural adaptation [55,58,84].	Three articles reported on challenges [55,58,84].	Two articles reported on facilitators [55,58].
Virtual reality (n=5)	—[c]	—	One article reported on cultural adaptation [88].	—	—
Videoconferencing (n=4)	—	—	—	Two articles reported on challenges [66,98].	—
Telemedicine (n=4)	—	—	—	—	—
Social media–based interventions (n=1)	—	—	—	—	—
More than one delivery platform type (eg, delivered via app or the web or reviews that included various DMHIs; n=10)	Three articles reported on fidelity [71-73].	Four articles reported on usability [51,73,78,101].	Three articles reported on cultural adaptation [71,72,101].	Four articles reported on challenges [72,73,78,101].	Three articles reported on facilitators [49,73,101].

[a]DMHI: digital mental health intervention.
[b]LMIC: low- and middle-income country.
[c]Not applicable.

Types of Digital Health Interventions for Depression and Anxiety Being Used in LMICs

This search and review of the 80 articles showed that, of the DMHIs identified, the largest category was mobile apps (n=46, 58%). Other DMHIs involved web-based programs (n=10, 12%), VR (n=5, 6%), videoconferencing (n=4, 5%), telemedicine (interventions delivered via an instant messaging app; n=4, 5%), and social media–based interventions (n=1, 1%). A total of 12% (10/80) of the articles reported on delivery of mental health care using more than one platform (eg, delivered via app or the web or reviews that included various DMHIs). DMHIs can be stand-alone self-guided programs or incorporate a hybrid model whereby human assistance, either from a therapist (ie, mental health specialist) or a lay health worker to augment their care, is available with varying levels of support.

Most of the articles (64/80, 80%) reported strengths of DMHIs either on improving symptoms of depression or anxiety or other factors such as high level of usability, acceptability, and satisfaction during usability and pilot-testing. Overall, DMHIs show promise as a way to bridge the mental health treatment gap for depression and anxiety in LMICs.

Fidelity, Usability, and Cultural Adaptation

Fidelity

Despite the accelerated increase in the development and application of DMHIs in recent years, with many being adapted from existing in-person interventions, only 20% (16/80) of the articles reported on fidelity. Of these 16 articles, only 4 (25%) discussed fidelity in relation to the original in-person or paper-based intervention format. One of these articles mentioned adherence to the original intervention structure and format in the adapted digital format [80]. Another article described the process of involving psychologists and psychiatrists to ensure theoretical alignment of app content with psychosocial components [83]. The third article mentioned the development of 1 video per session to deliver the therapeutic ingredients with fidelity and at the right dose [57]. The last of the 4 articles mentioned that the intervention delivery format (mobile app) ensured that key therapeutic elements were delivered with fidelity and at the appropriate dose using the app's automated features [64].

Most of the articles that discussed fidelity (13/80, 16%) described the process for ensuring fidelity or adherence by lay health workers to the intervention protocol. This included fidelity and audit checks of lay health workers by supervisors and reviews of case notes [55,70-73,79] and use of various tools (eg, fidelity checklist [71,72,79] or the practical robust implementation and sustainability model framework [95]). Regarding those reporting on the use of a tool, 2% (2/80) of the articles provided further information, indicating that 5% of the guidance calls and messages were rated (no additional information was provided on who performed the rating) [71,72]. Another article reported that the structured steps on the app made it easier for lay workers to adhere to fidelity when navigating the sessions [73], whereas another article indicated that the intervention itself, which was used for detection and treatment, could increase consistency in diagnosis and treatment [89]. Finally, one article stated that fidelity to the intervention protocol was demonstrated by lay health workers delivering the intervention adapting easily to the technology (smartphones) due to familiarity with the protocol [57]. Regarding the articles that reported on measuring fidelity of lay health workers to the intervention protocol, overall, it was shown that lay counselors adhered to the intervention delivery components.

Usability

Less than half (29/80, 36%) of the articles described usability in some manner, including through usability testing or qualitative exploration. Most of the articles (23/29, 79%) were related to mobile apps. Of the 29 articles, only 7 (24%) reported the use of measures, either standardized (eg, the System Usability Scale or mHealth App Usability Questionnaire [MAUQ]) or created by the authors for the study (eg, satisfaction survey), to capture usability [73,78,84,95,111,115]. In addition, only 31% (9/29) of the articles described the usability testing process along with findings in detail, with most (7/9, 78%) related to mobile apps [62,64,65,80,95,105,110,111,115] and the rest (2/9, 22%) pertaining to web-based programs [55,84]. In total, 10% (3/29) of the articles were protocol papers that indicated how app development would follow a user-centered iterative design.

Most of the articles that described usability testing outcomes (19/80, 24%) reported high satisfaction. For example, the study by Nurbaeti et al [100] showed that the evaluation of an app for postpartum depression symptoms in Indonesia was mostly positive, with a large percentage of the participants reporting the following: appearance of the app being adequate (92.7%) and the app being easy to download (89.9%), understandable (96.3%), easy to fill in (94.5%), and beneficial (96.3%) and reflecting psychological conditions (90.8%). Another article reporting the protocol for a feasibility cluster randomized controlled trial to be conducted in Nepal and Nigeria indicated that health workers found the prototypes of the app for the adapted WHO electronic Mental Health Gap Action Programme Intervention Guide to be intuitive, appropriate, and feasible for clinical work [112].

Of the 10 articles that reported more than one delivery platform, 4 (40%) reported on usability testing [51,73,78,101]. In total, 75% (3/4) of these articles indicated the evaluation of a usability-related construct using particular measures—a usability questionnaire (MAUQ) [73], satisfaction survey [78], and completion rates with participant feedback [51]. The remaining article mentioned that piloting had been conducted to evaluate the appropriateness of the intervention without describing this in detail [101]. Usability was reported as being high (eg, the MAUQ score was 78.5, and the satisfaction survey showed that 92% of participants were very satisfied).

Cultural Adaptation

Finally, 39% (31/80) of the articles described a process for adapting the DMHIs to the local cultural context. Of these 31 articles, 23 (74%) reported on mobile apps. Various methods were used, including a narrative approach involving local women, a participatory approach, identification of measures that had been validated in the implementation country or working with local partners to enhance cultural validity where

XSL•FO
RenderX

needed, and the intervention being led by a local partner. Many of the articles (13/80, 16%) discussed the involvement of a broad range of stakeholders in the adaptation process using a "participatory approach" [67]. For example, one article mentioned how "the vignettes were developed in consultation with local women who had suffered from depression" [64]. Another article described that, to improve cultural fit, "a team of clinical psychologists, psychiatrists, and researchers from the U.S. and India adapted the intervention," and "modifications were informed by student feedback" [84].

A few articles (7/80, 9%) described the cultural adaptation process in detail. For example, one article described how the VR space was designed to be similar to the environment of the end users (urban refugee youths in Kampala) and presented in their language of choice combined with training materials and content adapted with peer navigators to enhance relevance [88]. Another article detailed the extensive cultural adaption process conducted by the WHO and the Lebanon National Mental Health Programme to develop relevant content (story, local idioms, and illustrations) for the Lebanese population, displaced Syrians, and other groups in Lebanon. The article also included descriptions of piloting for face and content validity, clarifying language, assessing readability, and establishing content appropriateness within the intended context [55].

Most of the articles (18/80, 20%) were vaguer, indicating simply the importance of identifying what would be culturally acceptable, that the app was designed for the specific population, or the use of a guide adapted for the health system of the target country. A total of 2% (2/80) of the articles, which reported on web-based DMHIs, indicated that cultural adaptation was conducted with the intervention or culturally adapted approaches were used, resulting in high cultural relevance and acceptability; however, the process was not described in detail [58,84]. Similarly, 67% (2/3) of the articles that reported more than one delivery platform mentioned cultural adaptation but did not describe the process in detail [71,72]. These 2 articles pertained to the same intervention. Another article mentioned that the narrative was adapted to the local context considering cultural and linguistic nuances among displaced Syrians and that participants could choose the appearance of the avatar used in the program, reflecting the main cultural groups in Lebanon (Lebanese, Syrians, and Palestinians) [64].

Challenges to and Facilitators of Intervention Uptake in LMICs

Challenges to Uptake

A total of 28% (22/80) of the articles reported on challenges. In total, 59% (13/22) of these articles were related to mobile apps, describing challenges that pertained to the technological system (eg, system lags, app navigation challenges, and bugs); user engagement issues (sustained engagement of individuals who are depressed and may have low motivation, high churn, and issues with adherence to treatment), which are linked to poor usability; contextual issues (eg, illiteracy, technological proficiency, accessibility of mobile phones, data limits, battery charging issues, and lack of family involvement); structural barriers (eg, network connectivity issues and resource constraints); and concerns about privacy and confidentiality [48,57,62,64,79,80,89,90,107,111,117,125,127]. Of the 22 articles, 2 (9%) highlighted how many of these challenges contribute to the digital divide, or the division between individuals or populations who have access to and use digital technology and those who do not [64,117]. Other challenges mentioned included that of a practice gap between health care providers and application developers [48] and challenges with the online delivery method where participants complete tasks in their own time [79].

In addition to similar challenges described previously, other challenges reported in relation to web-based programs and those delivered via more than one platform included individuals forgetting their log-in credentials, time constraints due to busy schedule of the participants, retention of lay health workers, sustained engagement, and stigma [55,66,84]. There were also concerns reported about the interventions' efficacy, effectiveness, and usability [73].

Facilitators of Uptake

In total, 21% (17/80) of the articles reported on facilitators. Of these 17 articles, 12 (71%) were related to mobile apps, describing various facilitators that supported their uptake and scale-up, including widespread mobile phone use, built-in supervision and training features, and an app's convenience and integration into existing social (eg, schools) and health care systems [53,57,64,67,79,83,89,90,105,111,117,125]. One of these studies suggested a web-based delivery platform rather than an app-based one as the former does not require regular updating and tailored interventions or distinct adaptations that account for the unique needs of the target population [79]. Other articles (3/80, 4%) reported on the importance of orientation and training programs and mobilization of community health volunteers [89,111] and how an understanding of the intervention and its potential benefits will likely support its uptake [90]. In line with some of the concerns that clinicians expressed, described previously, one article reported on the importance of buy-in from frontline health care providers and clinical experts, which may be facilitated by demonstrated clinical utility and efficiency [117]. Other facilitators reported in relation to web-based programs or interventions involving more than one delivery platform included facilitators at the individual level, such as being technologically savvy and literate and having access to devices [55], and incorporating features to boost user engagement [101]. Finally, the importance of cultural appropriateness was emphasized by a number of the articles (11/80, 14%; see, eg, the studies by Alavi and Hirji [58] and Pozuelo et al [105]).

Discussion

Principal Findings

The 80 articles identified in this rapid scoping review reported the use of mobile apps, web-based programs, VR, videoconferencing, telemedicine (interventions delivered via instant messaging apps) platforms, and social media, in addition to instances in which the DMHIs were delivered via more than one platform (eg, delivered via app or the web). To our knowledge, this rapid scoping review is the most comprehensive presentation of articles examining DMHIs for depression and

XSL•FO
RenderX

anxiety and their fidelity, usability, and cultural adaptation, along with challenges to and facilitators of their uptake in LMICs.

Fidelity

Active elements of these DMHIs are often modeled on evidence-based psychological interventions developed for in-person delivery [17], offering further promise to provide scalable effective mental health care. As such, it is critical that the interventions are implemented with high fidelity while balancing the need for necessary adaptations to the digital context, including the different motivational needs and preferences of digital users. However, inconsistencies regarding treatment fidelity have been identified as a main contributor to the mixed evidence on the effectiveness of many DMHIs [128]. Similarly, results from this review showed that less than a fifth (16/80, 20%) of the articles reported on fidelity, with heterogeneity in process and presentation format. Most of these articles (13/80, 16%) described the process for ensuring adherence by lay health workers to the intervention protocol rather than for ensuring fidelity of the DMHI to its original in-person or paper-based format. Furthermore, only 1% (1/80) of the articles mentioned specifically adherence of the DMHI to the original intervention structure albeit delivered in an automated digital format [80]. Interestingly, 2% (2/80) of the articles mentioned that the delivery format of the intervention (app) supported fidelity via the nature of its automated and structured format [64,89]. This is consistent with previous research demonstrating that less complex interventions are easier to implement with high fidelity [129]. As more DHMIs are being developed and adapted from in-person or paper-based formats, it is crucial to ensure intervention fidelity to maintain consistency in intervention delivery across platforms while balancing necessary adaptations to suit digital modes of delivery and the local context [130,131].

Usability

Poor usability has been cited as a primary reason for failed adoption of and engagement with digital health apps [31,32], where approximately one-third of users who download health apps stop using them after a short time, often no more than 2 weeks [132]. Hurdles to app usability include being difficult to set up or use or being buggy, not working well, requiring too much time to enter data, or having small screens that display limited information at a time [32,133]. Other challenges include concerns about privacy. An additional consideration for individuals with depression include specific symptoms such as low motivation, concentration difficulties, and behavioral avoidance that may make it more difficult for them to engage with DMHIs, posing further challenges to real-world efficacy [133]. Although usability testing is understood increasingly as an important component of app development and evaluation [134], usability currently remains underexplored in depression app development [135,136]. Findings from this review reflect this as only 36% (29/80) of the articles described usability testing in some manner despite overwhelming evidence highlighting how the efficacy of mobile apps can be greatly enhanced by conducting usability testing to determine factors impacting user adherence and satisfaction [137-139].

Articles that reported on usability outcomes (9/80, 11%) demonstrated mostly positive findings, with above-average usability and satisfaction scores being reported. Certain challenges to usability were also reported, including a confusing registration process and content that could be improved to be more engaging [80], which was a barrier to adherence [55]. Despite the generally positive usability and satisfaction scores reported by the various articles, poor usability has been clearly identified as a barrier to sustained user engagement across various digital health interventions [140,141]. A lack of user engagement with the DMHI regardless of users' self-reports on satisfaction and utility likely indicates poor usability [142] as usability is a precursor for engagement [143]. This is also reflected in the fact that, despite the large number of medical health apps available, their overall downloads are decreasing [31]. Methods to increase usability include incorporating interactive features (eg, tooltips) [144] and gamification (eg, badges and avatars) [145]. Usability is also intricately linked with acceptability, which includes the intuitive attitudes toward the intervention, use intentions, actual use, and satisfaction after using [146]. Acceptability is intricately linked with prevailing social and cultural norms [147], highlighting further the importance of cultural adaptation.

Cultural Adaptation

Ensuring that interventions are culturally appropriate and relevant is important to their success [148,149]. While depression and anxiety affect people from all cultures, the experience of these illnesses is culturally bound, shaped by local beliefs, practices, and norms. This cultural variation profoundly influences mental illness expression; patterns of coping and help seeking; the process of recovery; adherence to treatment; and relationships between individuals and their networks of family, friends, and health care providers [150,151]. Cultural adaptations to increase relevance for individuals from ethnic minority groups have been shown to have greater efficacy [152] and more favorable health outcomes [153].

However, there has been limited focus on cultural adaptations of DMHIs to ensure relevance and acceptability [19,20]. Most of the 39% (31/80) of the articles that reported on cultural adaptation only touched on the cultural adaptation process undertaken, for example, "clarify[ing] language, and establish[ing] the appropriateness of the developed content within the intended context of use" [101] and "the narrative was adapted to the local context, considering gender, linguistic, and cultural nuances" [71,72]. Only 9% (7/80) of the articles described the cultural adaptation process in detail. While it is encouraging that many of the articles included in this review (31/80, 39%) discussed cultural adaptation in some form, there is a need for researchers and developers to place more emphasis on the cultural adaptation process to ensure that evidence-based interventions are properly adapted to enhance favorable health outcomes.

Promisingly, a number of the articles (13/80, 16%) discussed the involvement of a broad range of stakeholders in the development and cultural adaptation process. Engaging a broad range of stakeholders, including experts, end users, and community members, has been shown to contribute critical

XSL•FO
RenderX

insights for development, implementation, and evaluation [153]. Developing DMHIs that address the culture and context of the diverse groups in LMICs by including necessary cultural adaptations while maintaining intervention fidelity is critical to increasing engagement of historically underserved cultural groups [21].

Challenges and Facilitators

A total of 28% (22/80) of the articles reported on challenges, whereas 21% (17/80) reported on facilitators. Unlike the topics of fidelity, usability, and cultural adaptation, where most of the articles discussed mobile apps, articles that discussed challenges and facilitators were spread more evenly across the different delivery platforms, highlighting the consistency of challenges and facilitators experienced with different types of DMHIs. Many of the challenges reported in the articles (eg, contextual issues and structural barriers) were perceived as possibly leading to inequitable digital access and contributing further to the digital divide. These findings are consistent with the literature [12], which indicates that, while DMHIs offer an accessible and promising method for delivering mental health care, a number of challenges remain from the end user and developer side that must be addressed. For example, many of the individuals who use these types of DMHIs may live in rural areas where contextual (eg, being busy with multiple responsibilities such as farming, taking care of family, and side jobs) and structural issues (underdeveloped technological infrastructure) may prevent them from engaging fully with DMHIs. Structural issues and digital health literacy have been widely reported in the literature for a number of years [154,155]. A lack of digital literacy, especially among the older adult population and those from lower socioeconomic brackets, is one of the main challenges in scaling up digital health interventions [155,156]. In addition, DMHIs may not be accessible for subpopulations such as racial and ethnic minority groups due to language barriers [157], emphasizing again the importance of ensuring cultural appropriateness. Finally, for DMHIs that incorporate a hybrid model involving human assistance, in particular lay health workers to augment their care, the articles emphasized the heavy burden on the providers, who often have heavy existing workloads and are largely underpaid or even unpaid [158]. This may pose a challenge for sustainability.

Clinician buy-in was reported as a challenge to the overall implementation of DMHIs into routine care and centered on time management, regulatory structures and licensure, lack of nonverbal evidence, and payment. Similar challenges have been reported in the literature, demonstrating that there has been a reticence from mental health professionals to engage with DMHIs due to the perceived threat to the therapeutic alliance, which some believe can only be established in person [25,26]. Research suggests that there is presently limited theoretical and practical training on novel digital tools and interventions in psychiatry, which influences clinicians' understanding and perceptions of DMHIs [159]. The importance of in-person contact in psychotherapy has also been widely discussed in the literature [160-162]. However, Newman et al [163] showed that, while clinician-assisted treatments are indeed optimal, interventions with reduced in-person contact and at reduced intensity have also been shown to be effective and cost-effective. This has been researched most heavily in the case of mobile apps [164,165]. For example, 2 systematic reviews of mobile apps (both self-guided and hybrid models) demonstrated their effectiveness in reducing depression symptoms [16,139]. Nevertheless, clinician concerns need to be addressed to enhance their acceptance of and engagement with DMHIs, particularly for those that are integrated into standard care and may require their support. One method may be engaging clinicians more throughout the app development process to provide expert input and also increase their understanding and acceptance of DMHIs [13].

Facilitators of the uptake and scale-up of DMHIs in LMICs included widespread mobile phone use, built-in supervision and training features, their convenience, and integration into existing social and health care systems. For the hybrid models that required lay health workers for ongoing implementation, mobilization of community health volunteers, including through training and professional support, was considered an important facilitator. Training and professional support have been shown to increase lay health workers' satisfaction and enhance their agency and social status [166]. Ensuring cultural appropriateness to the local context by using tailored adaptations was also emphasized. This can increase the reach of and engagement with DMHIs and increase equity by avoiding the systematic exclusion of cultural groups who have been historically underserved [21]. Furthermore, increased mental health awareness was highlighted as an important facilitator to increase understanding of the DMHI and its potential benefits. In addition to demonstrated clinical effectiveness of DMHIs for depression and anxiety, their use has been shown to increase mental health literacy and awareness [154]. Finally, the importance of buy-in from clinicians and other providers was highlighted. In addition to DMHI integration into standard care, clinician behaviors could support adherence. For example, Paxling et al [167] demonstrated that certain clinician behaviors, such as task reinforcement, task prompting, self-efficacy shaping, and empathetic utterances, were correlated with module completion [168].

Limitations

A limitation of this review is that we only included English-language papers, leading to an unknown number of articles from LMICs published in languages other than English being excluded. However, we believe that this review of 80 articles identified many of the key issues concerning DMHIs in LMICs. A second limitation is that this review focused only on depression and anxiety; examination of DMHIs for other mental health conditions may elucidate additional considerations. However, as depression and anxiety are the 2 most common mental health conditions [5] and many DMHIs are developed for depression and anxiety [6,15,169], the results of this review can inform the further development and delivery of DMHIs for these 2 conditions and provide information on general rather than condition-specific features of DMHIs focusing on other conditions. Finally, research published before the search time frame may have contributed additional findings. Considering the rapid advancement of DMHIs and related research stimulated by the COVID-19 pandemic, we believe

XSL•FO
RenderX

that this review of research published during the applied time frame captured the most crucial and timely evidence.

Given the rapidly changing landscape of development and application of DMHIs, further research is warranted to capture emergent changes, including the interventions' fidelity, usability, and cultural appropriateness and challenges to and facilitators of their uptake in LMICs. Additional future research should also focus on underexplored areas, including an examination of the percentage of DMHIs that have no basis in evidence; the potential for harms in the unrestrained development and delivery of DMHIs; and the threats to privacy and security, such as potential for financial harm through unregulated mobile apps, including those presented as DMHIs. Finally, the accelerated growth of artificial intelligence (AI) and its increasing application in various health care fields in recent years could transform the landscape of digital mental health, including DMHIs [168,170]. While AI represents a potential means to advance mental health care, there will be an ensuing urgent need to examine in detail ethical implications associated with the integration of AI into digital mental health [171].

Conclusions

DMHIs are one of the most promising ways to better meet population mental health needs and respond in culturally appropriate ways to diverse population groups. Despite the opportunities they offer for reducing the severe and persistent mental health treatment gap, there were several key issues identified in this scoping review that warrant further examination. These include further work on the fidelity, user engagement, and cultural adaptation of DMHIs. In addition, various challenges to the uptake of DMHIs in LMICs, including challenges pertaining to the technological system, contextual issues, structural barriers, and concerns about privacy and confidentiality, must be mitigated in the ongoing implementation of DMHIs in LMICs to avoid contributing further to the digital divide. In summary, DMHIs in isolation are not a solution to address the significant mental health care system deficiencies that are present; rather, they may serve as a low-cost and low-barrier treatment option—especially those DMHIs that are appropriately adapted from evidence-based in-person interventions—in low-resource settings where community-based care is severely limited.

Abstract

Background: With the ubiquity of smartphones, digital self-report instruments have enormous potential to support the general population in monitoring their mental health. A primary challenge for researchers committed to advancing this work is simply to scope the plethora of widely used candidate instruments. The overarching aim of this study was to address this challenge to support and guide future research in this burgeoning area.

Objective: This study aimed to conduct a literature review of self-report instruments used in empirical studies to measure mental health (1) in the general population, (2) delivered in a digital format, and (3) in longitudinal designs. Given the wide range of recognized "mental health" constructs, the review's search strategies were guided by Keyes' dual continua model of mental health, recognizing both deficits- and strengths-based constructs. This study's primary objective was to develop a first-of-its-kind ranking and synthesis of the most frequently used instruments that are potentially suitable for mental health self-monitoring. It was not an objective of this study to evaluate psychometric properties of the identified instruments—we hope the present ranking and synthesis will provide the foundation for future research into optimal digital, prospective self-report of mental health.

Methods: Five major electronic databases were searched. Studies that administered digital mental health instruments (in English) repeatedly to community dwellers in the general adult population were eligible. The included studies were grouped by instruments for synthesis using a narrative approach.

Results: Preliminary screening of 95,849 records identified 8460 eligible records, among which 1000 records were randomly selected over 4 iterations for full-text screening. A total of 223 records were included. We found that the top 30 most commonly used instruments accounted for 78.4% (308/393) of the total usage across studies. These instruments predominantly measure deficits-based mental health constructs. The Patient Health Questionnaire 9 Items and Generalized Anxiety Disorder 7 Items were by far the most used instruments. The most commonly measured strengths-based constructs were life satisfaction and mental well-being.

Conclusions: The findings of this review strongly suggest that scientific investigation of mental health constructs across time on digital platforms still prioritizes deficits-focused instruments originally developed for pen-and-paper administration using classical test theory. These findings are discussed in light of evidence in the literature that deficits-focused instruments demonstrate inferior distributional properties (floor effects) in the general population and theory suggesting that both deficits- and strengths-focused measurements are required to holistically assess mental health. Limitations of the review include the restricted focus on English language instruments and the pragmatic approach to selecting records for full-text screening. It is concluded that, in the smartphone age, it would be timely to develop new digital instruments framed by holistic models of mental health and using contemporary test construction approaches.

Introduction

Background

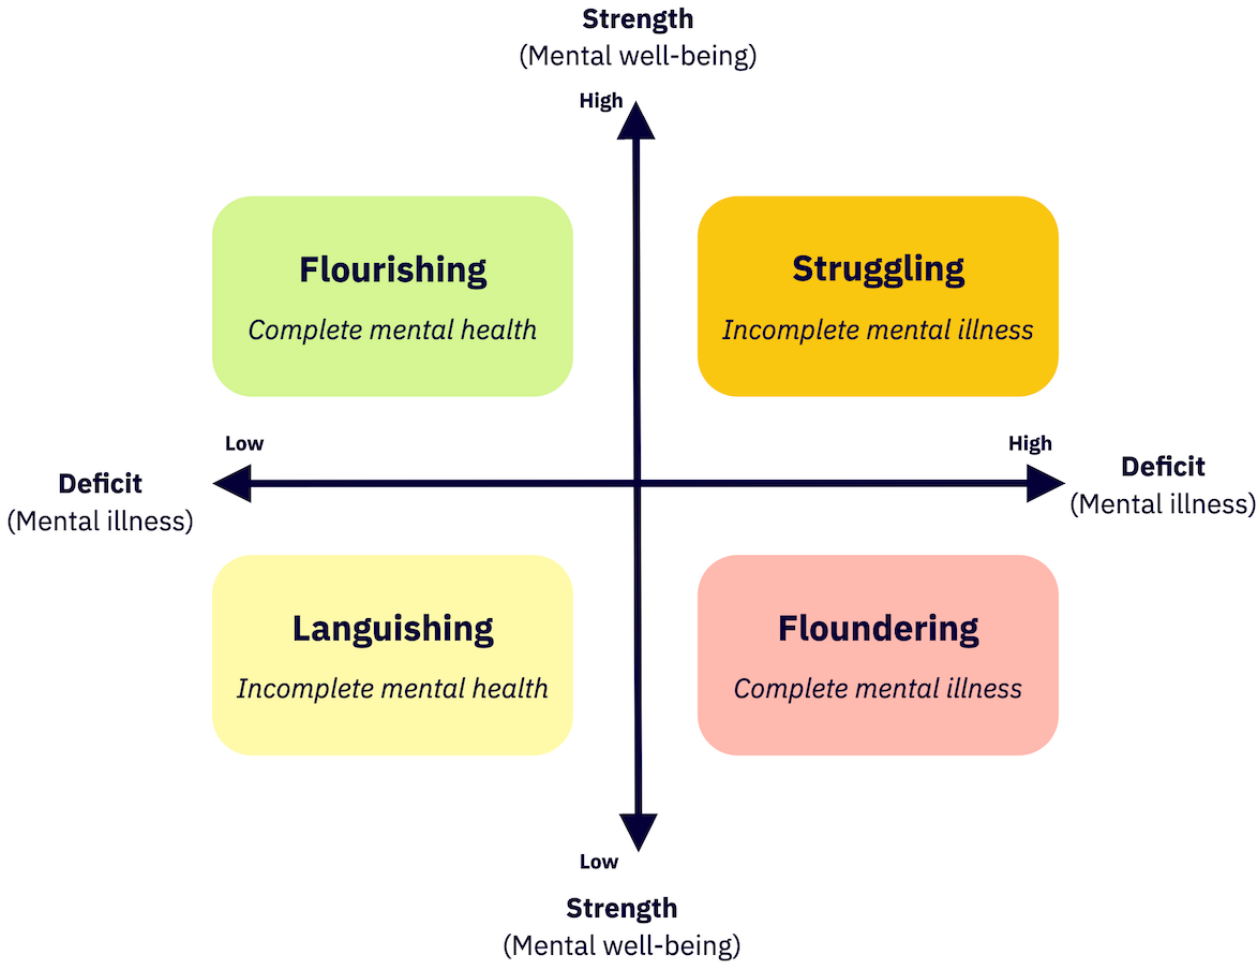
As mental health researchers with a digital interest, we are increasingly approached by researchers and industry partners to recommend self-report instruments that can be offered to the general public for monitoring mental health digitally. A barrier to providing an evidence-based answer to this apparently simple question is the lack of an overview of instruments that have already been used for this or related purposes. The overarching aim of this review, consequently, was to scope existing instruments that could fulfill this role, as demonstrated by their use in published empirical research. Broadly, we sought to answer the question: which instruments have been most frequently used, and what are their characteristics? First, we briefly review evidence that digital technologies render self-monitoring more feasible than ever before, and introduce contemporary approaches to test construction. We then introduce the dual continua model of mental health that was used to guide the systematic search strategy and results synthesis of this study.

Self-Monitoring of Mental Health

Self-monitoring has proven effective and economical in managing many chronic illnesses [1-6], and is potentially a useful component of population-based approaches to managing mental health [7-10]. In the realm of mental health, self-monitoring via self-report inventories can raise emotional self-awareness [11] and promote positive health behavioral change over time [12]. Self-monitoring mental health can detect early symptoms of mental illness [13] while also providing a better understanding of factors that influence positive mental health [14-16], aligning with the goals of mental illness prevention and mental health promotion programs [17]. The focus here was on the full range of mental health constructs that have been measured by self-report, including general mental health measures (eg, the Kessler Psychological Distress Scale [K10] [13]), and instruments designed to screen for (eg, the Patient Health Questionnaire 9 Items [PHQ-9] [18]), or monitor severity of diagnosable disorders (eg, the Beck Depression Inventory II [19]).

Ubiquitous digital platforms have enormous potential to support self-monitoring of mental health in the general population. These opportunities are increasingly recognized in fields including digital monitoring [20], digital assessments [21], digital phenotyping [22], and self-management [3]. Remarkably, it is estimated that more than 10,000 mobile apps are available in the digital mental health market [23,24], and common mental illnesses such as anxiety and depression are measured in numerous associated apps [25-28]. Importantly, these apps typically incorporate existing validated self-report instruments in a digital format for self-tracking purposes [11]. For example, the PHQ-9 is often used as a measure of depressive symptoms, despite being developed in the predigital era.

A shift toward digital modalities of data collection also supports a transition in survey development from classical test theory (CTT) to item response theory (IRT). CTT [29] has been the dominant approach to survey development for traditional paper-and-pen surveys. However, advances in measurement theories such as IRT [30,31] highlight several shortcomings of CTT and are starting to positively influence psychological test development through improved measurement precision [30,32,33]. One notable application of IRT, originating from educational assessments, is the Computerized Adaptive Test (CAT) [34], which harnesses the computational power of digital technologies to provide dynamic survey administration. CAT can maintain the precision of mental health measurement while significantly reducing the total number of questions and thereby alleviating the response burden [35,36]. A prominent example of this contemporary approach to measurement is the PROMIS (Patient Reported Outcome Measures Information System), a program initiated by the US National Institutes of Health [37]. PROMIS includes suites of mental health outcome measures designed with digital administration in mind, available in various formats such as fixed-length (eg, comprehensive long-form or equivalent short-form self-report assessments) and computerized adaptive testing assessments.



Dual Continuum Model of Mental Health

Although originally linked to mental illness diagnoses [38-41], contemporary theorizing [14,42-50] conceptualizes mental health as multifaceted, subsuming deficits-based constructs related to mental illness, but also strengths-based constructs such as subjective well-being [51], the mental health continuum [52], and flourishing (in positive psychology) [53].

The influential dual continua model of mental health [14] recognizes 2 correlated but separable dimensions, typically named “mental illness” and “mental well-being” (for clarity, we use the terms “deficit” and “strength” here [54], see Figure 1). This conceptual model explains more variance in diverse populations than an alternative model in which mental illness and mental well-being are placed at opposite ends of a single continuum [55]. As described in the protocol paper for this study, the dual continua model directly informed the present search strategy and the synthesis of findings (Multimedia Appendix 1 [56]).

This Review

The present review is unique because it intends to advance understanding of the range of instruments that could function as mental health self-monitoring tools in the digital era. Specifically, we systematically searched for empirical studies that used instruments measuring mental health in (1) the general population, (2) digital format, and (3) longitudinal designs. While there is a growing body of research investigating measures of mental health in the nonclinical adult population [58-63], there is a lack of reviews that focus specifically on studies that meet the 3 aforementioned criteria. Consequently, this review has a narrow focus on instruments that have been applied in a manner comparable to digital self-monitoring of mental health. To the best of our knowledge, no review shares the specific focus of the present review. We anticipate that the review findings will be useful to the burgeoning number of researchers who share our interest in valid digital self-report measurements of mental health in the general population [59,64].

The aim of this scoping review was therefore to systematically identify empirical studies that used instruments measuring mental health (broadly defined) in (1) the general population, (2) digital format, and (3) longitudinal designs. This aim was addressed with the following research question (RQ):

RQ: Which self-report mental health instruments have been most frequently used in empirical studies via digital delivery to measure the mental health of the general adult population at more than 1 time point?

In this review, usage of the instrument is operationalized as the frequency of the instrument being administered in identified empirical studies over the number of years since the release of the instrument, bounded by the time frame of the review (ie, papers published between January 1, 2010, and December 31, 2021, inclusively).

The peer review process has led to some changes to study reporting that represent deviations from the original study protocol [56]. Most importantly, the study was originally designed as a systematic review, but through peer review, the authors learnt that it is easier to understand the study as a scoping review with a systematic literature review step. Second, we have reorganized the presentation of this study's RQs as described in the protocol. The primary RQ above is a more succinct wording of the erstwhile questions RQ1 and RQ4. To avoid misunderstanding about their status in the study design, ancillary questions about the characteristics of the most popular instruments (erstwhile RQ2, RQ3, and RQ5) have been removed from the main text (see Multimedia Appendix 2), and the findings now appear only in Section S2 in Multimedia Appendix 3 [13,14,16,18,19,56,64-237].

XSL•FO
RenderX

Methods

Study Design

This scoping review adheres to the PRISMA-ScR (Preferred Reporting Items for Systematic Review and Meta-Analysis Extension for Scoping Reviews) 2018 guidelines [238]. Methods such as eligibility criteria, information sources, search strategy, selection process, data collection process, data extraction, risk of bias (quality) assessment, and data synthesis plan are described in our published protocol [56]. The following section elaborates on deviations from the original protocol and the execution of these methods. Section S1 in Multimedia Appendix 3 presents the full search terms and strategies used for all databases in this review.

Selection Process

Eligibility Criteria

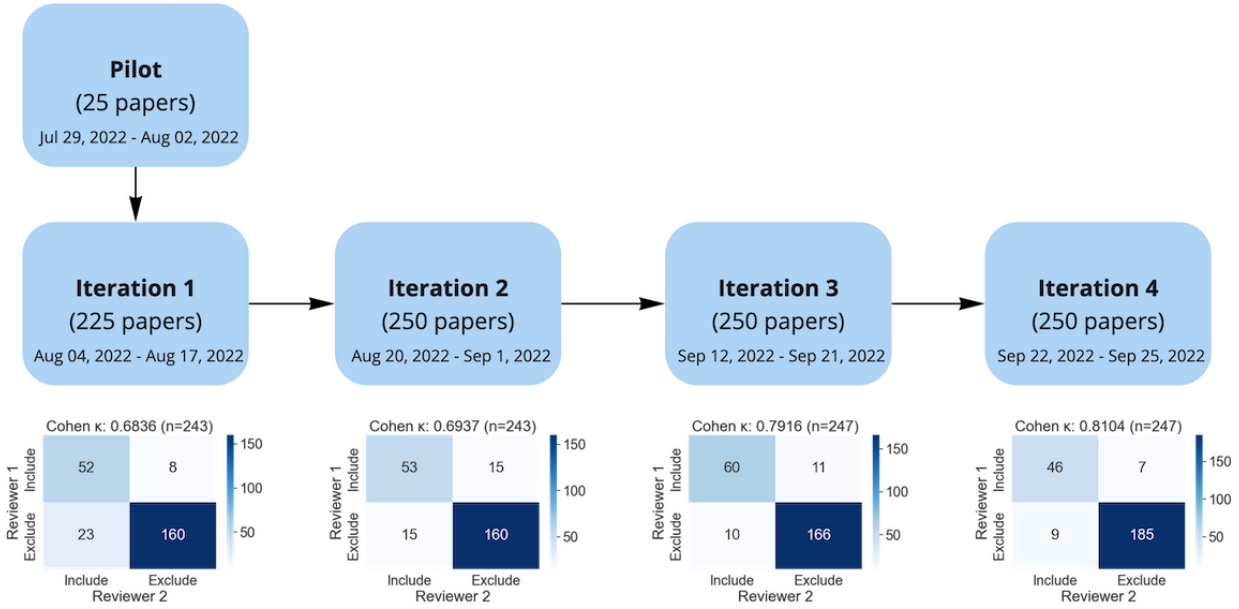
In the original protocol [56], eligibility criteria were defined in the Population, Intervention, Comparison, Outcome, and Time (PICOT) [239] format. For this scoping review, a mapping from the PICOT format to the population, concept, and context [240] format is detailed below. The population is identical to the protocol. The concept represents the types of empirical studies included and the scope of the mental health constructs considered, which were associated with the section "Intervention of Interest" of the protocol [56]. The context in this review represents the timeframe of the included published papers, which is between January 1, 2010 and December 31, 2021 (inclusive).

Preliminary Screening of Titles and Abstracts

In a preliminary scoping of the literature, a large number of search results (over 90,000 records) were returned, requiring the application of various tools to help screen records. One reviewer (ZHK) screened the titles and abstracts of the search records using text-mining techniques [241]. Subsequently, the screening effort was validated using a semiautomated screening tool (ASReview [242]). The details of this preliminary screening process are described elsewhere [243].

Full-Text Screening

A large number of eligible records (N=8460) were identified for full-text review after preliminary screening. This large record count is a result of our broad interest in the most frequently used mental health instruments being administered by past empirical studies. Furthermore, our three inclusion criteria (instruments being used in (1) the general population, (2) digital format, and (3) across multiple time points) are often not mentioned in the records' title or abstract, as they relate more to methods than the substantive questions of the study.



Considering that a typical review takes, on average, 5 members and approximately 67.3 weeks to conduct and publish [244,245], full-text screening of 8460 records was not feasible with 2 reviewers and limited resources. This feasibility challenge has been acknowledged by COnsensus-based Standards for the selection of health Measurement INstruments (COSMIN) when reviews are conducted on patient-reported outcome measures [246]. The large return of eligible studies, therefore, forced us to develop a pragmatic approach to full-text screening. Previous systematic reviews facing similar challenges, for example, these studies [247-251] have screened a subset of the eligible records using either a random sampling strategy (eg, stratified sampling by time period) or a data saturation strategy to ensure the representativeness of the variables of interest.

Here, we also decided to screen a subset of eligible records, but adopted a statistical strategy to test whether or not the subset was representative of the entire population of eligible records. We randomly selected a subset of 1000 records from the 8460 records eligible for full-text screening in batches of 250 (no repeats) over 4 iterations of sampling. As the primary focus of the present review was instruments' usage frequency (above), usage frequency was the variable used to statistically investigate the representativeness of the subset of n=1000 records. It was hypothesized that if the distribution of the usage frequency of instruments in each of the 4 batches was not statistically different, given the 4 batches were randomly selected from the same population of 8460 records, it could be inferred that the distribution of the usage frequency of instruments in each batch was likely to reflect in the full set of 8460 records [252-256]. The hypothesis was tested using statistical techniques (chi-square test of homogeneity [257] and Fisher exact test [258], significance level α of .05) once the 1000 records were screened in full-text and the data were extracted from the included records.

Informed by these approaches, 2 reviewers (ZHK and DS) screened the selected 1000 records in 4 iterative batches of 250 (Figure 2). To help manage the screening process, we developed a tool [259] to facilitate full-text screening and data extraction (hereafter referred to as "the custom tool"). Both reviewers pilot-tested the custom tool with 25 randomly selected records before commencing the full-text screening and data extraction. In each iteration, both reviewers independently screened 250 records in full text. If the record was still eligible, relevant data were extracted using the custom tool. If further information was required, ZHK contacted the researchers of the studies. After each iteration, both reviewers reconciled the review results and resolved any disagreements. The interrater agreement between reviewers was calculated using Cohen κ [260] (Figure 2). Suggestions to improve the custom tool were considered and implemented in subsequent iterations.

XSL•FO
RenderX

Figure 2. Full-text screening process of 1000 randomly sampled records in 4 iterations.

After 2 iterations, it became apparent that one of the main disagreements between reviewers was determining whether the instruments used in these records were in English, as not all records explicitly declared the language of the instruments. A decision flowchart was created (Multimedia Appendix 4) to facilitate the decision-making between reviewers after iteration 2. Since then, the interrater agreements were improved in iteration 3 and were maintained in iteration 4.

Data Extraction Process

Both reviewers (ZHK and DS) independently extracted data from each record using a separate copy of the custom tool. After completing each iteration, ZHK reconciled the instruments extracted from both reviewers. Then, both reviewers discussed any discrepancies and resolved disagreements before commencing the next iteration.

Quality Assessment

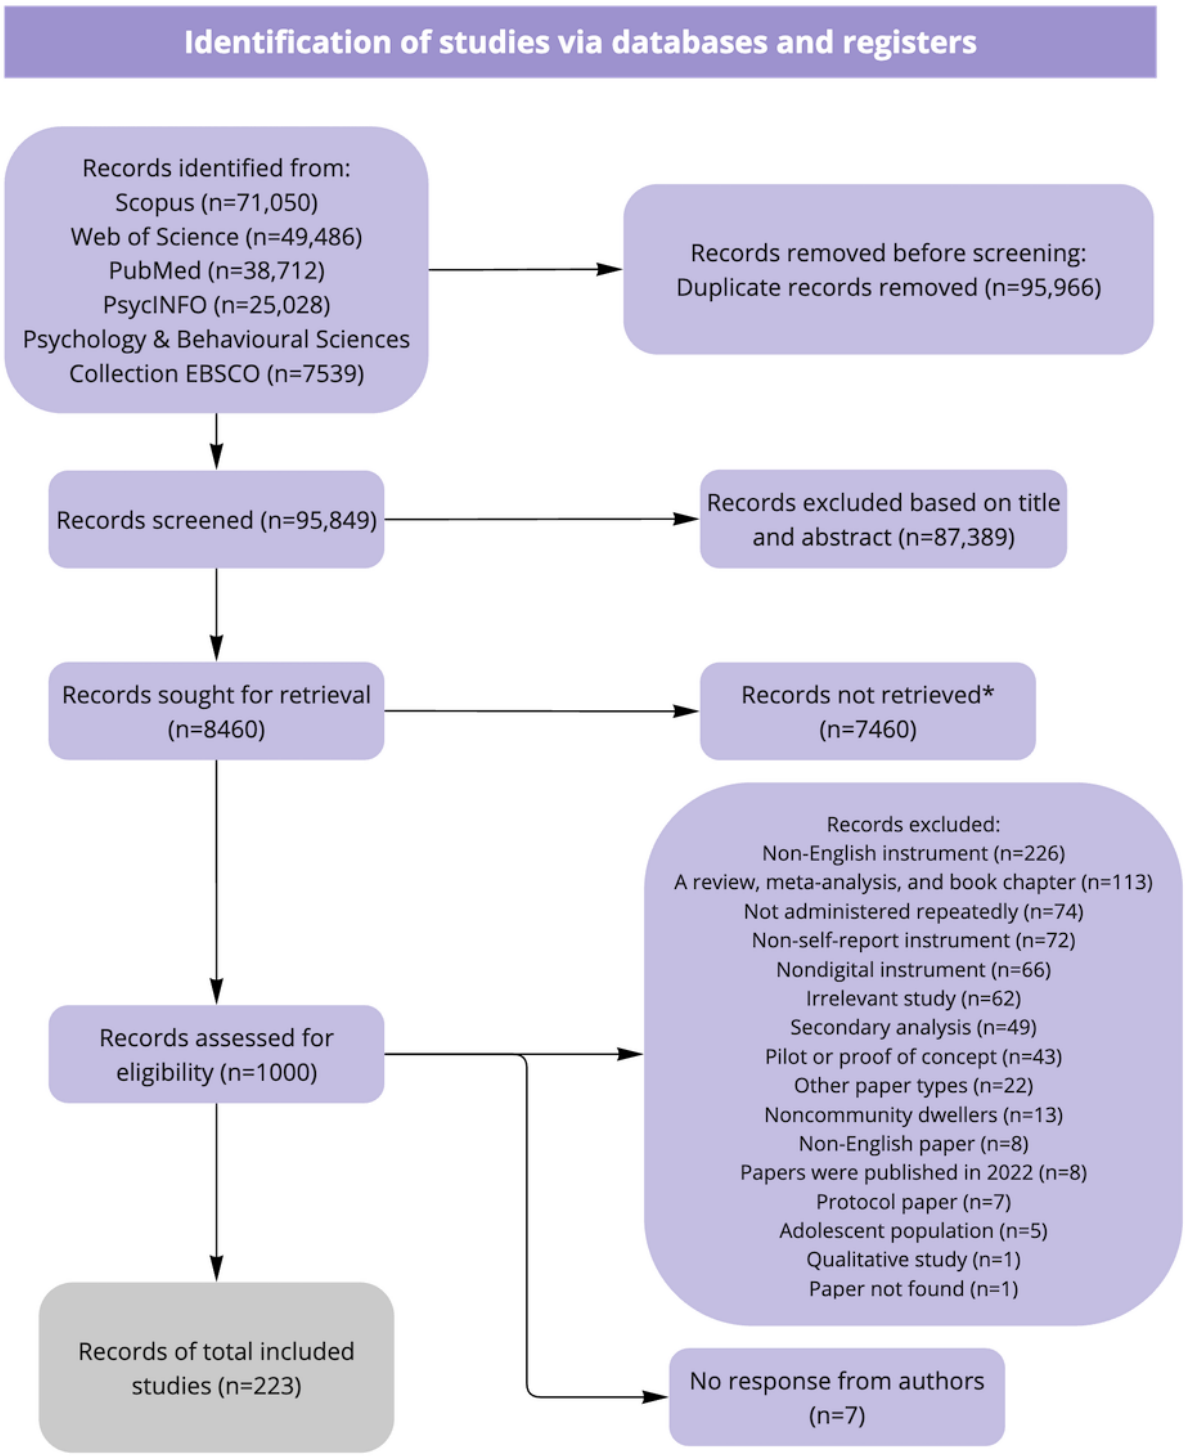
While the usage frequency of instruments is the main focus of the present scoping review, to ensure this review is useful to future researchers, similar to past reviews [64-66], we briefly commented on the quality assessment at the instrument level instead of individual studies, with a provisional evaluation of their core psychometric properties using studies from secondary searches (Section S2 in Multimedia Appendix 3).

Data Synthesis

Findings are summarized using a narrative synthesis approach [261] guided by the Synthesis Without Meta-Analysis (SWiM) reporting guideline [262] and framed by Keyes dual continua model (above). As described in our published protocol [56], the included studies were grouped by instruments and synthesized in tabular format, summarizing the properties of all studies associated with each instrument. The usage of instruments among the included studies is presented descriptively as figures.

Ancillary Information

This study was not designed to rank identified instruments in terms of psychometric properties. It is expected that the present frequency-of-use ranking and synthesis will provide the foundation for future researchers to ask questions about the optimal approach to digital, prospective self-report of mental health (eg, selecting the best instrument for a particular population or building new adaptive instruments from item content in established instruments). For each instrument identified, ZHK manually searched the literature to elicit the ancillary information, such as the instrument's structure, format, and psychometric properties. The ancillary information was then synthesized in tabular format (Section S2 in Multimedia Appendix 3). The psychometric properties of each instrument were provisionally rated based on the quality criteria defined by Terwee et al [67].



Results

Overview

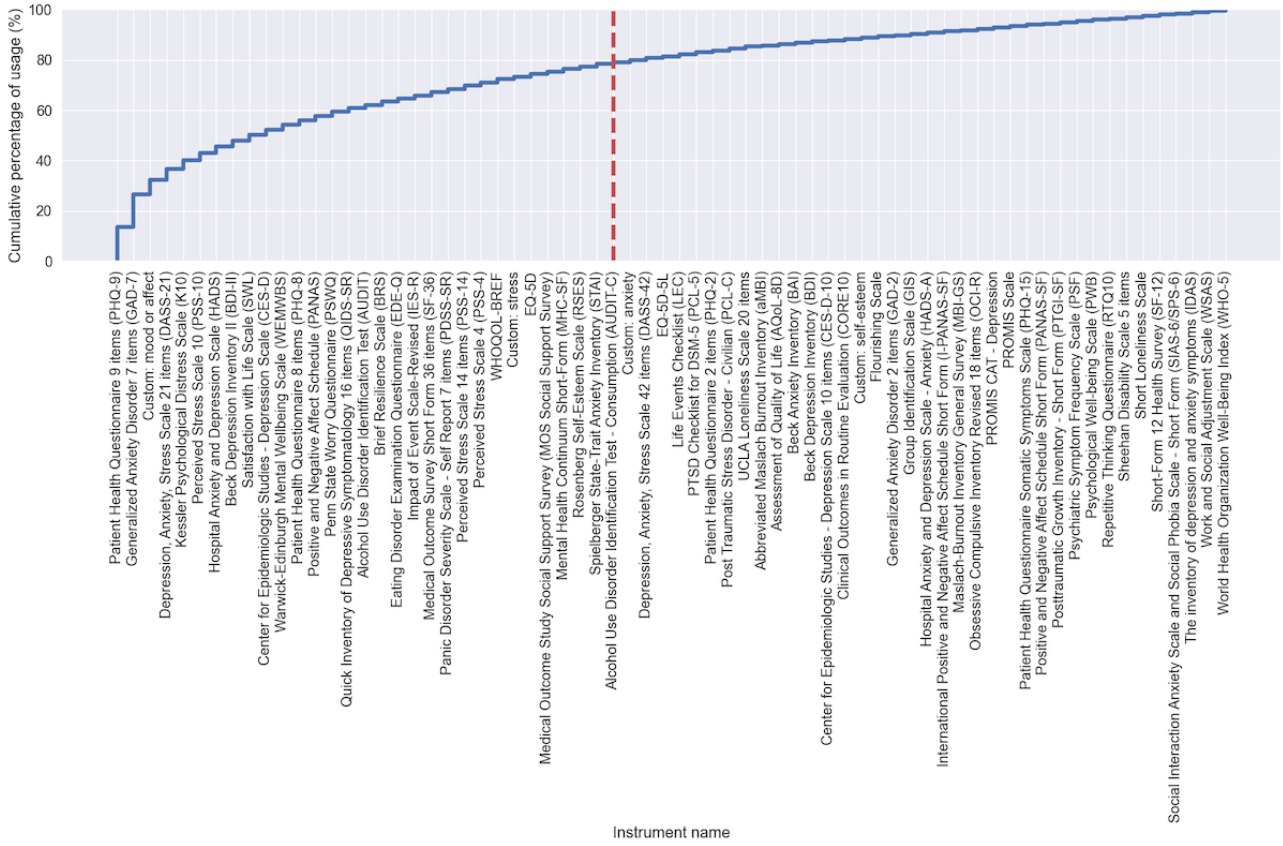
Searches on 5 databases (Scopus, Web of Science, PubMed, PsycINFO, and Psychology & Behavioral Sciences Collection [via EBSCOhost]) returned 191,815 records, of which 95,849 were unique records after deduplication (Figure 3). Preliminary screening of titles and abstracts resulted in 8460 eligible records for full-text screening. As noted above, 1000 of 8460 eligible records were randomly selected in batches of 250 for full-text screening over 4 iterations. Statistical tests were conducted to evaluate the representativeness of the instruments' usage distribution (the key variable of interest) within each iteration across the 1000 records, as described in the results below. Among these 1000 records, 770 were deemed ineligible, and 7 records were excluded through author nonresponse to queries from ZHK. A representative group of 223 records was included for data extraction and synthesis.

XSL•FO
RenderX

Figure 3. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart showing how records were identified from the initial search to the final decision. *: for pragmatic reasons, 1000 records were randomly sampled from 8460 records over 4 iterations for full-text screening. Statistical testing of the validity of this pragmatic strategy is described above and reported below.

Among the 770 records deemed ineligible during full-text screening, the most common reasons for excluding records were that the instrument was non-English [263-265], records were reviews, meta-analyses, or book chapters [25,266], the instrument had not been administered repeatedly [267,268], was not self-reported [269,270], or was nondigital [271,272].

The 223 included records (empirical studies) reported the usage of 278 eligible self-report mental health instruments, of which 68 were used in more than 1 record. To ensure our synthesis was manageable, we selected instruments that were most commonly used across studies, resulting in 30 of 68 instruments, which accounted for approximately 78.4% (308/393) of the



XSL•FO
RenderX

total instruments' usage across studies (see Figure 4 for details about the selection).

Six instruments in Figure 4 were excluded from the 30 instruments to narrow the measurement construct more precisely onto states of mental health. Specifically, instruments were excluded for the following reasons: first, the Penn State Worry Questionnaire, Brief Resilience Scale, and Rosenberg Self-Esteem Scale were excluded because they measure traits, which are not the focus of this review. These instruments were not excluded during screening and data extraction because it was unclear that they measured trait-like constructs based on their repeated usage in the included empirical studies. It became apparent that subsequent secondary searches that obtained the original publication of these instruments have illuminated the ineligibility of these instruments in this review (n=3). Second, the MOS Social Support Survey measures social support rather than mental states (n=1). Third, custom questions on mood or affect and stress were excluded because they were nonstandardized instruments, with question items varying from study to study (n=2). The synthesis from here on will focus only on the remaining 24 instruments (Table 1) among 147 studies.

The statistical investigation of our pragmatic strategy for reducing the number of records for full-text review involved, first, a chi-square test of the distribution of instruments' usage across the 4 iterations of sampling. As expected, the test was not significant (χ^2_{69}=60.98, *P*=.74). However, one of the assumptions (80% of the expected values >5) of the chi-square test was not met. Hence, a Fisher Exact Test was subsequently conducted, which was also not significant (*P*=.74). Therefore, we could not reject the null hypothesis of no difference, indicating that the usage distribution of instruments across batches was not significantly different. Given that each batch of records was randomly sampled from a population of 8460 records, this finding suggests that the usage distribution of instruments presented in these batches most likely approximates the overall instrument usage of all eligible records.

Figure 4. Cumulative percentage of the 68 instruments' usage across studies. Thirty instruments were selected for synthesis (left of the red dotted line) and accounted for 78.4% (308/393) of the total instruments' usage across studies. Instruments with names prefixed with "custom:" are groups of custom questions created by researchers to measure similar mental health constructs commonly used in ecological momentary assessment studies. For example, the instrument named "custom: mood or affect" includes custom questions measuring mood or affect.

XSL•FO
RenderX

Table 1. The 24 instruments selected for synthesis, sorted by descending usage frequency.

Instrument	Mental health constructs measured	Deficits- or strengths-focused
Patient Health Questionnaire 9 Items (PHQ-9) [18]	Depression	Deficits
Generalized Anxiety Disorder 7 Items (GAD-7) [68]	Anxiety (generalized anxiety disorder)	Deficits
Depression, Anxiety, Stress Scale 21 Items (DASS-21) [69]	Depression, anxiety, and stress	Deficits
Kessler Psychological Distress Scale (K10)[a] [13]	Psychological distress	Deficits
Perceived Stress Scale 10 Items (PSS-10) [70,71]	Stress	Deficits
Hospital Anxiety and Depression Scale (HADS) [72]	Anxiety and depression	Deficits
Beck Depression Inventory II (BDI-II) [19]	Depression	Deficits
Satisfaction With Life Scale (SWL) [73]	Life satisfaction	Strengths
Center for Epidemiologic Studies-Depression Scale (CES-D) [74]	Depression	Deficits
Warwick-Edinburgh Mental Well-Being Scale (WEMWBS) [16]	Mental well-being	Strengths
Patient Health Questionnaire 8 Items (PHQ-8) [75]	Depression	Deficits
Positive and Negative Affect Schedule (PANAS) [76]	Positive affect and negative affect	Deficits and strengths
Quick Inventory of Depressive Symptomatology 16 Items (QIDS-SR)[a] [77]	Depression	Deficits
Alcohol Use Disorder Identification Test (AUDIT) [78]	Alcohol use	Deficits
Eating Disorder Examination Questionnaire (EDE-Q) [79]	Eating disorder	Deficits
Impact of Event Scale-Revised (IES-R) [80] (first edition) [273]	Posttraumatic stress disorder	Deficits
Medical Outcome Survey Short Form 36 Items (SF-36)[b] [81,82,274]	Vitality, social functioning, role-emotional, and mental health	Deficits and strengths
Panic Disorder Severity Scale-Self Report 7 Items (PDSS-SR) [83,84]	Panic disorder	Deficits
Perceived Stress Scale 14 Items (PSS-14) [70,71]	Stress	Deficits
Perceived Stress Scale 4 Items (PSS-4) [71]	Stress	Deficits
WHOQOL-BREF[b,c] [85]	Psychological (positive feelings, cognitions, self-esteem, body image, negative feelings, and spirituality)	Deficits and strengths
EQ-5D (also known as EQ-5D-3L)[b] [86]	Anxiety or depression	Deficits
Mental Health Continuum Short-Form (MHC-SF) [14,15]	Mental well-being (emotional well-being, psychological well-being, and social well-being)	Strengths
Spielberger State-Trait Anxiety Inventory (STAI) [87]	Anxiety (state and trait)	Deficits

[a]These instruments were developed or psychometrically evaluated using item response theory during the first publication of the instruments.

[b]These are instruments measuring quality-of-life domains; only relevant mental health constructs are listed.

[c]WHOQOL-BREF: The World Health Organization Quality of Life (abbreviated version).

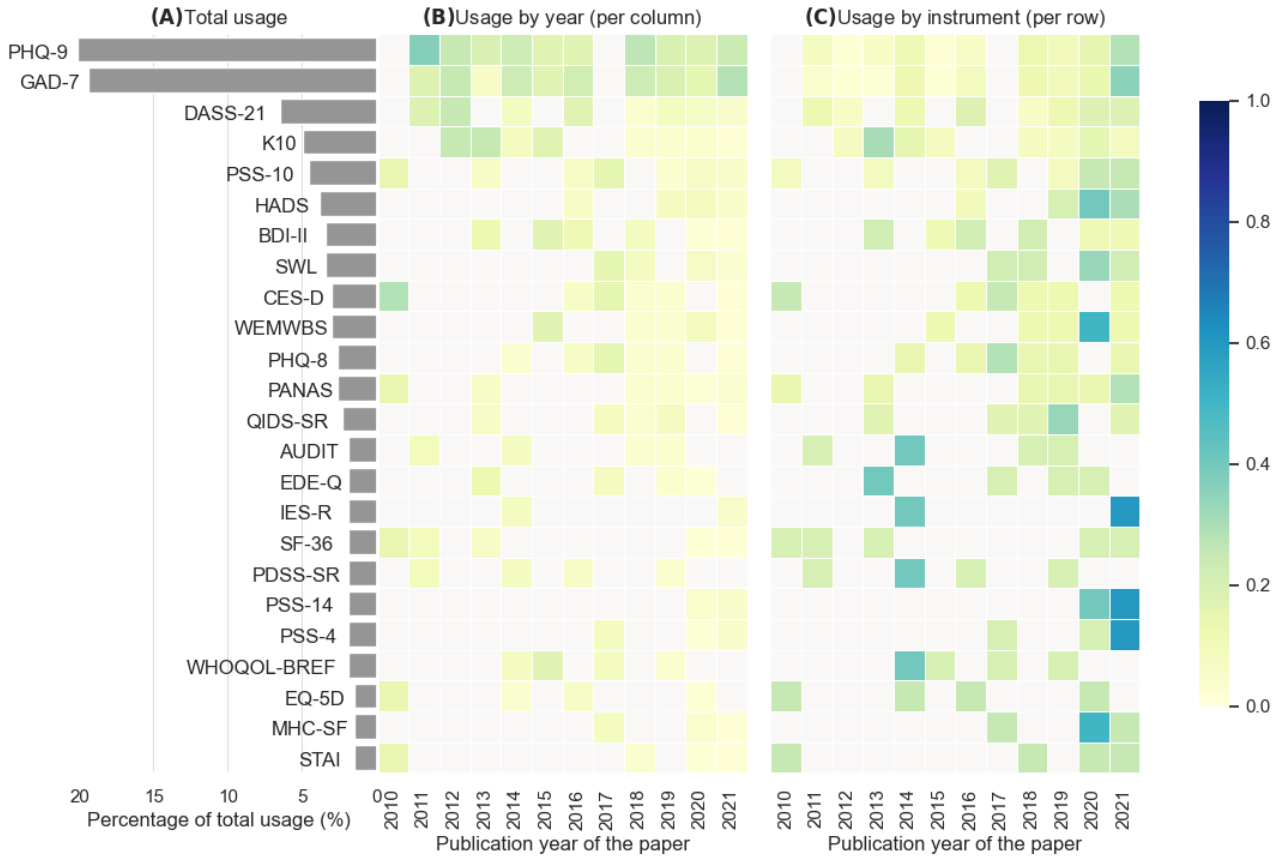
Instrument Synthesis

Some instruments in Table 1 are shorter versions of the same instruments, which are listed separately due to usage differences. For example, Patient Health Questionnaire 8 Items [75] is identical to PHQ-9 [18] except without the item measuring suicidal thoughts or self-harm. Likewise, the Perceived Stress Scale 10 Items (PSS-10) and Perceived Stress Scale 4 Items are shorter versions of the Perceived Stress Scale 14 Items [70,71]. The 24 instruments that were included for synthesis in Table 1 can be loosely categorized into 3 groups: deficits-focused (18 instruments, 75%), strengths-focused (3 instruments, 12.5%), and "holistic" (deficit and strength, 3 instruments, 12.5%). The top 7 most commonly used instruments were deficits-focused, measuring perceived stress (eg, Perceived Stress Scale 14 Items), psychological distress (eg, K10), and early symptoms of anxiety (eg, Generalized Anxiety Disorder 7 Items [GAD-7]) and depression (eg, PHQ-9). In contrast, among the 3 strengths-focused instruments, the Satisfaction With Life Scale (SWL) measures life satisfaction while the other 2 (Warwick-Edinburgh Mental Well-Being Scale [WEMWBS] and Mental Health Continuum Short-Form [MHC-SF]) measure broad mental well-being constructs. SWL has the highest usage compared to the other 2 strengths-focused instruments. Among the 3 instruments measuring deficits- and strengths-based constructs, 2 measure health-related quality-of-life (HRQoL)

XSL•FO
RenderX

instruments (Medical Outcome Survey Short Form 36 Items [SF-36] and The World Health Organization Quality of Life [abbreviated version, WHOQOL-BREF]), which typically subsume multiple constructs in different domains apart from mental health, such as physical health and functioning. EQ-5D is an HRQoL instrument, but was categorized as a deficits-focused instrument here because it measures only symptoms of anxiety or depression within the mental health domain. The final "holistic" measure was the Positive and Negative Affect Schedule, which measures positive and negative affect.

It is noteworthy that the original versions of all 24 instruments were developed and published before the year 2008 (Table 1 and RQ2 under Section S2 in Multimedia Appendix 3). Indeed, the Center for Epidemiologic Studies-Depression Scale (CES-D), PSS (14-item, 10-item, and 4-item), Hospital Anxiety and Depression Scale, Spielberger State-Trait Anxiety Inventory, SWL, and Positive and Negative Affect Schedule were published before the year 1990. Between the years 1990 and 2000, instruments measuring symptoms of mental illness other than anxiety and depression emerged such as Alcohol Use Disorder Identification Test (measuring alcohol use), Eating Disorder Examination Questionnaire (measuring symptoms of eating disorders), Impact of Event Scale-Revised (measuring symptoms of posttraumatic stress disorder) and Panic Disorder Severity Scale-Self Report 7 Items (measuring symptoms of panic disorder). During this period, SF-36, an HRQoL instrument, was also being developed. From the year 2000 onward, instruments screening symptoms of anxiety and depression, and measuring multifaceted mental well-being began to arise, such as PHQ-9, GAD-7, K10, MHC-SF, and WEMWBS. The HRQoL instrument WHOQOL-BREF was also developed after the year 2000.



Only 2 instruments (K10 and QIDS-SR) used IRT in the original publication (annotated [a] in Table 1 and RQ2 under Section S2 in Multimedia Appendix 3). The remaining instruments were typically developed using the factor analytical approach of CTT. It is noteworthy that the emerging PROMIS instruments, which were developed with digital administration in mind using contemporary test construction approaches such as IRT and CAT, have lower usage (less than 4/393, 1% of the total usage in Figure 4) compared to other instruments that were originally developed in paper-and-pen format.

Instrument Usages

Figure 5 presents the 24 instruments' usage from different perspectives across 147 studies. Figure 5A shows the distribution of the usage percentage of instruments. The top 3 instruments, which are deficits-focused, collectively contributed 46.2% (121/262) of the total usage of the 24 instruments (N=262): PHQ-9 (53/262, 20.2%), GAD-7 (51/262, 19.5%), and Depression, Anxiety, Stress Scale 21 Items (DASS-21; 17/262, 6.5%). Figure 5B breaks down the instrument's usage by the record's publication year. For each instrument, the usage pattern each year appeared to mimic its total usage pattern (Figure 5A), with the top 2 instruments (PHQ-9 and GAD-7) showing consistently high usage patterns across years since 2010. All included instruments were developed and released before 2010, so there is no need to consider the creation year when calculating usage frequency, as defined in our protocol [56]. Figure 5C presents a different perspective on each instrument. This figure shows the usage frequency by instrument (between 2010-2021), in which most instruments have higher usage toward the years 2020 and 2021, most likely influenced by the number of published records in 2020 and 2021 (Multimedia Appendix 5). Nonetheless, some top instruments (eg, PHQ-9, GAD-7, DASS-21, K10, and PSS-10) have been used almost consistently since 2010 among the included studies. In contrast, instruments measuring mental well-being, such as the SWL, WEMWBS, and MHC-SF, have only been used since 2015.

Study Characteristics

Table 2 summarizes how the 24 instruments were administered in the studies identified (n=147). Among the included studies (grouped by instruments) in Table 2, each instrument was administered in various digital modalities and frequencies to the general population. The most common digital modalities for administering these instruments were through web applications accessible by any internet-connected device and mobile apps. The frequency of administration of the included instruments varies from multiple times a day [275,276] to yearly [277,278]. Studies that administered the same instrument multiple times per day typically used an experience sampling design such as ecological momentary assessment (EMA) [279]. The response time frame of instruments was typically adapted by including studies despite the original scales having a default recommended duration (eg, past 2 weeks and past 4 weeks).

Comparison With Existing Literature

The set of frequently used instruments identified here broadly aligns with findings of past reviews examining outcome measurements. Points of difference are likely due to the unique focus of this review on digital and longitudinal applications of the instruments. The commonly used measurement instruments that Breedvelt et al [66] found were included in the initial 68 instruments in the present review, except for the Edinburgh Postnatal Depression Scale [415] and General Health Questionnaire-12 [416]. The Edinburgh Postnatal Depression Scale was excluded because it is outside the scope of the present review. It is noteworthy that Breedvelt et al [66] found that the CES-D was the most commonly used instrument in measuring

XSL•FO
RenderX

depression, followed by the Beck Depression Inventory II and the PHQ-9, whereas in the present review, we found that the usage of the PHQ-9 is substantially higher than that of any other instrument. This difference may be due to the present focus on digital, repeated measures application, especially given that the PHQ-9 is commonly used in mobile apps for EMA studies [417,418].

Most instruments measuring mental well-being and HRQoL found in the present review were also identified in an earlier review by Lindert et al [61] of well-being measurement scales. An exception, however, is the MHC-SF. The difference in review timeframes between Lindert et al (2007-2012) [61] and the present review (2010-2021) may explain this discrepancy. Another plausible explanation is that Lindert et al [61] focused on subjective well-being, whereas MHC-SF is conceptually broader than subjective well-being. In contrast, a recent scoping review focusing on the dual-continua model of mental health [55] found SWL and MHC-SF to be the most used measurements for positive mental health—both instruments appear in Table 1 here. Beidas et al [96] found 29 validated mental health screening instruments for the general adult population that are free and brief. Some instruments found in the present review, such as the DASS-21, CES-D, K10, and PSS-10, were not included in their review, most likely due to differences in search scopes and review aims.

Discussion

Overview

The present scoping review aimed to advance our understanding of the range of instruments that could function as mental health self-monitoring tools in the digital era. This was achieved by identifying empirical studies that administered instruments in (1) the general population, (2) digital format, and (3) longitudinal designs. To the best of our knowledge, this is the first review that focuses on studies that administered instruments meeting these 3 criteria. The primary outcome was an ordered list of commonly used instruments that measure mental health longitudinally using digital technologies in the general population.

Principal Findings

The literature review and synthesis generated 2 major findings. First, among the 24 most commonly used instruments, the majority (18/24, 75%) were deficits-focused. PHQ-9 and GAD-7 were by far the most used instruments, with consistent yearly usage between the years 2010 and 2021, measuring symptoms of depression and generalized anxiety, correspondingly. In the present review, the considerably higher usage of PHQ-9 and GAD-7 (Figure 5) was unsurprising because they have been used extensively as longitudinal measures for mental health, from web-based applications to mobile apps for EMA studies [417,418]. These 2 instruments are also nominated for use in a recent global effort to standardize mental health measures [419].

The list of commonly used instruments also included strengths-focused instruments (eg, SWL, WEMWBS, and MHC-SF). Instruments measuring HRQoL (eg, SF-36 and WHOQOL-BREF) are a different type of commonly used instrument—from Keyes' framework, they can be understood as measuring aspects of deficits-based (eg, anxiety or depression) and strengths-based (eg, positive effects or energy level) mental health constructs in conjunction with ratings of physical health domains and functioning. Among the strengths-focused instruments, SWL, WEMWBS, and MHC-SF, measuring life satisfaction and mental well-being, were found to be the most used instruments.

The predominance of deficits-focused instruments found here is at least partly due to the traditional elevation of illness-focused constructs in psychology and mental health research and practice (not to mention medicine and psychiatry [420]). The granularity of the deficits-based constructs measured by these instruments may also contribute to their disproportionate usage. For example, deficits-focused instruments are typically unidimensional and high-fidelity [421,422] as these instruments emphasize the accuracy and specificity of screening for or diagnosing specific mental disorders. In contrast, strengths-focused instruments and HRQoL instruments are typically multidimensional, containing broad constructs of measurement (also known as high bandwidth), addressing the complexity and variability of the domain of mental health or general health [62,423].

It is important to note that, used in isolation, the population deficits-focused instruments identified here may have limited utility as longitudinal mental health self-monitoring tools in the general population. The prevalence of mental disorders in the general population is relatively low, so deficits-focused instruments measuring symptoms of mental illnesses tend to exhibit floor effects [97,424,425]. While these screening instruments play a role in potentially detecting early symptoms of mental illnesses, they may not be so helpful in providing a general picture of individuals' mental health over time. The dual continua model of mental health suggests that measuring strengths-based constructs could complement deficits-focused measurement and consequently provide more ecologically valid and statistically sensitive assessments for the general population.

Second, while the 24 instruments synthesized in this review have been frequently administered in digital modalities (1 of the review's 3 inclusion criteria), they were all developed at least 2 decades ago, and most followed CTT and were designed for paper-and-pen format. Since then, we have seen substantial work using IRT to revalidate the psychometric properties of these instruments [426-428], but (except for the PROMIS project) less attention has been devoted to new instrument development.

Next-generation mental health assessments could harness the computational power offered by digital technologies, coupled with contemporary psychometric practices such as IRT and computerized adaptive testing, to advance evidence-based assessments. Undoubtedly, a holistic instrument that measures both deficits- and strengths-based constructs may contain a larger number of self-report items compared to deficits- or strengths-based instruments alone. However, the combination of IRT and computerized adaptive testing can significantly reduce the number of questions asked in a survey [35], which reduces respondent fatigue burden [429], a common phenomenon where participants lose motivation when

XSL•FO
RenderX

completing long or repeated surveys, affecting the data quality. This phenomenon is particularly prominent in self-monitoring instruments, which are typically administered multiple times over a period [430]. Therefore, there is a golden opportunity to lift the capability of evidence-based assessments through digital technologies, which provide an excellent launching platform for a digital tool that encourages people to monitor their mental health.

Limitations

Due to the sheer volume of eligible records for full-text screening, for pragmatic reasons, we randomly selected 4 batches of 250 records (a total of 1000 records) of the 8460 eligible records for full-text screening and synthesis after the preliminary screening. Although we demonstrated that the distributions of instruments' usages were statistically indicative of the full records, we cannot definitively exclude the possibility that this pragmatic strategy biased our findings. However, given the prominence of a few commonly used instruments at the top of the list (eg, PHQ-9 and GAD-7) and previous studies in the literature, it seems unlikely that we missed any instruments that would have warranted inclusion in the top 30 (Figure 4). Our primary objective is to develop a novel ranking of the most frequently used instruments that are potentially suitable for mental health self-monitoring in the general population. Future studies can elaborate on and update the results presented in the present study by considering records that were not selected for full-text screening. Additionally, the restriction on English-only instruments in this review may limit the generalizability of the results.

Implications

This study has several implications for future research. First, the finding that deficits-focused instruments predominate the ranking of usage frequency despite their known distributional problems in the general population (floor effects) calls for serious consideration of more holistic instruments. As positive psychology, recovery, and mental health promotion and prevention gain traction [420], future research studies should work toward the development of more holistic measures, potentially informed by the dual continua model [431-434]. Such measures for general population use would adequately capture both deficits (constructs relevant to a significant minority of the population, and of great interest clinically) and strengths (constructs that have the potential to support the majority of the population to advance their positive mental health).

Second, the 24 instruments included in the final synthesis of measures, while commonly used, were originally designed more than a decade ago for use in paper-and-pen format without taking advantage of the great possibilities of digital measurement, such as computerized adaptive testing. Although these instruments have been translated into digital format, we observed that the implications of such direct translation may not have been fully investigated, especially when these instruments were administered in repeated measurements with short intervals (eg, multiple times per day), such as EMA studies.

Finally, we highlight that advances in technology's power and reach (eg, smartphones [435-437]) and developments in psychometric practice (eg, IRT and computerized adaptive testing [34,35]) provide exciting opportunities for optimizing digital delivery of psychological measures. While existing deficits-focused instruments could be (and often are) used alongside a strengths-focused measure (eg, HRQoL [438] or SWL [439]), this strategy has some significant limitations. Specifically, it does not recognize the overlap between the 2 dimensions of mental health as proposed in the dual continua model, generates unnecessary response burden, and limits construct validity. Given that the intercorrelated relationship between deficits- and strengths-based mental health constructs is well-established in the literature [14,55], measuring both of them in a single instrument, as we argued, has the optimal construct validity. Theoretically, with the advances in digital technologies, a next-generation low-burden mental health monitoring tool that can measure both deficits and strengths of individuals' mental health that is relevant and engaging is entirely feasible. Indeed, findings from the present review suggest that a novel computerized adaptive testing instrument could be purposely built to achieve this aim [440].

Conclusions

Although the last decade has seen a shift in the conceptualization of mental health to recognize strengths-focused concepts alongside traditional deficits-focused constructs, our review found that when it comes to an important translational opportunity—measuring mental health digitally and longitudinally in the general population, as is required for mental health monitoring, the literature remains skewed toward illness- and deficits-based constructs. The review also found that this legacy conceptualization of mental health comes along with a legacy approach to test development. We conclude that the computational power and ubiquity of digital technologies have untapped potential to advance mental health measurement by supporting a more holistic characterization of the complexity intrinsic to the mental health construct. Specifically, IRT-based development of a dual-continua mental health instrument to be delivered via CAT is an exciting possibility for the near future.

Acknowledgments

We would like to acknowledge librarian Mr David Bradley from Swinburne University of Technology for his valuable input in formulating the search strategy for this review. We also would like to acknowledge Dr Hailey Tremain, Dr Armita Zarnegar, and Ms Piyumi Kahawage from Swinburne University of Technology for providing insightful input on using text-mining techniques in this review. This research is supported by Digital Health CRC (Cooperative Research Centres) Limited ("DHCRC") [441] and SiSU Health [442] through a PhD scholarship (DHCRC-0049) and supporting the project costs for data collection, data management,

Abstract

Background: There has been an increase in the use of online mental health forums to support mental health. These forums are often moderated by trained moderators to ensure a safe, therapeutic environment. While the moderator role is rewarding, it can also be challenging. There is a need to understand the impact of the role on moderators and how they can best be supported to maintain psychological well-being.

Objective: This study aimed to understand how, why, and in what contexts moderator well-being is affected by the moderator role and produce actionable recommendations for how moderators can best be supported to maintain workplace psychological well-being.

Methods: We conducted realist synthesis of (1) published and gray literature from 2019 to 2023, (2) stakeholder interviews with forum moderators and hosts, and (3) moderator training manuals developed by organizations that host online mental health forums. Self-determination theory was used as the theoretical basis for this synthesis.

Results: We developed 24 context-mechanism-outcome configurations from our realist analysis of 9 published papers, 18 interviews, and 5 training manuals. The findings highlight the specific ways in which moderator well-being can be supported through meeting the psychological needs for autonomy, competence, and relatedness. Forums that allow moderators to work in alignment with their personal motivations can increase moderator well-being. Forum organizations should support moderator competence through initial expectation setting, especially around moderator responsibility for user well-being, and ongoing support, such as meaningful supervision and peer support. Co-designed training, reflective practice, and experiential learning are

XSL•FO
RenderX

all key to increasing moderator competence and satisfaction in the workplace. Working within a diverse team with access to innovative forum design can increase moderator psychological well-being. Organizational support for moderators' well-being through monitoring and encouraging self-care is vital to ensure moderators can effectively carry out their role. Making and supporting meaningful relationships in the forum can boost psychological well-being and the therapeutic value of the moderator role. Key challenges for moderators were dealing with conflicts between supporting open discussion and ensuring a safe community environment, sharing lived experiences in positive ways for both moderator and user, and supporting people within the limitations of an anonymous forum.

Conclusions: This realist synthesis is the first to examine the impacts on well-being of being a moderator of an online mental health forum. Recommendations to support moderator psychological well-being are proposed, targeted at specific stakeholder groups to aid implementation. Organizational-level endorsement and facilitation of support are particularly important for the realization of recommendations and interventions to support moderator well-being.

Introduction

Background

Online support for mental health (MH) problems is growing in line with the increasing demand for digitization [1] and problems with restricted access to health care services [2]. Online MH forums are a type of online support, providing a space for people with MH problems and their loved ones to receive and provide information and support related to MH difficulties [3]. Online MH forums offer 24-7, asynchronous access and the freedom for users to post what and when they choose (within the limits of forums' terms and conditions), often in an anonymous environment [4,5].

Many online MH forums are overseen by moderators whose primary role is to ensure a safe, therapeutic [6], and engaging [7] environment by (1) providing direct support when needed, (2) managing content through editing or deleting potentially distressing posts, and (3) ensuring safety by identifying and responding to risk of harm to users or other safeguarding concerns [8]. While moderation is acknowledged as an integral role within online MH forums [9] and may have some benefits for moderators, such as satisfaction derived by helping others [8], it is also associated with challenges, such as exposure to distressing content; unclear role expectations; balancing conflicting tasks; and communicating about emotional issues in a limited, text-only environment [10]. Furthermore, the role and associated support needs may be experienced quite differently depending on the moderators' backgrounds. Some moderators are specifically employed based on their lived experience (eg, the Relative Education and Coping Toolkit trial employed carers of people with severe MH problems as moderators of a forum for carers [11]) and may be motivated to help others in a similar situation [6] by drawing on their shared personal experience to tell relevant stories, normalize experiences, and empathize with forum users. Other moderators are practitioners with formal MH training (such as the registered MH professionals who moderate Togetherall [12]), bringing another type of experience to the role. In other contexts, moderators are employed or work voluntarily without any prerequisite that they have lived experience or formal MH training (such as the volunteer moderators on Reddit [13]). Moderators who draw mainly on their lived experience of MH problems may find that negative emotions are provoked by the personal resonance of potentially distressing content, depending on the support and training they have received. These moderators are often volunteers in a role that may not be supported in the same way as other professional MH support roles, for example, through access to supervision and forums related to guidance and protocols. Given the challenging nature of the role, there is an urgent need to better understand the experiences of moderators in online MH forums and understand how best to support their psychological well-being.

While recent literature has paid more attention to the crucial role of the moderator in online MH forums from the perspective of supporting the forums and their users [3,8] and suggested some ways to support moderators of self-harm and suicide content specifically (eg, broadening practitioner-moderator scope to deal with crisis, provision of timely support, clear guidelines for practice, peer support from other moderators, and multiple channels for interaction with users [4,14]), no research to date has explored the general support needs of moderators of broader online MH forums. Without adequate support themselves, moderators may be less able to offer high-quality support to forum users and more likely to leave their role. As a result, online MH forums may either shut down, leaving users without access to needed information and support, or continue operating with inadequate or no moderation, which can make them potentially unsafe.

Objectives

The aim of this study was to understand how, why, and in what contexts moderator well-being is affected by the moderator role and how moderators can best be supported to maintain workplace psychological well-being. This was achieved by conducting a realist review of relevant academic literature, synthesized with moderator training manuals and interviews with moderators (conducted by the research team)—hereafter referred to as realist synthesis [15]. The goal was to develop a program theory to explain the key contexts and mechanisms that impact moderator workplace psychological well-being. The findings were used to produce actionable recommendations, based on the program theory, for how support for moderators can be designed, implemented, and iterated in contextually

sensitive ways. The study is part of the larger improving Peer Online Forums (iPOF) program to support MH [16].

Realist synthesis is a theory-driven review that draws on a realist philosophy of science to understand contexts and causal mechanisms, which, in this case, explain how and why the moderator role impacts moderator well-being [17]. Self-determination theory (SDT [18,19]) was chosen as the theoretical basis for this synthesis. The definition of well-being according to SDT emphasizes both subjective states, including positive emotion and the significance of functioning well in accordance with personal goals and values [20]. Well-being emerges from the satisfaction of what the theory identifies as universal, basic psychological needs for autonomy (feeling in control of one's own actions and an alignment between action and personal goals and values), competence (feeling able to carry out one's role and being effective in doing so), and relatedness (feeling a meaningful connection with others). SDT has well-established, strong empirical support as a framework for understanding well-being, including specifically within a workplace setting (refer to the review by Nunes et al [21]), and therefore provides an appropriate lens through which to explore moderator workplace well-being.

Methods

Informed by guidance for realist methods [22], the synthesis followed 5 stages.

Stage 1: Defining the Scope of the Synthesis

At the beginning of the iPOF project [16], the research team—which included mental health academics and clinicians, forum hosts (senior staff with managerial roles at organizations that host online MH forums) and moderators, people with lived experience of MH challenges, and realist methodologists—held a stakeholder consultation workshop. Group discussions highlighted that the demands of conducting moderation are considerable and that a well-supported workforce is essential for the safe and effective delivery of online forums. Improving moderator well-being and retention were identified as key priorities for host organizations. Our initial intention was to focus on the impacts of forums on users only; however, following this consultation, we designed this synthesis to focus specifically on understanding the moderator role and what support was needed to enhance moderator workplace well-being. A parallel realist synthesis conducted by the iPOF team, focused on the impact of forums on user MH, is reported elsewhere [23].

Stage 2: Developing Initial Program Theories

Initial program theories are preliminary ideas regarding how a process is expected to operate [22]. We built an initial program theory by first drawing on ideas generated through creative brainstorming by the research team based on personal and research experience and through field notes from the initial stakeholder consultation workshop. These initial ideas were mapped onto the psychological needs for autonomy, competence, and relatedness, as defined by SDT. This led to the development of an initial program theory framework tentatively identifying factors that could influence moderators' psychological needs and therefore their well-being, such as training, supervision, and moderators' professional backgrounds.

Stage 3: Searching for Evidence

This synthesis drew on 3 evidence sources: published and gray literature, stakeholder interviews conducted by the research team, and moderator training manuals developed by organizations that host online MH forums.

To identify relevant literature, a systematic search for evidence related to online MH forums was conducted, covering the period from January 2019 to May 2023. The rationale for restricting our search to 2019 was that recent evidence is more likely to reflect the current context in which moderators work within online forums, increasing the relevance of any recommendations made on the basis of this evidence synthesis [24]. This includes website functions, current online culture, trends in use, and the wider context of MH support. Furthermore, initial practice searches suggested that limiting the search to 2019 would mean that the screening burden would be manageable, given the resources available for the review. Databases used to identify evidence sources were Academic Search Ultimate, Embase, Scopus, Web of Science, PsychINFO, MEDLINE, and Allied Health Literature (CINAHL). Search terms were developed with the support of an information specialist at Lancaster University. In addition to database searches, we searched gray literature on Google, Overton, Trip medical database, National Grey Literature Collection, International Clinical Trials Registry, National Health Service Knowledge, ProQuest, and Library Hub. Multimedia Appendix 1 shows the full search strategy.

This synthesis also included an analysis of interviews conducted for the iPOF study [16]. Participants were forum moderators (n=13) and senior forum staff responsible for supervising moderators (n=5), all from UK-based MH forums operated by the National Health Service, charities, and the private sector. Forums were primarily text-based, asynchronous discussion platforms, targeting support for adults and young people (aged >13 years). Participants were recruited through the forum partners as part of the iPOF study via email, provided with written information about the study, and gave written informed consent. These exploratory interviews were consistent with the "theory gleaning" stage of realist interviewing, where key informants provide details regarding how a program operates [25]. Interviewers used a topic guide focused on articulating the impacts of forums, including the role of moderators. As realist evidence synthesis selects only data that are relevant to the development of program theories, only data from these interviews related to the experience of online forum moderation were extracted for this synthesis. Data relevant to the impacts of forums on service users were analyzed for a separate realist synthesis. The topic guide and demographic details of participants are available in Multimedia Appendix 2.

Moderator training manuals were obtained via requests to organizations participating in the iPOF study that host online mental health forums, as well as through Google searches for publicly available documents published by forum providers, which included guidance for moderators on how to perform their role. In total, 5 moderator training manuals were included in this synthesis.

XSL•FO
RenderX

Stage 4: Selecting and Appraising Evidence

Evidence sources from relevant literature were eligible for inclusion if the evidence referred to forums that met the following criteria:

- The forum included a primarily text-based, asynchronous discussion platform.
- The forum was intended to support user MH, broadly defined to include any issue related to psychological distress. This included forums established to support people with specific MH difficulties, forums aimed at providing general MH support, forums providing support for those caring for someone with an MH difficulty, and forums for those experiencing issues such as loneliness and substance misuse.
- The forum was used by adults and young people, with >50% of users aged ≥13 years.
- The evidence source referenced the experience of forum moderators. Evidence related to forum moderators of any background was included, including paid or voluntary roles.
- No document or study type criteria were applied. Consequently, any document that met these criteria and was available in English was eligible for inclusion.

Titles and abstracts of articles identified by database searches were uploaded to the online systematic review platform Rayyan (Rayyan Systems) [26]. The review team, consisting of 9 researchers, initially screened 100 articles, discussed any discrepancies, and revised the screening procedure as needed. The reviewers were allocated a separate set of articles to screen. When reviewers were uncertain about the eligibility of a source, they flagged it for discussion during the weekly team meeting, where decisions were made collaboratively. The full text of each evidence source that passed the title and abstract screening was then reviewed by a second reviewer to confirm eligibility and appraised with reference to realist informed principles of relevance and rigor [27]. With regard to relevance, evidence sources were eligible if they included data highly relevant to developing program theories about the impacts of moderation. Relevant articles were included if they were also judged to be sufficiently rigorous [28]. Articles were judged as rigorous if their data collection methods were clearly articulated and methods used were consistent with associated results and conclusions. Screening instructions are included in Multimedia Appendix 3 [27,29]. The same initial, large literature search result was used to inform user-focused realist synthesis, reported elsewhere [23]. Each evidence source was therefore screened twice—once to identify content relevant to user impacts, and again to extract evidence related to moderators' experiences for the purpose of this synthesis.

Stage 5: Extracting and Synthesizing Evidence

Full texts of documents identified by evidence searches, interview transcripts, and moderator training manuals were analyzed simultaneously. This involved reviewing evidence sources for data related to moderator well-being that could be used to support the development of the initial program theory framework; relevant data segments were copied into an Excel (Microsoft Corp) spreadsheet organized around the 3 psychological needs for autonomy, competence, and relatedness. Codes were added to the data segments to identify important outcomes for moderators, the underlying mechanisms that lead to these outcomes, and what contextual factors were important in triggering these mechanisms. Contextual factors included characteristics of the forums and the individual moderators.

Context-mechanism-outcome configurations (CMOCs) are analytic outputs used in realist research to articulate causal processes that generate specific outcomes related to the process under investigation, which in this case was the moderator role. Following the study by Dalkin et al [30], the mechanism was subdivided into mechanism-resource and mechanism-reasoning. This helps distinguish the part of the underlying mechanism attributable to the program itself (in this case, the moderator role) from the moderators' responses to that resource (Multimedia Appendix 3 provides details of how CMOCs were operationalized). Initial CMOCs were refined iteratively as the data extraction progressed, with reference to initial program theories, accumulating evidence, and regular discussion within the research team. In the final stages of analysis, CMOCs were explicitly linked to the SDT framework to create an overarching program theory, highlighting how different aspects of the moderator role can support or frustrate moderators' psychological needs.

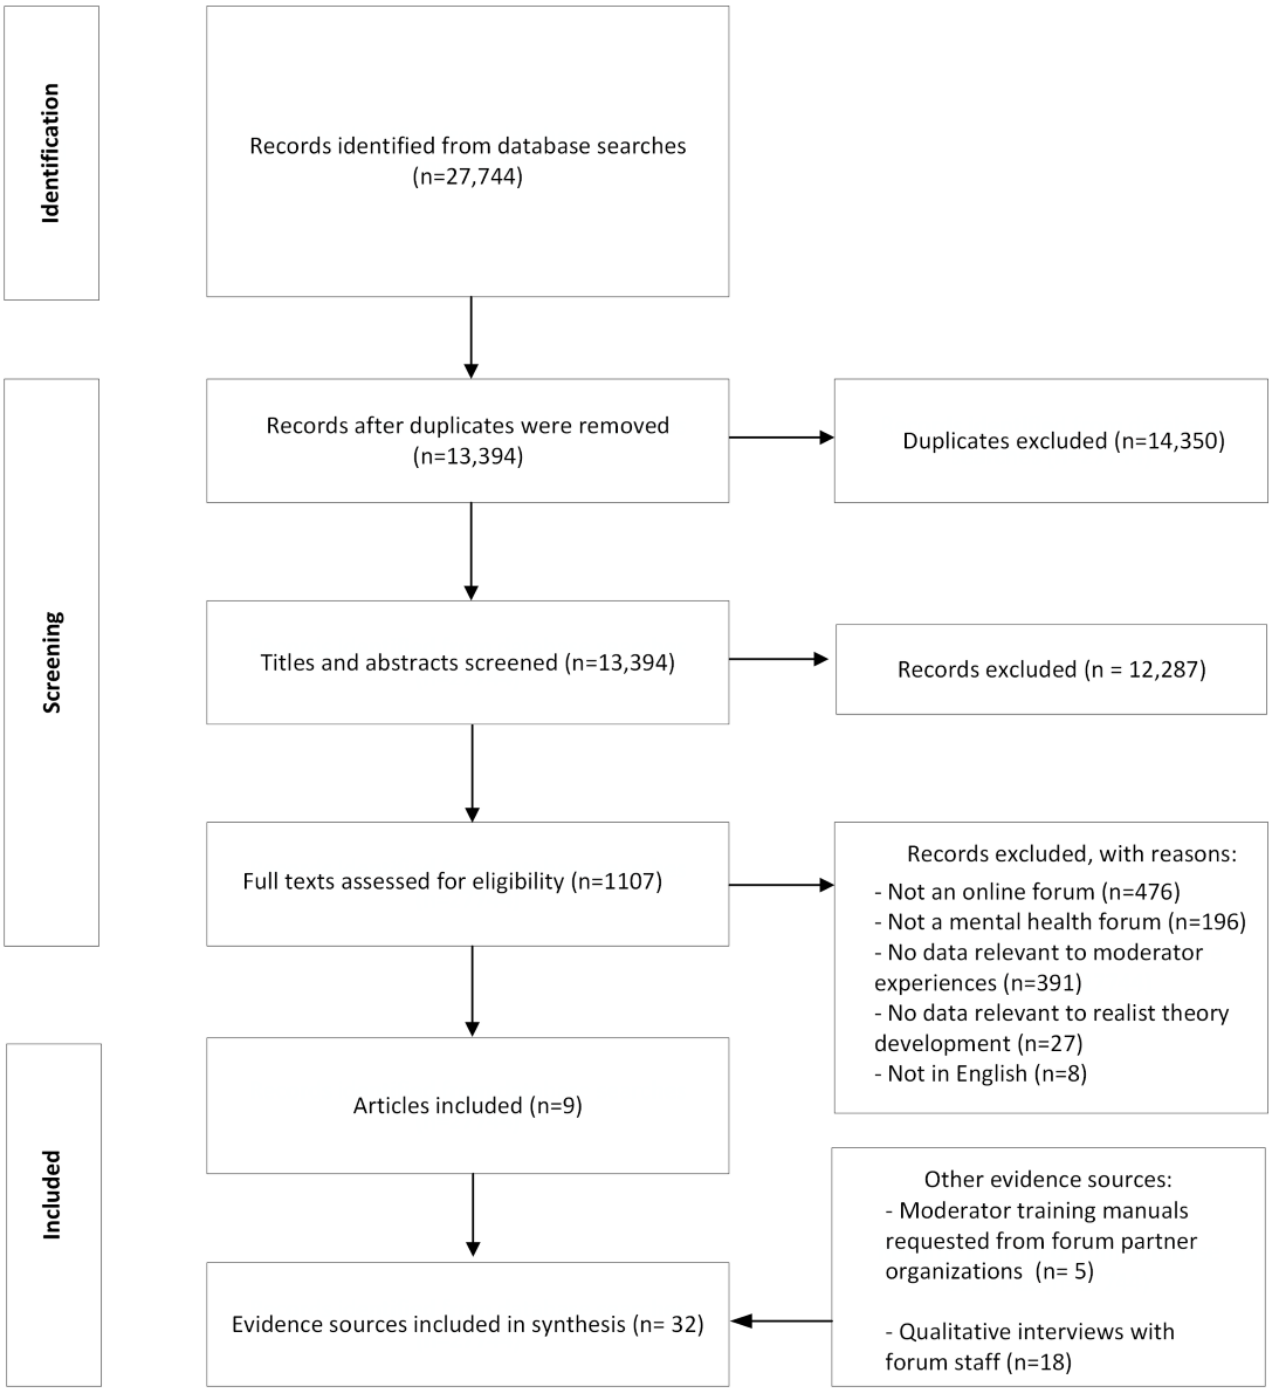
Example evidence to support the CMOCs is provided in Multimedia Appendix 4 [3-6,8,14,31-33], but edits have been made to replace any data that identify a specific forum or an individual with a generic term in square brackets. The aim is to protect the anonymity of participants contributing to any of the datasets used.

Stage 6: Developing Recommendations

We developed recommendations for how moderators can best be supported in the role based on the CMOCs developed from the evidence synthesis and in consultation with key stakeholders, including MH academics and clinicians, forum hosts and moderators, and people with lived experience of MH challenges. Specific and separate recommendations for support were developed for all key stakeholders involved in forum design, implementation, delivery, use, and evaluation.

Ethical Considerations

This study was granted ethics approval by the Solihull Research Ethics Committee (Integrated Research Application System 314029) on June 20, 2022, as part of the iPOF study [16] and was conducted and reported in line with Realist And Meta-narrative Evidence Syntheses: Evolving Standards guidance [34].



Results

Evidence Sources

We included 9 published academic papers (Figure 1), 13 interviews with forum moderators, and 5 interviews with forum hosts. We also included 5 forum manuals (Multimedia Appendix 5 [3-6,8,14,31-33]) requested from partner organizations. No further gray literature evidence sources were identified.

Figure 1. Evidence identification.

Context-Mechanism-Outcome Configurations

Overview

We developed 24 CMOCs from our realist analysis, structured around the psychological needs for autonomy, competence, and relatedness. Multimedia Appendix 6 provides a summary of the 24 CMOCs, which together make up the program theory. The narrative summary in the subsequent sections, along with Multimedia Appendix 6, should be read with reference to Multimedia Appendix 4, which provides quotes from the data in support of each CMOC. Finally, based on the CMOCs, Table 1 presents recommendations of ways in which moderators can be supported to achieve workplace psychological well-being.

XSL•FO
RenderX

Table 1. Key recommendations for supporting moderators of online mental health forums.

Stakeholder group	CMOCs[a]	Recommendations
For forum hosts	3-15 and 17-19	Forum hosts have a broad responsibility for enhancing moderator well-being and for facilitating them to effectively carry out the role. Hosts should do the following: • Consider the value of payment for moderators. • Prewarn moderators of exposure to potentially distressing contact and ensure they are aware of the support available to them. • Monitor moderator well-being and provide access to support, such as individual reflective supervision and peer support in a safe space that fosters trust and openness. • Provide training that is personalized to the culture and content of the specific forum and co-designed with (and delivered by) people with experience of moderation. • Allow space within training for shadowing more experienced moderators, exposure to the forum, and practice shifts and feedback. • Remind moderators of what is realistic in terms of how much control they have over users' situations. • Support moderators to respond to user posts with a unified voice in line with the forum culture. • Provide evolving, up-to-date guidance on how to identify and respond to risk appropriately. • Provide training focused on developing mental health literacy related to the specific mental health experiences likely to be discussed on the forum. • Provide access to resources that enhance moderator knowledge and expertise, such as trusted information and services. • Ensure moderators work as part of a team with diverse skills and experiences. • Provide support to help moderators manage competing demands on their time. • Encourage moderators to monitor their own well-being and implementation of self-care strategies (a valuable ethos may be "you can't support others if you don't support yourself").
For forum designers	14-16	Forums should be designed in such a way that moderators are supported to do their job. Forums could be designed to include the following: • A function for moderators to message a user privately and directly. • A function to flag potentially problematic posts for continued monitoring. • Access to interaction mechanisms other than post-comment based, such as emojis.
For forum moderators	4-12 and 17-24	Forum moderators should do the following: • Familiarize themselves with the role and what to expect before commencing the role of a moderator. • Engage in ongoing training provided. • Reflect on and refine their practice in line with feedback from supervision, other moderators, and forum users. • Take care to ensure expectations are realistic regarding how much control they have over a user's situation. • Signpost users to host-approved up-to-date resources when appropriate. • Draw on the diverse skills within the team. • Monitor their own well-being. • Implement personalized self-care strategies as needed. • Reach out for support from other moderators, supervisors, and hosts as needed. • Proactively moderate to collaboratively shape the tone and community environment. • Be mindful of when their input is needed and when it could impede peer support, that is, by "jumping in too soon" and preventing users from connecting with one another. • Ensure everyone gets a timely response, particularly if they are new users or their post indicates risk. • Take care to ensure professional boundaries are maintained. • Ask open questions to find out more about a user's situation if it is not clear. • Draw on lived experience, where applicable.
For forum team members, for example, other moderators	5, 12 , and 17	Forum team members should do the following: • Try to recognize and monitor the challenges moderators face. • Be available to provide support and guidance (eg, reiterating role boundaries and expectations for support provision), particularly when other moderators are struggling.
For forum users	1 and 17	Forum users should do the following: • Try to provide positive affirmation whenever appropriate—a thank you from a user goes a long way! • Recognize the emotional challenges associated with moderating (eg, they cannot please everyone all the time). • Try to be sensitive to the needs of the moderators as well as the forum community.
For researchers	1-24	Future research should aim to do the following: • Refine the theories. • Explore the impact of the recommendations on moderator (and user) well-being in online mental health forums. • Test the transferability of recommendations to general health forums.

[a]CMOC: context-mechanism-outcome configuration.

Autonomy (Feeling in Control of One's Own Actions and an Alignment Between Action and Personal Goals and Values)

Where moderators' motivations for engaging in the forum align with the role requirements, the psychological need for autonomy is more likely to be met (CMOCs 1-3). A key motivation for moderators to take up the role was to support others. Moderators felt a sense of accomplishment when they witnessed supportive communication and success stories on the forum because they interpreted this as evidence that their work had been beneficial in supporting users (CMOC 1). Moderators may experience distress when their required duties conflict with their personal motivations, for example, wanting to support the needs of users. A particular example of conflict was between respecting the needs of an individual user sharing a sensitive post versus protecting the wider forum community from harm through exposure to distressing content by editing or removing a post (CMOC 2). Where payment is the norm in specific organizational contexts, moderator motivation may be increased through payment congruent with the demands of the role. Payment may make moderators feel valued and decrease perceptions of the need for additional paid work, increasing moderator motivation and the likelihood of retention (CMOC 3).

Competence (Feeling Able to Carry Out One's Role and Being Effective in Doing So)

On commencing the role as a moderator, some feel a lack of competence and worry they might "say the wrong things and make someone's day already worse than they were feeling" (moderator 9). Increasing moderator competence to fulfill the requirements of the role is likely to increase workplace psychological well-being and can be done in several ways, as outlined in the subsequent sections (CMOCs 4-18).

Increasing Competence Through Initial Expectation Setting and Ongoing Support

Moderator competence can be increased by improving their understanding of the role from the outset and providing support to help them manage the ongoing emotional impact of exposure to potentially distressing online content (CMOCs 4 and 5). Before commencing the role, a clear outline of what moderators can expect from the role, in terms of exposure to distressing content and access to support, allows moderators to decide if or to what extent they are able to moderate (CMOC 4). Access to ongoing, regular reflective individual supervision and peer support, such as teaming up with (buddying), observing (shadowing), or informally chatting with or meeting (informal daily support) another moderator or moderators provides an opportunity for joint decision-making and reflection on how to manage challenging posts. Supervision and peer support also allow a space for refinement and validation of practice in line with feedback. All of this diffuses feelings of individual responsibility for user well-being and increases feelings of support (CMOC 5).

Increasing Competence Through Training

Moderator competence can be increased through forum-specific, comprehensive, ongoing training (CMOCs 6-10) that includes shadowing more experienced moderators, exposure to the forum, practice shifts, and feedback so that moderators feel clear about how to moderate and less worried about making a mistake (CMOC 6). Training is more likely to be effective at building competence when it is co-designed with (and delivered by) people with experience of moderation and detailed understanding of the specific forum culture and the challenges the moderators are likely to face because moderators understand the relevance and applicability of the training information provided (CMOC 7). Ensuring that moderators do not feel isolated or overwhelmed by their responsibility for user safety and well-being is an important aspect of training (CMOCs 8 and 9). This can be achieved by (1) managing moderator expectations about how much control they have over a user's situation, given the constraints of some anonymous online forums (CMOC 8); for example, emphasizing that the lack of control moderators have over what users do, that their role is to provide guidance and support, and that their supportive responses may be comparatively much faster than waiting for access to face-to-face services, and (2) providing evolving, up-to-date risk protocols so that moderators feel competent and confident to identify and respond to risk without making a mistake in an already high-risk situation (CMOC 9). Risk protocols may be especially important for moderators in an online environment where the potential for risk-related posts is high and nonverbal cues are removed. They are also critical for MH service staff who are used to working with established protocols and may be concerned about the impact on their professional status if protocols are not provided (CMOC 9). Where applicable, training should include a specific focus on increasing MH literacy for moderators with limited MH experience in relation to the specific forum content, so that moderators feel more prepared and comfortable to respond to users' personal situations (CMOC 10).

Increasing Competence Through Access to Resources

Moderator competence is increased through access to resources that enhance knowledge and expertise (CMOCs 11 and 12) and decrease burden (CMOC 13). Specifically, access to host-approved, up-to-date resources (eg, psychoeducational information from reputable sources) and the contact details of relevant services allows moderators to more easily respond to posts outside their area of expertise because they feel reassured by the option to signpost users to trusted alternative resources (CMOC 11). Working within a team of moderators with diverse skills and experience decreases moderator anxiety around responding because they do not feel individually responsible for user well-being and more supported to provide a collaborative response (CMOC 12). However, moderators may find it tough to fulfill conflicting responsibilities where they have another role, such as an MH professional delivering in-person services, and the associated responsibilities conflict with forum moderation. In this context, there is a risk that moderation will be deprioritized (CMOC 13).

XSL•FO
RenderX

Increasing Competence Through Forum Design

Forums should be designed in a way that supports moderators to do their job effectively (CMOCs 14-16). Having a private space to communicate with individual users directly may enhance moderators' ability to communicate openly and in a more personalized style because they feel comfortable doing so, which may be especially helpful where the content is sensitive or personal (CMOC 14). However, it has been suggested that moderators should be cautious not to encourage users away from the peer support offered on the forum and toward dependency on the moderator for support (CMOC 14). Well-designed systems that include design features outside the post-comment text-based format, such as emoji responses, allow moderators to focus on more detailed text-based responses because they feel supported by the community in providing appropriately matched support to other users (CMOC 16). The option to flag potentially problematic content for continued monitoring can also enhance moderator ability to meet the demands of the role because moderators feel able to respond quickly if there is a need to intervene (CMOC 15).

Increasing Competence by Supporting Moderator Well-Being

It is vital that forum hosts are aware of moderator well-being and make efforts to ensure well-being is supported so that moderators have the capacity to fulfill the role (CMOCs 17 and 18). Moderator resilience to the emotional impact of the role fluctuates depending on their own levels of well-being. Where moderators are in the right frame of mind, familiarity with forum content through repeated exposure or lived experience can increase moderator resilience to the emotional impact of moderating distressing posts. However, repeated exposure to distressing content can lead to desensitization if moderators do not make efforts to ensure that this does not happen (CMOC 17). Forum hosts should provide moderators with appropriate measures to ensure their own well-being so that they feel supported to engage in personalized self-care strategies to minimize the negative impact of forum moderation. Self-care strategies, such as taking regular breaks, not working overtime, reaching out for support, and boundary setting (time, location, and role), are particularly important for moderators working from home. These strategies are important in all forums but are particularly necessary in forums related to suicide and self-harm or where forum content can be distressing and may have high personal resonance (CMOC 18).

Relatedness (Feeling a Meaningful Connection With Others)

Moderators are more likely to experience workplace psychological well-being when they make or support meaningful connections within the forum (CMOCs 19-24).

Supporting Users to Connect With the Forum and Each Other

One of the main responsibilities of moderators is to facilitate user engagement with the forum and with each other by creating "a space where conversations can happen" [31]. By giving moderators guidance on response styles and how to enforce rules, for example, by editing text; requesting users to use language more appropriate to the forum culture; or modeling helpful posts, moderators better understand how to collaboratively shape the tone and community environment in line with the forum's culture, producing a supportive, productive, and judgment-free community (CMOC 19). Our analysis highlights the importance of moderators being supported to understand when it is safe to avoid responding to a user's post so that they are able to judge when their input is needed (eg, when a post is from a new user or it has not received a response) and when it could impede support, that is, by "jumping in too soon" and preventing users from connecting with one another. This creates an opportunity for the forum to become self-reliant, connected, and engaged (CMOC 20), which is particularly important for the provision of support when moderators are not online.

Making a Connection With Users

Developing connections with users can be very rewarding for moderators and can facilitate their ability to carry out the role; however, such connections can also make the role more challenging in terms of the impact on moderator well-being. Connections can be facilitated by moderators drawing on their own lived experience (if appropriate) and that of the community, but this requires careful navigation in terms of how and when this is done (CMOCs 21-24). Moderators often get to know users over time through the stories they tell and develop meaningful connections; therefore, it is important that moderators are supported to identify personal and professional boundaries to avoid potentially unhealthy dependency of users on moderators and worry about users on a personal level (CMOC 21). By exploring users' experiences and needs for support through asking open questions to invite users to expand their post, moderators can reduce any anxiety associated with not knowing what is happening for the user and increase the likelihood that their response matches user needs and is therefore helpful because they feel more knowledgeable about the users' situation (CMOC 22). Complete anonymity may promote the disclosure of distressing experiences but also limits the support and follow-up moderators are able to offer, which can lead to moderators feeling disempowered and uncertain about user safety, which undermines moderator well-being (CMOC 23). One way to provide effective support is by drawing on shared lived experience; by drawing similarities with a user's situation, moderators can provide an authentic, empathetic response based on personal experience and a detailed understanding of the user's mental illness experience (CMOC 24).

Discussion

Principal Findings

This realist synthesis is the first to explore the impacts of being a moderator of MH online forums on moderator well-being. The review highlights ways in which moderator autonomy (CMOCs 1-3), competence (CMOCs 4-18), and relatedness (CMOCs 19-24) are linked to workplace psychological well-being. The findings have clear and direct implications for practice, which are explored in the Implications for Practice section and summarized in Table 1. Recommendations are

XSL•FO
RenderX

organized by stakeholder group to support targeted and effective implementation.

Alignment With Previous Research

Feeling in control of one's actions and that those actions align with personal goals, values, and motivations is important for supporting the psychological need for autonomy. We found that working in a way that specifically aligned with personal motivations was important for moderator psychological well-being. Contexts in which people are free to be autonomous promote motivation [35], which in turn increases the likelihood of retention [36]. We found that a key motivation for moderators was to support others and that where evidence, such as supportive communication and success stories on the forum, was interpreted as this motivation being met, moderators felt a sense of satisfaction. In addition, feedback from supervisors and peers through reflective supervision, peer support, and training is important for enhancing moderators' ability to carry out the role effectively, thereby increasing the likelihood that their motivation to support others is met. Feedback from an organizational level, as well as adequate payment, may also demonstrate value for the moderator role and the challenges associated with it. Indeed, organizational-level feedback has been shown to be important for well-being in other health-related workplace settings [37].

Positive feedback (whether explicit or interpreted through positive forum content) also leads people to feel effective [38], which is a key factor underlying the psychological need for competence [19]. Competence has been found to be foundational to workplace well-being in the broader organizational literature [39]. Our findings align with previous research in highlighting the importance of recognizing the emotional needs of employees and providing support through ongoing, regular, individual supervision [40], which provides a space for moderators to explore what is expected of them, discuss challenges, and refine practice. A particular parallel with previous findings was the importance of aligning support and training with the organizational culture and forum content and reflecting key stakeholder views through co-design to increase the relevance and applicability of information provided. The incorporation of experiential learning and peer support into training also emerged as important to enhance moderator ability to understand and respond to the more dynamic demands of the role and feel less worried about making a mistake (which would undermine the goal of supporting others). In similar roles, such as peer support workers, the importance of peer support has also been highlighted [41]. For moderators working online, peer support, such as buddying and informal contact with other moderators, may be particularly important to reduce feelings of isolation, especially when moderators are working from home.

A key threat to moderator competence was holding unrealistic perceptions of how much control they have over a user's situation within the context of an anonymous online forum. Indeed, role ambiguity and conflicting role boundaries have previously been linked to poor employee MH [42]. We suggest that this threat to moderator competence can be reduced by setting clear expectations early regarding role responsibilities and the limits of personal responsibility for user well-being. In addition, ensuring moderators work within a diverse team can help them assess their capacity to moderate, manage unrealistic expectations, and feel less solely responsible—while more supported—in providing a collaborative response. A further threat to moderator efficacy also highlighted in the literature [6] is the increasing burden placed upon them as communities grow. Adequate staffing may go some way to alleviating this threat, but we suggest this could be bolstered by innovative forum design, such as alternative response formats (eg, emojis), which are quicker and, in some cases, more appropriate to implement. This allows moderators to focus their time and attention on posts that require more detailed, text-based responses. Implementing these features when user posts do not require a tailored response could aid scalability of forums by decreasing moderator burden.

In line with broader organizational literature [43], we found that forming positive relationships with other moderators in a forum context satisfies the psychological need for relatedness. Forging meaningful relationships with coworkers in the same role has also been shown to prevent mental ill-health in a health care context [37]. Moderators' relationship with users may provide another avenue for enhancing the psychological need for relatedness, particularly for those who have been moderating the same user group for a prolonged period. However, we found that it is important to support moderators with identifying personal and professional boundaries so that they avoid potentially unhealthy dependency while maintaining positive relationships with users. We found that drawing on lived experience, where their specific role facilitates the disclosure of advice and support based on those experiences, could lead to personal satisfaction, but that there may be complexity around decisions related to how and when to share, which is recognized elsewhere in the peer support literature (eg, Gillard et al [44]). We suggest that the psychological need for relatedness could also be met by going beyond developing relationships with others, as posited by SDT [45], to include facilitating relationships between others, in this case between forum users. Moderators may derive satisfaction and enhanced well-being from cultivating and witnessing a positive, supportive environment in which users support each other. Therefore, it is important that moderators are given guidance to ensure they understand how to collaboratively shape the community environment to be a positive space and when it is safe to avoid responding to allow the forum to become self-reliant.

Implications for Practice

Moderated online MH forums are potentially a very valuable way to support people and have great potential. However, uncertainties regarding the moderator role and how to best support moderators may make organizations reluctant to host a forum, moderators unsure about taking on the role, and users unclear about the support they provide and therefore the safety of the forum [23]. On the basis of our theories, we have proposed some key recommendations for supporting moderators of online MH forums for different audiences (Table 1). Implementation of these recommendations requires significant buy-in at an organizational level [37,40] and commitment to cultivating a supportive environment in which the ethos is for everyone involved in a forum to be aware of, and supportive

XSL•FO
RenderX

of, moderator well-being. Supervisors need to be familiar with forums, which requires training from the organization. Moderators should be trained in relation to the specific forum they are working on, which requires endorsement by the organization. As detailed elsewhere [16], we have developed co-designed best practice guidelines for moderator training, but support from the organization is key for these guidelines to be effectively implemented. All recommendations require modification to align with the specific forum contexts, such as forums involving lived experience moderators or forums in which moderators work from home.

Limitations and Future Directions

There are some limitations to this research. Interviews were conducted with stakeholders recruited from UK-based MH organizations; therefore, their experiences may not represent those of individuals in other locations, settings, and cultural contexts. Although we have paid particular attention to the importance of context, we acknowledge that context is constantly changing, particularly around perceptions of who holds responsibility for what happens in forums. For example, in the United Kingdom, the Online Safety Act [46] requires platforms to ensure that children are prevented from accessing harmful content, such as content encouraging suicide, self-harm, or eating disorders. The emphasis on ensuring safety and removing potentially distressing content in forums is likely to increase —along with the associated pressure on moderators. Therefore, this work is timely in exploring ways we can support moderators to thrive and continue to keep forums safe.

Our findings call for further realist research to evaluate and refine the program theories proposed. This should be done with reference to impacts on moderator well-being and the indirect impacts on user well-being to ensure that there are no unanticipated negative impacts for users. To our knowledge, there are no workplace well-being interventions for moderators of online MH forums, despite the importance of this role and increasing demand for online support; therefore, this is an important focus for future work. Future research should also consider the potential of artificial intelligence tools to manage some of these tasks, which will change the role of moderators.

Conclusions

Online MH forums are increasingly being used to support MH and are often moderated by trained moderators to ensure a safe, therapeutic environment. The moderator role is rewarding but can also be challenging. Moderator well-being can be supported by meeting the psychological needs for autonomy, competence, and relatedness, for example, by allowing moderators to meet personal motivations; supporting moderators' emotional and practical needs through supervision, peer support, and co-designed training; and supporting the formation of positive, meaningful relationships with other moderators, with users, and among users. Organizational-level endorsement of support and the cultivation of a supportive organizational philosophy are particularly important for the realization of recommendations and interventions to support moderator well-being. However, the role is likely to change in response to increased forum use, increased demand from society for hosts of online spaces to take responsibility to keep people safe, and the developing role of artificial intelligence in forum moderation. Further research is needed to test the effectiveness of the recommendations proposed while recognizing the need for constant refinement as the landscape of online MH forums continues to change.

Abstract

Background: The field of speech emotion recognition (SER) encompasses a wide variety of approaches, with artificial intelligence technologies providing improvements in recent years. In the domain of mental health, the links between individuals' emotional states and pathological diagnoses are of particular interest.

Objective: This study aimed to investigate the performance of tools combining SER and artificial intelligence approaches with a view to their use within clinical contexts and to determine the extent to which SER technologies have already been applied within clinical contexts.

Methods: The review includes studies applied to speech (audio) signals for a select set of pathologies or disorders and only includes those studies that evaluate diagnostic performance using machine learning performance metrics or statistical correlation measures. The PubMed, IEEE Xplore, arXiv, and ScienceDirect databases were queried as recently as February 2025. The Quality Assessment of Diagnostic Accuracy Studies tool was used to measure the risk of bias.

Results: A total of 14 articles were included in the final review. The included papers addressed suicide risk (3/14, 21%), depression (8/14, 57%), and psychotic disorders (3/14, 21%).

Conclusions: SER technologies are mostly used indirectly in mental health research and in a wide variety of ways, including different architectures, datasets, and pathologies. This diversity makes a direct assessment of the technology challenging. Nonetheless, promising results are obtained in various studies that attempt to diagnose patients based on either indirect or direct results from SER models. These results highlight the potential for this technology to be used within a clinical setting. Future work should focus on how clinicians can use these technologies collaboratively.

Introduction

Background

Emotions play a pivotal role in human interaction and communication, influencing various aspects of social exchange, decision-making, and overall well-being. While emotions can be expressed through multiple modalities, including facial expressions, body language, and gestures, human speech remains one of the most prominent and accessible channels for conveying emotional states.

Intonation, rhythm, pitch, and other acoustic features of speech convey subtle emotional cues, reflecting an individual's psychological well-being [1,2]. In recent years, there has been increasing interest in leveraging advancements in machine learning (ML) to analyze and interpret emotional cues from speech, a field known as speech emotion recognition (SER). Interest in the automated detection of mental disorders through vocal features is growing, particularly in the context of mental health assessment and monitoring. The ability to automatically analyze and interpret emotional cues from speech offers several advantages for improving patient care, enabling early detection of mental health issues, and enhancing the overall health care experience [3-6].

To better understand the foundations of SER and its evolving landscape, it is important to consider its historical development, theoretical models, and methodological challenges.

History of SER

The field of SER originated in the 1990s, when it emerged as a subsection within the field of speech processing. Initial work approached the task by extracting acoustic features from recordings and then performing statistical analysis using various algorithms to derive correlations between the extracted features and the emotional state of the speaker [7]. The original papers published on the topic suggested that the automatic detection of emotions could be applied in the context of human-machine interaction.

These initial publications led to further interest within the field and prompted questions such as the modeling of emotions and the contrast between acted and nonacted emotions. The choice of how to represent emotions is a nontrivial issue and has historically required coordination with the field of psychology to ensure the model used is both compatible with the machines being used for automatic recognition and consistent with the psychological literature on emotions [8].

The models typically used fall into 2 groups. First, *categorical models* represent emotions as separate "classes" (eg, happy, sad, and angry). The "big six" model proposed by Ekman et al [9] is a well-known example, encompassing happiness, sadness, anger, fear, disgust, and surprise. A more nuanced extension of this categorical approach is the model developed by Plutchik [10], which expands the core emotions by incorporating trust and anticipation, forming an 8–primary-emotion framework. The model also introduces the concept of emotional intensity and relationships between emotions, visualized in the "wheel of emotions" (Figure 1), where primary emotions blend to form more complex emotional states. Subsequent research has often adapted emotional classifications by adding new categories, removing some, or merging similar emotions into a single class.

Second, *dimensional* or *continuous* models interpret emotions as degrees of some underlying features. These models typically involve plotting emotions on 2 or 3 axes, the most common of which is the 2-dimensional model of arousal and valence [11]. In this paradigm, valence reflects the positive or negative quality of emotion. Happiness has high valence, while sadness has low valence. Arousal reflects the level of physiological activation or intensity associated with emotion. For example, surprise and anger typically have high arousal, while sadness and contentment often have low arousal (Figure 2).

Much of the existing work in SER predominantly relies on the 6-scale model developed by Ekman and the 8-scale model developed by Plutchik [10], as they offer well-defined categories that facilitate annotation and classification [12]. In contrast, dimensional approaches, which conceptualize emotions along continuous axes, remain comparatively underexplored. However, the dimensional perspective provides a more nuanced framework for capturing emotional complexity and extends beyond speech processing to psychopathology.

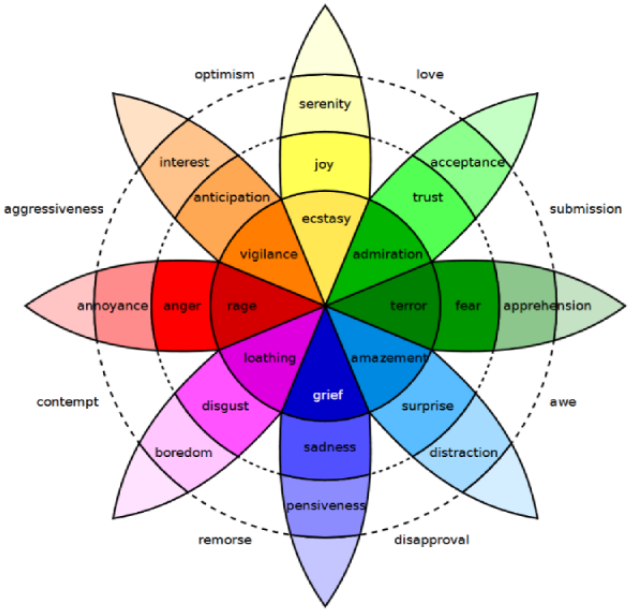
Figure 1. The wheel of emotions proposed by Plutchik.



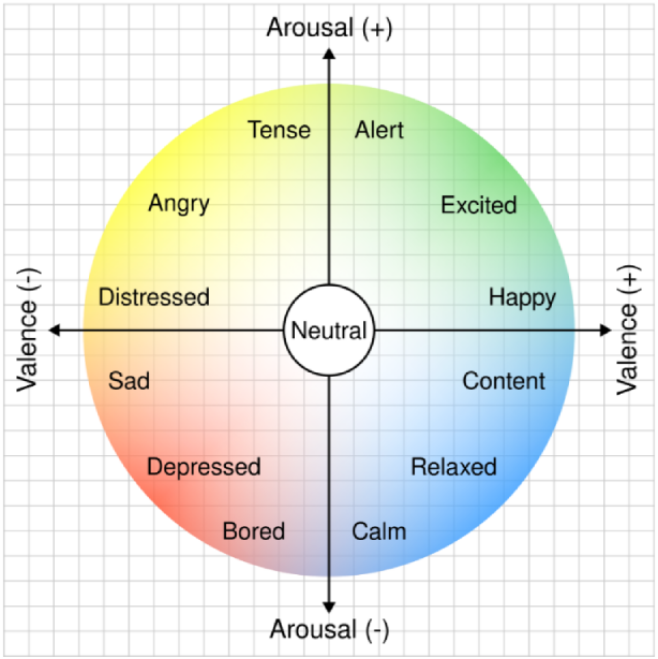


Figure 2. The circumplex model of emotion with its 2 axes: valence and arousal.

From Initial Works to Challenges

By the late 2000s, the field of SER had garnered more widespread interest in speech processing, with the development of a wide variety of feature extraction methods and ML algorithms. However, these advancements gave rise to several problems, most notably a lack of comparability among results.

Facing these problems in the late 2000s, researchers in the field initiated a series of SER challenges, including the INTERSPEECH 2009 Emotion Challenge [13]. These competitions aimed to standardize key aspects of the SER process, such as datasets, feature extraction methods, and algorithms, to facilitate the generation of comparable results within a unified context. One significant outcome of these efforts was the development of the open-source Speech and Music Interpretation by Large-Space Extraction (openSMILE) tool for feature extraction [14].

Arrival of Neural Networks to SER

With the introduction of convolutional neural networks in automatic speech recognition in 2012 [15] through their application to spectrograms, these algorithms were quickly adopted for use in SER contexts [16].

Following trends in both natural language processing (NLP) and automatic speech recognition, various neural network (NN) architectures were also applied. These methods ranged from training NN models directly on SER-related data to training on large quantities of unrelated speech data and then fine-tuning on SER datasets.

XSL•FO
RenderX

Convergence Between SER and Mental Health

Just as emotions can be viewed from a categorical or dimensional perspective, these approaches can also be applied to mental health disorders. Traditional diagnostic classifications, for example, the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*) and the *International Classification of Diseases*, adopt a categorical view of mental disorders, which has long served as the standard reference, despite this approach not always being relevant to clinical issues. However, these models come with some limitations when applied to clinical issues. The shift toward viewing disorders as existing along a continuum rather than within rigid diagnostic categories is exemplified by the research domain criteria (RDoC) classification in psychiatry, developed by the National Institute of Mental Health. The RDoC marks a significant evolution in the approach to mental disorders by focusing on biological, cognitive, and behavioral criteria rather than just clinical symptoms. Thus, the RDoC classification proposes a dimensional approach that aims to investigate the underlying processes of mental disorders by addressing transnosographic domains, such as emotion, cognition, or motivation [17]. This shift from categorical classification to a dimensional approach leads to the study of psychiatric disorders as spectrums of dysfunction rather than as distinct entities.

Operational Definition of Direct and Indirect SER

For the purposes of this review, we distinguish between direct and indirect SER approaches as applied in mental health research. This distinction refers to whether emotion is explicitly modeled and analyzed as a task in its own right or implicitly captured through emotionally relevant features. Direct SER refers to approaches in which emotion recognition is an explicit step in the analysis pipeline. This typically involves training or fine-tuning models on emotion-labeled datasets or applying pretrained SER systems to detect emotional states in speech recordings. The detected emotions are then analyzed in relation to mental health conditions. Indirect SER, by contrast, involves the use of features, models, or techniques that capture emotional characteristics of speech without explicitly recognizing or classifying emotions. For example, acoustic features used in SER may be extracted and used in models for mental health classification, even though emotion labels are not used at any point. These features carry emotional information, but emotion itself is not the target variable.

Given the role of emotion recognition in identifying psychiatric disorders and the increasing interest in applying SER within clinical psychiatry, where vocal emotional cues offer a noninvasive and objective window into patients' mental states, this study examines the specific role of emotion recognition in identifying psychiatric disorders. To provide context, we review the advancements, applications, and challenges of SER in health care, highlighting its potential in mental health monitoring, suicide prevention, and diagnosis of mood and psychotic disorders. This review emphasizes the advantages of SER, including its noninvasive nature, objective assessment capabilities, and potential for automated analysis, while addressing key challenges, such as the need for diverse datasets, interpretability of ML models, and generalization across populations.

This paper is structured as follows: in the first section, we introduce the history and advancements in SER. Subsequently, we review the available SER datasets, followed by an overview of existing applications of speech- and emotion-related technologies in clinical settings. Finally, we discuss current challenges, limitations, and prospects for collaboration between the fields of SER and mental health.

Methods

Preferred Reporting Items for Systematic Reviews and Meta-Analyses Review

Recognizing and analyzing emotions is an essential tool for the clinician. The fields of psychiatry and psychology have long recognized that learning and mastering this skill is at the very core of the diagnostic and therapeutic process, not only for health care professionals but also for patients. However, this clinical skill is neither infallible nor sufficient for systematic precision diagnosis. Several studies have focused on the automated recognition of emotions using a variety of computational techniques. What can these new techniques offer to clinicians in the analysis and interpretation of emotions?

To answer these questions, we conducted a systematic review of literature following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines, registering our review in the PROSPERO system (1006669). This review aims to cover studies adopting an acoustic- or speech-related analysis of mental health questions, with a particular focus on works involving an analysis of the emotional aspect of speech when studies paid attention to the emotional dimension.

Inclusion and Exclusion Criteria

The inclusion criteria for this review are described in Textbox 1.

XSL•FO
RenderX

Textbox 1. Study inclusion and exclusion criteria.

Inclusion criteria

- Studies containing an analysis of speech (ie, audio) signal
- Studies containing either a direct or indirect emotion recognition component. Indirect components include analyses that could be interpreted from an emotional perspective, for example, the use of the open-source Speech and Music Interpretation by Large-Space Extraction (openSMILE) feature sets widely used in speech emotion recognition tasks
- Speech data was derived from a clinical context

Exclusion criteria

- Audio was only analyzed in conjunction with another modality (eg, text).
- No diagnosis or prognosis aspect was included, for example, analyzing emotions in isolation without a correlation to patient conditions or outcomes.
- The pathology examined could be classified as a neurological disorder rather than a mental health disorder, for example, Alzheimer disease.
- The study was a review with no experimental component.

Search Strategy and Screening Process

Database queries were performed using the PubMed, IEEE Xplore, arXiv, and ScienceDirect databases up until February 2025, with the following keyword search: (“emotion recognition” OR “affective computing” OR “emotional analysis”) AND (“psychiatry” OR “psychology”) AND (“speech” OR “voice”).

During the screening process, 2 authors applied the eligibility criteria and selected the studies to be included in the systematic review. In case of doubt, it was established that the article would be submitted to the rest of the review group, and no such cases were encountered.

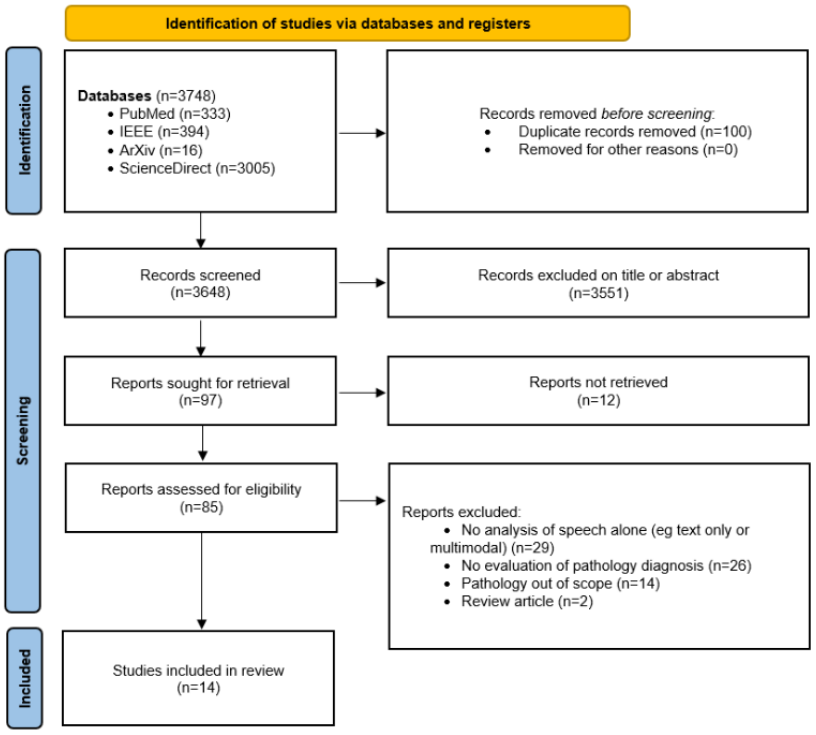
An initial screening based on the title and abstract of the search results was performed, removing any articles that did not meet the inclusion criteria.

From this initial screening, the remaining articles were assessed to determine whether their design included a direct evaluation of the models’ performance in a diagnostic task, measured by either ML metrics (F_1-score, accuracy, and area under the curve [AUC]) or statistical correlation measures. Most articles excluded in this step did not include an audio component, did not evaluate the clinical diagnostic performance of their model, or applied their model to patients whose pathology was outside the scope of this review (sometimes analyzing only healthy control participants).

After filtering based on these criteria, a total of 14 studies were retained. The Quality Assessment of Diagnostic Accuracy Studies–2 framework was used to estimate the risk of bias in these selected studies.

The Results section is organized in subsections to enhance the reader’s understanding, particularly regarding the methodological context of SER. First, we provide an overview of the methods used within SER and several existing databases. We then present the results of the systematic review.

Results



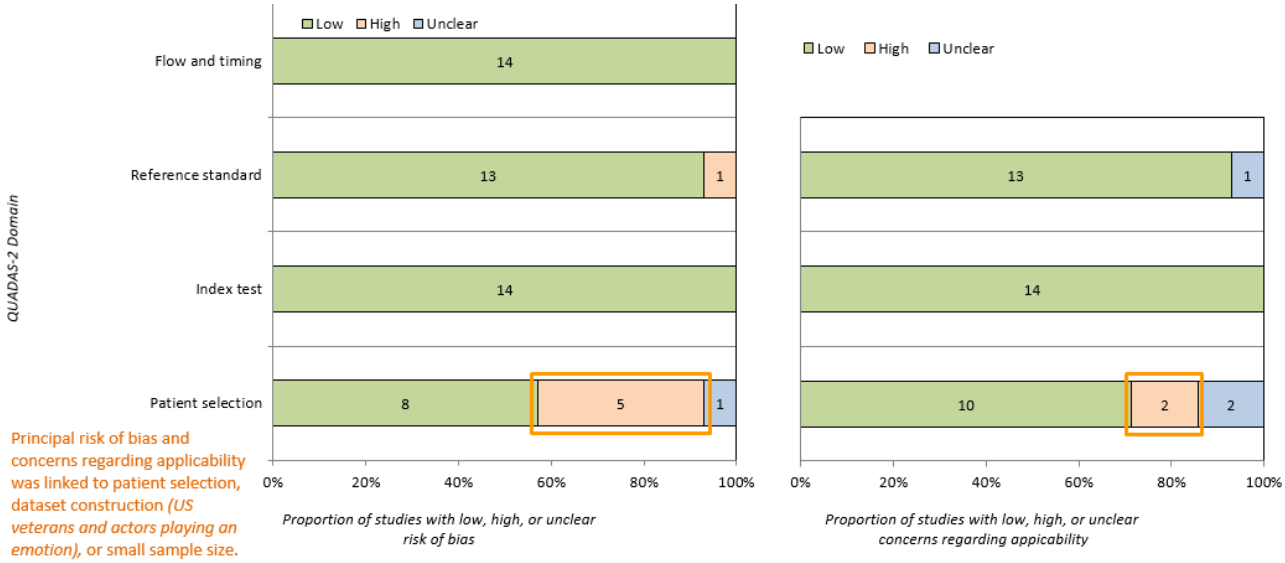
PRISMA Review Results

As outlined in the flowchart in Figure 3, a total of 3648 studies were screened, with 85 (2.33%) reports retrieved and assessed. From these 85 studies, 14 (20%) were included in the final review, with the most common reasons for exclusion being the lack of speech analysis alone (ie, models using only text or a combination of audio and other modalities) or the absence of a diagnostic perspective within the study (ie, no prediction of pathological severity or comparison between patients and controls). Of the 14 studies included in the final selection, 3 (18%) addressed suicide risk and suicidal ideation (SI), 8 (53%) analyzed depression and mood disorders, and 3 (18%) studied psychotic disorders.

Several studies screened did not analyze the emotional state of the patients but examined their capacity to detect emotional expressions in others, that is, to determine whether their pathologies impacted their perception of emotional expressions.

XSL•FO
RenderX

Figure 3. Flow diagram of the study selection process based on the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines.



Risk of Bias Assessment

Most of the included studies had a low risk of bias across all fields. As shown in Figure 4, the main exception was in patient selection, where 5 studies were deemed to have a high risk of bias. Among these 5 studies, 3 selected participants only from within clinical populations (ie, no control group), and the remaining 2 did not select from a representative sample [3,18-21]. In addition, high concerns regarding the applicability of patient selection were noted in 2 cases [3,19]. 4 studies raised unclear concerns regarding patient selection [5,7,11]. The full Quality Assessment of Diagnostic Accuracy Studies–2 results are available in Multimedia Appendix 1.

This section is divided into 2 parts. First, we present a narrative review of established methodologies within the field of SER. Second, the results of the PRISMA review are presented.

Figure 4. The Quality Assessment of Diagnostic Accuracy Studies 2 (QUADAS-2) results, highlighting risk of bias and applicability concerns. Patient selection was associated with a high risk of bias owing to sampling methods and sample size.

Narrative Review

Here, we present a brief overview of the methods and technical architectures used within the field of SER, covering the transition from traditional ML methods to NNs and state-of-the-art transformer-based methods [22].

XSL•FO
RenderX

Established Methodologies

Speech, serving as a primary mode of communication, harbors a wealth of emotional cues that can be harnessed to assess an individual's mental and emotional well-being. Various methodologies have been devised to extract, analyze, and interpret these cues, each providing distinct perspectives on the underlying emotional states.

Acoustic or Prosodic Feature Extraction

Acoustic or prosodic feature extraction involves the analysis of various acoustic properties of speech signals, such as pitch, intensity, duration, and spectral characteristics [1,2,23,24]. Acoustic features are related to the physical properties of sound waves and can be observed at the level of milliseconds, for example, frequency, which is related to how humans perceive pitch. Prosodic features are typically observed over a longer timescale, with pitch contours, for example, measuring how pitch changes over time, and other measures, including speech rate and pauses. Both sets of features serve as the basis for quantifying emotional cues present in speech and are commonly used as input for ML models. Techniques such as mel-frequency cepstral coefficients (MFCCs), pitch contour analysis, and formant analysis are commonly used in acoustic feature extraction for emotion detection tasks [25].

These measures correlate with various aspects of speech production, which can be impacted by the emotional state of the speaker. MFCCs, for example, capture the spectral characteristics of speech (ie, how energy is distributed across different frequencies), which can be linked to certain emotions (eg, higher energy in mid to high frequencies for anger or joy). Pitch contour analysis tracks variation in the fundamental frequency of speech, that is, the perceived pitch, over time. Variation in a speaker's pitch allows listeners to distinguish between sadness and excitement. Finally, formant values are influenced by the shape and tension of the vocal tract during speech. Physiological aspects of emotions (eg, smiling) may impact these values.

The OpenSMILE Toolkit

Among the most prevalent tools used for acoustic feature extraction is the *openSMILE* toolkit [14]. This toolkit is available in both a Windows executable (.exe) file and a Python-accessible package and contains several widely used collections of acoustic and prosodic measures (referred to as feature sets). These feature sets encompass a variety of acoustic characteristics, such as frequency, loudness, MFCCs, and other speech attributes. These features can then be analyzed using the methods presented in subsequent sections to detect emotions or, in the context of computational paralinguistics, to aid in the recognition of mental health conditions. Among its strongest advantages are the ease of use for feature extraction and the standardization of feature sets, allowing for more straightforward comparison between results.

Traditional ML Approaches (Before NNs)

Traditional ML approaches involve the use of statistical and pattern recognition algorithms to classify emotional states based on extracted features. These approaches typically include algorithms such as support vector machines (SVM), k-nearest neighbor (KNN), and decision trees [26-30]. By training these models on labeled datasets of emotional speech samples, they can learn to classify new instances into predefined emotional categories.

Recurrent NNs: Long Short-Term Memory and Bidirectional Long Short-Term Memory

Recurrent NNs, particularly Long Short-Term Memory (LSTM) and bidirectional LSTM architectures, gained popularity in speech emotion detection tasks because of their ability to capture temporal dependencies in sequential data [31-34]. These NNs excel at processing time-series data, such as speech signals, allowing them to capture long-range dependencies and subtle temporal patterns in emotional expression.

Transformers

Transformers, originally developed for NLP tasks, have emerged as the state-of-the-art approach for analyzing speech signals for emotion detection [22,35-39]. These architectures, including models such as the Bidirectional Encoder Representations from Transformers, excel at capturing contextual information and semantic relationships within sequential data. By fine-tuning pretrained transformer models on emotion detection tasks, researchers can leverage their powerful language understanding capabilities to analyze emotional content in speech. One study involved the use of transformer, specifically, a self-attention-based deep learning (DL) model combining a 2-dimensional convolutional neural network and an LSTM network. This model focuses on optimizing feature extraction from speech using MFCCs and achieved an impressive average test accuracy of 90% [40].

Available Datasets

A multitude of datasets for the SER task exist, each falling into one of several categories based on certain characteristics (eg, the type of data collected, the classification of emotions, or the relation to other tasks). However, few to no datasets are available that serve both SER and mental health applications. This section provides an overview of some of the most widely used datasets and their characteristics.

Distress Analysis Interview Corpus–Wizard of Oz

The Distress Analysis Interview Corpus–Wizard of Oz (DAIC-WOZ) dataset is part of the larger Distress Analysis Interview Corpus [41]. It includes audio and transcript recordings of semistructured clinical interviews between participants and an interviewer. The interviews were designed to detect signs of depression, anxiety, and posttraumatic stress disorder. Using scores from several questionnaires related to psychological distress and current mood, the audio and transcript data can be used for a classification of the interviewees.

While the dataset does not explicitly include annotations of the emotional states of the interviewees, labels could be derived using another SER model to directly analyze correlations between the participants' emotional and mental states. A total of 193 interviews are available, with each interview lasting between 5 and 20 minutes, and all the interviews were conducted in North American English.

XSL•FO
RenderX

Ryerson Audio-Visual Database of Emotional Speech and Song

Ryerson Audio-Visual Database of Emotional Speech and Song is a multimodal database (including both audio and face recordings), containing both acted speech and song [42]. The recordings, in North American English, feature 24 professional actors (12 male and 12 female actors).

Each expression (ie, emotion) is produced at 2 levels of emotional intensity, as well as at a neutral level. The dataset comprises a total of 7365 recordings (4320 speech and 3036 singing).

FAU-AIBO Dataset

The FAU-AIBO dataset consists of spontaneous speech from German children's interaction with a human-controlled robot, which they were told was autonomous [43].

The data is annotated on the word level for the presence of 11 emotional states, as evaluated by 5 judges.

This dataset was used in the initial 2009 INTERSPEECH SER Challenge [13]. Recent work has shown that this dataset presents a significant challenge in achieving strong classification performance, even for state-of-the-art methods [16].

Interactive Emotional Dyadic Motion Capture Dataset

The Interactive Emotional Dyadic Motion Capture dataset is a multimodal resource, including both audio and motion capture data, allowing analysis of both speech and facial expressions, and gestures [44]. The dataset comprises scripted speech as well as improvised scenarios, all produced by actors who were specifically instructed to produce or elicit certain emotions.

Both categorical and dimensional labeling approaches are used. The dataset contains approximately 12 hours of data.

Canadian French Emotional Dataset

The Canadian French Emotional dataset is a Canadian French emotional speech dataset [45]. It includes recordings from 6 male and 6 female actors reading 6 different sentences in the 6 basic emotional states described by Ekman and in a neutral state, containing approximately 69 minutes of recordings in total. While this dataset is smaller than many other available datasets, it highlights how few resources exist for languages other than English.

PRISMA Selected Studies

The selected studies are presented in the subsequent sections, categorized based on mental health pathologies. Table S1 in Multimedia Appendix 2 provides a full overview of the included studies. This overview summarizes key characteristics such as methodology (eg, NNs, transformer models, or acoustic feature–based ML). Several trends can be observed, including the predominance of English and Mandarin datasets and the frequent use of LSTM and transformer models in recent years. The table also shows the potential risk of bias owing to population selection, as highlighted in the QUADAS assessment earlier. The details of each included study are presented in the subsequent sections.

Suicide Risk and SI

Gerczuk et al [19] explored differences in speech based on sex in the context of suicide risk, using both interpretable (ie, acoustic) and deep features. The authors reported the best results using an emotion fine-tuned wav2vec 2.0 model, achieving 81% balanced accuracy (ie, the model had an 81% chance of making a correct prediction for a given example, accounting for differences in sample sizes between groups) in high- versus low-risk suicide classification. Notably, this result was achieved by training the model separately for each sex. The authors reported a difference in the relationship between acoustic measures and suicide risk across sexes—agitation in male individuals was associated with increased suicide risk, whereas the opposite was true in female individuals—explaining the advantage of training the model separately for each group.

Another study analyzed interviews from patients who were recently discharged from the hospital after experiencing SI or other circumstances (ie, patients who had attempted suicide, those receiving psychiatric care, and healthy control participants) [20]. Two separate experiments were conducted. First, SER classifiers were trained and evaluated using acoustic features based on self-reported Positive and Negative Affect Schedule emotion labels from the interviews. Second, a comparison of the SI group and the other groups was performed based on the variability of the reported emotions.

The authors reported a maximum AUC of 0.78 when classifying the different emotion labels, and an AUC of 0.79 was achieved using the variability between these emotional states to distinguish between participants with SI and the other groups. The authors noted that the SI group showed lower emotional variability compared with the other groups, indicating that emotional states can be a good indicator of discrimination between control and pathological groups. These scores demonstrate a good level of discrimination between the groups, with AUC indicating the capacity of a model to differentiate between a randomly selected positive case and a randomly selected negative case (an AUC >0.7 indicates the model is achieving a fair discrimination rate, whereas an AUC of 0.5 is equivalent to random chance).

Suicidal ideas among US veterans were investigated by Belouali et al [3]. The study extracted a wide range of features (acoustic, prosodic, and linguistic) from recordings of veterans and trained several models (eg, random forest, logistic regression, and deep NNs). Feature selection was applied to identify the most relevant features for each model. The best results in classifying veterans with SI from their nonsuicidal counterparts were obtained using a combination of acoustic and linguistic features, achieving a sensitivity of 0.86, specificity of 0.70, and AUC of 0.80. The voices of individuals with SI differed from those of their nonsuicidal counterparts regarding energy (lower SD of energy contours in voiced segments, lower kurtosis, and lower skewness), indicating a flatter and less animated voice. Individuals with SI were also found to have more monotonous voices.

Overall, studies addressing suicide risk and SI demonstrated good discrimination between the patients with SI and control groups (AUC approximately 0.8 and accuracy approximately

XSL•FO
RenderX

80%), indicating that these methods can prove useful in a clinical context to identify patients at high risk of committing suicide.

Depression and Mood Disorders

Using both the emotional labels as well as the Patient Health Questionnaire-8 (PHQ-8) depression scores for each participant, Wang et al [6] attempted to find a link between speech features and depression scores as well as depression status (ie, participants with depression vs control). Several models were used: from traditional ML approaches (SVM and random forest) to transformer-based approaches (combining several complex models). The best performance was achieved by this complex transformer-based model, reaching an accuracy of 77% (ie, a 77% chance of assigning a given participant to the correct group) and an F_1-score of 0.63, indicating the capability of complex models to outperform more traditional ML approaches on the same dataset.

Yang et al [46] highlighted how confusion between patients with low-mood bipolar depression and those with unipolar depression can lead to patients not receiving appropriate treatment. The patients were shown videos to elicit various emotions (happy, sad, disgust, fear, surprise, and anger) and asked to respond aloud to several questions. The recordings were labeled (with emotion profiles, ie, probabilities of each emotion for a given recording) using an SVM classifier trained on the eNTERFACE dataset. Different classifiers were then trained to distinguish between bipolar, unipolar, and healthy control groups based on these emotional profiles. The model (a combination of both LSTM and bidirectional LSTM architectures) achieved a classification accuracy of 77% when distinguishing among the 3 groups.

Correlations were found between vocal prosody measures and change in the measures of the Hamilton Rating Scale for Depression over the course of 21 weeks, as outlined in Yang et al [47]. The participants were diagnosed with major depressive disorder according to the *DSM-IV* guidelines, and the measures of switching pause (ie, the time between utterances from the patient and the interviewer) and fundamental frequency were taken from interviews conducted throughout the duration of the study. When analyzing within-subject variation in depression scores, the authors found that as depression severity decreased, pause duration became shorter and less variable, accounting for 32% of the overall variation over time in the patient's depression scores. Furthermore, the depression scores obtained using hierarchical linear modeling, with linear discriminant classifiers reaching an accuracy of 69.5% when determining depression severity.

Stepanov et al [48] addressed the question of determining depression severity in the 2017 Audio-Visual Emotion Challenge using the DAIC-WOZ dataset. This challenge involved predicting PHQ-8 scores based on the patients' speech. The best performance was achieved using low-level acoustic features extracted through openSMILE to train an LSTM model.

Extracting prosodic features (glottal flow, voice quality, and spectral features) from the DAIC-WOZ dataset, Mao et al [49] trained a range of DL models, with a hybrid model achieving an impressive accuracy of 98.7% and an F_1-score of 0.987, indicating that the model could almost perfectly distinguish between the control and depression groups.

By applying the transformer architecture to frequency-related parameters from both the DAIC-WOZ dataset and their own proprietary data, Yang et al [50] achieved maximum F_1-scores of 0.78 and 0.87, respectively. By analyzing the frequency components most important to their model's predictions, the authors found that the frequency range from 600-700 Hz was the most important, corresponding to the Mandarin vowel /e/ or /ê/. The authors presented this as a potential biomarker for depression.

Studies applied to depression and mood disorders were the most prevalent among the results of this study (8 of the 14 selected articles). A range of different results were achieved, with newer methods showing strong improvement compared with older works (an accuracy of 69% in 2013 using only 2 prosodic features [47] vs 98% in 2023 using a range of prosodic features and DL methods [49]). These findings suggest that automated methods can be useful to clinicians for diagnostic purposes (notably for determining severity) and may help guide clinicians in adapting their therapeutic approaches.

Psychotic Disorders

Chakraborty et al [51] used the *emobase* feature set of low-level descriptors from openSMILE to discriminate between a group of patients with schizophrenia and a group of healthy controls, based on an interview conducted with a psychologist. In addition, a negative symptom assessment 16 (NSA-16) score, ranging from 1 to 6, was assigned by the psychologist to indicate the severity of negative symptoms of schizophrenia, that is, mainly motivational and emotional impairments. Prediction of these scores was also evaluated. A range of classifiers was trained on the data after conducting feature selection. The best-performing classifier for patient versus control classification was a linear SVM classifier using principal component analysis feature selection, reaching 79.49% accuracy (compared with 66.67% for a classifier predicting the majority class). For negative symptom assessment 16 prediction, classifiers were trained for each of the different items, with accuracy ranging from 62% to 85%. The best-performing classifiers were SVMs, KNN, and decision trees, with a range of different feature selection techniques.

Using a proprietary dataset of patients with schizophrenia with and without formal thought disorder (FTD), first-degree relatives, and neurotypical controls (15 of each; 60 total), Çokal et al [18] elicited spontaneous speech using an image description task. Pauses were measured in the participants' speech and classified based on the duration of pause, the presence or absence of a filler word (eg, *umm* and *ehh*), and the syntactic context in which the pause occurred.

Patients without FTD produced significantly more unfilled pauses (ie, pauses without a filler word) than the controls in both utterance-initial contexts and before embedded clauses, and had more pauses before embedded clauses compared with patients with FTD. When compared with the control and first-degree relative groups, patients with FTD produced longer utterance-initial pauses.

XSL•FO
RenderX

The extended Geneva Minimalistic Acoustic Parameter Set (eGeMAPS) [52], available through openSMILE, was used by de Boer et al [53] along with a random forest classifier to distinguish between patients with schizophrenia spectrum disorders and healthy controls. The model achieved a classification accuracy of 86% between healthy controls and patients and an accuracy of 74% among patients between those with negative symptoms and those with positive symptoms. They also indicated that their work was a positive step toward validating language features as biomarkers in psychiatry.

Once again, the results from these studies applied in the context of psychosis performed well when distinguishing between groups, as well as among subgroups of patients with schizophrenia. In a clinical context, these methods can be of notable use for patient screening and early detection, areas in which clinicians often struggle to clearly orient their patients. It is worth noting that none of the works included in the reviewed sample involved a direct analysis of emotions in the context of psychotic disorders.

Overview of Biomarkers in Mental Health Prediction

Several of the studies included in this review propose that the acoustic measures used could be considered as speech-derived biomarkers for mental health prediction. These biomarkers span the prosodic, spectral, and temporal domains and are often extracted using standardized tools, such as the openSMILE toolkit.

Prosodic and Temporal Markers

Markers, such as pitch (F0), energy, pause patterns, and speech rate, were commonly explored. For example, shorter and less variable within-subject pauses were associated with increasing depression severity [47]. Çokal et al [18] observed longer utterance-initial pauses in patients with FTD and more unfilled pauses in patients with schizophrenia without FTD. Belouali et al [3] reported lower energy variability and flatter energy contours in suicidal speech, suggesting a dull and monotonous prosody.

Spectral Features

Many studies relied on MFCCs, spectral slope, formants, and related features. Gerczuk et al [19] highlighted spectral slope (0-500 Hz), alpha ratio, and F1 bandwidth as predictive of suicide risk, with nuanced gender differences. Both F2 and spectral flux were found to be negatively associated with depression (indicating lower levels of energy and motivation), while a higher MFCC 4 was positively associated with depression [21]. Yang et al [50] emphasized specific frequency bands corresponding to Mandarin vowel formants that were positively associated with depression.

Feature Rankings and Model-Driven Importance

Some studies [19,53] analyzed feature relevance using importance rankings from models trained on the eGeMAPs and the ComParE feature set to identify features, such as voiced segments per second, spectral flux, and pitch percentiles, as top contributors for schizophrenia and depression, respectively. Stepanov et al [48] found spectral features to be more predictive than prosodic or voice quality features for PHQ score prediction.

While a few studies [46,51,54] applied acoustic features without further interpretation, this diversity of biomarker use demonstrates the strength of acoustic feature–based models as interpretable alternatives to end-to-end models.

Discussion

Principal Findings

Within the fields of psychology and psychiatry, the emotional states of patients can be linked to their condition. This is the case both in a pathological sense, with patients with depression being characterized as having low moods associated with sadness, or in a symptomatic sense, where the emotional state of a patient with depression can vary depending on their current circumstances. While several works exist at the intersection of these fields and the emerging field of SER, the diversity in methodologies, datasets, and results makes it difficult to determine what the practical application of these results in a clinical context could look like.

Nonetheless, the results presented in the selected studies are promising, with many of the models discussed earlier differentiating between pathological and healthy control groups at a significant rate (accuracy approximately 70%-80% and AUC approximately 0.8). The application of these technologies across a wide variety of domains is also promising, indicating that these technologies could be used for early screening (eg, in the diagnosis of psychotic disorders, where clinicians may struggle to guide patients early on).

The use of the *openSMILE* toolkit and its various feature sets (eg, eGeMAPS) throughout several of the selected studies highlights the possibility of integrating SER approaches within a clinical context. Furthermore, the results achieved using these feature sets are promising, especially given their ease of use and interpretation.

Recent research on the application of SER techniques in psychiatry appears promising, particularly in highlighting the potential clinical utility of such tools. As evidenced by several studies included in this review, SER can be used in between-subjects designs to differentiate patients from healthy controls or to distinguish between individuals with different psychiatric diagnoses, thereby providing support for the diagnostic process.

Beyond diagnostic discrimination, the potential of SER extends to within-subject applications, particularly in the context of longitudinal monitoring. For instance, SER systems could be used to assess the daily emotional states of individuals with various psychiatric conditions—such as major depressive disorder or borderline personality disorder—for example, integrated into ecological momentary assessment frameworks.

Moreover, SER technologies may hold predictive value with respect to clinical course, offering support in the monitoring of critical symptoms, such as SI, depressive, manic, or psychotic symptoms. This could help with the early identification and treatment of conditions that may pose significant risks to patients.

XSL•FO
RenderX

Finally, SER tools may serve as a complementary measure in the assessment of treatment efficacy, providing objective data on emotional expression that can enrich traditional clinical evaluations.

To the best of our knowledge, this study is the first systematic review to provide a synthesized overview of SER in psychiatry. This work could help standardize future studies and improve the reproducibility and comparability of results.

Challenges and Limitations

While SER holds promise for health care applications, several challenges and limitations must be addressed to realize its full potential. One such challenge is the exploration of multimodal emotion recognition, which involves integrating multiple sources of emotional cues, including speech, body language, and facial expressions. While SER primarily focuses on analyzing speech signals, incorporating additional modalities could enhance the accuracy and robustness of emotion recognition systems, particularly in complex health care settings.

In addition, the interpretability of ML models and the ethical considerations surrounding the use of sensitive health data present significant challenges in the development and deployment of SER systems in health care settings. Ensuring transparency and accountability in the decision-making process of these algorithms is essential for building trust and confidence among health care professionals and patients. As outlined earlier, some complex models (ie, models whose added complexity makes clinical interpretation of predictions increasingly difficult) can achieve results superior to those of traditional ML methods applied to acoustic or prosodic features, which are more easily interpreted [6]. If these methods are to be applied within a clinical context, a trade-off must be found between classification performance and interpretability.

Furthermore, the generalization of SER algorithms across diverse populations and cultural contexts remains a significant hurdle. The major datasets used within the field of SER (eg, Interactive Emotional Dyadic Motion Capture) are in English, and as shown in Table S1 in Multimedia Appendix 2, most of the studies included in this review examined either English-speaking participants or those who spoke Mandarin or other Chinese languages. In all cases, these datasets are composed of participants from a single cultural context, which may limit their applicability to the expression of emotion across different cultures. Variations in speech patterns, dialects, and cultural norms can impact the performance of SER systems, highlighting the need for robust validation and adaptation strategies to ensure the reliability and effectiveness of these systems across different demographics [24].

In addition to these limitations, translating NLP results into routine clinical practice in psychiatry—implying rapid, replicable, and scalable analysis—presents specific challenges.

First, possible issues with the inaccuracy of vocal recording or transcription can hinder detailed analyses when integrating NLP tools into existing clinical workflows. Although linguistic analyses are generally considered fairly robust regarding the quality of the transcripts [55], conducting fine-grained analysis, such as SER, may require higher-quality data, which is not always available in a clinical context.

Addressing these challenges requires interdisciplinary collaboration among researchers, clinicians, and technologists to develop innovative solutions that prioritize patient privacy, data security, and ethical considerations while harnessing the potential of SER to enhance mental health assessment and treatment in health care settings.

Future Directions

Separately, the tasks of SER and mental health screening have been addressed using methods that span statistical analysis of acoustic measures, ML, and DL approaches. These techniques have been applied to a range of pathologies, conditions, and disorders within the field of mental health. In this paper, we have specifically addressed those works that exclusively use the audio from the speaker's speech as the input to their models. Some works have proposed that acoustic measures of patients' speech be developed as biomarkers of pathology, as it is the clinician's perception of these measures that allows a diagnosis [53]. This highlights these measures' obvious advantage compared with the use of transformers and other DL models when collaborating in a clinical context: their ease of interpretation.

Among the various applications, similarities can be observed, notably in the reuse of certain methods, especially the use of acoustic measures, both in mental health and SER, which can be linked back to the emotional state of the patient. Given that the same methods are used both for the recognition of pathologies and the recognition of participants' emotional states, the question arises: Could the direct automated analysis of patients' emotional states be useful for investigating the aforementioned pathologies?

Proposed Pipelines for Audio Processing

Here, two possible approaches are proposed for the detection of pathologies from patients' speech. From our review, most studies adopt the first approach described in the subsequent section, which involves mapping directly from a patient's speech to a possible pathology.

Speech to Pathology

This pipeline is represented in the vast majority of studies in the literature, in which feature extraction or ML and DL methods are applied directly to the signal from recordings of the participants.

Speech to Emotion and Emotion to Pathology

In this approach, speech from a patient is first analyzed using a SER system (based on one of the various methodologies outlined earlier). The emotional states recognized by this system are then analyzed to gain insight into the patient's pathological status. Although some studies have adopted a similar approach [20], this approach for the detection of mental health conditions has not been widely explored.

The pipeline from speech to emotion, then emotion to pathology, presents a notable advantage in a clinical context, because it offers a clear interpretation of why a given classification was

XSL•FO
RenderX

made. Furthermore, this approach can be used collaboratively with health care professionals to facilitate and complement their work.

One possible challenge associated with this approach is the introduction of error by the SER system. To mitigate this risk, the selection of the SER system is of utmost importance, ensuring that its design (eg, training data) allows it to perform effectively on a given set of data.

Shared Challenges

From our review, the variety of methods observed (eg, a wide range of audio processing methods and feature sets, datasets of different sizes and compositions, and the use of various feature sets) led to difficulties in directly comparing different studies, even those applied to the same pathologies. This difficulty in comparison is similar to that encountered during the early days of the field of SER.

Further emphasis on the organization of shared challenges could promote the sharing of methods, data, and results, thus, improving the comparability of work in the field, as was the case in SER. Several challenges have been conducted within this field (or adjacent ones), with the most recent including the Audio-Visual Emotion Challenge 2019 for depression [56] and the Alzheimer dementia recognition through spontaneous speech challenge for Alzheimer disease [57].

One hurdle to overcome in the organization of these challenges, especially in a context relating to health care, is the sharing of confidential data.

Dimensional Approach to Pathology

Dimensional approaches to pathology in mental health can offer a more refined perspective on disorders by focusing on symptom severity and underlying mechanisms rather than rigid diagnostic categories.

To be consistent with the papers we reported, we grouped mental health conditions in this review according to disease categories. In contrast to this categorical approach, a dimensional approach could provide different insights [58]. In practice, this paradigm shift is conducive to the identification of (linguistic) biomarkers [59]. This conceptual change in understanding psychiatric disorders aims to facilitate collaborative work by proposing a common framework through which specialists from different fields can study pathological mechanisms.

Thus, the RDoC classification in psychiatry, described previously, proposes a dimensional understanding of mental disorders, facilitating the understanding of individual variability and accounting for the different clinical presentations among patients with the same pathology from a categorical perspective.

In the same way, the Hierarchical Taxonomy of Psychopathology (HiTOP), proposed by Kotov et al [60], is a promising model, especially for SER. Rather than replacing traditional categorical classifications, HiTOP hierarchically organizes symptoms into spectra and subfactors. It conceptualizes mental disorders along broad dimensions that reflect underlying emotional and behavioral patterns. Internalized disorders are characterized by self-directed emotional and psychological symptoms, such as anxiety, depression, or phobias. Individuals affected by these disorders tend to internalize their struggles, often isolating their emotions. Externalized disorders, on the other hand, manifest in outwardly directed disruptive behaviors, such as aggression, impulsivity, or transgression of social norms. Thought disorders (eg, schizophrenia) are characterized by confusion, detachment from reality, and unusual experiences. By framing psychopathology as a continuum, HiTOP moves beyond discrete diagnostic categories to capture the overlapping nature of emotional and behavioral dysfunctions.

At the same time, the integration of NLP and emotion recognition into this approach is opening new perspectives. NLP enables the analysis of language data by detecting linguistic cues associated with mental disorders, such as depression or anxiety. These analyses facilitate the extraction of psychological and emotional dimensions, enriching the RDoC criteria with behavioral and cognitive data. The use of linguistic data in the RDoC approach could thus improve diagnostic processes, offering a more detailed and dynamic view of psychiatric disorders, and contribute to more personalized treatments adapted to the specific profiles of each patient. This convergence of neuroscientific and technological advances could truly transform the way psychiatry approaches mental disorders.

It should be stressed that proposing a clear and systematic mapping from emotions to dimensional approaches to pathologies remains a complex task. Emotional models in SER are based on theoretical presuppositions derived from psychology or cognitive science, while psychiatric classification systems rely on distinct clinical and diagnostic logics, with sometimes divergent levels of granularity and objectives. For example, the circumplex model offers a fine-grained, continuous representation of emotions along the valence and arousal axes, but does not directly align with the diagnostic criteria of the *DSM* or the functional domains of the RDoC.

Multimodal Approaches

This study was limited to works that involved the analysis of audio exclusively; however, some of the included studies showed that a multimodal approach could outperform approaches based solely on the speech signal (eg, Mao et al [49]). Many architectures have been proposed; one such example is the contrastive language-audio pretraining architecture [61]. This model is based on the transformer architecture and is trained on audio and text pairs using 2 encoders. In its introduction, this model was shown to outperform state-of-the-art models in several speech-related tasks without the need to train the model on data related to those tasks (a technique referred to as 0-shot learning).

While these approaches can be more effective than audio-only methods, it is worth noting that they can introduce more invasiveness to procedures, for example, through the recording of video.

Conclusions

SER is emerging as a promising tool in mental health care, offering potential for early detection, continuous monitoring,

XSL•FO
RenderX

and personalized interventions. This approach is based on ML and artificial intelligence technologies and involves the recognition of emotions from recordings of patients in a health care context, followed by the analysis of these emotions, with possible applications of other ML methods to either the emotions from the model or the use of the output of the SER model as input into a classifier to distinguish between populations (eg, control or pathological groups, or other classes fitting the dataset at hand).

This is the approach we suggest in the framework of the Apprentissage Profond pour l'Analyse Informatisée de la Subjectivité et des Emotions dans les troubles psychotiques émergents (DL for digital analysis of subjectivity and emotions in emerging psychotic disorders) project. This project, a collaboration between Sorbonne University, the French National Institute of Health, and the Brest University Hospital Centre, aims to develop automated methods for predicting psychotic transition among patients and, in doing so, improve the prognosis for patients. With this program, we aim to better understand the convergences and discontinuities between dimensional approaches, such as the RDoC, and models of emotion, to contribute to the development of speech analysis tools that are more aligned with clinical needs.

SER presents several advantages in this context, as an objective, noninvasive technique that potentially offers real-time insights into patients' emotional states, with a promising role in diagnosis support and clinical evolution monitoring.

However, to be successful, interdisciplinary collaboration among computer scientists, psychologists, linguists, and health care professionals will be essential to refine these technologies and ensure their precise, nonbiased, and ethical implementation. Further work should explore the within-subject application of SER, particularly in the context of longitudinal monitoring. This approach would allow the regular assessment of patients' emotional states and thus early identification and treatment of conditions, such as SI, depression, or psychotic episodes.

Beyond that, the next challenge for SER applications in mental health will likely be to integrate SER with other clinical data, as well as biological, genetic, and imaging data, in large-scale multimodal analyses to better characterize and predict psychiatric disorders.

Acknowledgments

The authors would like to express their heartfelt gratitude to the Fondation de France and the Fondation de l'Avenir for their invaluable support. This work was also supported by the "Investissements d'Avenir" program of the French government, which is managed by the Agence Nationale de la Recherche, under the reference PsyCARE ANR-18-RHUS-0014.

The authors also thank Jean-Marie Tshimula for his contribution to part of the initial version of this document during his contract for the project.

Abstract

Background: Despite the high prevalence and significant burden of depression, underdiagnosis remains a persistent challenge. Automatic speech analysis (ASA) has emerged as a promising method for depression assessment. However, a comprehensive quantitative synthesis evaluating its diagnostic accuracy is still lacking.

Objective: This systematic review and meta-analysis aimed to assess the diagnostic performance of ASA in detecting depression, considering both machine learning and deep learning approaches.

Methods: We conducted a systematic search across 8 databases, including MEDLINE, PsycInfo, Embase, CINAHL, IEEE Xplore, ACM Digital Library, Scopus, and Google Scholar from January 2013 to April 1, 2025. We included studies published in English that evaluated the accuracy of ASA for detecting depression, and reported performance metrics such as accuracy, sensitivity, specificity, precision, or confusion matrices. Study quality was assessed using a modified version of the Quality Assessment of Studies of Diagnostic Accuracy-Revised. A 3-level meta-analysis was performed to estimate the pooled highest and lowest accuracy, sensitivity, specificity, and precision. Meta-regressions and subgroup analyses were performed to explore heterogeneity across various factors, including type of publication, artificial intelligence algorithms, speech features, speech-eliciting tasks, ground truth assessment, validation approach, dataset, dataset language, participants' mean age, and sample size.

Results: Of the 1345 records identified, 105 studies met the inclusion criteria. The pooled mean of the highest accuracy, sensitivity, specificity, and precision were 0.81 (95% CI 0.79 to 0.83), 0.84 (95% CI 0.81 to 0.86), 0.83 (95% CI 0.79 to 0.86), and 0.81 (95% CI 0.77 to 0.84), respectively, whereas the pooled mean of the lowest accuracy, sensitivity, specificity, and precision were 0.66 (95% CI 0.63 to 0.69), 0.63 (95% CI 0.58 to 0.68), 0.60 (95% CI 0.55 to 0.66), and 0.64 (95% CI 0.58 to 0.70), respectively.

Conclusions: ASA shows promise as a method for detecting depression, though its readiness for clinical application as a standalone tool remains limited. At present, it should be regarded as a complementary method, with potential applications across diverse contexts. Further high-quality, peer-reviewed studies are needed to support the development of robust, generalizable models and to advance this emerging field.

Introduction

Depression represents a significant global health challenge, ranking among the leading causes of disability and premature mortality. Approximately 280 million people worldwide are estimated to endure major depressive disorder, representing 3.8% of the global population [1]. Depression is associated with substantial societal and economic costs [2], loss in productivity [3], and a reduced quality of life [4,5]. Additionally, depression is a key risk factor for a spectrum of chronic health conditions, including arthritis, asthma, cancer, and cardiovascular diseases [6]. Notably, there is evidence that patients who endure both depression and chronic physical conditions tend to have considerably lower quality of life than those enduring a chronic physical condition solely [7], with patients with depression dying 5 to 10 years earlier due to chronic physical conditions [8]. Perhaps most alarmingly, depression is inextricably linked to suicide [9], with people enduring depression being 20 times more likely to commit suicide than the general population [5]. Consequently, the early detection of depression and its timely intervention assume paramount significance.

Current state-of-the-art depression assessment primarily relies on operational diagnostic criteria from the *DSM-5-TR* (*Diagnostic and Statistical Manual of Mental Disorders* [Fifth Edition, Text Revision]) [10] and the *ICD-11* (*International Classification of Diseases, 11th Revision*) [11]. When considering screening, the Patient Health Questionnaire-9 [12] is the most commonly used tool for depression due to its brevity, ease of use, and validation across various languages and contexts [13]. However, these assessments are susceptible to a range of biases arising from the interviewer's experience, the quality of the question protocol, and the patient's willingness to communicate their symptoms [14]. Field trials of the *DSM-5* criteria for major depressive disorder have revealed strikingly low interrater reliability [15]. Hence, the acquisition of diagnostic information through these traditional means is not only time-consuming but also demands considerable clinical training and practice to yield reliable results [16]. Adding to these complexities is the stark shortage of mental health professionals worldwide, which represents one of the biggest obstacles to the early detection of depression [17]. For instance, there are approximately 9 psychiatrists per 100,000 people in developed countries [18] and as few as 0.1 for every 1,000,000 in middle- and lower-income countries [19]. Therefore, there is an urgent need to objectively screen and diagnose individuals with depression, particularly those who face geographical, financial, or practical barriers to accessing traditional psychological or psychiatric services [20].

In response to these pressing needs, ongoing efforts have been made to identify efficient and objective biological, physiological, and behavioral biomarkers for depression. A wide range of biological markers, such as low serotonin levels [21], neurotransmitter dysfunction [22], genetic abnormalities [23], electroencephalogram signals [24,25], eye movements [26], gaits [27], and inflammatory biomarkers [28], have been associated with depression. Nevertheless, a specific biomarker with adequate predictive value for diagnosing depression remains elusive.

With recent advancements in the machine learning field, automatic speech analysis (ASA) has gained popularity as an attractive objective biomarker for depression assessment. ASA presents a variety of benefits that make it particularly attractive for both research and clinical applications. First, it is cost-effective, noninvasive, unobtrusive, and suitable for remote monitoring. In contrast to other biological metrics, speech can be easily collected using modern technologies, such as smartphones, tablets, and computers, which are broadly accessible to the population, thereby eliminating the need for expensive wearables or invasive neuroimaging techniques. Second, ASA may offer greater objectivity compared to self-reported measures. While self-report questionnaires are subject to bias and intentional or unintentional symptom masking, speech features, particularly acoustic features, are more difficult to consciously manipulate. This is because depression can disrupt motor and cognitive processes associated with speech production, resulting in subtle acoustic and linguistic changes that reflect underlying physiological and neurocognitive alterations. Third, speech conveys both what is said and how it is said, providing a dual perspective on the speaker's cognitive and emotional states. While the linguistic content serves as a direct manifestation of these states, variations in motor and acoustic features can indirectly reveal underlying neural activity [20]. Finally, speech may be generalized across different languages due to the shared aspects of vocal anatomy, which allow for the comparison and application of speech-based metrics across diverse linguistic contexts (for a more in-depth review of the advantages of speech as a biomarker, see the study by Low et al [20]).

An increasing number of studies have investigated the potential of speech analysis for depression detection, which has led to the publication of several reviews [14,20,29,30]. However, to date, only Liu et al [30] has conducted a meta-analysis to evaluate the diagnostic performance of ASA to detect depression, and their review was limited to studies using deep learning algorithms. This underscores the need for a comprehensive quantitative synthesis of the evidence that includes both machine learning and deep learning approaches. Therefore, this systematic review and meta-analysis aimed to synthesize published data on the performance of ASA for depression detection.

Methods

Overview

This systematic review and meta-analysis were conducted in accordance with the PRISMA-DTA (Preferred Reporting Items

XSL•FO
RenderX

for Systematic Reviews and Meta-Analyses—Extension for Diagnostic Test Accuracy) [31]. The PRISMA-DAT checklist is provided in Multimedia Appendix 1 [32-136]. We registered the review protocol with the PROSPERO (International Prospective Register of Systematic Reviews; ID: CRD42023444431). There was no prior published protocol for the current study.

Search Strategy

We systematically searched 8 electronic databases on April 1, 2025, including MEDLINE (via Ovid), APA PsycInfo (via Ovid), Embase (via Ovid), CINAHL (via EBSCO), IEEE Xplore, ACM Digital Library, Scopus, and Google Scholar. For Google Scholar, only the first 100 results were considered. Our search used the following terms as index terms or free-text words: “speech analysis” and depression. The full electronic search strategy used for MEDLINE was the following: ((“speech analysis”[tw] OR “speech processing”[tw] OR “speech feature”[tw] OR “speech features”[tw] OR “speech signal”[tw] OR “speech signal processing”[tw] OR “speech classification”[tw] OR “speech recognition”[tw] OR “speech model”[tw] OR “acoustic analysis”[tw] OR “acoustic processing”[tw] OR “acoustic feature”[tw] OR “acoustic features”[tw] OR “acoustic signal”[tw] OR “acoustic signal processing”[tw] OR “acoustic classification”[tw] OR “acoustic recognition”[tw] OR “acoustic model”[tw] OR “vocal analysis”[tw] OR “vocal processing”[tw] OR “vocal feature”[tw] OR “vocal features”[tw] OR “vocal signal”[tw] OR “vocal signal processing”[tw] OR “voice recognition”[tw] OR “vocal recognition”[tw] OR “voice model”[tw] OR “vocal model”[tw]) AND (exp Depression/ OR depress*[tw] OR exp Depressive Disorder/ OR depressive disorder*[tw])). The full search strategies for all databases are detailed in Table S12 in Multimedia Appendix 2. The screening process involved 2 stages. First, titles and abstracts were reviewed, followed by a thorough examination of full-texts. The entire selection process was independently conducted by 2 reviewers (PLM and AV), and discrepancies were resolved through dialogue and consensus.

Eligibility Criteria and Study Selection

We limited the inclusion to studies that (1) evaluated the accuracy of ASA to detect depression; (2) reported performance metrics such as accuracy, sensitivity, specificity, precision, or confusion matrices; and (3) were published in English since 2013. We excluded studies focusing on the prediction of depression severity or treatment outcomes. Studies that used multimodal data (eg, face features) in addition to speech data were excluded, except those that reported distinct performance values for each separate model. For the publication type, we included journal papers, conference papers, and thesis dissertations, but excluded reviews, preprints, conference abstracts, posters, protocols, editorials, and comments. We did not apply any constraints in terms of setting, reference standard, or country of publication.

Data Extraction

Data extraction covered study metadata, speech variables, artificial intelligence (AI) algorithms, and performance metrics. From studies providing raw data or confusion matrices, we computed accuracy, sensitivity, specificity, and precision. Many studies have conducted multiple experiments to assess distinct speech features, validation methods, and AI techniques, yielding a range of results. To comprehensively represent this variability, we extracted both the lowest and highest values reported for each performance metric across different algorithms. Data extraction was conducted by PLM, while AV and MTA-C verified the extraction for quality assurance.

Risk of Bias and Applicability Appraisal

Two reviewers (AV and MTA-C) independently used a modified version of the Quality Assessment of Studies of Diagnostic Accuracy-Revised (QUADAS-2) by Abd-Alrazaq et al [137] to evaluate the risk of bias and applicability of the included studies. Similar to the original QUADAS-2, the modified version covered 4 domains: participants, index test (AI algorithms), reference standard (ground truth), and analysis [137]. Disagreements were resolved through either consensus or adjudication by a third reviewer (PLM).

Statistical Analysis

Given that many studies conducted more than 1 experiment and reported multiple performance metrics, there was a potential for these studies to disproportionately influence the meta-analysis compared to those reporting a single result. Moreover, experiments from the same study cannot be regarded as independent, which challenges the independence assumption for effect sizes, underlying traditional meta-analytic techniques [138]. Therefore, to calculate the pooled mean of the highest and lowest accuracy, sensitivity, specificity, and precision, we used a 3-level meta-analysis using restricted maximum likelihood [139]. This approach accounts for 3 distinct sources of variance: population differences between study population effects, population differences between effects of experiments from the same study, and, finally, sampling variance [140]. Anticipating significant heterogeneity, we applied a random-effects model.

Meta-regression and subgroup analyses were conducted to assess potential variations in ASA performance across different factors, including type of publication, AI algorithms, speech features, speech-eliciting tasks, ground truth assessment, validation approach, dataset, and dataset language, participants’ mean age, and sample size. To ensure the robustness of our findings, we restricted our analyses to subgroups containing 5 or more estimates [141]. To quantify and assess the study heterogeneity, we used the Cochran Q-test and I^2. Cochran Q test determines whether the observed variability exceeds the study’s sampling error alone, and a Cochran P value ≤.05 indicates statistically significant heterogeneity [142]. I^2 statistics estimate the proportion of total variation due to true heterogeneity rather than sampling error, and values of 25%, 50%, and 75% reflect low, moderate, and high heterogeneity, respectively [143]. All analyses were performed using the *metafor* package in R [144,145].

Results

Study Selection

The initial search through 8 databases yielded a total of 1345 studies. After removing 473 duplicates, 872 papers remained. Following titles and abstract screening, a further 579 publications were excluded. Twelve publications were not retrieved. After reading the full text of all the remaining 293 records, a total of 105 studies were ultimately included in the current review. Figure 1 shows the process of the study selection process.

Figure 1. PRISMA flow diagram of the study selection process. This diagram describes the process of identifying, screening, and selecting studies for inclusion. Initially, a total of 1345 records were identified from databases. After the removal of 473 duplicates, 872 records remained for the screening phase. Of these, 579 records were excluded, and 293 reports were sought for retrieval. Further, 12 reports could not be retrieved, resulting in 281 reports assessed for eligibility. Ultimately, 176 reports were excluded based on the predefined inclusion criteria. The final review included 105 studies. PRISMA: Preferred Reporting Items for Systematic Reviews and Meta-Analyses.

General Study Characteristics

The 105 studies included in this review were published between 2013 and 2025, with 21 (20%) published in 2022 and 2023. A total of 33 (31.4%) studies were carried out in China, 12 (11.4%) in India, and 10 (9.5%) in Hungary. Regarding the publication type, the majority (55/105, 52.4%) were conference papers, followed by peer-reviewed journal papers (48/105, 45.7%), and theses (2/105, 1.9%). The number of participants included was reported in 98 studies, with sample sizes ranging from 14 to 9337. The age of participants, reported in 34 studies, ranged between 19.0 and 71.7 years, with an average age of 37.47 (SD 10.41) years. The percentage of female participants, reported in 53 studies, varied between 30.8% and 100%. The percentage of depressed participants, as reported in 57 studies, ranged between 21% and 69%, with an average of 45.9% (SD 11.9). Table 1 and Table S2 in Multimedia Appendix 2 detail the specific characteristics of the included studies.

Features of ASA Classifiers

In terms of speech features, spectral features (91/105, 86.7%) were the most frequently analyzed, followed by prosodic features (58/105, 55.2%), source features (53/105, 50.5%), format features (39/105, 37.1%), and lexical features (15/105, 14.3%). The most commonly used speech-eliciting task was free speech (76/105, 72.4%). Reading tasks were used in 36.2% (38/105) of studies, while only a few used counting (3/105, 2.9%) or sustained vowels (2/105, 1.9%). Many studies conducted multiple experiments to evaluate various AI algorithms, with support vector machine (SVM) being the most frequently used (43/105, 41%). The most commonly used assessment instruments to establish ground truth were the Patient Health Questionnaire-8/-9 (51/105, 48.6%). The included studies applied 4 different validation methods, the most common of which were hold-out cross-validation (64/105, 61%) and K-fold cross-validation (38/105, 36.2%). More than half of the studies used hand-crafted datasets (56/105, 53.3%), while the DAIC-WOZ (Distress Analysis Interview Corpus–Wizard of Oz) was the most frequently used public database (35/105, 33.3%). The specific details of the models used in the included studies are detailed in Table 2 and Table S2 in Multimedia Appendix 2.

Results of Risk of Bias Appraisal

Almost half of the studies (50/105, 47.6%) were classified as high risk in at least 1 domain. Most of the studies (85/105, 81%) used an appropriate consecutive or random sampling method to select eligible participants. A significant portion of the studies (64/105, 61%) avoided inappropriate exclusions, and a balanced representation of depressed versus nondepressed subgroups was maintained in 60% (63/105) of them. Additionally, 66.7% (70/105) included a sufficient sample size. Thus, in the participant domain, almost half (49/105, 46.7%) of the studies had unclear or high risk of bias.

All the studies (105/105, 100%) thoroughly described the AI models used. Additionally, the predictive features (ie, speech features) were clearly outlined in 94.3% (99/105) of the cases, and 93.3% (98/105) of the studies assessed these features consistently for all participants. Nonetheless, in 74.3% (78/105) of the studies, information was insufficient to confirm that feature collection was blinded to outcome data. Risk of bias related to the index test was deemed low in 94.3% (99/105) of the studies.

Most of the studies (96/105, 91.4%) used appropriate reference standards for classifying the outcome (ie, depressed vs nondepressed). Consistent outcome definition was maintained for all participants in 87.6% (92/105) of the studies, and 86.7% (91/105) of the studies determined the outcome without predictor information. However, more than three-quarters (85/105, 81%) of the studies did not provide sufficient data to ensure that an appropriate interval was maintained between the index test and

XSL•FO
RenderX

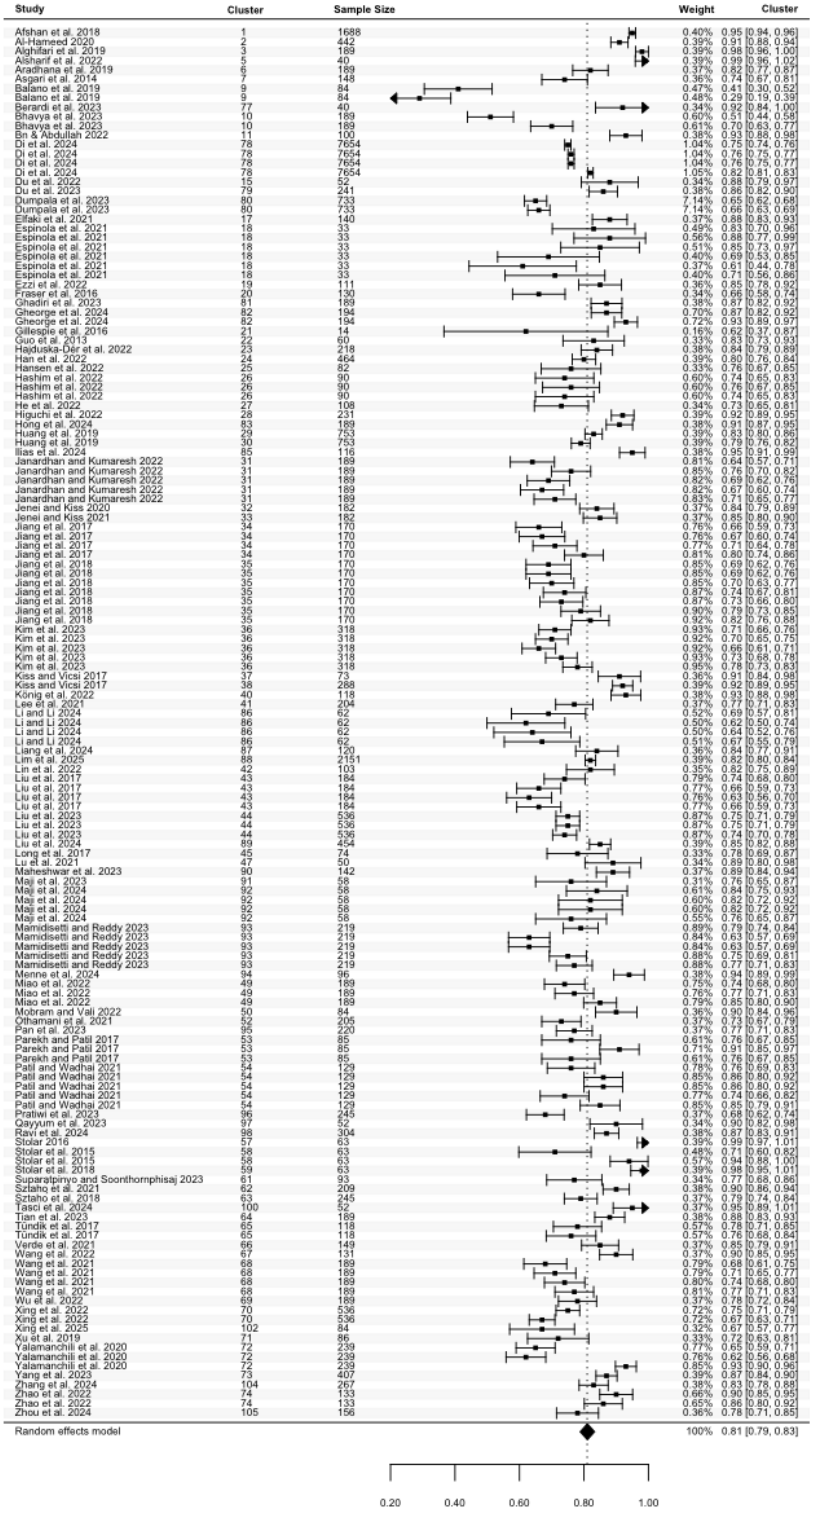
the reference standard. Accordingly, the risk of bias due to the reference standard was low in 81% (85/105) of the studies.

Only 21.9% (23/76) of the studies included all enrolled participants in the data analysis. In 93.3% (102/105) of the studies, there was insufficient information to confirm proper data preprocessing. The breakdown of the training, validation, and test sets was adequate in 91.4% (96/105) of the studies, and model performance was evaluated using appropriate metrics in 81.9% (86/105) of the studies. Consequently, 43.8% (46/105) of the studies were considered to have a low risk of bias in the analysis domain.

Regarding the evaluation of model applicability, most of the studies, 5 (97/105, 92.4%), were identified as having a low concern of applicability in the participants' domain, and almost all studies (102/105, 97.1%) had a low concern of applicability in the index test domain. In the outcome domain, 92.4% (97/105) of the studies were adjudged to have low concerns regarding outcome definition, timing, or outcome determination. Figure S1 in Multimedia Appendix 2 illustrates the overall risk of bias and applicability concerns assessment. Table S3 in Multimedia Appendix 2 details reviewers' assessment of each study included.

Meta-Analysis of Included Models

Overview



A 3-level meta-analysis summarized the highest and lowest results for accuracy, sensitivity, specificity, and precision. Meta-regressions and subgroup analyses were conducted to examine potential differences in the ASA performance across various factors, including type of publication, AI algorithms, speech features, speech-eliciting tasks, ground truth assessment, validation approach, dataset, dataset language, participants' mean age, and sample size. All meta-regression and subgroup analyses results are shown in Tables S4-S11 in Multimedia Appendix 2.

Accuracy

Accuracy was reported in 86 studies, comprising 148 estimates (N=27,039). The highest accuracy ranged from 0.29 to 0.99, with a pooled mean of 0.81 (95% CI 0.79 to 0.83; Figure 2). There was significant heterogeneity among studies (Cochran $P<.001$; $I^2=96.74\%$). The lowest accuracy estimates, derived from 114 estimates in 65 studies (N=16,394), ranged between 0.23 and 0.94. The pooled mean for lowest accuracy was 0.66 (95% CI 0.63 to 0.69; Figure 3), also showing considerable heterogeneity (Cochran $P<.001$; $I^2=94.44\%$). Meta-regression and subgroup analyses revealed statistically significant differences in the highest accuracy for speech features (Cochran $P=.04$) and algorithms (Cochran $P=.04$) groups (Table S4 in Multimedia Appendix 2). No other statistically significant differences were observed.

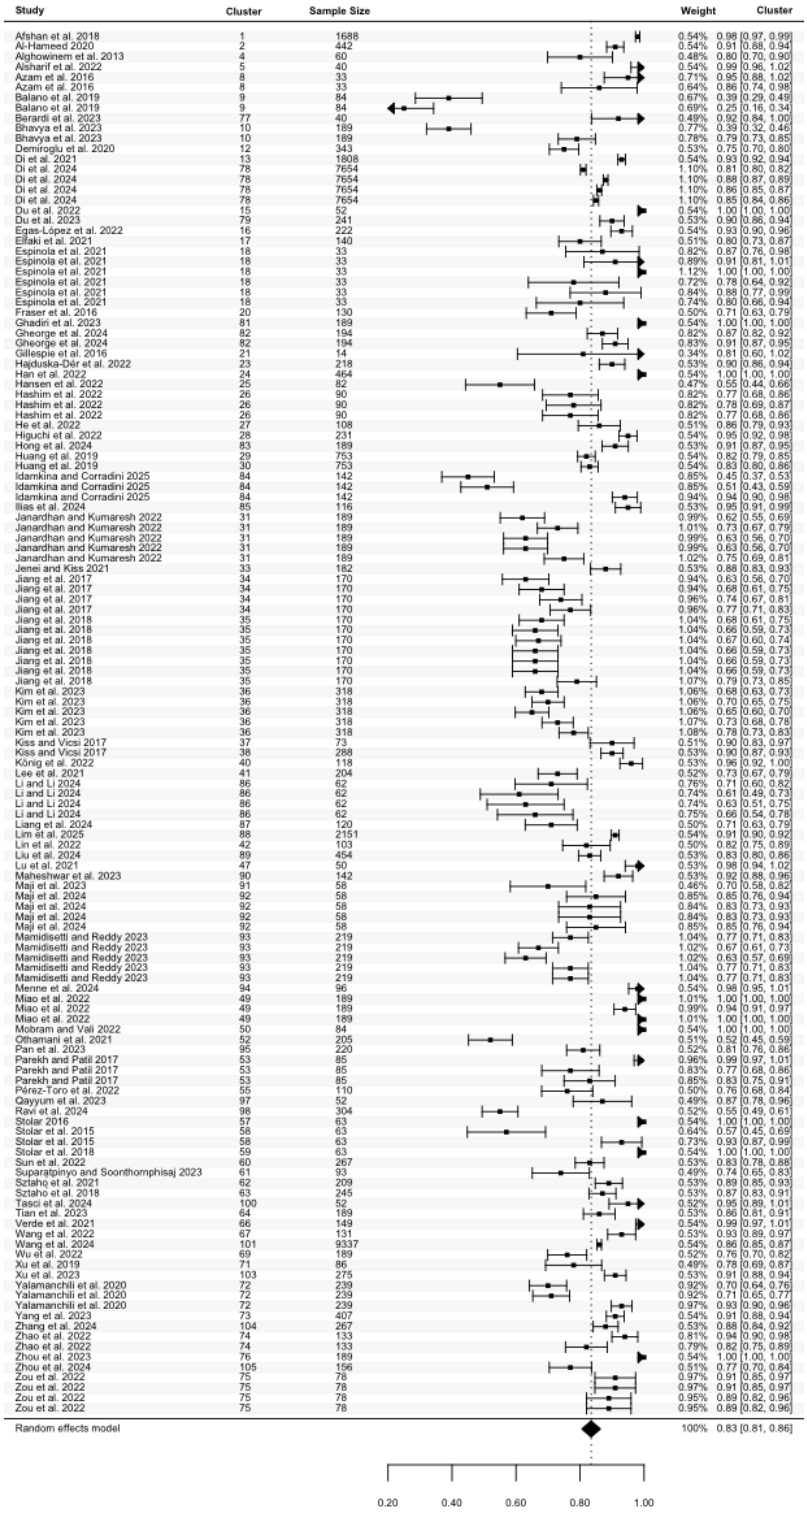
Figure 3. Three-level forest plot of the lowest accuracy estimates. This forest plot illustrates the results of this 3-level meta-analysis based on 114 estimates of the lowest accuracy, reported in 65 studies [33, 34, 36, 37, 39-45, 47, 49, 51, 53, 58-61, 63-65, 67, 68, 72-74, 77, 78, 81-84, 86, 87, 90-92, 94, 96, 100, 101, 104, 107, 109, 111-115, 117-121, 123-126, 128, 129, 131-133, 136]. The solid squares represent point estimates of accuracy, with horizontal lines indicating the 95% CIs. The rhombus at the bottom represents the pooled lowest accuracy estimates.



Sensitivity

Sensitivity data were reported in 81 studies, including 135 estimates (N=36,096). The highest sensitivity ranged from 0.25 to 1.00, with a pooled mean of 0.84 (95% CI 0.81 to 0.86; Figure 4), and considerable heterogeneity (Cochran P<.001; I^2=99.93%). For the lowest sensitivity, 105 estimates from 64 studies (N=25,913) ranged between 0.00 and 0.98. The pooled mean was 0.63 (95% CI 0.58 to 0.68; Figure 5), with significant heterogeneity (Cochran P<.001; I^2=99.93%). Meta-regression and subgroup analyses revealed no statistically significant differences in sensitivity across groups except for speech features subgroups in the highest sensitivity (P=.05; Table S6 in Multimedia Appendix 2).

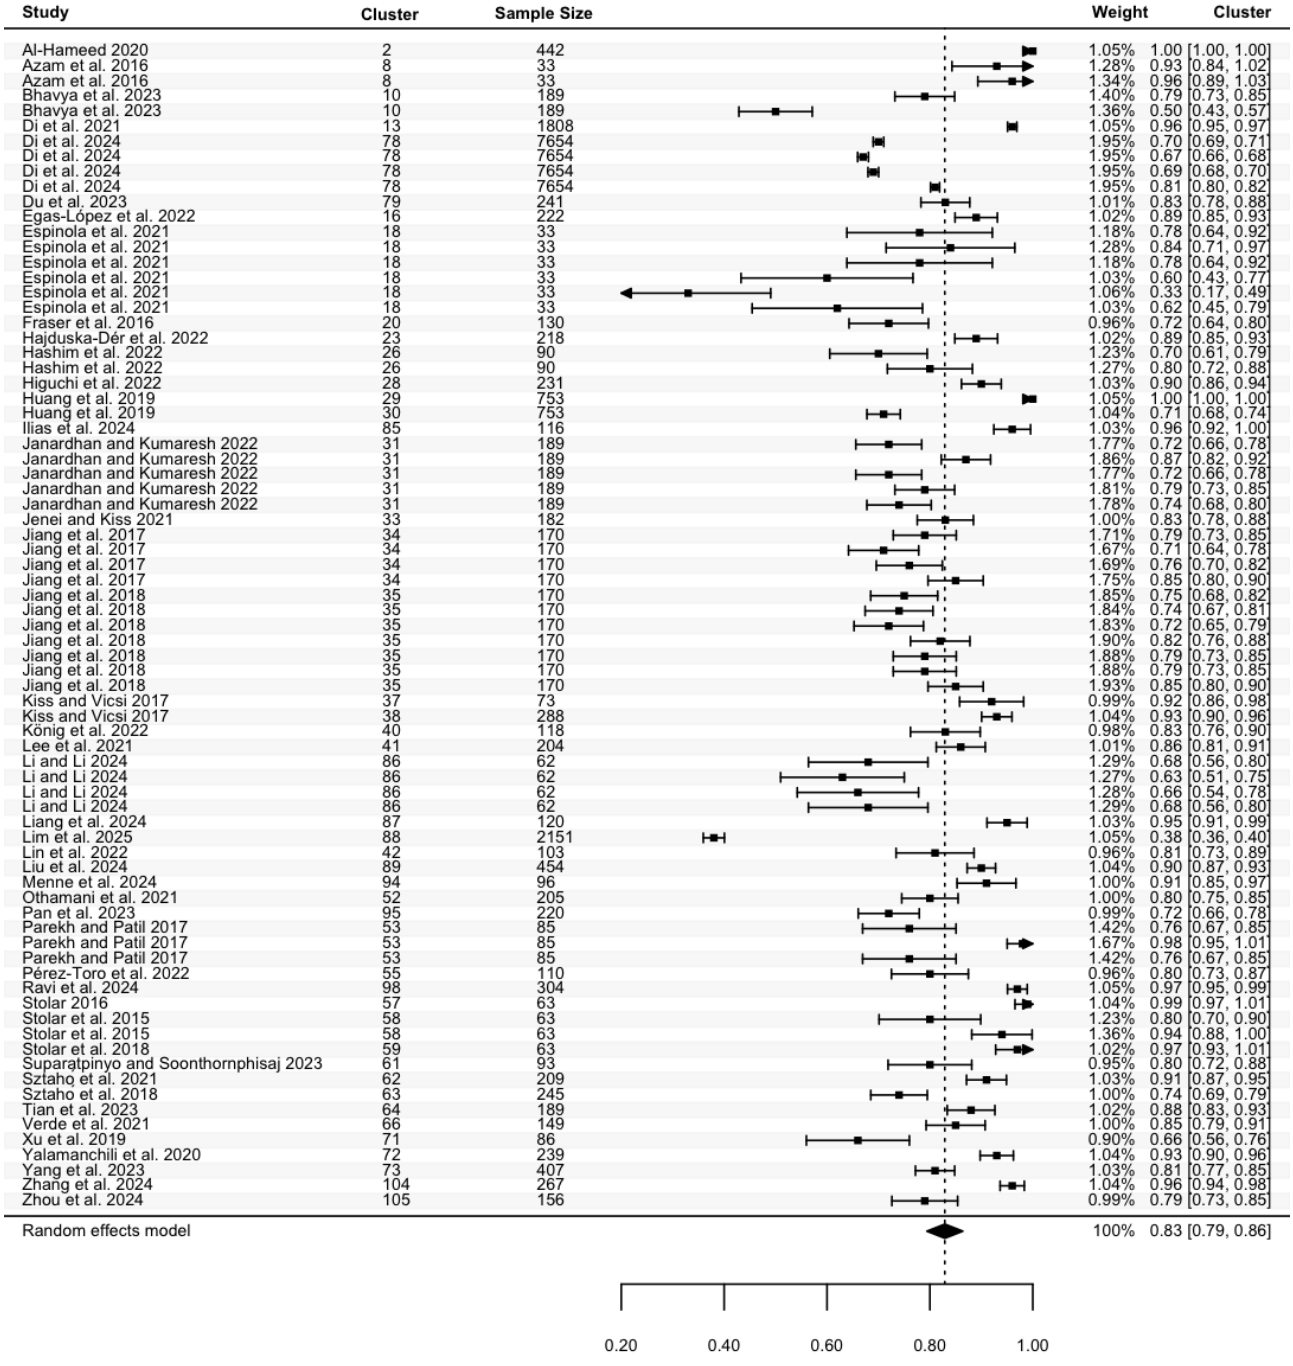
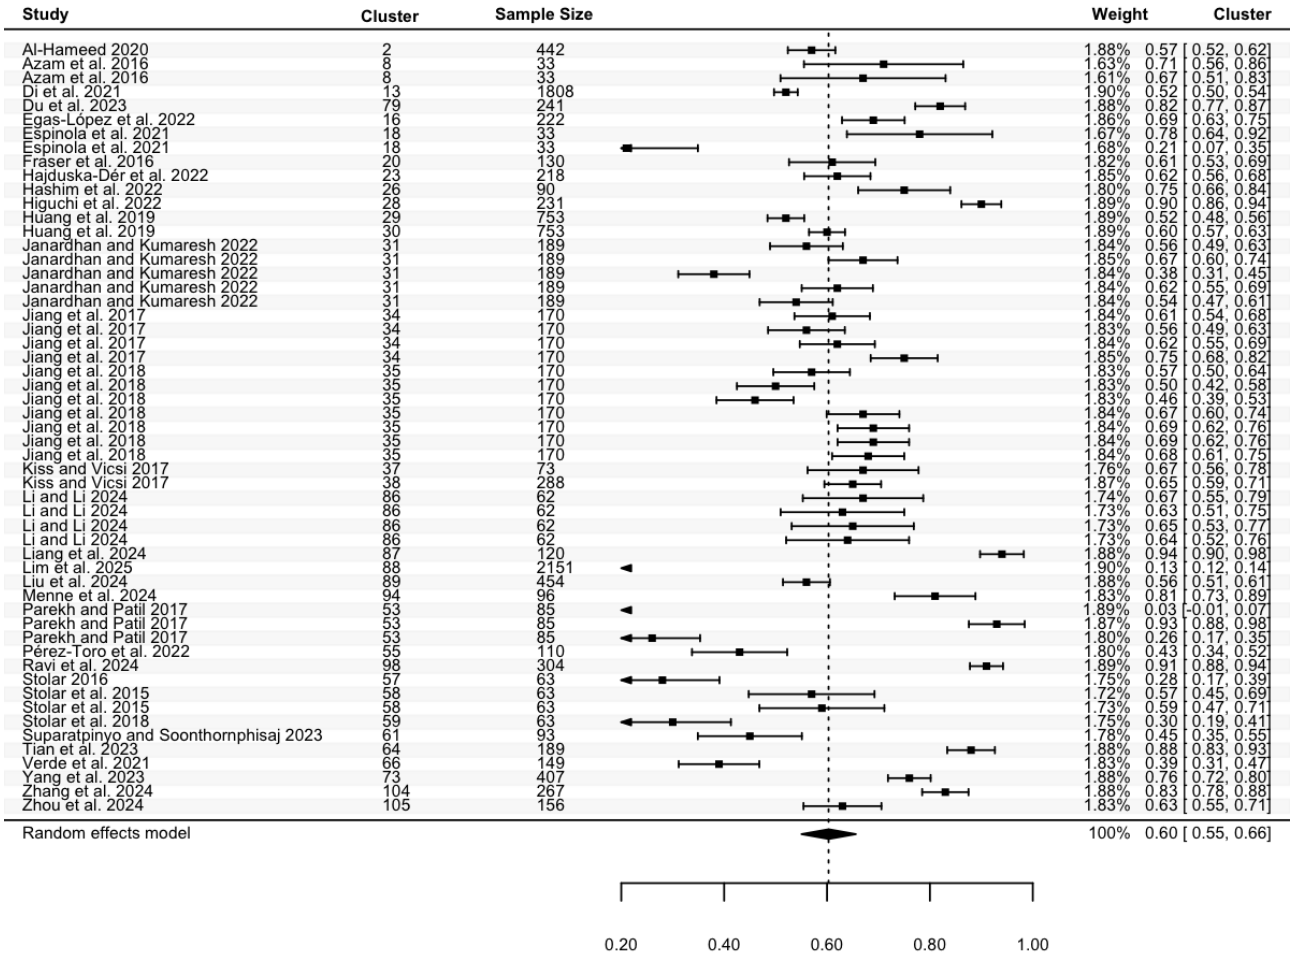
Figure 5. Three-level forest plot of the lowest sensitivity estimates. This forest plot illustrates the results of this 3-level meta-analysis based on 105 estimates of the lowest sensitivity, from 64 studies [34-45, 47, 49-51, 53, 55, 59-61, 64, 65, 67-70, 73-78, 81-84, 86, 88, 90, 92, 96, 97, 100, 101, 103, 104, 108, 109, 112, 113, 117-120, 123, 125-129, 131, 132, 135]. The solid squares represent point estimates of sensitivity, with horizontal lines indicating the 95% CIs. The rhombus at the bottom represents the estimated pooled lowest sensitivity.



Specificity

Specificity was reported in 47 studies, with a total of 77 estimates (N=20,207). The highest specificity ranged from 0.33 to 1.00, with a pooled mean of 0.83 (95% CI 0.79 to 0.86; Figure 6), and high heterogeneity (Cochran P<.001; I^2=99.81%). The lowest specificity estimates, from 55 estimates in 34 studies (N=10,553), ranged between 0.03 and 0.94. The pooled mean was 0.60 (95% CI 0.55 to 0.66; Figure 7), with significant heterogeneity (Cochran P<.001; I^2=97.81%). Meta-regression and subgroup analyses indicated no statistically significant differences in specificity across groups except for speech features subgroups in the highest specificity (P=.004; Table S8 in Multimedia Appendix 2).



XSL•FO
RenderX

Figure 6. Three-level forest plot of the highest specificity estimates. This forest plot illustrates the results of this 3-level meta-analysis based on 77 estimates of the highest specificity, from 47 studies [34, 36, 37, 40, 41, 43-46, 48, 49, 51, 54, 65, 66, 68, 76, 79-82, 84, 86, 88, 92, 93, 95, 97, 99, 100, 103, 104, 109-112, 116-118, 120, 123, 125-128, 131, 132]. This forest plot illustrates the results of this 3-level meta-analysis based on 55 estimates of the lowest specificity, from 34 studies [34, 36, 37, 40, 41, 43-45, 49, 51, 65, 68, 76, 81, 82, 84, 86, 88, 92, 100, 103, 109, 111, 112, 117, 118, 120, 123, 125-128, 131, 132]. The solid squares represent point estimates of specificity, with horizontal lines indicating the 95% CIs. The rhombus at the bottom represents the estimated pooled lowest specificity.

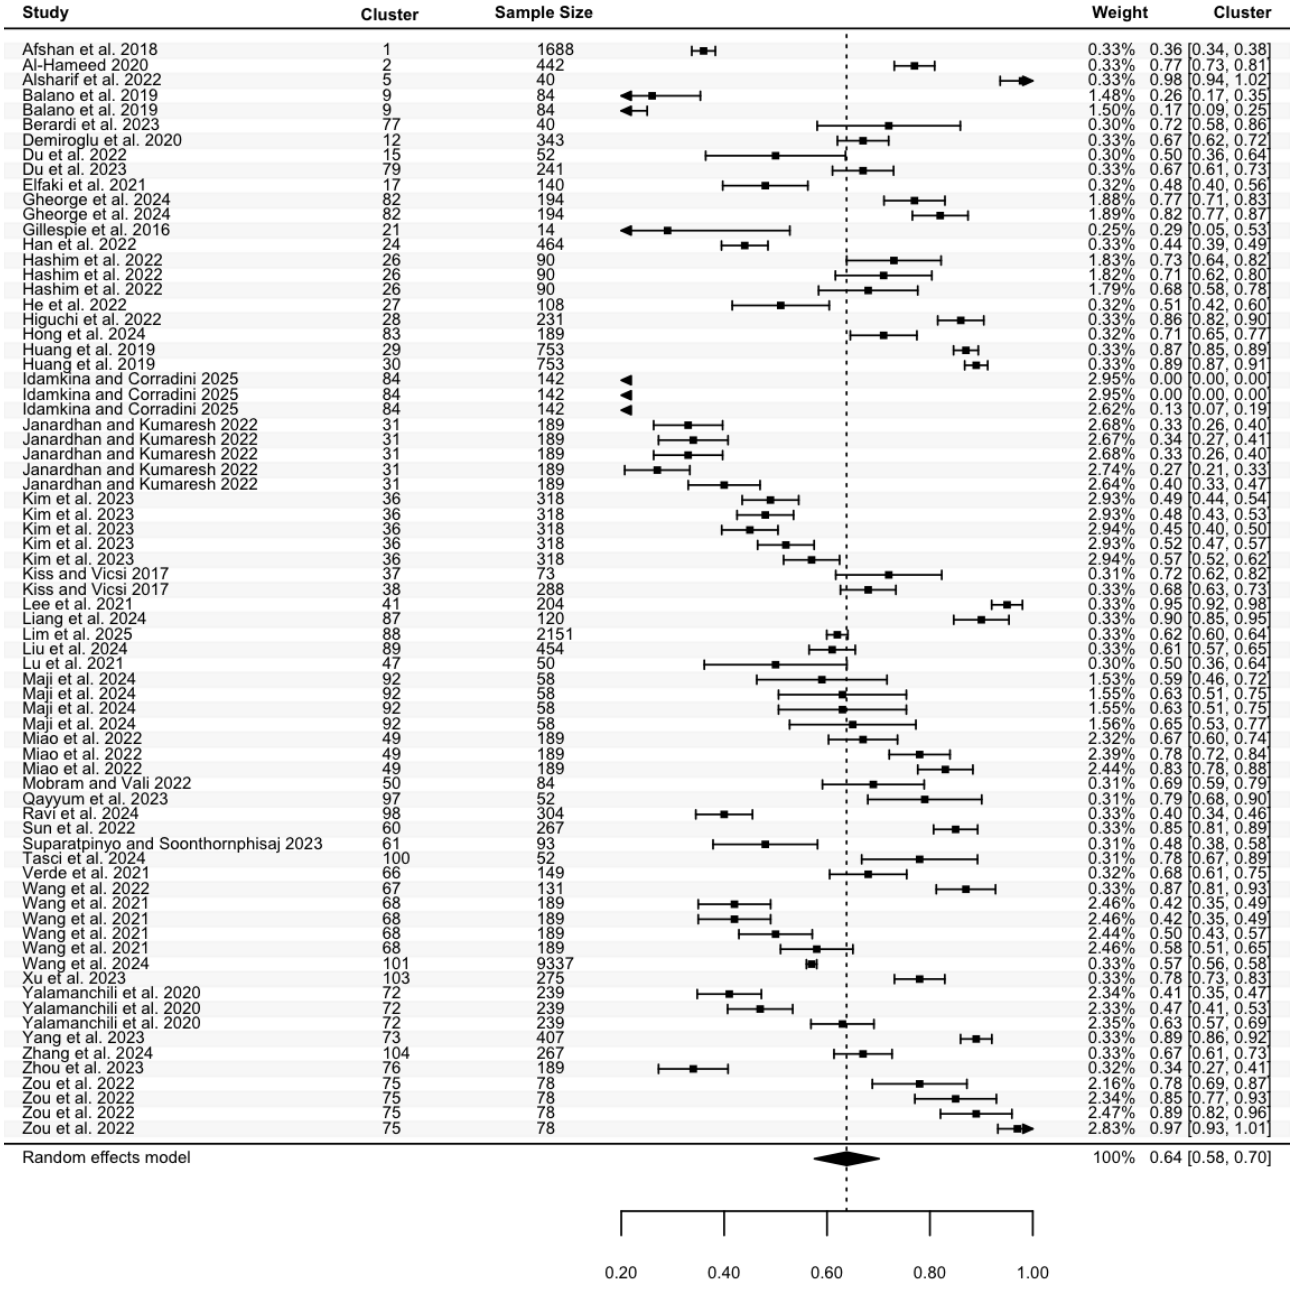
Precision

Precision was reported in 62 studies, with 95 estimates for the highest precision (N=24,696). The highest precision in these studies ranged from 0.25 to 1.00, with a pooled mean of 0.81 (95% CI 0.77 to 0.84; Figure 8), and considerable heterogeneity (Cochran P<.001; I^2=99.81%). For the lowest precision, 73 estimates from 46 studies (N=22,215) ranged between 0.00 and 0.98. The pooled mean was 0.64 (95% CI 0.58 to 0.70; Figure 9), with considerable heterogeneity (Cochran P<.001; I^2=99.81%). No statistically significant differences in precision were identified across groups.



XSL•FO
RenderX

Figure 8. Three-level forest plot of the highest precision estimates. This forest plot illustrates the results of this 3-level meta-analysis based on 95 estimates of the highest precision, reported in 62 studies [34, 35, 37-40, 42-44, 46, 47, 49-51, 53-57, 59-62, 64-71, 74, 75, 77-85, 90-93, 95, 96, 99, 101, 104, 108-113, 116, 119, 125, 126, 129]. Figure 9. Three-level forest plot of the lowest precision estimates. This forest plot illustrates the results of this 3-level meta-analysis based on 73 estimates of the lowest precision, reported in 46 studies [34, 35, 37-40, 42-44, 47, 49, 50, 53, 59-61, 64, 65, 67-70, 74, 75, 77, 78, 81-84, 90-92, 96, 97, 101, 104, 108, 109, 111-113, 119, 125, 126, 129]. The solid squares represent point estimates of precision, with horizontal lines indicating the 95% CIs. The rhombus at the bottom represents the estimated pooled lowest precision.

Discussion

Principal Findings

To the best of our knowledge, this is the first meta-analysis aimed at assessing the performance of ASA in detecting depression, including both machine learning and deep learning algorithms. Pooled data from 105 studies reveal that ASA demonstrates good, although not optimal, performance in classifying depression. Given that multiple studies conducted multiple experiments, we calculated the pooled mean of both the lowest and highest accuracy, sensitivity, specificity, and precision. Our results indicate that across studies, the pooled accuracy for depression detection was between 65% (ie, pooled mean of the lowest accuracy) and 81% (pooled mean of the highest accuracy), with comparable sensitivity (63%-84%) and specificity (60%-83%). This suggests that the ability of ASA to detect individuals with depression (sensitivity) was relatively consistent with its ability to identify those without depression (specificity). Additionally, pooled precision, which reflects the ability of ASA to correctly classify individuals who truly have depression among all those classified as depressed, ranged between 64% and 81%.

Our results revealed significant heterogeneity among studies. Meta-regression and subgroup analyses indicated a statistically

XSL•FO
RenderX

significant difference between speech features, with Teager Energy Operator (TEO)–based features outperforming others in the pooled mean of the highest accuracy, sensitivity, and specificity. TEO-based features are based on the studies conducted by Teager and Teager [146], which demonstrated that airflow propagation in the vocal tract has a nonlinear character [146]. Moreover, convolutional neural network and deep neural network (DNN), in general, outperformed other algorithms in highest accuracy, while naïve bayes performed the worst. DNNs are often regarded as "black boxes" because their decision-making processes are not easily interpretable [147], which hinders clinicians' trust and willingness to incorporate these models into the routine clinical workflow [148]. To foster trust in AI solutions for the detection of psychiatric conditions, it is important to implement a participatory approach, involving clinicians and other specialists in the model design process to create more interpretable algorithms that can better align with clinical needs and standards, thereby facilitating the incorporation of these potential solutions into clinical practice. Nevertheless, these results should be interpreted with caution as most studies in the current meta-analysis had a small sample size, which might have obscured further potential differences between AI algorithms. ASA performance is likely influenced by a complex interplay of factors that were not fully captured by the subgroup analyses. Beyond the measured variables, cultural and linguistic diversity, confounding factors such as comorbid conditions (eg, fatigue and anxiety), lifestyle influences, or medication effects, as well as differences in study protocols and dataset characteristics, may all contribute to the observed heterogeneity. These findings highlight the urgent need for standardized methodologies, diverse and inclusive datasets, and further research to understand and address these sources of heterogeneity.

Comparison With Prior Work

In the context of AI diagnostic efficacy for depression detection, a recent meta-analysis conducted by Liu et al [30] assessing the diagnostic performance of deep learning algorithms in detecting depression through speech reported a superior accuracy of 0.87 (ie, highest accuracy). Notably, their analysis was restricted to peer-reviewed journal papers that included confusion matrices. In contrast, our review applied broader inclusion criteria, including conference papers, journal papers, and theses, and incorporated studies even if they reported a single performance metric. It is also important to note that their analyses were based on only 8 studies and exclusively focused on deep learning algorithms, whereas our meta-analysis included both machine learning and deep learning approaches. Similarly, Abd-Alrazaq et al [137] performed a meta-analysis focused on AI performance in detecting depression using wearable devices. Based on 38 studies, they reported superior accuracy (70%-93%), superior specificity (73%-93%), and slightly better sensitivity (61%-87%). Notably, their meta-analysis included studies using wearable devices that monitored a range of parameters, including physical activity, sleep patterns, and heart rate. Given the complex and multifaceted clinical profile of depression, integrating ASA into complex statistical models alongside other data sources, such as biological (eg, genetic, inflammatory, and neuroimaging data), psychological (eg, psychometric scales), and clinical variables, could significantly improve the accuracy and reliability of AI tools for depression detection. Another promising avenue is the use of facial expression analysis in combination with speech. However, this approach may raise additional ethical concerns, particularly regarding data privacy, consent, and the risk of algorithmic biases [149].

SVM was the most used algorithm to classify individuals with depression in the present meta-analysis. SVMs are highly regarded in machine learning for their robust ability to handle noisy, interrelated features and process datasets with high-dimensionality efficiently. Convolutional neural network and DNN, in general, were also commonly used. Our findings, in line with those of Liu et al [30], suggest that these architectures hold a significant potential in ASA. Therefore, we recommend that future research efforts go in this direction, particularly in combination with participatory methodologies that involve clinicians throughout the development process. This collaborative approach is essential to ensure the clinical relevance, feasibility, and eventual adoption of such algorithms in mental health care settings. Nonetheless, several challenges remain, such as the large sample sizes typically required to train deep learning models effectively and the considerable computational power needed to support their development and implementation.

DAIC-WOZ [150] was the most commonly used open-source dataset, which includes 189 clinical interviews conducted by Ellie, a virtual interviewer [150]. Although this dataset has facilitated significant advancements in the field, it presents several limitations that warrant attention. First, the participants were volunteers whose depressive symptoms were assessed using the Patient Health Questionnaire-8, rather than through formal clinical diagnosis. Second, the metadata associated with DAIC-WOZ and other datasets is sparse, leaving potential confounding factors unspecified [151]. Third, the dataset endures a significant class imbalance, with nondepressed participants outnumbering depressed ones by a ratio of approximately 4:1 [152]. Furthermore, the dataset exhibits a notable gender bias in depression prevalence, with females having a higher proportion of depressed patients (ratio of approximately 5:8 depressed to nondepressed) compared to males (ratio of about 2:7 depressed to nondepressed) [153]. This imbalance raises concerns about biased model training, as machine learning algorithms may overfit to the majority class [154], thereby reducing their ability to generalize effectively across diverse populations [155]. One promising direction for future research is to integrate principles of fair machine learning [156] as well as prior domain knowledge, such as gender-specific linguistic patterns or balanced sampling strategies, into the design of depression detection models, ensuring that algorithms account for gender and class imbalances while avoiding overfitting to unintended features [154].

In terms of speech features used, most studies included in this review focused exclusively on acoustic features, while only 15 studies incorporated lexical features. Linguistic studies have shown that depression also manifests in language use, specifically in semantic and syntactic patterns that reveal heightened self-focus and pervasive negative affect [157].

XSL•FO
RenderX

Recent advances in deep learning, particularly the development of transformer-based models, such as BERT (Bidirectional Encoder Representations From Transformers) and RoBERTa (Robustly Optimized Bidirectional Encoder Representations From Transformers Pretraining Approach), have shown significant promise in natural language and speech processing tasks, with some studies reporting accuracy rates of up to 98% in detecting depression [158-160]. BERT is a DNN model that generates bidirectional text representations while preserving contextual and semantic nuances, making it particularly suitable for analyzing language associated with mental health. However, most BERT-based studies to date have focused on text from social media platforms. Future research should explore the integration of such models with speech data to examine whether combining what is said (linguistic content) with how it is said (acoustic features) can offer a more comprehensive understanding of an individual's mental health.

Research and Practical Implications

This review highlights that ASA is an emerging technology with potential for detecting depression, though its readiness for clinical application is still limited. First, the ASA performance is not yet optimal, indicating room for improvement. Second, most included studies had small or modest sample sizes; for robust and reliable estimates, larger samples are required [161]. This is particularly critical as small training sets may lead to inflated accuracy estimates due to overfitting or random effects [162,163]. Third, more than half of the studies assessed had a high risk of bias in at least 1 domain. Fourth, there is a notable absence of large-scale studies that examine the generalizability of ASA across countries, settings, and depression severity levels. Moreover, the clinical and methodological variables that affect this generalization remain unclear. Fifth, more than half of the studies (52.4%) were conference papers, so more peer-reviewed, high-quality studies are warranted. Sixth, considering the diversity in speaker characteristics and individual speaking styles, it is imperative to conduct longitudinal studies to discern whether variations in speech patterns are indicative of depression symptoms or merely reflect inherent personal differences or related conditions such as increased anxiety or fatigue [14,29]. Such studies are essential for validating the diagnostic precision of ASA and ensuring its reliability across different individuals and contexts. Finally, most of the studies included in this review used self-reported questionnaires for depressive symptoms and applied commonly used cutoff scores to indicate the presence of depression. Only a small percentage used structured clinical interviews, such as the *DSM-IV* (*Diagnostic and Statistical Manual of Mental Disorders* [Fourth Edition]) criteria, the Composite International Diagnostic Interview, or the Mini-International Neuropsychiatric Interview, to establish a formal diagnosis. This methodological discrepancy has important implications for interpreting the findings. Self-report measures primarily capture symptom severity, and while useful for screening purposes, they do not equate to a clinical diagnosis of depression. As such, when relying on these instruments, the objective of the study shifts from predicting a clinical diagnosis to predicting questionnaire scores, which may not fully align with diagnostic criteria [103]. To determine whether ASA could serve as a viable method for diagnosing depression, future studies should incorporate clinical data based on a formal diagnosis of depression.

Early detection is paramount, particularly for conditions such as depression, where delays in diagnosis can significantly worsen outcomes [164,165]. Although ASA offers a potential cost-effective, clinically relevant solution that could make depression screening more feasible and accessible, these methods should still be considered complementary tools rather than a replacement for established diagnostic methods. Moreover, ensuring its equitable, effective, and sustainable deployment requires addressing critical ethical and implementation challenges. The Non-Adoption, Abandonment, Scale-Up, Spread, and Sustainability framework provides valuable guidance in this effort, offering an evidence-based approach for studying the nonadoption and abandonment of technologies by individuals and the challenges to scale-up, spread, and sustainability of such technologies in health care organizations and systems [166]. Specifically, future studies should explore how ASA interacts with organizational capacity, user adoption, decision-making processes, and broader policy contexts. For instance, disruptions to clinicians' workflows [167] or gaps in organizational readiness [168] can significantly impede adoption. Furthermore, the explainability of AI algorithms and reproducibility of results are critical to building trust among health care professionals and patients [169]. The adoption of explainable artificial intelligence techniques, such as SHAP (Shapley Additive Explanations) [170] and Local Interpretable Model-Agnostic Explanations [171], can help elucidate the influence of individual acoustic features on AI model predictions. In our review, only Verde et al [172] used Local Interpretable Model-Agnostic Explanations to assess the relevance of acoustic features in the best-performing machine learning models, while Lin et al [79] applied SHAP. Notably, no other included studies used such explainable artificial intelligence techniques. Additionally, comprehensive frameworks for accountability and liability are necessary to clarify stakeholder responsibilities during the deployment process [169]. Finally, compliance with data protection laws must remain a priority to safeguard patient privacy [169]. For example, speech features could be extracted in a manner that prevents raw speech signal reconstruction [152,173], or processed and encrypted on local devices before being securely transmitted to servers for further analysis [174].

Limitations

While this meta-analysis represents the first comprehensive review summarizing the performance of ASA in detecting depression, several limitations warrant mention. First, the analysis was confined to English-language papers, which may have excluded relevant research conducted in other languages. Second, we included only those studies that provide the performance metrics under examination. However, in cases where studies lacked complete information, we did not contact the authors to obtain the missing data. Third, the included studies encompassed diverse patient populations, which adds complexity to the interpretation of our findings due to the variability in demographic and clinical characteristics. For example, patients with chronic depression might exhibit different speech features compared to those experiencing a first episode of depression.

XSL•FO
RenderX

This heterogeneity may influence the diagnostic performance of ASA, potentially resulting in greater accuracy in identifying more severe cases of depression while missing milder cases. However, the assessment of ASA performance by severity level was beyond the scope of the present meta-analysis, as we excluded studies specifically focused on the prediction of depression severity. Moreover, most included studies did not provide sufficient information on the severity of depression within their samples. Future research should therefore examine the performance of ASA across varying levels of depression severity, with particular emphasis on mild cases, to better evaluate its potential as a screening tool for early detection and intervention. Fourth, while we used a modified version of QUADAS-2 as proposed by Abd-Alrazaq et al [137], we acknowledge that this tool still has notable limitations when applied to AI-based research. QUADAS-2 was originally developed for conventional diagnostic accuracy studies and does not adequately address AI-specific sources of bias, such as algorithm and input data quality, real-world clinical applicability, and algorithm generalizability, among others [175]. Additionally, the "flow and timing" domain in QUADAS-2 is often weakly applied in this context, as speech data collection and depression assessments are often conducted simultaneously, limiting its relevance for evaluating temporal relationships or diagnostic latency. Recent initiatives have proposed comprehensive frameworks to support the development and evaluation of trustworthy AI in health care based on 6 guiding principles, including fairness, universality, traceability, usability, robustness, and explainability [176]. Building on these principles, a dedicated, standardized checklist tailored to AI-based diagnostic studies is urgently needed. Such a tool would enhance the rigor of bias assessment, improve reporting practices, and support the effective translation of AI solutions into clinical settings. Fifth, while we reported accuracy, sensitivity, specificity, and precision, these metrics alone may not fully capture model performance in the context of imbalanced datasets, which are common in depression detection. Metrics such as the F_1-score, the area under the curve of the receiver operating characteristic curve, and the Matthews correlation coefficient are better suited for evaluating performance under class imbalance and should be considered in future research to provide a more comprehensive assessment of model effectiveness. Finally, our approach to pooling both the highest and lowest performance metrics across studies deviates from conventional meta-analytic practices and may limit direct comparability with prior work. However, we argue that this method offers specific advantages that justify its use in this context. Previous meta-analyses, such as that conducted by Liu et al [30], have typically reported only the highest performance, which may inadvertently overestimate model effectiveness, particularly in studies where multiple experiments are conducted and only the highest performance metrics are selected. By including both the highest and lowest reported outcomes, we sought to capture the inherent variability in AI-based research and mitigate potential reporting bias. This strategy is supported by prior work from Abd-Alrazaq et al [137], and aligns with ongoing calls for greater methodological transparency in AI research. For researchers seeking direct comparisons with more conventional meta-analyses, the highest pooled estimates in our analysis can serve as a benchmark.

Conclusions

In sum, this study showed that ASA is a promising method for detecting depression, though its readiness for clinical application as a standalone tool remains limited. More peer-reviewed, high-quality studies are warranted to further advance this emerging field. At present, ASA should be considered as a complementary method, with potential application across various settings, including the general population, clinical field, primary care, or environments where stigma still presents a significant barrier to care. Future studies should focus on exploring how ASA can generalize across languages and cultures, and how it might be integrated into complex statistical models, alongside other data sources, to significantly improve depression detection within the stratified psychiatry framework. Additionally, successful clinical implementation of ASA will require addressing critical challenges, including ensuring data reproducibility, improving the explainability of AI algorithms, among other ethical and legal considerations.

Abstract

Background: Digital conversational agents (or "chatbots") that can generate human-like conversations have recently been adapted as a means of administering mental health interventions. However, their development for youth seeking mental health services requires further investigation.

Objective: This youth-engaged scoping review synthesizes the recent research on digital conversational agents for youth seeking mental health or substance use services.

Methods: Studies were included if they were published between 2016 and 2025 and examined digital conversational agents for youth aged 11 to 24 years with mental health or substance use challenges in clinical settings. Systematic literature searches were conducted in February 2024 in multiple databases and updated in March 2025. Data were extracted using codeveloped forms and synthesized narratively.

Results: Ten studies were included, all focusing on mental health. Seven examined the acceptability and feasibility of digital conversational agents; others explored youth perceptions of use, design, and content, with some exploration of impact on mental health symptoms. Eight of ten studies reported high acceptability or positive user experiences. Three were randomized controlled trials that found potential reductions in depressive symptoms. Reporting on the ethical standards was limited. No studies focused on substance use alone.

Conclusions: Literature on digital conversational agents for treatment-seeking youth is emerging but limited. Future rigorous research is needed that prioritizes data security, safety measures, and youth co-design in the development of safe, engaging, digital conversational agents for youth with mental health conditions.

KEYWORDS

chatbot; artificial intelligence; youth; mental health; substance use

Introduction

Background

Digital conversational agents, or "chatbots," are tools that can simulate a human interaction in text format, using artificial intelligence to respond intelligently to user inputs. They may use human-generated algorithms to produce conversations, or natural language processing to recognize and respond to inputs with a programmed personality. Digital conversational agents have been used in mental health for tasks such as providing psychoeducation, building coping skills, delivering cognitive-behavioral therapy, and providing diagnostic support [1-4].

There is emerging research available on digital conversational agents for mental health or substance use in treatment-seeking populations such as youth who are seeking or accessing services to support their mental health or substance use. A recent set of

XSL•FO
RenderX

2 reviews found minimal research on digital conversational agents for mental illness, with a specific gap around youth, and the studies were not necessarily in treatment-seeking populations [3,4]. They did find some acceptability and positive effects for the tool's ability to establish diagnosis, but less so among youth. Some positive mental health impacts were found, but study limitations made these difficult to determine. Digital conversational agents in the psychiatric sphere have targeted various outcomes. For example, one was designed to promote activity engagement among individuals with severe mental illness [5]. Others have been designed to promote service utilization [6], develop mindfulness and emotion regulation [7], determine diagnoses [8], or promote medication adherence [9]. Evidence of the development of something akin to a therapeutic alliance has been demonstrated [10], while the responses of digital conversational agents have been rated as higher quality and more empathetic than physician responses [11]. However, the research evidence for treatment-seeking youth in clinical contexts (ie, receiving treatment) remains limited and has yet to be synthesized.

There is more research on the use of digital conversational agents as a prevention, promotion, or low-threshold mental health support tool, particularly for youth in school settings [12-15]. An acceptability study found that youth preferred to receive information through a digital conversational agent versus searching for it online, while the "personality" of the digital conversational agent was appreciated for its friendly, relational aspects [12]; the practical advice and referrals offered were also appreciated. Advantages include flexibility, accessibility, the capacity to reach more youth faster than in-person services, cost-effectiveness, and the ability to get help without stigma [12,13,15]. However, evidence on efficacy remains limited [16], and the need to empirically test these interventions has been highlighted [12,15,17].

As digital conversational agents expand around the world, a number of ethical issues have been raised. One team set out recommendations for minimal ethical standards in the use of digital conversational agents for youth mental health [17]. Some factors include ensuring confidentiality, being transparent about uses and limits, generating appropriate crisis responses, and protecting against addictive use. The article further highlighted the importance of testing efficacy, being transparent with users about the evidence base, encouraging in-person services, and explaining that these tools are not designed to treat severe mental illness. For vulnerable youth in treatment-seeking contexts, privacy and confidentiality is important, and addictive use might be a particular concern. These concerns have been reflected in discussions of the promise and necessary cautions regarding the implementation of digital conversational agents [18,19]. These issues must be attended to in the development, testing, and scale of digital conversational agents for mental health.

Youth are high users of digital technology [20] and often use digital means of seeking information about health [21]. They may be interested in receiving support through digital conversational agent technology. However, treatment-seeking youth with potentially complex mental health challenges have different needs and may have different preferences than school-based samples. Given ethical concerns about digital conversational agents for severe mental illness [17], further exploratory work is an essential prerequisite to digital conversational agent development. It is important to gain the perspectives of treatment-seeking youth around the possible utility, functionality, acceptability, and safety of digital conversational agents to address mental health challenges among them. It is also important to continue to do up-to-date work in this area, given the fast pace of technology development that leaves older research quickly out of date.

Objective

This scoping review aims to synthesize the recent literature on digital conversational agents for youth in clinical contexts seeking treatment for mental health or substance use challenges.

Methods

Overview

We used the scoping review methodology given the breadth and nature of the research and the exploratory nature of the research question in an emerging field, using established scoping review processes [22,23]. The scoping review incorporated the following major steps: (1) defining the research question, (2) identifying relevant studies, (3) screening and selecting studies, (4) extracting the data, and (5) summarizing the data and reporting. PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines have been followed in the reporting of this review (Multimedia Appendix 1) [24].

Youth Engagement

In accordance with the strategy for patient-oriented research [25], we engaged 2 youth engagement specialists with lived experience in the conduct of this review. We endorsed pragmatism as a fundamental worldview and valued youth contributions, as per lived experience engagement paradigms [26]. Youth engagement specialists helped identify keywords for the systematic search, coselected information to extract from the resulting studies, and assisted with interpreting and reporting on the findings. Collaboration with the youth engagement specialists helped guard against bias and ensured that the study was relevant to the real-world experiences of young people, enhancing rigor.

Defining the Research Question

This scoping review aims to understand the published academic literature on digital conversational agents for treatment-seeking youth with mental health or substance use challenges, in clinical contexts. Based on the PICO (population, intervention, comparison and outcomes) framework [27], this review focuses on youth with mental health or substance use challenges (population) and applications of digital conversational agents in treatment-seeking in clinical settings (intervention). Note that the treatment-seeking and clinical settings context was a key inclusion criterion that makes this review very specific to clinical contexts, which is a gap in the literature. It includes studies with or without comparison groups and reports on the full range of findings, regarding applications, acceptability, and outcomes related to digital conversational agents for the target

XSL•FO
RenderX

population, as well as other findings highlighted in the selected literature. Literature on preventive interventions and nonclinical settings was excluded.

Identifying Relevant Studies

A comprehensive search strategy was developed with a health sciences librarian (TR). Considering the subject areas of the research question, the search was developed, tested, and finalized in Medline, then translated and run on February 22, 2024 in the following bibliographic databases: APA PsycInfo, Medline, Embase, Cumulative Index to Nursing and Allied Health Literature (CINAHL), Web of Science, Applied Social Sciences Index and Abstracts (ASSIA), and Cochrane Central Register of Controlled Trials (CENTRAL). The search was repeated and updated on March 18, 2025. The search strategies used database-specific subject headings and keywords in natural language, as well as advanced search operators such as truncation and adjacency operators, to capture 3 main concepts: youth, digital conversational agent, and mental health or substance use. The review was limited to articles published in the past 8 years (2016-2025) due to the rapid advancement of AI technology. There were no limitations placed on language or study type. Conference abstracts were removed through the search strategy when allowed by a database, but were otherwise included. A supplementary hand search of reference lists and Google Scholar was conducted. Given the nature of the research question, the gray literature search was limited to dissertations in APA PsycInfo, registered clinical trials in the CENTRAL search, and nontraditional publications indexed in CINAHL.

Study Screening and Selection

To be included, articles had to present descriptive information or research results on digital conversational agents for youth mental health or substance use, focusing on treatment-seeking populations in clinical contexts. Articles could report on any study design and sample size and could include descriptive process papers. The digital agent and study had to be focused on youth approximately aged 11-24 years, or separate analyses had to be available for a subgroup within this age range. Articles had to be published in English or French consistent with the language skills available on the team, although no non-English language texts were found. We included any outcomes identified by the article in question, including acceptability and feasibility outcomes as well as mental health or substance use outcomes of any kind or intensity. Excluded were any studies not reporting on digital conversational agents for youth mental health or substance use, research conducted on children (majority aged younger than 11 years) or adults (majority aged older than 24 years), and commentaries that did not describe either research results or a specific digital conversational agent. Textbox 1 presents inclusion and exclusion criteria, which were developed to optimize the ability to address the research question. Selected articles were screened first at the title and abstract level by 2 of 3 research staff (include or exclude responses), with any conflicts resolved through discussion with the project lead. The resulting set of articles were screened in full using the same process. Article screening was conducted using Covidence software [28].

Textbox 1. Inclusion and exclusion criteria for literature search.

Inclusion criteria

- Addresses digital conversational agents
- Agent designed for youth aged 11-24 years
- Participants with mental health or substance use challenges (disorders or symptoms)
- Participants seeking mental health or substance use treatment (ie, connected with clinical contexts)
- Published between 2016 and 2025
- Reports on efficacy, effectiveness, feasibility, or acceptability
- Reports on youth perspectives using youth-reported data (any method)

Exclusion criteria

- Not a youth-focused agent and study
- Prevention or promotion that does not support known mental health or substance use challenges
- Youth were not treatment-seeking or were not exposed to the digital conversational agent in a clinical context
- Published before 2016
- Papers without original data

Data Extraction

A data extraction form was developed collaboratively among team members, including youth. From the final selected articles, data were extracted by 1 staff member and verified by a second staff member using a spreadsheet. The data extraction form included (1) study general information (eg, reference, location, and data collection years), (2) digital conversational agent description (eg, goal or objective, application and content, context of use, development and testing, youth engagement, software and data strategy, feedback learning integration, delivery method, financial investment, privacy, content monitoring, and sustainability plan), (3) study methods (eg, study objective, design, sampling method, sample size, sample

XSL•FO
RenderX

description, exclusion criteria, measures, and other treatments), (4) outcomes (eg, finding overview, youth perspectives, digital conversational agent benefits and limitations, adverse events, and study limitations), (eg, 5) ethical issues (privacy and confidentiality, efficacy, safety, and mitigating strategies), and (eg, 6) other information (author conclusions and recommendations).

Data Summarization and Reporting

The data were summarized narratively and in table format. Quality assessment was not conducted, as this is not a priority in scoping reviews in which a wide range of diverse research is mapped.

Ethical Considerations

Since this is a scoping review of the literature, ethics board approval was not required. There are no human participants in this article and informed consent is not required.

Results

Study Selection

Our search identified 8659 records, including 5875 records from the initial search in 2024 and 2784 from the updated search in 2025. After removing 3734 duplicates, we screened 4925 titles and abstracts, excluding 4900. We further assessed 25 full-text articles. Fifteen were excluded due to not meeting our inclusion criteria, which resulted in 10 studies included in the review. The study selection process is illustrated in the PRISMA flow diagram (Figure 1).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart.

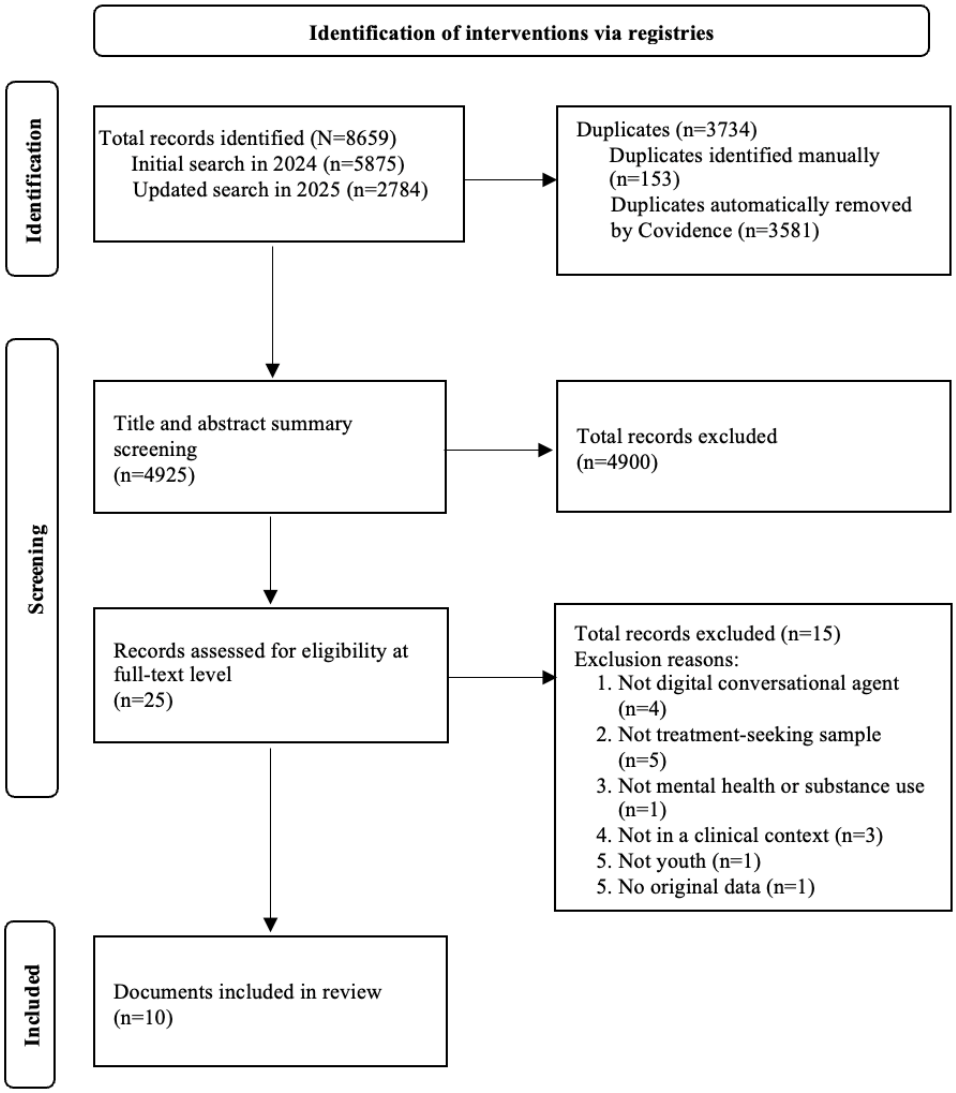

Table 1 summarizes the included articles and digital conversational agents studied. The 10 studies examined 9 digital conversational agents for youth mental health in clinical care contexts. Studies emerged from the United States [2,29,30], Germany [31,32], Australia [1,33], Thailand [34], Japan [35], and Hong Kong [36], with publication years ranging from 2017 to 2025. Only 3 articles stipulated that the digital conversational agents were co-designed with youth [1,31,33].

XSL•FO
RenderX

Table 1. Summary of the included articles and digital tools.

Author (year)	Country	Format	Technology described	Digital conversational agent objective	Intervention modality	Expressed digital conversational agent limitations	Codevelopment with youth
Wrightson-Hester et al [33]	Australia	Web application	Artificial intelligence conversational agent	Help youth manage mental health using curious questioning	Method of levels therapy	Repetitive content and input comprehension issues	Yes
Greenwood et al [37]	United States	Mobile app	Natural language processing and machine learning	Help youth develop emotion regulation skills	CBT, IPT-A[b], and DBT[c]	Effectiveness not rigorously tested for; not implemented in clinical practice	Not specified
Beilharz et al [1]	Australia	Web-based chat accessible on mobile and desktop devices	Artificial intelligence conversational agent	Provide support for body image issues and eating disorders	Psychoeducation, coping skills via CBT, acceptance and commitment therapy, mindfulness	Limited to psychoeducation and simultaneous coping skills	Yes
Fitzpatrick et al [2]	United States	Instant messenger app on mobile or desktop	Decision tree methodology with predefined responses, including natural language processing at certain points within the tree	Deliver self-help CBT to young adults with anxiety and depression symptoms.	CBT	Potential risk of violating psychotherapeutic processes related to limitations in conversational abilities	Not specified
Robinson et al [30]	United States	Mobile app	Not specified	Deliver CBT to adolescents at adolescent outpatient mental health clinic.	CBT	Not specified	Not specified
Mahmud and Porntrakoon [34]	Thailand	Not specified	AI[d]-generated or DCA[e] mental health application	No specific digital conversational agent introduced	Not specified	Lack of customization, depersonalization, algorithm bias, privacy concerns	N/A[f]
Kuhlmeier et al [31]	Germany	Mobile apps and web platforms	Text-based conversational agent prototype	Provide youth and young adults personalized therapy for depression	CBT, IPT[g]	Currently an early-stage prototype	Yes
Kuhlmeier et al [32]	Germany	Prototype accessed via laptop	Text-based conversational agent prototype	Support youth with depression through a behavioral activation exercise	Behavioral activation	Currently an early-stage prototype	No, but participant feedback will influence the future design
Hasei et al [35]	Japan	Accessible via mobile app LINE	GPT-4 large language model	Help pediatric, youth, and young adult cancer patient reduce anxiety and stress	Not specified	4-turn conversations	Not specified
Li et al [36]	Hong Kong	Accessible via Microsoft Teams	An interactive conversational system with natural language understanding	Support university students with self-reported depression through MBSR[h]	MBSR interventions	Technical issues with Microsoft Teams, required high self-discipline, limited interactivity	Not specified

[a]CBT: cognitive behavioral therapy.

Study Characteristics

Of the 10 included studies, 7 assessed feasibility or usability or the preliminary efficacy or effectiveness [1,2,29,33,35,36], while others investigated perceptions of using the agent [34], perceptions of their design [31], and youth's interaction experience with them [32]. Three studies used qualitative methods [1,31,32], 1 used quantitative methods [30], and 6 used mixed methods [2,29,33-36]. Three studies used randomized controlled trials to evaluate 2 digital conversational agents [2,29,30]. Participant demographics varied in the studies, covering age groups from adolescents to young adults with depression [31,32,36], anxiety or depression [2,29,30,33,34], anxiety and stress [35], and eating disorders [1]. None focused on substance use disorders. Some studies also included mental health professionals [31,34] and caregivers [1] as participants.

Intervention Characteristics

The technology driving the digital conversational agent was not always specified but included artificial intelligence, for example natural language processing, machine learning, and decision trees. While publications were dated 2016 to 2025, the year of the development of the digital conversational agent under examination was not reported. The interventions were delivered via a mobile app [2,29-31,35,36] or a computer browser [1,31-33]. Treatment modalities included cognitive behavioral therapy or components thereof [1,2,29-32]; an integration of cognitive behavioral therapy, interpersonal psychotherapy, and dialectical behavior therapy [29]; a method-of-levels approach [33]; mindfulness-based stress reduction interventions [36]; and unspecified modalities [34,35]. Some studies included screenshots or sample interactions to illustrate the digital conversational agent's responses [1,31-33,35]. For example, one study shows a screenshot of coping skill recommendations made by the chatbot [1]. Another shows a screenshot of behavioral activation recommendations [32]. However, others did not provide details about the exact nature of the responses of the digital conversational agent. The digital conversational agents were not generally described as being integrated into a system of care to accompany clinical services, except for one that was designed for young cancer patients [35].

Qualitative and Acceptability Findings

The methodology and outcomes of the included articles are summarized in Table 2. Most studies reported that the digital conversational agents were acceptable to youth, with high utilization [2,29], high satisfaction [2], and overall positive perceptions [1,2,31-33]. Participants appreciated the ease of use [33], appealing and accessible design [1,32], and friendly characters [1,32]. They also found that the content was helpful and appropriate [1,2,35], equipped them with new mental health insight [2], and offered them empathy [2,32]. Youth identified advantages, namely the neutrality, anonymity, and availability of these tools compared to traditional psychotherapy [31,35,36]; some youth indicated their willingness to use digital conversational agents for depression and anxiety, with cautions regarding privacy and security [34].

XSL•FO
RenderX

Table 2. Research methodology aspects of the included articles.

Author (year)	Study objective	Sample size	Sample age (years)	Mental health or substance use conditions	Exclusion criteria	Measurement	Amount of use of digital conversational agent within study	Outcome summary
Wrightson-Hester et al [33]	Assess feasibility and acceptability	13	16-24	Anxiety or depression	Severe depressive symptoms or frequent suicidal thoughts	Self-report measures of depression, anxiety, QoL[a], related psychological constructs, and system usability and engagement Interview/focus group guide	Week 1: 1-4 days, 1-3 chats/day (average length 2-30 min); Week 2: 1-7 days, 1-5 chats/day (average length 5-15 min)	Feasible assessments; acceptable system engagement; acceptable interface; acceptable therapeutic conversations; some frustration, but resolved through use; recommendations for improvement; possible improvements in some psychological measures
Greenwood et al [37]	Establish the feasibility, preliminary acceptability, effectiveness, and usability	18 (17 analyzed)	13-17	Depression and anxiety	Parent-reported history of severe depression, substance use, psychotic illness, OCD[b], PTSD[c], panic disorder, or specific phobias; psychiatric hospitalization in the previous month; unaccompanied by a guardian at diagnostic visit; no access to a mobile device for regular use; unable to read and write English.	Self-report measures of depression (primary outcome), anxiety, and self-efficacy; app usage rates; acceptability, feasibility, and usability; safety monitoring.	Average use of 6 days, 55 mood check-ins, 313.17 sent messages, 13.63 lessons, and 9 tools over 4 weeks	Acceptability and feasibility confirmed; decreased depression and anxiety; increased self-efficacy; satisfactory usage rates; acceptable safety monitoring.
Beilharz et al [1]	Evaluate the acceptability and feasibility	25 (17 youth, 8 caregivers)	Youth: 13-18; caregivers: 46-57	Body image concerns or eating disorders	Not specified	Focus group guide	Not specified	Appealing character and design; preference for brief content with a conversational tone; acceptable flow via button-based navigation; preference for free-text option; appreciation of accessibility.
Fitzpatrick et al [2]	Assess feasibility, acceptability, and preliminary efficacy	70	18-28	Anxiety and depression	Not specified	Self-report measures of depression, anxiety, affect, and acceptability and usability; open-ended questions; usage tracking	Up to 20 sessions, average 12.14 check-ins over 2 weeks	Feasibility confirmed; reduction in depression symptoms, but not anxiety or positive or negative affect; high engagement and satisfaction; some positive comments on process and content; some challenges with process, technology, and content; limitations existed.
Robinson et al [30]	Explore the feasibility and noninferiority	141	13-17	Depression or anxiety	Not specified	Self-report measure of depression and anxiety	Not specified	Noninferiority to clinician-delivered CBT[d]-skills group in reducing depression symptoms.

RenderX

Author (year)	Study objective	Sample size	Sample age (years)	Mental health or substance use conditions	Exclusion criteria	Measurement	Amount of use of digital conversational agent within study	Outcome summary
Mahmud and Porntrakoon [34]	Explore perspectives on DCAs[e] as alternative treatments	15 (10 youth, 5 psychologists)	Youth: 20-25	Depression or anxiety	Not specified	Interview guide; self-report measures of depression and anxiety.	Not specified	Interest in using DCA when experiencing depression or anxiety; concerns about privacy, confidentiality, and security; preferences varied on the extent and time of expert assistance
Kuhlmeier et al [31]	Design a personalized conversational agent to treat youth depression	Problem awareness phase: 15 youth; evaluation phase: 5 experts, 5 potential users	Problem awareness phase: 14-17; evaluation phase: experts: mean 29; potential users: mean 24	Depression	Not specified	Interview guide	Not specified	Personalization of the conversational agent and content is essential, combined with structure; areas of improvement identified
Kuhlmeier et al [32]	Investigate how youth interact with the conversational agent for depression	15	14-17	Depression	Suicidal ideation, psychosis, or low cognitive functioning.	User interaction data and think-aloud sessions documenting thoughts about the DCA	11:54-20:38 min	Engaging interaction style; preferences varied on emoji and language use; appreciation of predefined responses, optional reminders, and clear interface; varied perceptions of responding speed and the dialogue content
Hasei et al [35]	Assess feasibility and potential impact in pediatric, youth, and young adult cancer patients	5	13 to 20s	Not specified, but cancer patients usually experience anxiety and stress from cancer	Not specified	Self-report measure of anxiety and stress; open-ended questions.	Most used every 2-3 days for about 10-15 min/session over 1-2 weeks	Reduced anxiety and stress; possible increased cancer treatment engagement; possible increased self-expression and informal help-seeking.
Li et al [36]	Evaluate feasibility, acceptability, safety, and preliminary efficacy	30 (27 completed)	18-25	Depression	Diagnosed with a clinical psychotic condition preintervention or were currently involved in any mindfulness-based or other psychosocial interventions.	Self-report measure of depression, stress, anxiety, and mindfulness; open-ended questions.	8 weeks; encouraged at least 1 hour of daily interaction.	Feasibility, acceptability, safety, and preliminary efficacy confirmed; limitations identified.

[a]QoL: quality of life.

[b]OCD: obsessive compulsive disorder.

[c]PTSD: posttraumatic stress disorder.

[d]CBT: cognitive behavioral therapy.

[e]DCA: digital conversational agent.

A number of problems, challenges, or barriers were identified by participants across the studies. These included limited natural conversation [2,33,35], limited customization [1,31,33,34], technical glitches [2,36], and concerns regarding the quality of the therapeutic interventions [1,31,34]

XSL•FO
RenderX

Quantitative Findings

Six studies provided quantitative results on the digital conversational agents' ability to improve participants' mental health. A randomized controlled trial (RCT) of a digital conversational agent called Woebot found that, compared to a self-help e-book, the intervention significantly reduced depressive symptoms after 2 weeks, with a moderate effect size (d=0.44) [2]. In another RCT, 4 weeks of using Woebot was found to be noninferior to a standard clinician-led CBT group in reducing depression when comparing pre-post average scores and the number of participants with elevated depression; the effect size was not provided [30]. In a pilot RCT, the treatment group showed greater mean improvement in depression than the waitlist control group (d=0.98) [29]. No significance testing was reported for these trials [29,30]. A single arm study found a large effect size (d=1.26) for reducing problem-related distress and a medium effect size (d=–0.66) for improving goal conflict reorganization among participants with anxiety or depression [33]. Additionally, a single arm pretest-posttest study of a digital conversational agent delivering a mindfulness intervention reported significant and large improvements in depression, anxiety, stress, and mindfulness levels, with large effect sizes across all outcomes, at d=–1.95 for stress, d =–1.53 for depression, and d=–1.09 for anxiety [36].

Ethical and Safety Considerations

The minimal ethical standards proposed for digital conversational agents revolve around (1) privacy and confidentiality, (2) efficacy, and (3) safety [17]. One study encompassed these requirements by providing user participants with an information package regarding privacy, efficacy, and safety issues as part of the application onboarding process [29]. Another study emphasized rigorous approval and safety measures that include anonymized and secure data handling and adherence to the Declaration of Helsinki [35]. However, most of the included articles did not discuss ethical issues in depth. While concerns over privacy and confidentiality were mentioned by many youths and stakeholders [29,31,33,34], only half of the articles included any information on their privacy policies. A case series assessing feasibility and acceptability for depression or anxiety reported that secure user identification and anonymized data collection was not conducted within the study, but would be implemented in the future [33]. One study informed participants that they would not be monitored by a counsellor [1], while another disclosed that a psychologist would monitor participants' activities asynchronously [2].

Despite the ethical importance of ensuring efficacy, most of the articles described pilot trials examining acceptability and feasibility without adequate power to determine efficacy. Prominent limitations were small sample sizes and the lack of diversity. As a result, while many of the interventions were reportedly inspired by evidence-based therapeutic approaches [1,2,29,33,36], the delivery of the interventions via these tools has not been demonstrated efficacious or effective in real-world settings and thus requires further evaluation.

Safety issues are also worthy of note. Only 6 of the selected studies described safety features [1,2,29,33,35,36]. Among these, 3 reported that participants were informed of about the tool and given explanation of its function and capacities [1,2,29]. Only 1 study mentioned having a crisis response measure, in which the digital conversational agent could identify concerning language and confirm it with users [29]. One study emphasized that their safety measures include automated escalation systems for distress detection and professional involvement during development and testing [35]. Another study involved continuous monitoring by mental health professionals, weekly participants check-ins, and mental health support resources and referral pathways [36]. The digital conversational agents featured in these 4 trials offered additional mental health resources and provided easily accessible channels to connect users with suicide helplines or emergency services.

Discussion

Principal Findings

This review synthesized the recent literature on digital conversational agents for youth with mental health or substance use conditions, specifically in treatment-seeking clinical contexts. It was found that the literature is quite preliminary and is focused entirely on mental health, not substance use conditions. Yet, this is an emerging area of work that is a high priority to some research teams and health care organizations. Several of the digital conversational agents reviewed applied the principles of cognitive behavioral therapy, but this was not universal. Promising findings were identified in terms of feasibility and acceptability, together with reasonable usage rates and positive youth perspectives of acceptability. Preliminary findings suggested that digital conversational agents might be an acceptable means of delivering therapeutic content to treatment-seeking youth, with positive impacts on their mental health.

The literature was largely made up of feasibility and acceptability studies rather than efficacy trials. The digital conversational agents were not described as being embedded in intervention contexts, such as being integrated with in-person clinical care. Sample sizes were small and diversity was limited. People with different sociodemographic profiles and different clinical needs might be differentially interested in using e-health innovations [38,39], although differences across population subgroups have not been definitively established. This leaves the evidence base in a very premature state. For example, there is a lack of exploration of the impact the tools might have as an integrated component of youth mental health care among diverse youth.

All of the articles addressed mental health; none addressed substance use. It is important to consider mental health and substance use together, given the high levels of overlap and increasing trends toward treating concurrent disorders together [40]. Examining digital conversational agents for substance use challenges, or for concurrent mental health and substance use challenges, is a pressing area for future work. Investigations into suitability using different treatment modalities for specific diagnostic groups might also be worthy of consideration, given that specific symptoms may interact with whether and how one might use such a tool (eg, low motivation, paranoia, suicidal ideation, and mood instability).

XSL•FO
RenderX

This review focused on very recent literature on digital conversational agents, given the fast pace of technology. However, any article published in 2016 was likely examining a digital conversational agent developed at the latest in 2015, potentially earlier. These tools were not leveraging today's latest technology, and the technology used was not thoroughly described. The rapid pace of technology advancement is not a new challenge, but rather one that the health care sector has been grappling with for years [41]. This leaves two problems: (1) the technology is already out of date by the time the research is complete, and (2) the evidence base that a new study leverages is out of date and may no longer be relevant by the time it is used. Ongoing rapid research and publication in this area is essential, with thorough descriptions of the technology underpinning the tool, including the year of tool development to help readers understand the state of technological advancement of the digital conversational agent in question.

In digital intervention development, co-design with the end users is critical [42]. This can be done using appropriate patient engagement frameworks [43]. Co-design helps ensure that the digital tool is appropriate for the end users and relevant to their needs. However, multiple articles reviewed did not discuss co-design, which may reduce acceptability. Future digital design teams should adhere to patient engagement principles for e-health innovation [43] as well as youth engagement principles [44]. Co-design has the potential to be a meaningful opportunity for young people to gain experience in technology development and clinical research, supporting their personal and professional growth and development [45]. In conducting co-design, teams should incorporate principles of equity, diversity, inclusion and accessibility to ensure that a diverse range of voices are included, to generate a digital conversational agent that is appropriate for a wide range of diverse youth, and to mitigate the harms that can come from biases, discrimination, and inequities. Specifically, a lack of diversity at the co-design stage could perpetuate algorithmic bias, which should be guarded against. Engagement can also be leveraged to increase digital literacy and the use of resulting tools, potentially with the support of digital navigators [46].

From our review, it was clear that the minimum ethical standards for digital conversational agents were not adequately attended to [17]. Few studies reported directly on privacy, confidentiality, and safety, and efficacy has not been definitively established. We call on developers and trialists to directly attend to the proposed ethical standards in their initiatives, proactively integrate these minimum standards into their technology and trials, integrate an ethical review stage into their initiative, and report clearly on the use of these standards. The ethics of delivering evidence-based intervention modalities via digital conversational agents should be considered—and when which modality is appropriate and for whom—since a clinician may naturally adapt their services to the individual youth, while digital tools may function differently using artificial intelligence in attempt to do the same. Matching the tool's aim to the youth's need, ensuring youth can withdraw at any time, and offering access to a person to talk to would all further enhance tools' ethics and should be considered by interventionists. It should be transparent that a digital conversational agent can supplement clinical care but is not a replacement for it; integrating tools into clinical care rather than leaving them as stand-alone tools might address this challenge [47].

The use of digital conversational agents is not without risk. A recent news story highlights a case of youth suicide after the youth's ongoing interaction with a digital conversational agent [48]. It should be noted that youth are using digital conversational agents for mental health support even if these agents are not designed for that purpose. By developing a digital conversational agent with and for youth, with the explicit purpose of supporting mental health in appropriate ways using evidence-based content, it may be possible to provide young people with a safer tool and prevent such tragedies from occurring.

While some articles discussed soliciting youth feedback as part of a study, none discussed collecting youth feedback within the digital platform. Providing opportunities to submit feedback within the platform is a potential mechanism to enable continuous improvement and incremental alignment with the needs and preferences of the users. The feedback could be directed to programming teams for programming feedback, and potentially separately to clinical teams to support clinical care as part of an integrated treatment plan. It would be important to determine means to balance the importance of privacy and confidentiality [17] with the potential for identified clinical support.

The next steps in this line of work would be to address some of the limitations, such as co-design and ethical concerns, with the ultimate goal of moving forward to full-scale trials to examine efficacy. This would have to be followed by implementation and ongoing refinement. The evaluation of complex interventions is expected to begin with iterative stages of intervention development, feasibility testing, evaluation, and implementation [49,50], and the research for this type of intervention is in the early stages of this process.

Limitations

Strengths and limitations of this review should be kept in mind. Important partners were engaged in the review, including industry partners and youth with lived experience. These partnerships ensured that the search terms, data extraction, and interpretations are relevant to the artificial intelligence industry and youth. However, readers should note the methodological and scope limitations: the search included only an 8-year period to ensure that the findings are as relevant as possible to recent technology, but may have missed early findings. We excluded any articles focusing on prevention or promotion, which may have relevant findings. Any publications indexed after March 2025 were not captured. The search was run only in English-based databases.

Conclusions

Emerging but preliminary literature is examining digital conversational agents for treatment-seeking youth with mental health conditions, but not substance use challenges. Digital technology already exists and will inevitably expand, making it essential that we support its expansion with rigorous research. This research must therefore continue, with attention to

XSL•FO
RenderX

establishing efficacy, as well as ensuring appropriate protection of privacy and confidentiality and attention to safety and ethical concerns. While digital technology comes with challenges, it also comes with potential benefits. Co-design with youth, for youth, should be a priority. Nevertheless, promising early research justifies continuing this work with the possibility of codeveloping safe, accessible, youth-friendly, and potentially efficacious tools for youth mental health.

Acknowledgments

We would like to thank Shelby McKee for support with the article selection process. The authors disclosed receipt of the following financial support for the research, authorship, or publication of this article: this work was supported by the Ontario Brain Institute.

Data Availability

The data underlying this project are included herein. Additional data are available upon request.

Authors' Contributions

LDH conceptualized and led the project and drafted the manuscript. JH contributed to selecting the articles, extracting and verifying the data, and drafting the article. ATPN contributed to selecting the articles and extracting and verifying the data. TR formulated and conducted the search. All authors contributed to the design of the study and edited and approved the final manuscript.

Conflicts of Interest

Brian Ritchie is the founder and CEO of Kamazooie Development Corporation (“Kama.AI”), a private company specializing in artificial intelligence, including digital conversational agents. The other authors have no conflicts of interest to disclose.

Abstract

Background: Depression is one of the most prevalent mental health disorders globally, affecting approximately 280 million people and frequently going undiagnosed or misdiagnosed. The growing ubiquity of wearable devices enables continuous monitoring of activity levels, providing a new avenue for data-driven detection and severity assessment of depression. However, existing machine learning models often exhibit lower performance when distinguishing overlapping subtypes of depression and frequently lack explainability, an essential component for clinical acceptance.

Objective: This study aimed to develop and evaluate an interpretable machine learning framework for detecting depression and classifying its severity using wearable-actigraphy data, while addressing common challenges such as imbalanced datasets and limited model transparency.

Methods: We used the Depresjon dataset and applied Adaptive Synthetic Sampling (ADASYN) to mitigate class imbalance. We extracted multiple statistical features (eg, power spectral density mean and autocorrelation) and demographic attributes (eg, age) from the raw activity data. Five machine learning algorithms (logistic regression, support vector machines, random forest, XGBoost, and neural networks) were assessed via accuracy, precision, recall, F_1-score, specificity, and Matthew correlation constant. We further used Shapley Additive Explanations (SHAP) and Local Interpretable Model-agnostic Explanations (LIME) to elucidate prediction drivers.

Results: XGBoost achieved the highest overall accuracy of 84.94% for binary classification and 85.91% for multiclass severity. SHAP and LIME revealed power spectral density mean, age, and autocorrelation as top predictors, highlighting circadian disruptions' role in depression.

Conclusions: Our interpretable framework reliably identifies depressed versus nondepressed individuals and differentiates mild from moderate depression. The inclusion of SHAP and LIME provides transparent, clinically meaningful insights, emphasizing the potential of explainable artificial intelligence to enhance early detection and intervention strategies in mental health care.

artificial intelligence; explainable AI; depression; mental health; machine learning; activity data

Introduction

Mental disorder is a global phenomenon with over a billion individuals suffering from various types of mental disorders. Mental health disorder usually affects a person's thinking, interpersonal relationships, and emotions. It results in serious consequences such as risk of other diseases and suicide if not identified and treated properly in time. Depression is one of the most prevalent mental health disorders that can negatively impact an individual's daily functioning and well-being. Studies have shown an increase in the number of depression and anxiety disorders during and post-COVID–19 pandemic, affecting both males and female demographics [1,2]. Younger demographics are found to suffer more from mental disorders than older citizens [3]. It is estimated that approximately 280 million of the population is suffering from depression [4].

Depression is characterized by changes in one's temper or a sudden hysterical attitude to any circumstances or situation. Depression is regarded as the second most common reason for death, and 0.8 million deaths are attributed to depression [5]. Depression is an emotional disorder that triggers a sense of desolation, pessimism, and anhedonia that affect a person's life.

XSL•FO
RenderX

This leads to the disruption of daily activities in all aspects of life, influencing others around them as well. The etiology of these types of mental illness results from environmental and genetic factors [6]. A depressive illness can be classified as mild, moderate, and severe by degree of severity [7]. It is challenging for the physicians to diagnose it in the early stages and is often misdiagnosed as conditions such as vitamin deficiency [8]. It has also been linked with the rise of risk in cancer [9] and cardiovascular ailment [10] which can potentially decrease the life span of an individual. Even though it has high prevalence, it is often left untreated in many of the cases [11].

Depression rating scale is a screening tool that comprises a questionnaire that is used for detecting the severity phases of depression [12]. Montgomery-Asberg Depression Rating Scale (MADRS) was designed by Marie Asberg [13]. It focuses on ten signs of depression, which include apparent sadness, reported sadness, inner tension, reduced sleep, reduced appetite, concentration difficulties, lassitude, inability to feel, pessimistic thoughts, and suicidal thoughts [14]. The participant answers the questions with a score of 0 to 6. It is categorized as: 0 to 6 for normal or absence of symptom, 7 to 19 for mild, 20 to 34 for moderate and 35 to 60 for severe depression [15].

Variability is also seen in treatment response. While a person may respond well to treatment, others with the same symptoms may not respond to the same treatment in the same manner. Thus, posing a threat to an individual's life as prolonging its diagnosis and treatment can cause serious conditions [16]. The diagnosis of depression is very challenging, and it is often misdiagnosed as it often mimics other types of disorders [17]. One such example is it is often misdiagnosed as anxiety [18]. Therefore, early detection and diagnosis of depression is paramount.

Over the preceding years, the domain of artificial intelligence (AI) has been evolving, and it has shown success in a plethora of fields including health care [19]. Machine learning (ML, a sub-field of AI) can potentially predict whether a person has a mental disorder or not, and if there is a degree of inclination to suicide [20]. Therefore, implementation of ML may benefit mental illness domain by characterizing those who are vulnerable and thus help the practitioners in the early identification of mental health disorders including depression.

The existing ML-based models for depression detection face several challenges, such as their inability to accurately differentiate between various types of depression. More advanced and sophisticated techniques such as deep neural networks are often restricted in their usage due to their "black box" approach, thereby lacking transparency and explainability [19]. This lack of interpretability is a major hindrance in health care applications where understanding the decision-making process is crucial [19]. In the context of diagnosis and treatment of depression, transparency and explainability are even more important.

AI models for depression require huge amounts of data which capture behavioral, psychological, and physiological indicators for effective modeling, and thus accurate detection and differentiation of depressive states. However, the collection of such datasets is often not possible due to challenges and limitations of data-collection methods [21]. An alternative is to use wearable devices to collect continuous, real-time data on various aspects such as physical activity, sleep patterns, heart-rate variability, and many other physiological indicators [21].

A number of studies have been conducted using a variety of datasets and ML models for diagnosis of several types of mental disorders. Paul and Juliet [22] considered the prediction of mental health disorders problem based on a dataset of self-reported information by the patients. The authors used four ML algorithms, namely logistic regression, k-nearest neighbor, decision tree, and random forest (RF). RF is identified as the best performing algorithm achieving an accuracy of 81%. However, the authors did not discuss other performance measures such as recall, precision, and F_1-score. Zhang et al [23] suggested an architecture that uses magnetoencephalography to classify posttraumatic stress disorder. The authors used support vector machine as the main classifier with a recursive RF for feature selection. The model with selective features achieved an area under the curve value up to 0.9. Mikolas et al [24] focused on the automatic diagnosis of attention deficit hyperactivity disorder and argued that although recent advancements in the domain of ML helped in binary classification problem of identification of attention deficit hyperactivity disorder and healthy individuals, the problem of differentiating among multiple psychiatric conditions remains. The authors considered a dataset of 229 anonymized participants and observed that the best performance is obtained using automated feature selections. The study has certain limitations, such as a higher number of missing values in certain columns and lack of out-of-sample testing.

Spulber et al [25] explored whether activity data collected via actigraphy and depression severity levels are correlated. The study involved individuals experiencing major depressive episodes who were not receiving antidepressant treatment. The authors trained models to predict the MADRS score from activity data using ML techniques, selecting models based on accuracy and precision. These models were ranked as best, intermediate, or worst based on root mean squared error values. External validation was also conducted using data from patients undergoing treatment. However, this external validation introduced potential biases due to differences in patient conditions and treatment status. Garcia-Ceja et al [26] compared 2 models, namely RF and deep neural network (DNN), to identify healthy and nonhealthy participants from psychomotor data using the Depresjon dataset, which contains actigraphy data of control and condition groups. Due to class imbalance, different sampling methods such as random oversampling and Synthetic Minority Oversampling Technique (SMOTE) were adopted and were then compared with baseline and no oversampling after extracting three statistical features. It was found that RF with SMOTE achieved a higher F_1-score of 0.73.

Frogner et al [27] implemented 1D convolutional neural networks (CNNs) to detect depression using activity data. Models were trained with different time segments, with 48-hours segments found to be optimal, to perform 3 classification tasks. The first task classifies depressive groups, the second classifies

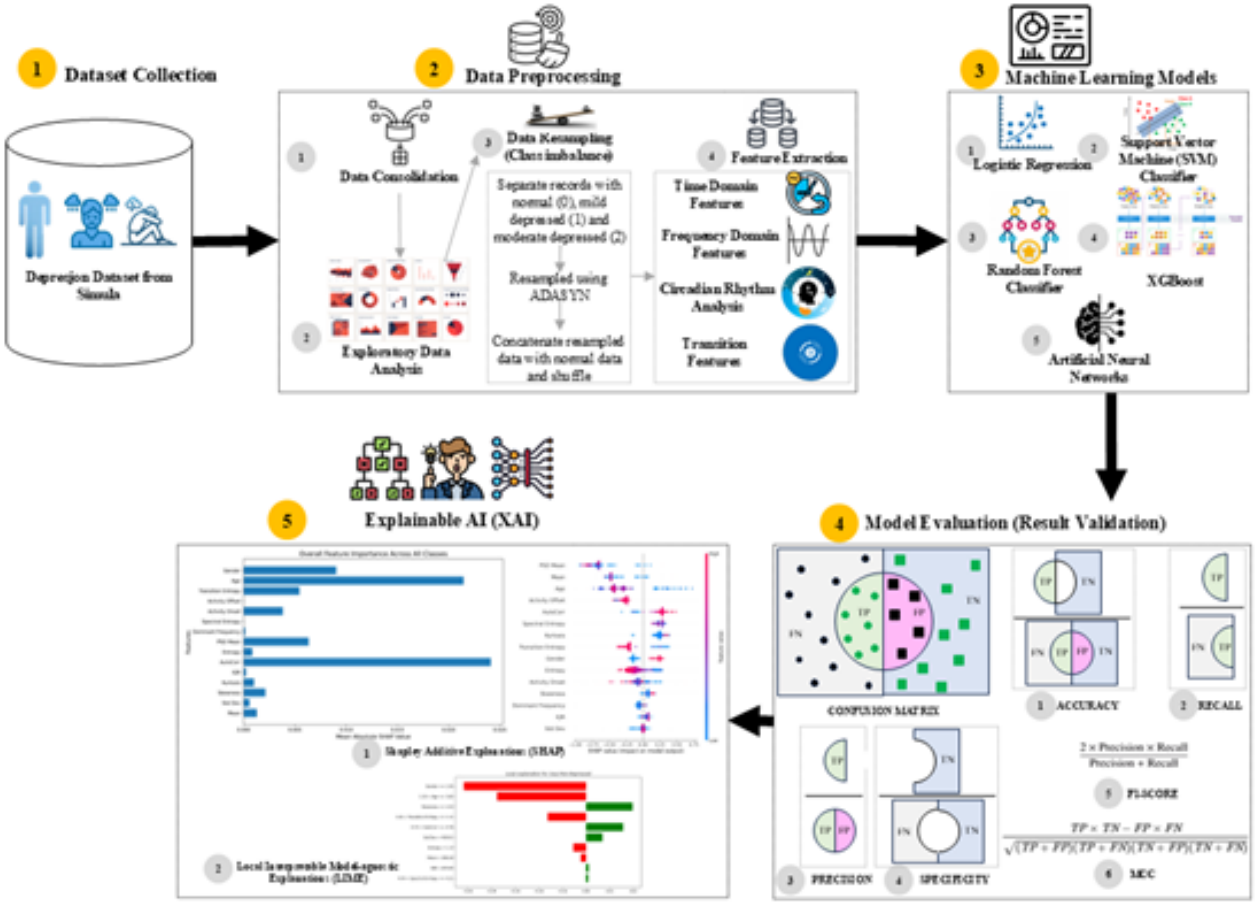
XSL•FO
RenderX

levels of depression (no depression, mild depression, and moderate depression based on MADRS score ranges: 0-10, 11-19, and >20, respectively), and the last task predicts the MADRS score. The evaluation was conducted using leave-one-participant-out cross-validation combined with majority voting. An F_1-score of 70% was achieved for the first task, 30% for the second, and a mean square error (MSE) of 4.0 for the last one. The model performed well in classifying nondepressed participants but struggled with mild and moderate depression levels. Jakobsen et al [28] examined whether objective metrics of activity data could enhance current diagnostic techniques for depression by analyzing activity patterns using ML models. Three statistical attributes (mean activity level, standard deviation, and proportion of zero activity) were derived for RF and DNN models. CNNs were trained using raw activity data represented as a 24 × 60 image matrix. DNN with SMOTE achieved an accuracy of 84%, a true positive rate of 82%, and a true negative rate of 84%. However, a significant amount of misclassifications was observed, particularly in groups with overlapping activity patterns, such as patients with agitation.

Espino-Salinas et al [29] used the Depresjon dataset to create a framework for depression classification. Preprocessing involved converting motor activity data into vectors and creating matrices for input into neural networks. A 2D-CNN and DNN were then used to classify depressive and nondepressive subjects. The 2D-CNN achieved an accuracy of 76% and an F_1-score of 72%, while the DNN achieved an accuracy of 72% and an F_1-score of 69%. The F_1-score was selected as the primary metric due to the imbalanced dataset, as it better reflects the model's ability to handle unequal class distributions. The 2D-CNN outperformed DNN by achieving a better balance between sensitivity and specificity, demonstrating its potential for depression classification. To maintain focus and address space limitations, we direct readers to [30-35] for further details.

Despite significant advancements in ML techniques for mental health diagnosis, several gaps remain. A recurring limitation across studies is the relatively lower performance in distinguishing overlapping or nuanced conditions, particularly for depression severity levels. Models perform well in binary classifications (such as distinguishing between depressed and nondepressed individuals), but struggle with multiclass classifications or subtle variations in conditions, such as mild versus moderate depression. Another critical gap is the lack of explainable artificial intelligence (XAI) techniques in these studies. Current ML models, including CNNs and DNNs, operate as black box approaches. The black box approach means that these techniques offer limited insight into their decision-making processes. This lack of interpretability reduces trust and limits the practical application in clinical settings, where understanding why a model makes a specific prediction is as crucial as the prediction itself.

In this work, we use the data collected from wearable devices to investigate the application of ML algorithms in depression detection and severity level classification tasks. We use Adaptive Synthetic Sampling Technique (ADASYN) for addressing imbalanced datasets. Further, feature engineering is performed to extract meaningful features from the activity data. For the binary (depression: yes or no) and multiclass (predicting severity levels) classifications, we implement logistic regression, support vector machines, RF, XGBoost, and neural networks. The performance of the models is evaluated using accuracy, precision, recall, F_1-score, and Matthew correlation constant (MCC). To further contribute toward the explainability of the model, we used Shapley Additive Explanations (SHAP) and Local Interpretable Model-agnostic Explanations (LIME) methods to explain the decision-making process of the best-performing models.



Methods

Overview

Figure 1 is a graphical representation of our methodology. We acquired data from the Depresjon dataset and conducted exploratory data analysis to understand the nature of the data. We observed a class imbalance, which is addressed using sampling techniques, followed by normalization of data. We then applied feature engineering to extract features from the data. This was followed by designing models for binary (depressed vs nondepressed) and multiclass (severity levels) classification tasks. After model implementation, we used accuracy, precision, recall, specificity, MCC, and F_1-score as performance evaluation criteria. Finally, we applied the SHAP and LIME methods to explain the decision-making process of the selected model.

XSL•FO
RenderX

Figure 1. Graphical representation of methodology.

Data Acquisition

The dataset adopted in this work is the “Depresjon” (Norwegian word for depression) dataset, available at Simula repository [36]. The dataset consists of motor activity of individuals recorded per minute for several days by using an actigraphy watch. The dataset consists of 2 parts: The first part comprises measurements of activity levels related to each individual in the condition and control group. The files consist of timestamp, date, and activity columns. The second part comprises the demographic information related to each participant. The dataset is enriched with several variables: an identification number (number), days with measurements (days), gender (1 for female and 2 for male), and age group of the participant (age). It also records the type of affective disorder (afftype). The presence of melancholia is noted with 1 for melancholia and 2 for lack of melancholia (melanch). The dataset differentiates between inpatients ‘1’ and outpatients ‘2’ (inpatient). Education level is categorized by years completed (education). Marital status is recorded as 1 for married or cohabiting and 2 for single (marriage). Work status is coded as 1 for working or studying and 2 for unemployed or sick leave or pension (work). Finally, the dataset includes MADRS scores before (madrs1) and after (madrs2) the inspection.

The original dataset comprised 2 folders (condition and control); it was important to merge the data into a single coherent set. The resultant dataset after the merge operation has 1440 data points. For binary classification (depressed vs nondepressed), the “condition” group is labeled as 1, and the “control” group as 0. For multiclass classification (assessing the severity levels of depression), the labels were assigned as follows: 0 for normal, 1 for mild depression, and 2 for moderate depression. Participants were categorized based on their MADRS score: 0 - 6 for “Normal” (no depression), 7 - 19 for “Mild” depression, and 20 - 34 for “Moderate” depression. Note that although the standard MADRS scale includes a “Severe” category for scores >=35, our dataset contained no cases with scores in the severe range, so no “Severe” class was included.

Addressing Data Imbalance

We observed that the data is imbalanced, which means that some output classes are more prevalent than others. Imbalance data can skew the performance of ML algorithms and require redressal. We used ADASYN for class imbalance problems. The intuition behind ADASYN is the usage of a weighted distribution for the less frequent instances in accordance with their difficulty of learning [37]. For the working of ADASYN, we refer the reader to He et al [37].

Feature Engineering

The dataset consists of activity measurements recorded by an actigraph watch, resulting in a continuous stream of data collected at regular intervals for each patient. However, using these raw time series values is not an effective approach, as it can lead to an unnecessarily large number of interconnected features and fails to capture the nuanced behaviors and physiological rhythms indicative of mental health status. In the

XSL•FO
RenderX

context of depression and related mood disorders, subtle variations in daily activity patterns, energy distribution across frequencies, and nonlinear fluctuations are particularly revealing. To address this, we summarized the continuous time-series data into key statistical features, thereby translating raw sensor data into indicators more closely tied to psychological and clinical insights. This feature engineering approach is a standard mechanism for managing continuous data streams while preserving essential patterns and variability [38], effectively reducing data dimensionality and computational requirements.

To capture the multifaceted nature of human activity and its potential connections to depressive symptoms, we systematically extracted features from 5 broad categories: (1) time domain, (2) frequency domain, (3) circadian rhythm analysis, and (4) transition features. Each category addresses different aspects of activity that can reflect mood changes or disruptions in daily routines often associated with mental health conditions.

Time-Domain Features

Time-domain features describe statistical properties and variability in the activity signal. Disruptions or heightened variability in these measures can be linked to changes in energy levels and daily routines often observed in individuals experiencing mood disturbances. Time-domain features (such as mean activity, variability, higher-order moments, autocorrelation, and entropy) have long anchored actigraphy research. Historic studies show these measures consistently distinguish depressive from nondepressive motor patterns, providing a compact, behaviorally interpretable window on psychomotor change [25-27,35,38].

The following time domain features are extracted from the continuous stream of data.

- Mean SD: summarize central tendency and overall variability of the recorded activity levels. Marked fluctuations might indicate irregular sleep-wake cycles or energy instabilities common in depressive episodes.
- Skewness and kurtosis: capture the asymmetry and the "peakedness" of the activity distribution. Drastic changes in these metrics could signify periods of lethargy or bursts of hyperactivity, reflecting possible mood state shifts.
- IQR: Measures the spread between the 25th and 75th percentiles, providing a robust indication of how condensed or spread out the daily activity is, which might correlate with mood variability.
- Autocorrelation (AutoCorr): examines how similar activity levels are to themselves at varying time lags, helping detect repetitive patterns or circadian disruptions often seen in mental health disorders.
- Entropy: assesses the randomness or irregularity in activity patterns. High entropy might suggest erratic daily schedules, potentially symptomatic of poor sleep hygiene or mood instability.

Frequency-Domain Features

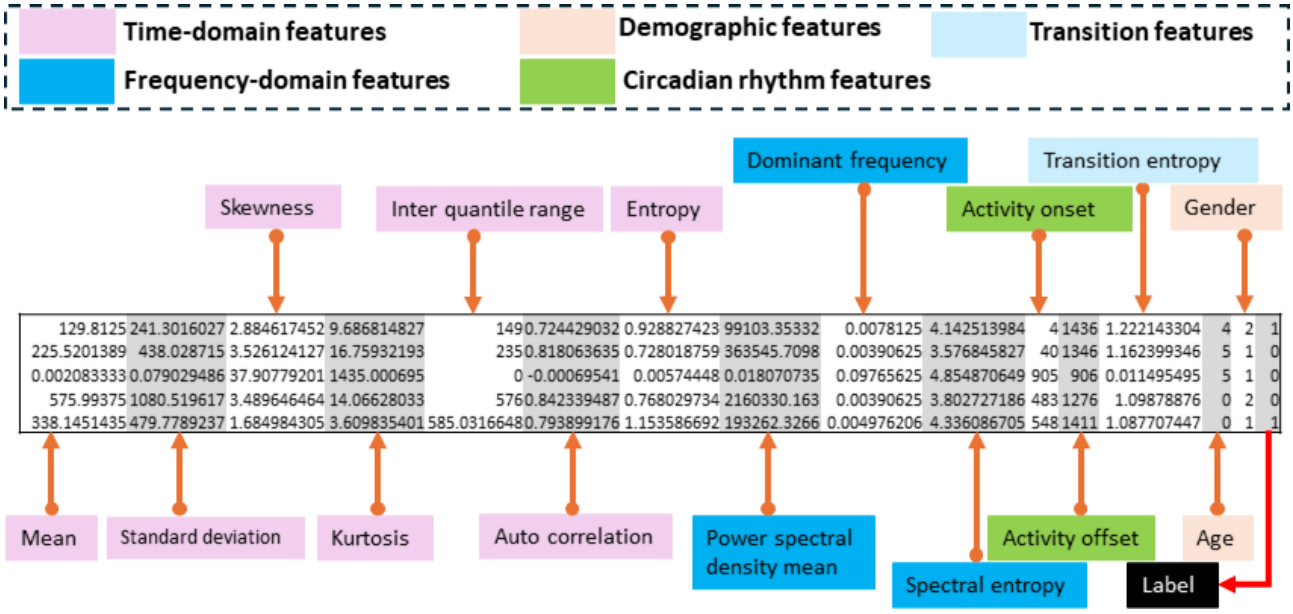
Analyzing the distribution of activity power across different frequencies can illuminate underlying periodicities. Alterations in these periodic components often correspond to disrupted sleep-wake cycles or abnormal energy distribution, which are common in depression. Multiple actigraphy studies link these spectral abnormalities to symptom severity, confirming their diagnostic value for mood inference [25,29,35,38].

The features extracted are:

- Power spectral density (mean): a measure of how the signal's power is spread across frequencies, reflecting the overall strength of periodic components in daily activity [39].
- Dominant frequency: identifies the frequency at which activity is most pronounced, commonly associated with daily (circadian) cycles. Deviations may mirror disrupted or shifted circadian rhythms in individuals with depressive symptoms.
- Spectral entropy: quantifies how "spread out" or concentrated the activity power is across frequencies. Greater spread could imply less stable routines and more variability in daily patterns, potentially linked to mood fluctuations.

Circadian Rhythm Analysis

Mood disorders are often accompanied by disruptions in circadian rhythms. Examining the timing of key transitions can yield valuable clues about sleep-wake irregularities [40] (Activity Onset and Offset: identify the start and end of the primary daily activity period. Shifts in these values can reveal delayed or advanced phases of sleep, which are frequently observed in individuals with depression or other affective disorders).



Transition Features

Activity does not always change smoothly throughout the day; abrupt transitions or steady patterns can be particularly telling of mental health status. Transition entropy captures the uncertainty or unpredictability inherent in the sequence of activity state transitions [41]. Transition entropy quantifies the randomness in the transitions between different activity states by evaluating the distribution of transition probabilities. Elevated transition entropy may reflect instability in daily routines or mood fluctuations, which are often observed in individuals with certain mental health conditions.

Alongside the time- and frequency-domain metrics, we also tested a set of nonlinear descriptors (notably Fractal Dimension and the Hurst Exponent) to better capture the self-similar structure and long-range dependencies often observed in human activity signals. We implemented several published algorithms and tuned their parameters across multiple window lengths. Despite these efforts, the extraction pipeline consistently produced a large fraction of undefined or zero values, signaling numerical instability with our data resolution. After troubleshooting and sensitivity checks, the issue persisted and threatened to compromise both model robustness and interpretability. To safeguard the overall validity of the study, we therefore documented the attempted nonlinear analyses and excluded these features from the final feature set. Figure 2 is a pictorial representation of the dataset after feature engineering.

XSL•FO
RenderX

Figure 2. Snap of data after feature engineering.

After feature engineering, we performed data normalization using *z*-score normalization technique as shown in Eq. (1).

$$z_i = x_i - \mu\sigma$$

Note that xi and zi represent the individual feature score before and after standardization, whereas μ and σ represents the mean and standard deviation of the activity level scores.

Logistic Regression

Logistic Regression (LR) is a widely used supervised learning algorithm primarily employed for classification tasks [42]. LR estimates the probability that a given input belongs to a particular class by applying the logistic (sigmoid) function to a linear combination of input features. LR is favored for its simplicity, interpretability, and efficiency, especially when the relationship between the features and the target variable is approximately linear. It also provides probabilistic insights, allowing for the assessment of confidence in predictions. In addition, LR can be extended to multiclass classification problems using strategies such as One-vs-Rest (OvR) or multinomial LR [43]. Despite its simplicity, LR serves as a strong baseline model and is effective in scenarios where the decision boundary is linear or nearly linear.

Support Vector Machines

Support vector machines (SVM) are a popular model notably for classification problems. The core concept of SVM is to identify an optimal hyperplane that separates or distinguishes data points into different classes in an n-dimensional space [44]. For binary classification problems, SVM finds the optimal hyperplane that separates the 2 classes in the feature space. For the multiclass problem, two approaches are typically used: OvR and One-vs-One (OvO). In OvR, a binary classifier is used for each class against all other classes, whereas in OvO, a binary classifier is trained for every possible pair of classes [44]. This means that for a k-class classification problem, OvO trains N·N-12 binary classifiers.

Random Forest

RF is a supervised ensemble learning algorithm that integrates the results of multiple decision trees to produce a more precise outcome [45]. Unlike decision trees, random forest has the ability to minimize overfitting [45]. RF is based on the bagging method where multiple models are trained using the subsets of features that are randomly selected, and the resulting predictions are aggregated either by voting or average mechanism. For regression, the prediction is the average prediction across all the decision trees, and for classification, it is the majority vote class predicted across the decision trees [46].

XGBoost

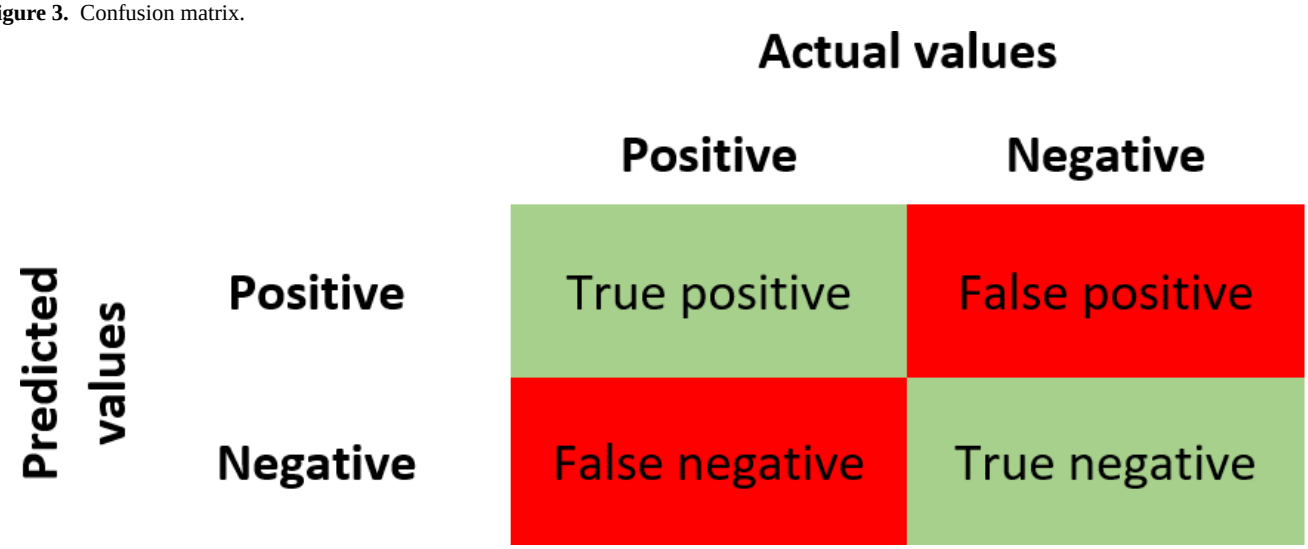
XGBoost (Extreme gradient boosting) is a ML algorithm based on the Gradient Boosting framework [47]. The idea of gradient boosting is based on developing multiple weak learners (like decision trees) with the expectation to aggregate the result to obtain a final strong learning model [47]. XGBoost builds an ensemble of decision trees sequentially, where each new tree attempts to correct the errors of the previous ones. XGBoost is particularly useful in dealing with imbalanced datasets [48].

Neural Networks

Neural networks (NN) are a class of powerful, flexible ML models inspired by the human brain's network of neurons. Comprising layers of interconnected nodes (neurons), neural networks are capable of modeling complex, nonlinear relationships between input features and target variables. Each neuron applies a weighted sum of its inputs followed by a nonlinear activation function, enabling the network to learn intricate patterns and representations from the data [49].

In the context of mental health analysis, neural networks can effectively capture the complex temporal and spatial dependencies present in actigraphy data, making them well-suited for tasks such as depression classification and severity assessment [50]. Their ability to automatically learn feature representations from raw data reduces the need for extensive feature engineering, although they typically require

XSL•FO
RenderX



larger datasets and more computational resources compared to traditional algorithms. The hyper-parameter settings are reported in Multimedia Appendix 1.

The hyper-parameter settings are reported in Multimedia Appendix 1.

Evaluation Metrics

In this study, we use accuracy, recall, specificity, precision, F_1-score, and MCC as performance evaluation criteria for ML models. These performance evaluation measures are based on the confusion matrix, which represents a summary of accurate and misclassified instances for a classification problem. A graphical representation of the confusion matrix is given in Figure 3. A confusion matrix has 4 key elements called true positive (TP), false positive (FP), false negative (FN), and true negative (TN), defined as follows [51].

Figure 3. Confusion matrix.

TP is an instance when the model classifies a positive instance correctly. FP is an instance when the model classifies a negative instance as a positive instance. FN is an instance when the model classifies a positive instance as a negative instance. TN is an instance when the model classifies a negative instance as a negative instance. Based on the definitions of various elements of the confusion matrix, in Table 1, we define our performance evaluation metrics.

Table . Performance metrics.

Metric	Formula
Accuracy (Acc)	TP+TNTP+TN+FP+FN
Recall (Rec)	TPTN+FN
Specificity (Spec)	TNTN+FP
Precision (Prec)	TPTP+FN
F_1-score (F1)	2·Precision×RecallPrecision+Recall
MCC	(TP×TN)−(FP×FN)(TP+FP)(TP+FN)(TN+FP)(TN+FN)

Results

Performance Evaluation for Binary and Multiclass Classification Task

Table 2 highlights the performance of various ML models on the binary classification task. Among the evaluated models, XGBoost achieved the highest accuracy of 84.94%, significantly outperforming all other models. In contrast, LR was the least effective, with an accuracy of 70.68%. This ranking based on accuracy is consistently reflected across other metrics: XGBoost also leads in precision (83.40%), recall (87.45%), F_1-score (85.29%), and MCC (0.7012), while LR scores the lowest in each of these categories. The remaining models, including SVM, RF, and neural networks, show a progressive improvement in performance, with SVM outperforming LR and RF and neural networks closely trailing XGBoost. This uniform trend across all evaluation metrics underscores the robustness of XGBoost as the superior model for this classification task.

XSL•FO
RenderX

Table . Performance comparison of various models.

Model	Accuracy	Precision	Recall	F_1-score	Matthew correlation coefficient
Logistic regression	0.7068	0.6937	0.7471	0.7187	0.4156
SVM	0.7789	0.7648	0.8056	0.7842	0.5595
XGBoost	0.8494	0.8340	0.8745	0.8529	0.7012
Random forest	0.8301	0.8096	0.8663	0.8358	0.6639
Neural networks	0.8368	0.8275	0.8543	0.8397	0.6758

Furthermore, XGBoost exhibited an enhancement over the average performance of the other models across all evaluation metrics. Specifically, XGBoost surpassed the average accuracy, precision, recall, F_1-score, and MCC by 7.2%, 6.42%, 6.83%, and 17.47%, respectively. This improvement underscores XGBoost's superior capability in capturing complex patterns and interactions within the data, making it the most effective model in our study. The findings demonstrate the effectiveness of ensemble methods like XGBoost in outperforming traditional and other ML models, thereby offering enhanced predictive accuracy and reliability.

Table 3 presents the performance of various ML models on the multiclass classification task. XGBoost achieved the highest accuracy of 85.91%, along with precision, recall, and F_1-scores exceeding 85%, and a MCC of 0.7895. In contrast, SVM and LR recorded the lowest accuracies of 53.22% and 54.12%, respectively, and underperformed across other metrics as well. RF and neural networks demonstrated strong performance with accuracies of 82.85% and 83.52%, respectively, and consistently higher precision, recall, F_1-score, and MCC. These results indicate that XGBoost surpassed the average accuracy, precision, recall, F_1-score, and MCC by 20.35%, 20.13%, 20.34%, 20.41%, and 33.07%, respectively.

Table . Performance comparison of various models for multi-class classification.

Model	Accuracy	Precision	Recall	F1	Matthew correlation constant
Logistic regression	0.5412	0.5414	0.5412	0.5386	0.3136
SVM	0.5322	0.5362	0.5322	0.5315	0.2999
XGBoost	0.8591	0.8602	0.8591	0.8581	0.7895
Random forest	0.8285	0.8308	0.8285	0.8276	0.7446
Neural networks	0.8352	0.8396	0.8352	0.8342	0.7554

Statistical Significance Testing

To verify that the superior performance of XGBoost was not due to random chance, we conducted rigorous statistical significance testing, as detailed below. We ran a 10×3 repeated stratified cross-validation protocol (30 folds in total), preserving the original class distribution in every split. Within each fold, the model was fit to the training indices and its binary predictions on the held-out set were scored with the F_1-metric, which is appropriate for moderately imbalanced problems. We then applied paired 2-tailed *t* tests between XGB and each rival model, followed by Holm correction to control the family-wise error rate at α=.05.

For binary classification, across the 30 cross-validation folds, XGB achieved the highest mean F_1-score (0.851 ± 0.034) while its nearest competitor RF averaged 0.832; SVM, LR, and NN trailed at 0.659, 0.723, and 0.687, respectively. Paired significance testing confirmed that these differences are not due to sampling noise: the Holm-adjusted *P* values for XGB versus RF, LR, SVM, and NN were 3.6×10^{-4}, 2.3×10^{-1}, 2.7×10^{-1}, and 1.7×10^{-2}, all well below 0.05, confirming that the superior performance of XGBoost is not by chance. Hence, XGB's performance advantage is statistically significant against every other baseline in the study, supporting its selection as the primary model for downstream explainability analysis. The same trend was observed for multiclass classification.

Discussion

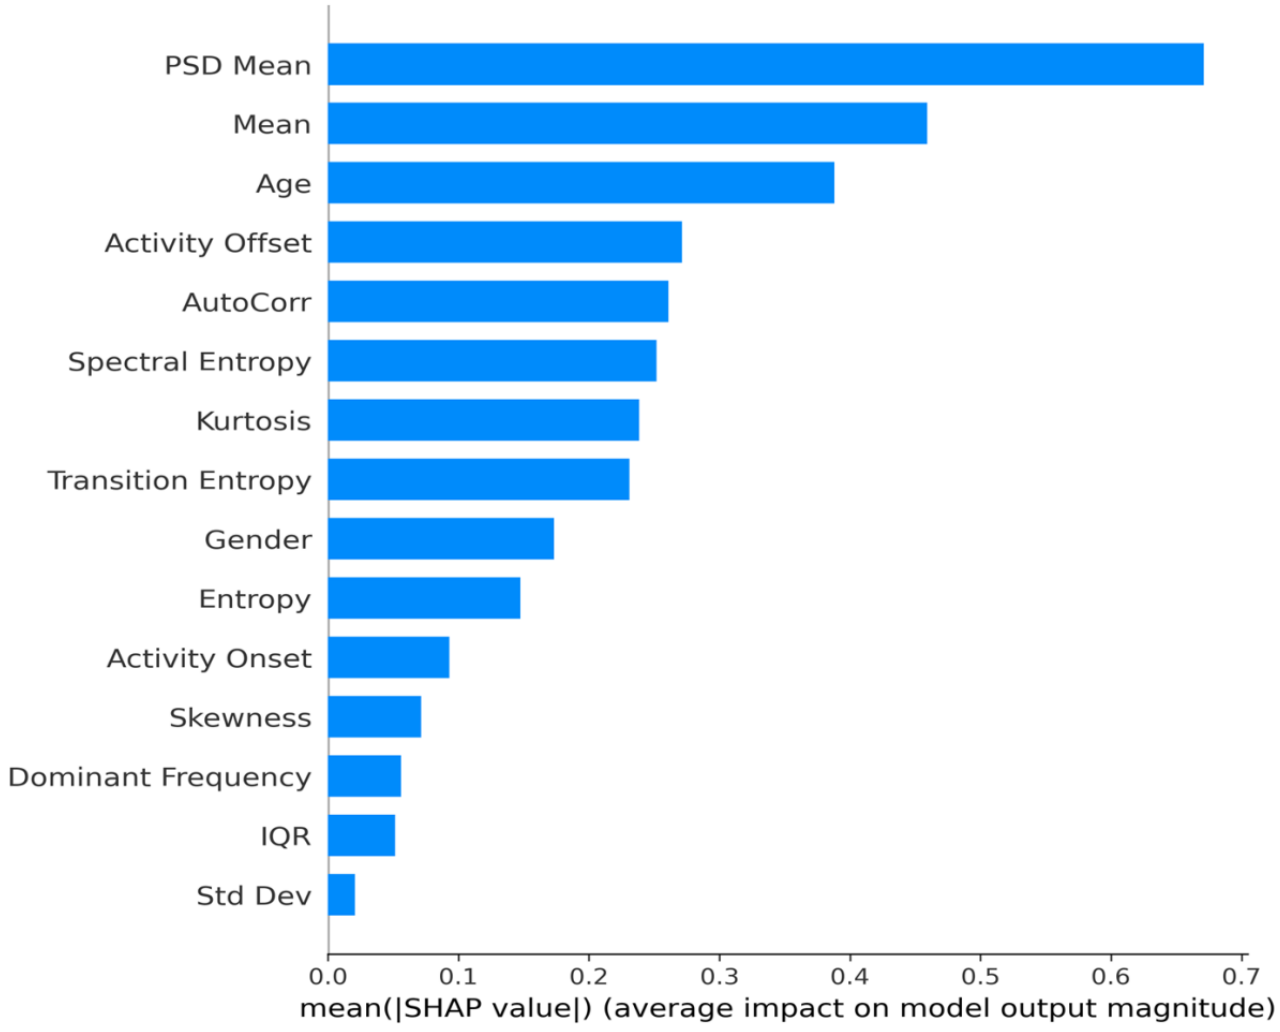
Principal Findings

In this section, we critically interpret XAI techniques (SHAP and LIME) to reveal the feature patterns that drive the depression-classification models, compare these explanations across XGBoost and neural-network architectures, and relate the findings to existing clinical evidence. One of the key critiques of ML models is their "black-box" nature [52]. ML models evolved over the last decade to become more complex, resulting in improved performance by virtue of modeling intricate relationships among the input features. However, the increased complexity also meant lower interpretability and explainability powers. In many use cases such as health care, the lack of transparency in decision making is critical, and the reasoning behind a model's outcome is crucial for trust, accountability, and decision-making [52]. A variety of techniques is proposed in XAI to enhance the explainability of complex ML models. SHAP is a type of XAI framework derived from the concept of coalition game where a prediction is

XSL•FO
RenderX

regarded as the "payoff" and the worthiness of the feature is assumed as the "player" [53]. It calculates the Shapley values and explains the prediction by showing how the features influenced the output. The importance of each feature that influenced the effectiveness of the ML algorithm is calculated as given in Eq. (2).

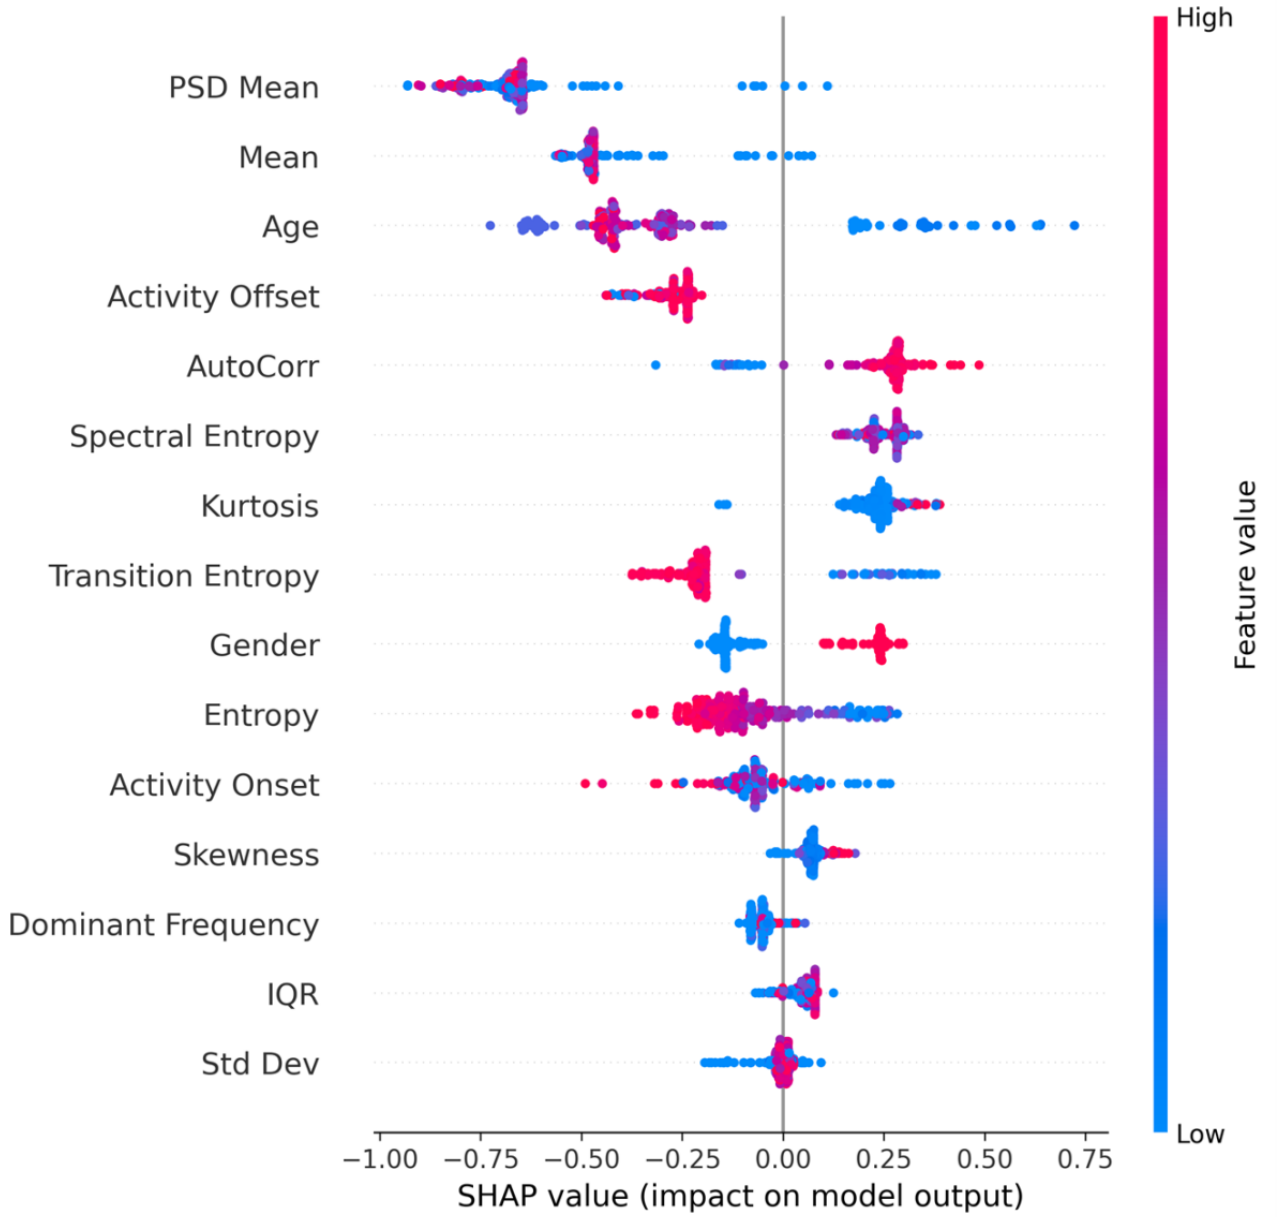
$$\varphi i(f,x)=\sum S\subseteq Ni|S|!\cdot(N-|S|-1)!|N|![f(xs\cup\{xi\})-f(xs)]$$



Where: f represents the prediction model, x is the input feature vector, N is the set of features, S is a subset of features excluding the feature i that is, feature under XAI analysis, xs is the feature vector with features in subset S replaced by baseline values and xi is the value of feature i in the input vector x. For XAI analysis, we restrict to the XGBOOST model only as it was identified as the best performing model.

LIME is a popular framework in XAI that helps make ML predictions easier to understand. LIME explains a model's predictions by simplifying it in the local context of a specific instance. It does this by slightly altering the input data around the instance and analyzing how these changes affect the model's predictions. This process highlights which features are most influential in the local neighborhood. To determine the importance of each feature, LIME builds a simple, interpretable model (such as a linear regression model) based on weighted data points. These weights are assigned according to how close the altered data points are to the original instance.

XAI for Binary Classification



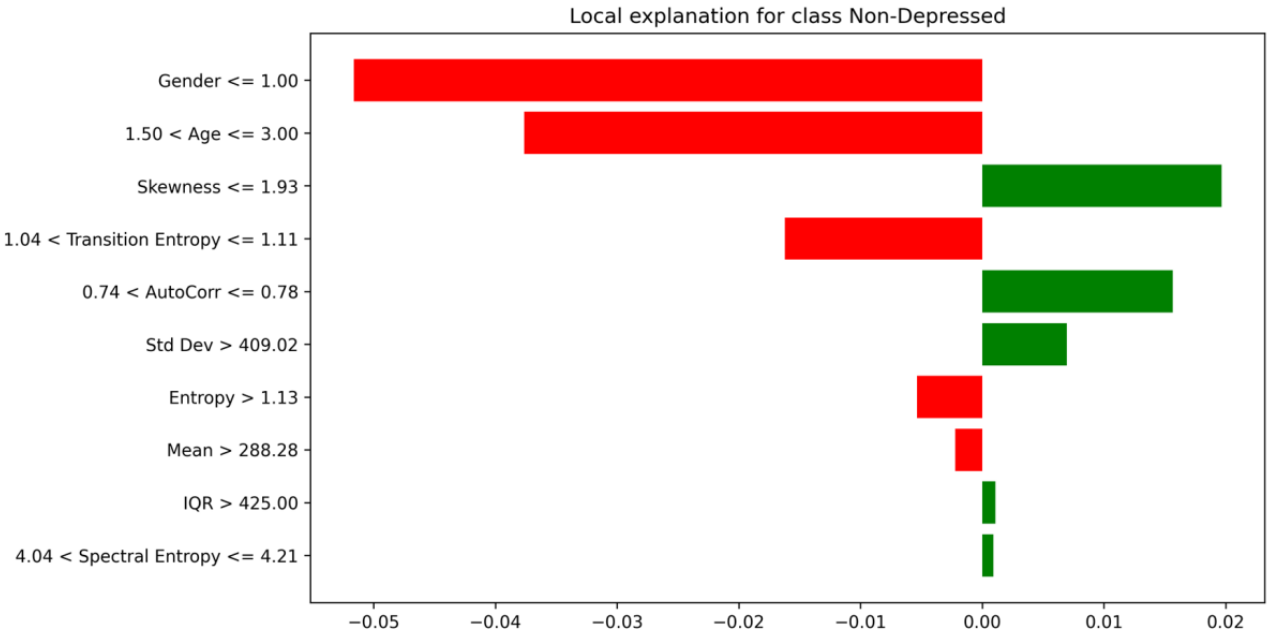
Two primary SHAP plots (Figures 4 and 5) indicate how each feature affects the model's decision boundary across the entire dataset. Figure 4 shows the average magnitude of SHAP values (mean absolute SHAP) per feature, highlighting the top predictors. Figure 5 depicts a dot summary where each point corresponds to a specific sample's SHAP value. Points to the right (positive SHAP) push the classification toward "Depressed," whereas points to the left (negative SHAP) favor "Non-Depressed." Colors (red to blue) represent the actual feature value (eg, higher PSD Mean in red and lower PSD Mean in blue).

Figure 4. Binary classification feature importance.

XSL•FO
RenderX

Figure 5. SHAPE summary plots for binary classification.

From these plots, we observe the following. PSD means consistently have the largest average impact. Larger values of the PSD mean (possibly reflecting a stronger low-frequency power in the activity data) correlate with a higher likelihood of depression. Mean activity level and age follow closely, indicating that demographic factors (eg, older individuals) and overall daily activity levels significantly shape the classification. Activity offset and AutoCorr also stand out, aligning with clinical findings that disrupted or rigid circadian rhythms (late offsets and high autocorrelation) are often associated with depressive behaviors.



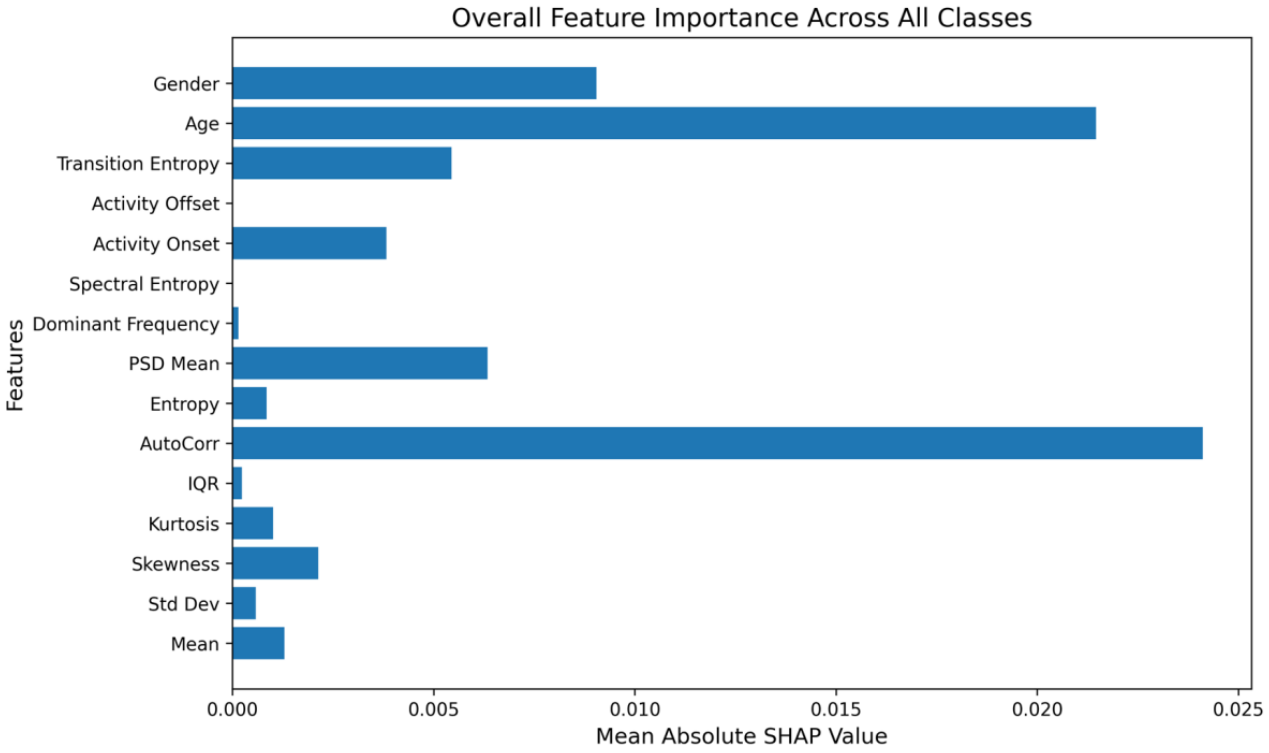
PSD Mean consistently has the largest average impact. Larger values of the PSD mean (possibly reflecting a stronger low-frequency power in the activity data) correlate with a higher likelihood of depression.

Mean activity level and age follow closely, indicating that demographic factors (eg, older individuals) and overall daily activity levels significantly shape the classification.

We applied LIME to explain a single test instance in Figure 6. LIME creates locally linear “rules” indicating how small perturbations around this instance shift its predicted probability for depression. Features with red bars push the instance toward “Depressed,” while green bars push it toward “Non-Depressed.” For example, a condition like “Gender≤1.0” (female) or older “Age” might increase the model’s belief in depression if other activity-related features also align. LIME reported numeric weights for each condition, revealing how thresholds in AutoCorr, Entropy, or Skewness shape local decision boundaries. These rules coincide well with the SHAP findings (eg, higher autocorrelation frequently signals depressive risk).

XSL•FO
RenderX

Figure 6. Local explanation for the non-depressed class.



While SHAP and LIME are theoretically different (SHAP uses game-theoretic Shapley values, and LIME uses local linear approximations), both converge on similar high-impact features, boosting confidence in the model's learned representations. Specifically, PSD mean, mean activity level, and daily rhythm indicators (like activity offset, AutoCorr) repeatedly appear among the strongest predictors.

XAI for Multiclass Classification

We extended our explainable AI approach to a 3-class setting, distinguishing among "Normal Case," "Mild Depression," and "Moderate Depression." SHAP was used for global insights (per-class and overall feature importance), while LIME was used for local (instance-level) explanations. Figure 7 displays the mean absolute SHAP values aggregated in all 3 classes, highlighting key characteristics that consistently influence the predictions of the model. Notably, AutoCorr and age emerge as dominant factors, aligning with clinical observations that older age groups, coupled with repetitive or rigid activity patterns, may exhibit a higher risk of depression.

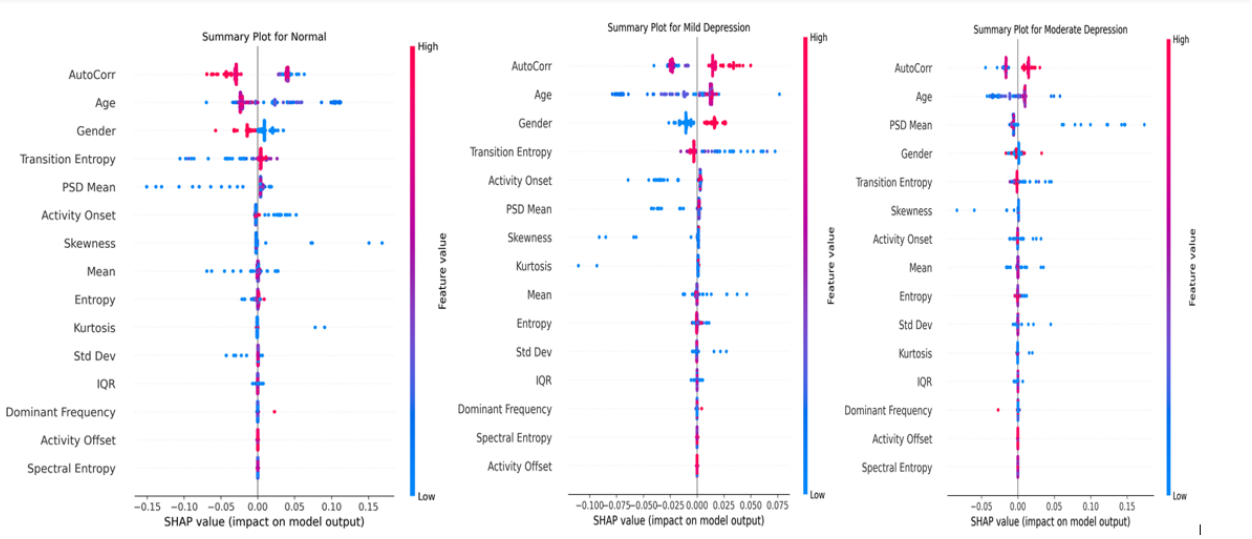


Figure 7. Multi-class feature importance.

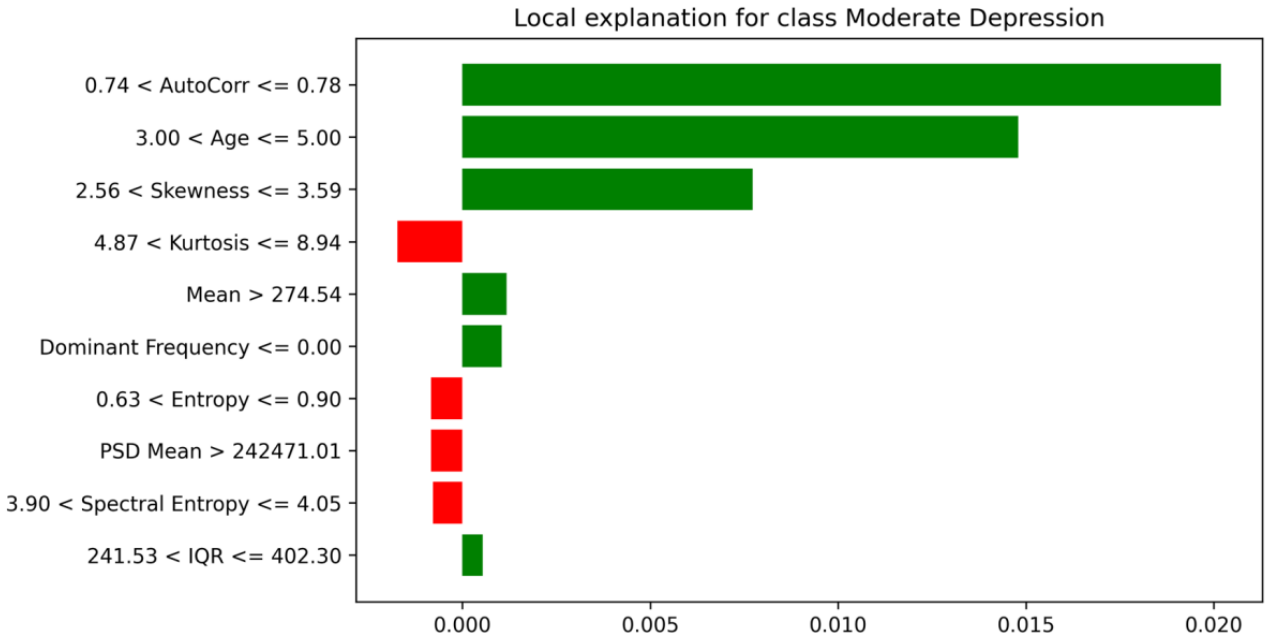
XSL•FO
RenderX

For a more in-depth analysis of each class, we generated separate SHAP summary plots. Normal (Figure 8A): Lower AutoCorr typically favors the normal class, suggesting that a more flexible or varied daily rhythm (less repetitive activity) aligns with nondepressed status. Moderate values of age and PSD mean also push predictions away from mild or moderate depression.

Figure 8. SHAP summary plots for multi-class classification.



Mild depression (Figure 8B): Mild cases show strong contributions from AutoCorr and transition entropy. In many instances, moderate daily rhythms—coupled with subtle changes in the frequency composition of activity (as captured by PSD Mean)—tilt the model toward mild depression. Moderate depression (Figure 8C): This class often manifests higher or more entrenched irregularities. Age, AutoCorr, and an elevated PSD mean appear to push an instance from mild toward moderate severity. Here, demographic and circadian disruptions intertwine more intensively, reflecting a deeper depressive state.

Across all classes, AutoCorr consistently ranks among the most critical features. However, its specific influence varies. Moderate autocorrelation can lead a case from normal to mild, while higher autocorrelation plus advanced age often indicates moderate depression. These distinctions underscore how the same feature can have class-dependent impacts based on subtle variations in its actual range or interaction with other features.

To validate SHAP's per-class findings at the instance level, we used LIME for a single test example. Figure 9 focuses on the model's explanation for the "Moderate Depression" class. LIME produces threshold-based "rules" (eg, "0.74<AutoCorr≤0.78") that locally shift the probability of class membership. Green bars push the model toward selecting "Moderate Depression." For instance, an *AutoCorr* range above 0.74 or age exceeding a certain threshold may substantially raise this class probability. Red bars pull the prediction away from "Moderate Depression," indicating features or thresholds that conflict with the typical profile for moderate severity (eg, a lower PSD mean or higher Kurtosis).

XSL•FO
RenderX

Figure 9. LIME explanation for the moderate depression class.

This local view converges with the SHAP observations: circadian-related variables (eg, AutoCorr and Transition entropy) and demographic factors (eg, age) become pivotal. In mild cases, these metrics may appear only partially disrupted, whereas for moderate severity, they consistently register in ranges linked to stronger depressive indications.

Comparing Explanations Across XGBoost and Neural Network Models

Although XGBoost delivered the highest accuracy, we repeated the XAI analysis for artificial-neural-network (ANN) to test whether the explanatory story was model-dependent. For binary classification, both models ranked PSD mean as the dominant driver of the depressed versus nondepressed decision, confirming the feature's robustness. Beyond that, the explanations diverged: XGBoost distributed moderate importance across roughly ten additional variables (eg, mean, age, activity offset, and AutoCorr), whereas the ANN concentrated nearly all remaining attribution on just three features (activity onset, kurtosis, and activity offset). This comparison strengthens interpretability in 2 ways: the cross-model agreement on PSD mean validates it as a consistent physiological marker and the differing secondary patterns reveal architecture-specific sensitivities, offering complementary insights that would be missed if explanations were reported for XGBoost alone.

For binary classification, both models ranked PSD mean as the dominant driver of the depressed versus nondepressed decision, confirming the feature's robustness. Beyond that, the explanations diverged: XGBoost distributed moderate importance across roughly ten additional variables (eg, mean, age, activity offset, and AutoCorr), whereas the ANN concentrated nearly all remaining attribution on just 3 features (activity onset, kurtosis, activity offset). This comparison strengthens interpretability in 2 ways: (1) the cross-model agreement on PSD mean validates it as a consistent physiological marker; and (2) the differing secondary patterns reveal architecture-specific sensitivities, offering complementary insights that would be missed if explanations were reported for XGBoost alone.

For multiclass classification, inspection of the mean-|SHAP| values reveals that XGBoost and the neural network rely on partly overlapping but ultimately different information in multiclass classification, and they do so on strikingly dissimilar attribution scales. XGBoost's strongest signals come from temporal-structure and demographic variables—AutoCorr carries the largest impact, closely followed by age, with gender and transition entropy also substantial—whereas features such as activity offset contribute almost nothing. The ANN tells a nearly opposite story: its 2 most influential cues are the higher-order statistic kurtosis and activity offset, while the variables that dominate XGBoost shrink to the noise floor. Both models nevertheless converge on PSD mean as a relevant marker, which bolsters confidence in that spectral feature's physiological validity even though its weight is modest in XGBoost and comparatively prominent in the ANN. It is also worth noting that the ANN's absolute SHAP magnitudes are roughly 2 orders of magnitude smaller than the tree ensemble's, reflecting the smoother decision surface learned by the network and the conservative estimates produced by KernelExplainer; consequently, comparisons should be made within each model's scale rather than across scales. Taken together, the agreement on PSD mean and the divergence elsewhere show that the 2 architectures extract complementary patterns—trees capitalize on heterogeneous temporal-demographic interactions, whereas the network distills the data into distribution-shape metrics—providing a richer, cross-validated picture of how depression severity is encoded.

Discussion of XAI Findings

The combined SHAP–LIME analysis reveals several consistent themes.

XSL•FO
RenderX

Circadian Rhythms and Activity Measures

Our model's emphasis on autocorrelation and spectral activity features matches a large body of research linking disrupted daily rhythms to mood disorders. For example, clinical and experimental evidence shows that blunted or shifted circadian cycles are closely associated with depression [54,55]. A recent longitudinal study using wearable devices found that circadian phase shifts often precede worsening mood symptoms in depressed patients [56]. Furthermore, therapies that realign circadian timing (bright light therapy, social rhythm therapy, etc) reliably alleviate depressive symptoms [55], suggesting a causal role for rhythm disruption. That said, mood and circadian processes are bidirectionally linked [55,57], so altered activity patterns may both influence and reflect depressive states. In short, our findings are consistent with known associations; however, they do not by themselves prove that these rhythm-related features cause depression.

Age and Demographic Influence

Age and gender differences in depression risk are well documented [57,58], and our model captures these patterns. For instance, older adults tend to show earlier and less variable sleep–wake timing [59], which may interact with late-life depression risk. Epidemiological studies report that women have roughly twice the odds of major depression compared with men [58]; our model's gender feature trends are in line with that. However, like other risk factors, age and gender effects are multifaceted and often indirect. Biological aging brings many changes (health, lifestyle, and brain function), and gender differences reflect hormonal, psychosocial, and diagnostic factors. Thus, while age and demographic features correlate with depression, the mechanistic pathways remain speculative. In practice, these variables likely modulate risk in complex, context-dependent ways [57], so caution is warranted in attributing causality to them without further study.

Distinction Between Mild and Moderate Depression

The multiclass SHAP plots show that certain transitions from mild to moderate often involve heightened daily-activity irregularities. The interplay of transition entropy and AutoCorr is particularly telling, resembling findings in psychological studies that link more chaotic sleep–wake transitions to deeper depressive states [60]. Nevertheless, these are still observational correlations. For example, it is unclear whether irregular sleep drives depression or mainly reflects its impact on physiology. Disentangling this requires targeted studies (eg, manipulating sleep schedules) beyond what SHAP and LIME alone can show.

Local Explanation Value

Per-instance force plots or LIME rules allow for clinically relevant breakdowns of risk factors, highlighting how subtle changes in demographic or circadian metrics can shift a patient's classification from "Normal" to "Mild" or "Moderate Depression." This local interpretability aligns with the literature's emphasis on personalized medicine and the necessity of context-aware diagnostics [61].

In general, the XAI approach confirms that data-driven detection of depression is highly dependent on circadian and demographic characteristics—echoing established work on the connection between daily behavioral patterns and mental health status. By offering both a holistic (global) and case-specific (local) view, SHAP and LIME collectively bolster the transparency and reliability of ML in mental health applications. Note that although these associations are promising, confirming true causality will require targeted longitudinal and interventional studies beyond the correlations revealed by SHAP and LIME.

In this study, we presented a ML framework augmented with explainable AI for the detection and severity-level classification of depression based on wearable-actigraphy data. We demonstrated how XGBoost, coupled with ADASYN and feature selection, consistently achieved superior performance compared to other methods. The SHAP and LIME explanations revealed that circadian-related and demographic factors (eg, PSD mean, age, and AutoCorr) play central roles in identifying depressive states. By providing both global and local interpretability, the proposed system can help clinicians and researchers understand and trust the model's decisions, supporting more targeted treatment plans and facilitating broader acceptance of AI-based tools in mental health care.

Abstract

Background: Although web-based mental health resources have the potential to assist millions, particularly those who face barriers to treatment, most mental health website visitors disengage before accessing resources that can help improve their mental health.

Objective: We used a sequential multiple assignment randomized trial to test whether personalized tailoring improved engagement on a self-guided mental health website.

Methods: Data were collected via voluntary response sampling on the Mental Health America website. Inclusion criteria included residing in the United States and viewing a postscreening survey after completing the Patient Health Questionnaire-9 (PHQ-9). Participants were randomized to 1 of 2 postscreening survey conditions: the demographics survey or the Next Steps survey, which included additional tailoring questions assessing perceived need and participants' intended next steps. Participants who viewed the following screening results page were subsequently randomized to 1 of 5 conditions that displayed nontailored or tailored messages and featured resources, as well as persistent general resources that did not vary by condition. Data were analyzed using logistic regressions predicting disengagement and clicks on featured resources (versus persistent general resources) by condition.

Results: Adding questions to inform tailoring significantly increased the odds of disengaging by 14% (demographics survey: 25%; Next Steps survey: 27.5%; odds ratio [OR] 1.14, 95% CI 1.11 - 1.16; *P*<.001). Among participants who viewed a postscreening survey (n=169,647), 87,712 participants were randomized to the demographics survey condition, and 81,935 participants were randomized to the Next Steps survey condition. Among participants who submitted the demographics survey (n=38,490), tailoring resources to demographics reduced the odds of disengaging by 10% (OR 0.90, 95% CI 0.87 - 0.94; *P*<.001) and, among those who engaged, increased the odds of clicking a featured resource versus a persistent general resource by 90% (OR 1.90, 95% CI 1.79 - 2.01; *P*<.001). Among participants who submitted the Next Steps survey (n=34,204), tailoring messages to perceived need (*P*=.33), tailoring resources to intended next steps (*P*=.51), and a combination of both (*P*=.52) did not significantly reduce the odds of disengaging compared with the nontailored condition. However, tailoring resources to intended next steps and combining a tailored message to perceived need with tailored resources to intended next steps increased the odds of clicking a featured resource by 25% (OR 1.25, 95% CI 1.14 - 1.37; *P*<.001) and 34% (OR 1.34, 95% CI 1.23 - 1.47; *P*<.001), respectively. Tailoring resources to demographics was significantly more effective in improving engagement than tailoring to perceived need or intended next steps (*P*≤.004).

Conclusions: There was a small but statistically significant cost to engagement from adding tailoring questions assessing perceived need and intended next steps. Among the strategies tested in this study, tailoring resources to demographics was the most effective strategy for increasing engagement among visitors who viewed their screening results. This study demonstrates how personalization may increase engagement with mental health websites and provides design implications for future research.

sequential multiple assignment randomized trial; SMART; Mental Health America; MHA; tailoring strategies; personalization; mental health website

Introduction

In 2023, 53.9% of the 58.7 million United States adults living with a mental illness received mental health treatment in the past year [1]. Self-guided mental health websites may be especially helpful for those who face structural barriers (eg, time, geographic constraints, and cost) and individual barriers (eg, stigma, low perceived need, and lack of readiness) to treatment [1-3]. Mental health websites bypass many of these obstacles by maintaining user privacy and offering accessible and free resources; they may also be preferred by some over face-to-face care [4]. For instance, the Mental Health America (MHA) [5] website annually attracts approximately 10 million visitors and provides free screening tools and resources, such as psychoeducational articles, therapist directories, and self-help tools. These resources are designed to support individuals at any stage of their mental health journey, ranging from those exploring mental health topics for the first time to those actively seeking treatment.

Helping individuals find and use quality web-based mental health resources has positive implications for future treatment decisions and stabilization [6,7]. However, visitors to mental health websites, including MHA's, typically engage for only seconds to minutes [8]. One qualitative study of young adults who completed screening tools on MHA found that most participants did not have plans for immediate action after completing a screening tool [9]. Given the underutilization of web-based mental health resources and their potential benefits, there is a critical need to identify strategies that encourage visitors to access resources that can help improve their mental health.

Personalization may be an effective strategy for promoting engagement with mental health websites [10,11]. Research shows that tailored information sometimes influences health behaviors more effectively than nontailored information [12,13]. For example, one meta-analysis found that tailoring was associated with greater efficacy of web-based interventions in health-promoting behavior change compared with control [14]. However, whether personalization improves engagement with a real-world self-guided mental health website remains unclear.

Tailoring in this study was based on factors associated with engagement identified by previous research. In preparation for this study, our team conducted unpublished micro-randomized trials (MRTs) testing design elements that might optimize engagement from April 2022 to September 2023. These MRTs and previous research indicated different usage patterns by age group (eg, older adults tend to access resources related to treatment, younger adults are more likely to use mental health websites than older adults) [6]. In addition, our MRTs indicated that lesbian, gay, bisexual, transgender, and queer (LGBTQ+) individuals tended to have lower engagement rates than visitors who did not identify as LGBTQ+, despite evidence that mental health websites are vital sources of information for LGBTQ+ individuals [15]. One literature review found that tailoring content to LGBTQ+ identity was important for LGBTQ+ people who used digital mental health interventions [16].

Tailoring was also informed by the Health Action Process Approach (HAPA), a stage-based theoretical framework that proposes that health behaviors are adopted and maintained through a process of developing behavioral intentions (ie, the motivation phase) followed by planning to action (ie, the volition phase) [17,18]. Mechanisms that influence an individual's progression through these stages include, for example, outcome expectancies, perceived risks, and perceived need [17-19]. Research indicates that perceived need may be associated with the formation of behavioral intentions to engage with eHealth interventions [19] and mental health websites [20]. The aim of tailoring to perceived need in the current study was to facilitate engagement by encouraging individuals with low perceived need to transition from preintention to intention and to provide positive reinforcement to those with a perceived need to take action to improve their mental health. In addition, the purpose of tailoring to visitors' intended next steps on the website was to provide resources relevant to each individual's stage of change. For instance, individuals who wanted to learn more about depression were provided with links to psychoeducational articles, and those who wanted to find a treatment provider received links to therapist directories and articles related to seeking treatment.

The goal of this study was to determine whether engagement with a mental health website could be improved by tailoring content to age, LGBTQ+ status, perceived need, and intended next steps via a sequential multiple assignment randomized trial (SMART) [21]. Before this study, visitors who completed the Patient Health Questionnaire-9 (PHQ-9) [22] were shown an optional demographics survey before the screening results page. However, acquiring information to inform tailoring necessitates the addition of tailoring questions, and previous research shows that longer surveys are associated with higher dropout [23]. For this study, we used the Next Steps survey, which included 2 tailoring questions before the items on the demographics survey, to assess whether the addition of tailoring questions hindered engagement. Submitting the demographics or Next Steps survey took visitors to the screening results page, which showed nontailored or tailored messages and featured resources (ie, prominently displayed links to resources on MHA). Additional persistent general resources were displayed underneath featured resources on the screening results page to all participants independent of condition. This study addressed the following aims:

1. Does adding tailoring questions negatively impact engagement?

XSL•FO
RenderX

2. Does personalization to demographics improve engagement?
3. Does tailoring to perceived need, intended next steps, or a combination of both improve engagement?
4. Among the strategies examined in this study, which is the optimal tailoring strategy?

These findings will inform the implementation of tailoring on the MHA website, offer novel insights on how to optimally deliver information to people seeking web-based mental health information, and provide empirical evidence on the effectiveness of tailoring on a large, real-world self-guided mental health website.

Methods

Overview

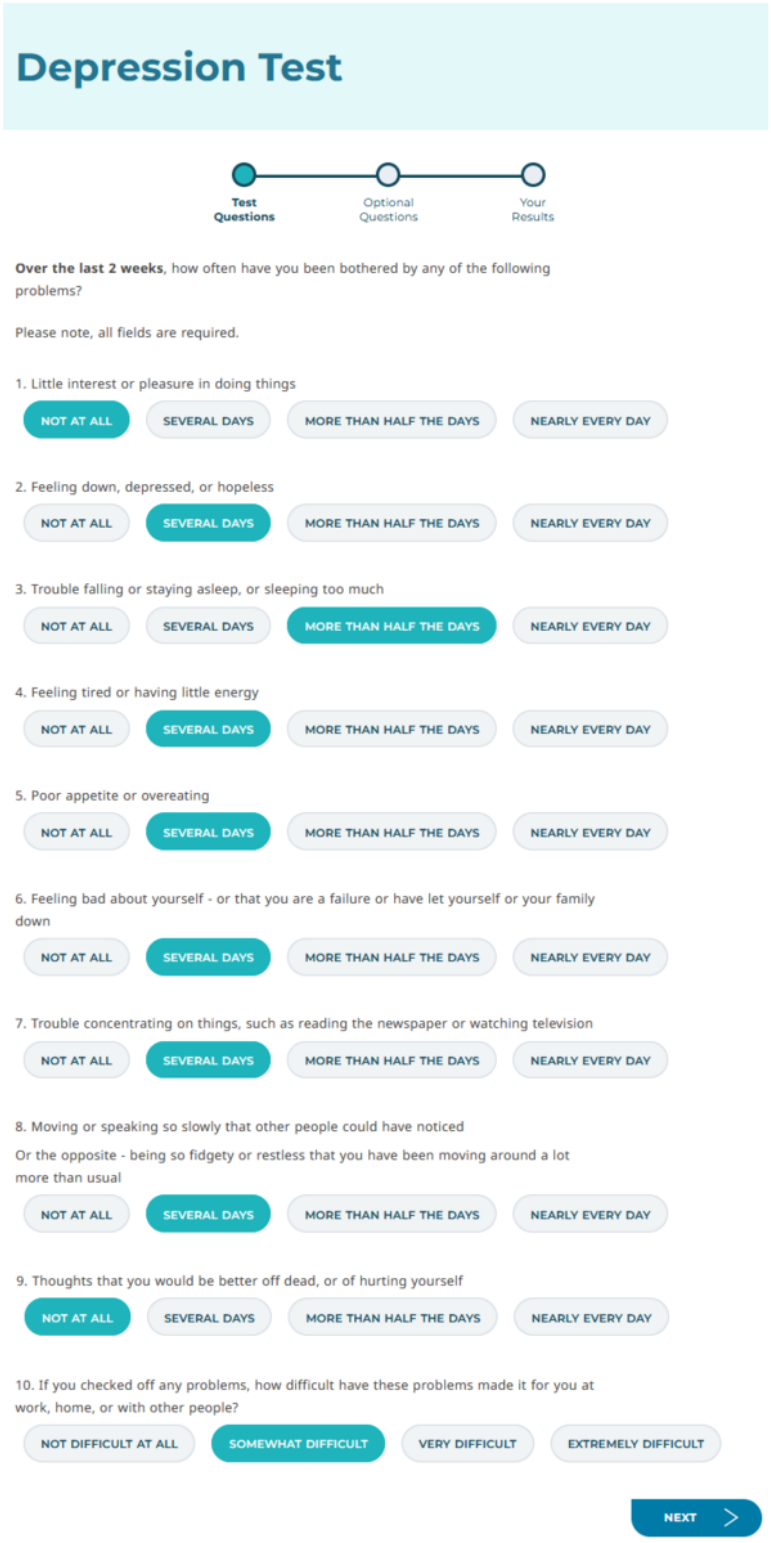
A session was defined as activity on the MHA website from a unique IP address bounded by 30 minutes of inactivity. Visitors with ≥30 minutes of inactivity were considered to have disengaged, and only the first session of each unique IP address was used for analyses. Data were collected from 258,383 sessions from December 1, 2023 to February 6, 2024 and from April 1, 2024 to April 30, 2024 on MHA. Data from February 7, 2024 to March 31, 2024 were excluded due to minor programming errors that were subsequently resolved by MHA.

Participants

Participants were recruited on MHA through voluntary response sampling. Inclusion criteria were residing in the United States and viewing a postscreening survey after completing the PHQ-9 (n=169,647). See Multimedia Appendix 1 for MHA's data cleaning procedures.

Procedure

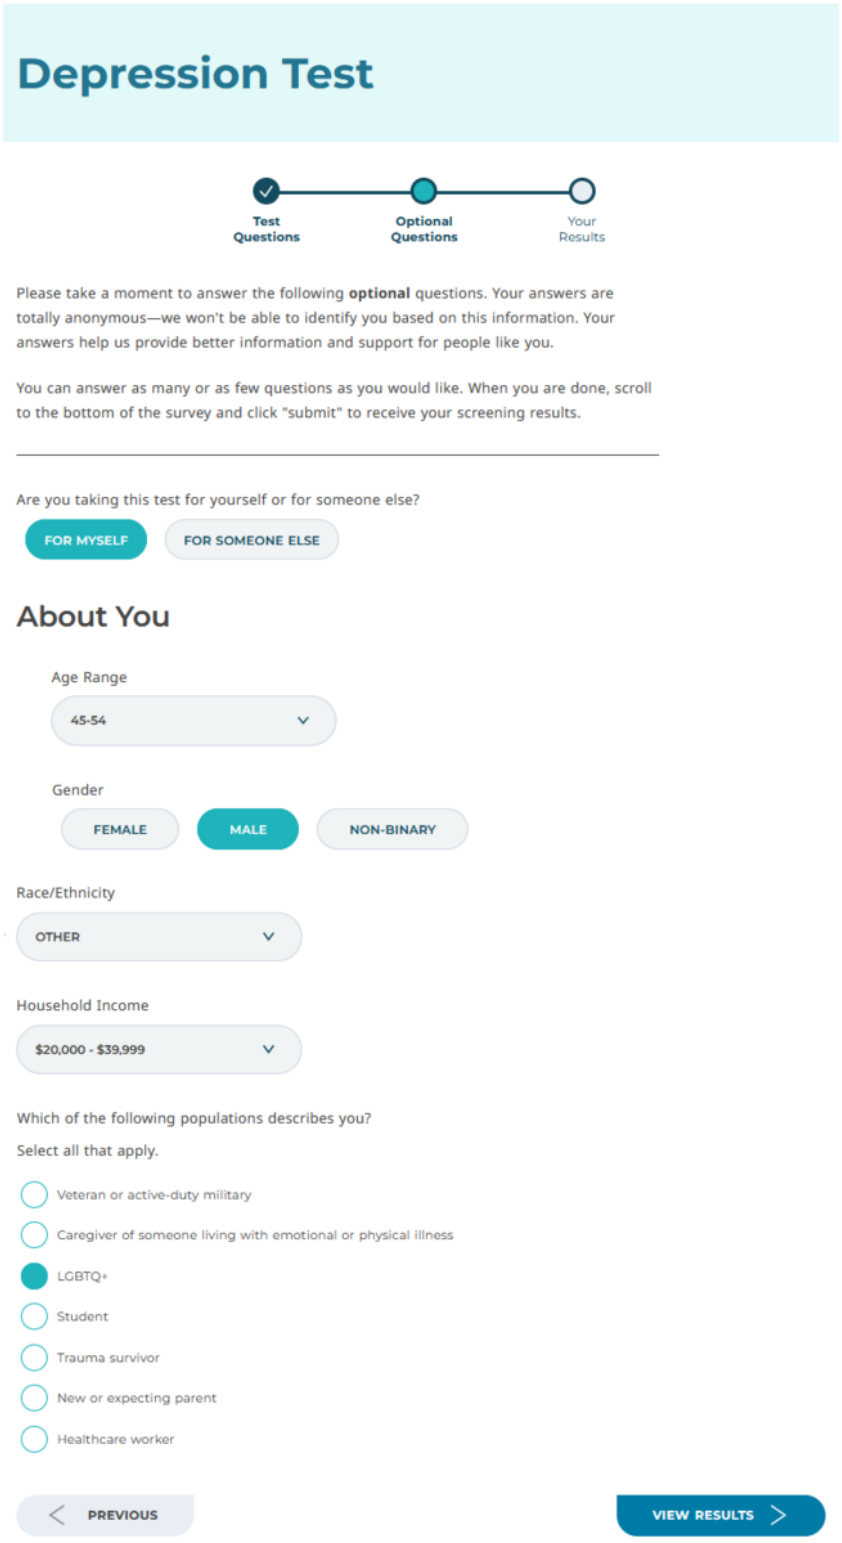
Overview



This study used a SMART design. Participants could progress through 3 web pages displaying: (1) the PHQ-9, (2) a postscreening survey, and (3) their screening results. Participants began on the PHQ-9 web page (see Figure 1), which did not vary by condition. Participants were randomized via simple randomization to 1 of 2 Level 1 conditions (ie, demographics survey or Next Steps survey) upon clicking the PHQ-9 web page, on which a link to the appropriate postscreening survey was generated. Upon completing the PHQ-9 and clicking the "Next" button, participants were taken to the postscreening survey web page, which displayed either the demographics survey or Next Steps survey (see Figure 2 for a sample demographics survey web page).

Postscreening survey items were optional. Participants who clicked the "View Results" button at the bottom of the postscreening survey progressed to the screening results page and were randomized to 1 of 5 Level 2 conditions. Participants who submitted the demographics survey were randomized to 1 of 2 possible conditions: (1) nontailored or (2) tailored resources to demographics (TR-D). Participants who submitted the Next Steps survey were randomized to 1 of 4 conditions: (1) nontailored, (2) tailored message to perceived need (TM-PN), (3) tailored resources to intended next steps (TR-INS), or (4) tailored message to perceived need + tailored resources to intended next steps (TM-PN+TR-INS).

The following descriptions of Level 2 conditions provide examples of messages and resources shown in each condition. For a complete list of messages and featured resources, see Multimedia Appendix 2.



XSL•FO
RenderX

Figure 1. Web page 1: participants began on a web page displaying the PHQ-9, which did not vary by condition; the figure shows sample responses selected. PHQ-9: Patient Health Questionnaire-9.

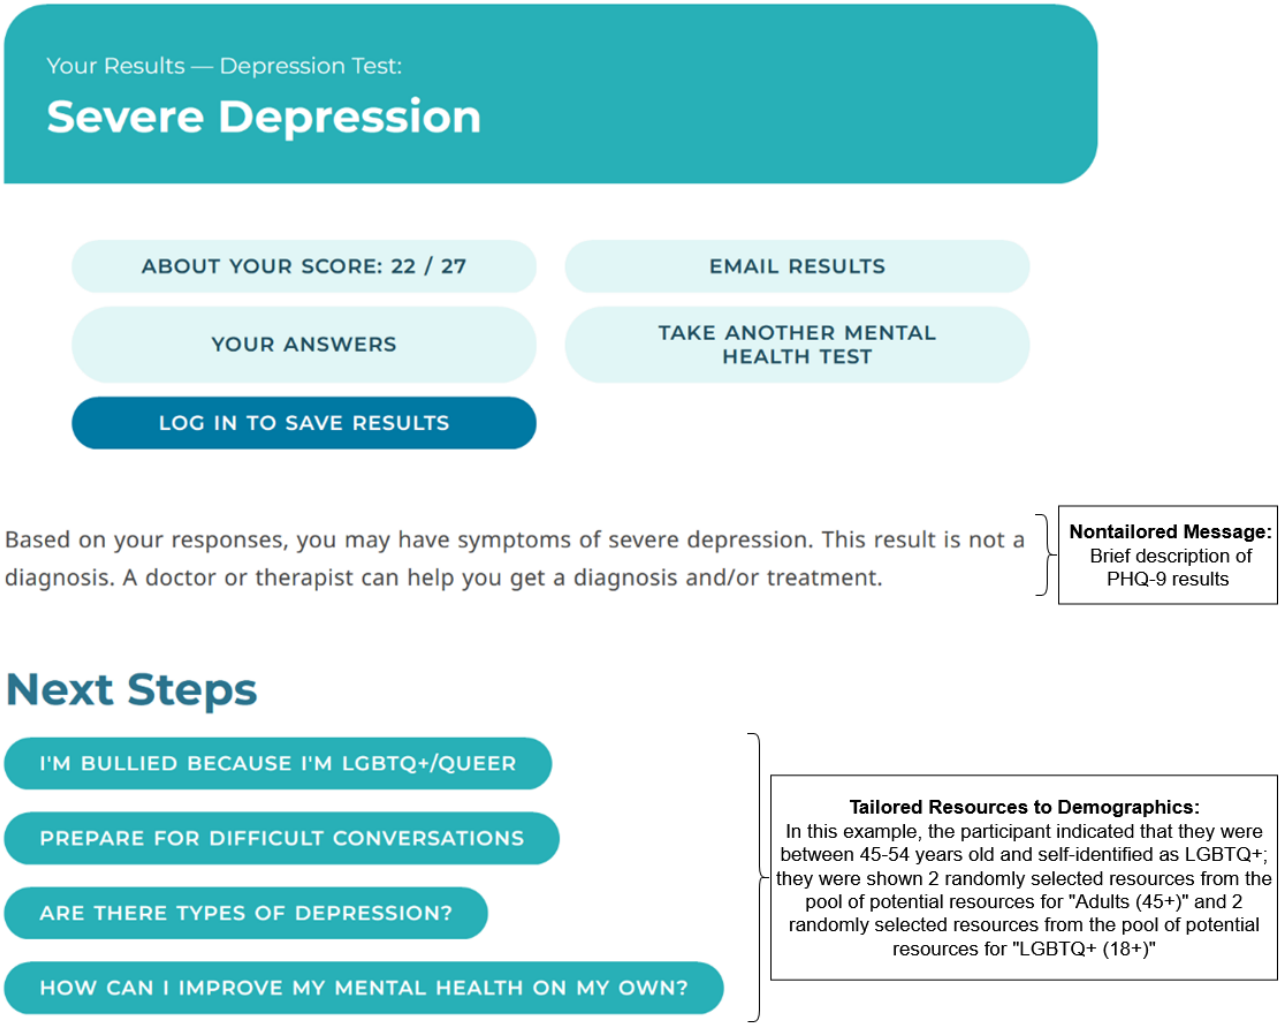
XSL•FO
RenderX

Figure 2. Web page 2: after submitting the PHQ-9, participants were shown a postscreening survey (ie, demographics survey or Next Steps survey); the figure displays select items from the demographics survey with sample responses selected. PHQ-9: Patient Health Questionnaire-9.

Nontailored Condition

Participants from either Level 1 condition could be randomized to the nontailored condition on the screening results page. The nontailored condition included nontailored messages and nontailored featured resources. A nontailored message showed visitors a brief description of their PHQ-9 results, which was shown across all conditions. For example, participants with a PHQ-9 score from 20‐27 were shown, “Based on your responses, you may have symptoms of severe depression. This result is not a diagnosis. A doctor or therapist can help you get a diagnosis and/or treatment.” Nontailored featured resources comprised 4 featured resources (ie, links to resources on MHA that were prominently displayed in large, colorful bubbles across all conditions), shown in random order, that were selected by

XSL•FO
RenderX



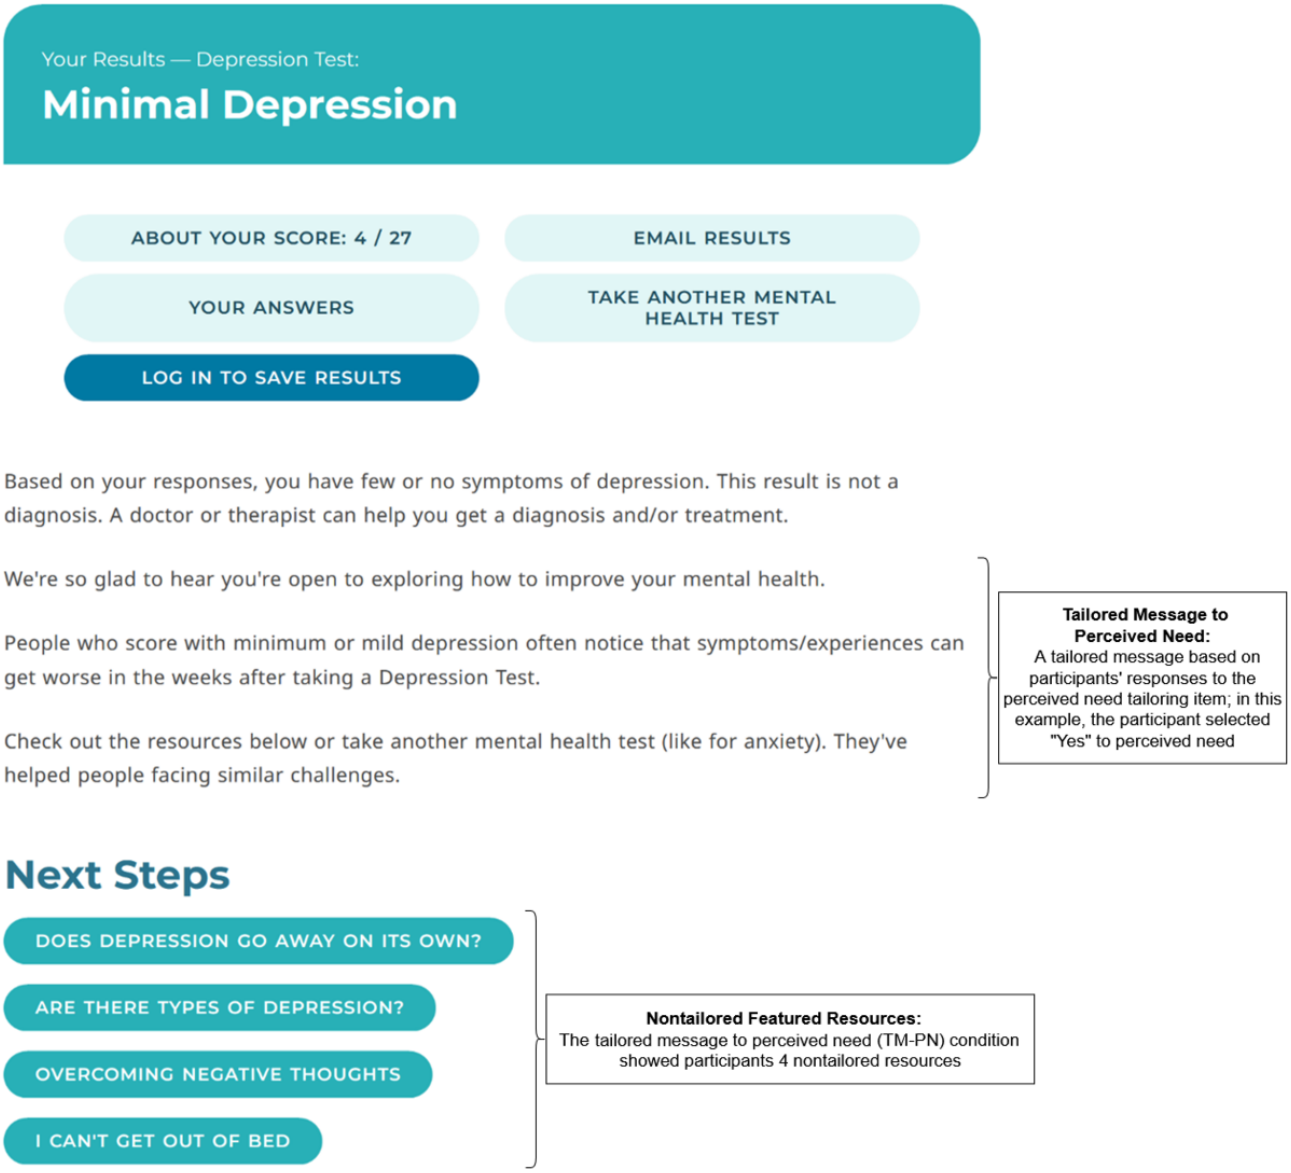
MHA's algorithm as the most popular resources accessed by visitors who complete the PHQ-9.

Tailored Resources to Demographics (TR-D) Condition

Participants who completed the demographics survey could be randomized to the TR-D condition, which showed participants a nontailored message (ie, brief description of PHQ-9 results) and featured resources tailored to age and LGBTQ+ status. A pool of 3 to 4 possible resources for each age group was chosen by an algorithm that identified the most popular resources within each age group. Participants who provided their age and did not self-identify as LGBTQ+ were shown all possible resources for their age group. For example, a participant between 25 - 45 years old who did not self-identify as LGBTQ+ was shown the following links in random order: "I can't do anything right—depression," "I feel numb," "I can't get out of bed," and "Does depression go away on its own?"

Tailored resources to LGBTQ+ status comprised resources on MHA that cater to the LGBTQ+ population. Participants who self-identified as LGBTQ+ and did not provide age were shown all 4 possible LGBTQ+ resources: "I'm bullied because I'm LGBTQ+/queer," "Q-chat space," "Prepare for difficult conversations," and "How do I find LGBTQ-friendly therapy?" LGBTQ+ participants who also provided age were shown 2 age-tailored resources and 2 LGBTQ+ resources; the 2 LGBTQ+ resources were selected from a pool of 4 possible resources for participants under 18 years or 3 possible resources for those 18 years and older. See Figure 3 for an example of a screening results page for a participant randomized to the TR-D condition who was between 45 - 54 years old and self-identified as LGBTQ+.

Figure 3. Sample screening results page: tailored resources to demographics condition, which included a nontailored message and featured resources tailored to age and LGBTQ+ status. LGBTQ+: lesbian, gay, bisexual, transgender, and queer.



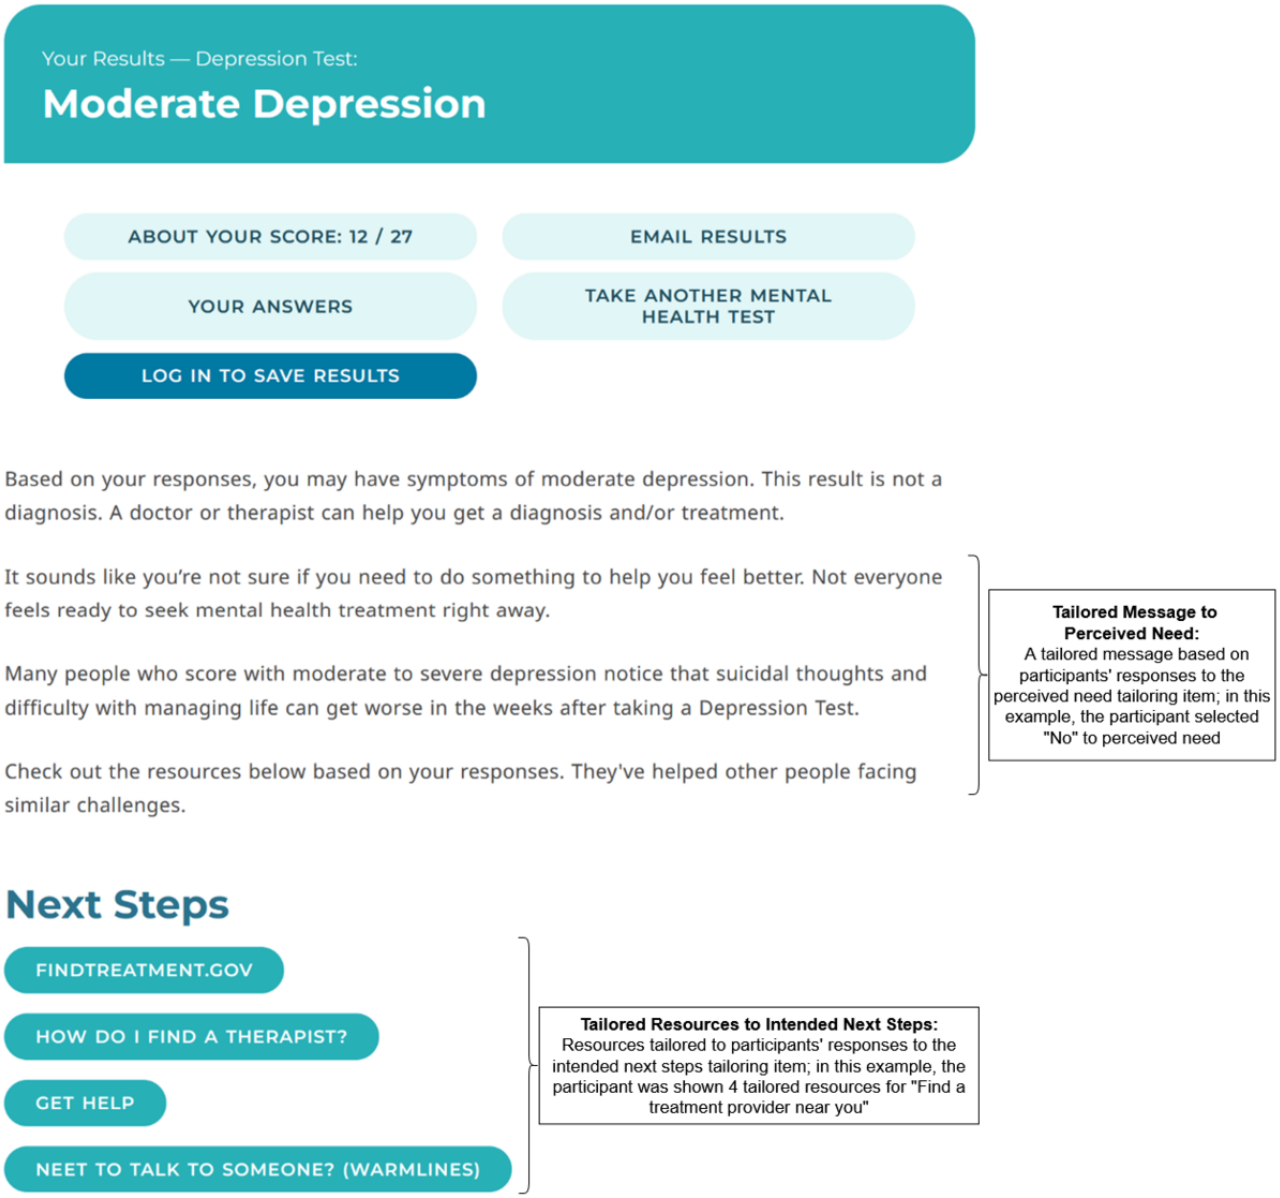
Tailored Message to Perceived Need (TM-PN) Condition

The TM-PN condition was 1 of 4 conditions available to participants who completed the Next Steps survey. Tailored messages were based on participants' responses to the perceived need item, followed by text based on their PHQ-9 results. The TM-PN condition displayed nontailored featured resources. See Figure 4 for an example of a screening results page for a participant randomized to the TM-PN condition who endorsed "Yes" to perceived need.

XSL•FO
RenderX

Figure 4. Sample screening results page: tailored message to perceived need condition, which included a tailored message to perceived need and nontailored featured resources.

Tailored Resources to Intended Next Steps (TR-INS) Condition



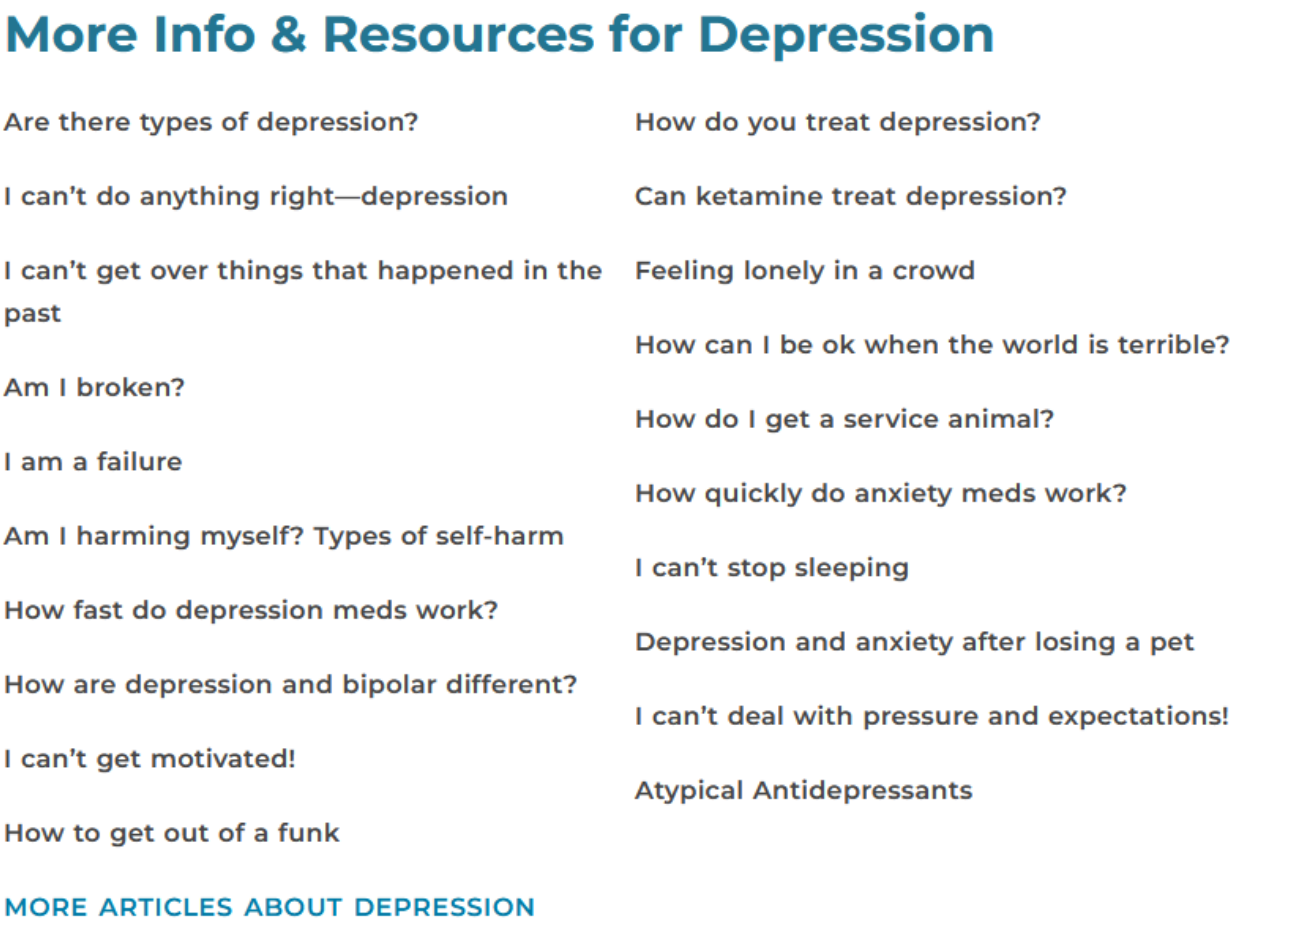
Participants who completed the Next Steps survey could also be randomized to the TR-INS condition, which included a nontailored message and 4 featured resources tailored to participants' responses to the intended next steps item. For example, a participant who selected "Understand what depression is like (reading articles)" was shown "What is depression really like?," "Am I depressed or just sad?," "Are there types of depression?," and "Am I broken?" in random order.

Tailored Message to Perceived Need + Tailored Resources to Intended Next Steps (TM-PN+TR-INS) Condition

The TM-PN+TR-INS condition was available to participants who completed the Next Steps survey. The TM-PN+TR-INS condition included a tailored message to perceived need and 4 featured resources tailored to participants' intended next steps. See Figure 5 for an example of a screening results page for a participant randomized to the TM-PN+TR-INS condition who endorsed "No" to perceived need and "Find a treatment provider near you" as their intended next steps.

XSL•FO
RenderX

Figure 5. Sample screening results page: tailored message to perceived need + tailored resources to intended next steps condition.



Persistent General Resources

Persistent general resources included links to resources related to depression. Persistent general resources were shown underneath featured resources on the screening results page to all participants, independent of condition (see Figure 6).

XSL•FO
RenderX

Figure 6. Examples of persistent general resources (shown to all participants independent of condition) displayed underneath featured resources on screening results pages.

Programming Errors

Two minor programming and execution errors occurred. All conditions were intended to receive 4 resources, but only 3 were shown to participants in the 45+ years age group in the TR-D condition, unless they also indicated being LGBTQ+. However, this only affected a small portion of the sample. People who reported that they lived in Minnesota (2.1% of the 77% of participants who provided their state of residence) were shown a Minnesota-specific resource in place of one of the featured resources.

Measures

Demographics Survey

Participants were invited to provide their age range, gender, race and ethnicity, and household income. They were also asked to select applicable descriptors among veteran or active-duty military, caregiver of someone living with emotional or physical illness, LGBTQ+, student, trauma survivor, new or expecting parent, and healthcare worker.

Next Steps Survey

The Next Steps survey included 2 tailoring questions shown before the demographics survey items. The first question asked about participants' intended next steps: "What is the main thing you want to do after taking this mental health test? (Select one)." Response options included, but were not limited to, "Take another mental health test," "Understand what depression is like (reading articles)," and "Understand and manage self-harm or suicidal thoughts." The second tailoring item assessed perceived need ("Do you feel like you need to do something to improve your mental health?") with options of "Yes," "No," and "I don't know."

Engagement

Our primary engagement outcome was disengagement, operationalized as leaving the website or having ≥30 minutes of inactivity (0=engaged, 1=disengaged). We also measured engagement on the screening results page by whether participants clicked a featured or persistent general resource (0=clicked a persistent general resource, 1=clicked a featured resource).

Analyses

Impact of Adding Tailoring Questions on Engagement

Data were analyzed in R Version 4.3.3 (R Core Team) [24], and all research questions were examined via logistic regressions. We assessed whether Level 1 condition (ie, demographics survey or Next Steps survey) was a significant predictor of disengaging from the postscreening survey to examine the costs, if any, of adding tailoring questions. For the remaining analyses, we used 2-part models to first examine the odds of disengaging from the screening results page by Level 2 condition. We then examined the odds of clicking a featured

XSL•FO
RenderX

versus a persistent general resource among participants who chose to engage on the screening results page. Statistical significance was not impacted after corrections for multiple comparisons using the Benjamini-Hochberg procedure with a false discovery rate of 0.05 [25]. We report odds ratios (OR) with 95% CIs and *P* values.

Impact of Tailoring on Engagement

Among participants who submitted the demographics survey (n=38,490), we examined whether the odds of disengaging (versus engaging) and clicking a featured resource (versus clicking a persistent general resource) on the screening results page significantly differed for participants in the TR-D condition compared with the nontailored condition. Among participants who submitted the Next Steps survey (n=34,204), we tested whether engagement significantly differed for participants in the TM-PN, TR-INS, and TM-PN+TR-INS conditions compared with the nontailored condition.

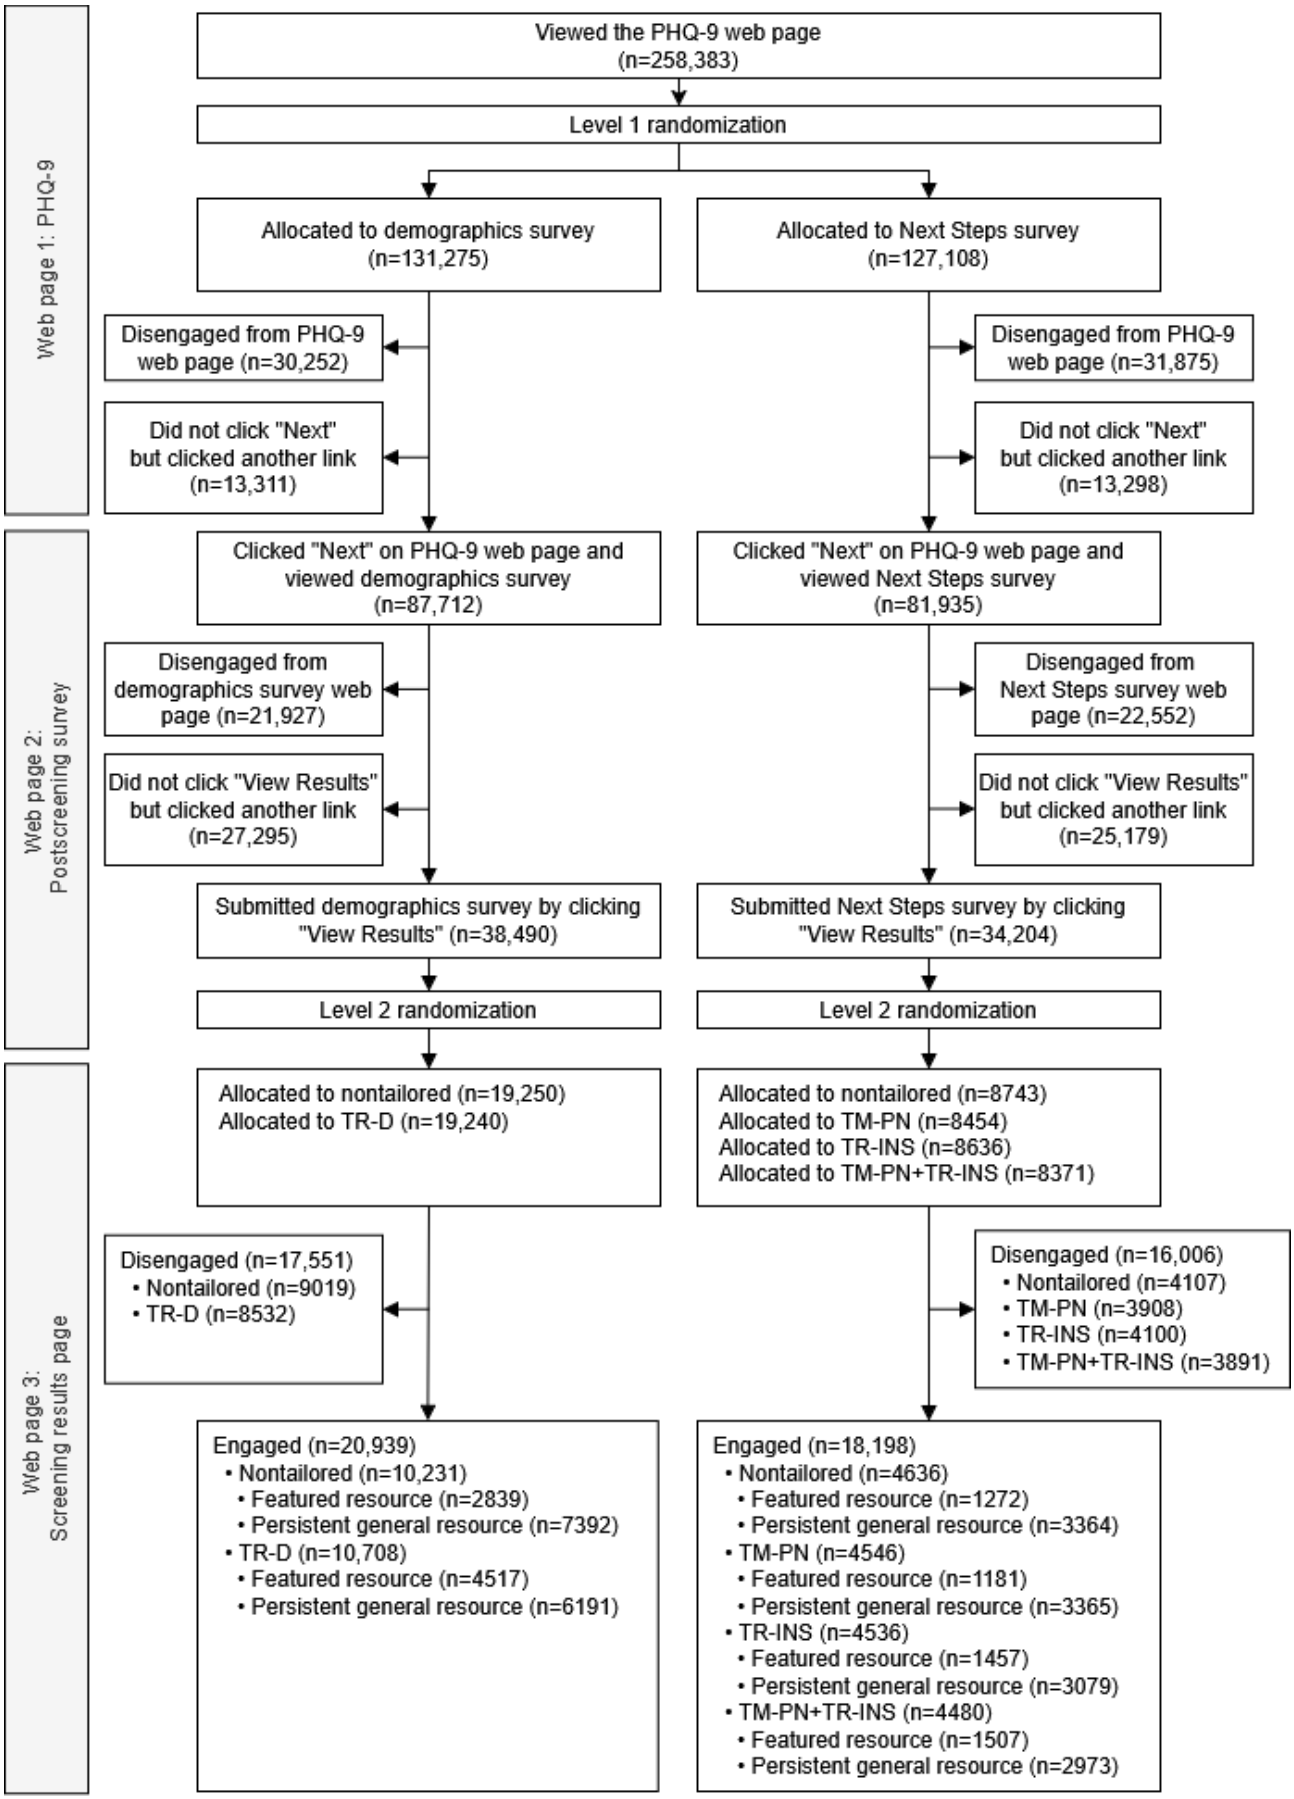
Identifying the Optimal Tailoring Strategy in This Study

We aimed to identify the optimal tailoring strategy among those tested in this study by comparing engagement across all possible conditions on the screening results page, with TR-D set as the reference group. Conditions included nontailored (including participants from both the demographics survey and Next Steps survey conditions), TR-D, TM-PN, TR-INS, and TM-PN+TR-INS.

Ethical Considerations

This study was approved by the University of Washington Institutional Review Board (STUDY00010958). The Institutional Review Board and the study's external Data Safety and Monitoring Board concluded that there were no foreseeable risks associated with participation in the study, and further application for ethical approval was not necessary. MHA visitors engaged with the website naturalistically, and the website's terms and conditions include provisions around the use of user data for research. Thus, the Institutional Review Board waived informed consent, and participants were not compensated for their involvement in the study. Data were protected under the University of Washington Institutional Review Board and were deidentified via random identifiers before data transfers between MHA and the University of Washington in accordance with a Data Security Protocol. The deidentified data were stored on a secure encrypted institutional server with access restricted to approved research personnel only.

Results



Sample Characteristics

Among participants who clicked the PHQ-9 (n=258,383), 131,275/258,383 (50.8%) were randomized to the demographics survey, and 127,108/258,383 (49.2%) were randomized to the Next Steps survey. See Figure 7 for the study flow diagram. Among participants who viewed a postscreening survey (n=169,647), 87,712/169,647 (51.7%) participants were allocated to the demographics survey condition, and 81,935/169,647 (48.3%) were allocated to the Next Steps survey condition. Most participants who submitted a postscreening survey (n=72,694) had moderately severe or severe depression (mean 15.9, SD 6.1). Among participants who also provided demographic data, most were White (n=37,311/69,385, 53.8%); Hispanic or Latino (n=10,218/69,385, 14.7%); Asian (n=6647/69,385, 9.6%); Black or African American (n=6532/69,385, 9.4%); women (n=43,517/71,963, 60.5%); and between 18 - 24 years old (n=15,604/71,529, 21.8%; see Table 1). Among participants who responded to the intended next steps tailoring question (n=33,002), the most common responses were "I don't want to do anything" (n=12,034, 36.5%) followed by "Take another mental health test" (n=4740, 14.4%). Among participants who responded to the perceived need item (n=33,352), 60.9% (n=20,325) of participants endorsed "Yes" to perceived need (see Table 2). Among participants randomized to a Level 2 condition (n=72,694), disengagement rates on the screening results page ranged from 44.3% to 47.5% by condition. Among those who engaged on the screening results page (n=39,137), rates of clicking a featured resource ranged from 26% to 42.2%, and rates of clicking a persistent general resource ranged from 57.8% to 74% by condition.

Small Cost to Engagement by Adding Tailoring Questions

Table 3 displays logistic regression model estimates. Compared with the demographics survey condition, 625 more participants in the Next Steps survey condition disengaged from the postscreening survey web page. Disengagement rates were 25% for participants in the demographics survey condition and 27.5% for participants in the Next Steps survey condition. Participants who viewed the Next Steps survey had a 14% increase in the odds of disengaging from the postscreening survey (odds ratio [OR] 1.14, 95% CI 1.11 - 1.16; *P*<.001) compared with participants who viewed the demographics survey.

Table . Logistic regression model estimates predicting the odds of disengaging (versus engaging) and clicking a featured resource (versus clicking a persistent general resource) by condition.

Predictors	Disengagement[a]		Click on featured resource[b]	
	OR[c] (95% CI)	*P* value	OR (95% CI)	*P* value
Model 1: disengagement on the postscreening survey web page by Level 1 condition				
Demographics survey	Reference	Reference	—[d]	—
Next Steps survey	1.14 (1.11 - 1.16)	<.001	—	—
Model 2: demographics survey; disengagement on the screening results page by Level 2 condition				
Nontailored	Reference	Reference	Reference	Reference
TR-D[e]	0.90 (0.87 - 0.94)	<.001	1.90 (1.79 - 2.01)	<.001
Model 3: Next Steps survey; disengagement on the screening results page by Level 2 condition				
Nontailored	Reference	Reference	Reference	Reference
TM-PN[f]	0.97 (0.91 - 1.03)	.33	0.93 (0.85 - 1.02)	.11

TM-PN+TR-INS[h]	0.98 (0.92 - 1.04)	.52	1.34 (1.23 - 1.47)	<.001
Model 4: optimal tailoring strategy; disengagement on the screening results page by Level 2 condition				
TR-D	Reference	Reference	Reference	Reference
Nontailored[i]	1.11 (1.07 - 1.15)	<.001	0.52 (0.50 - 0.55)	<.001
TM-PN	1.08 (1.02 - 1.14)	.004	0.48 (0.45 - 0.52)	<.001
TR-INS	1.13 (1.08 - 1.19)	<.001	0.65 (0.60 - 0.70)	<.001
TM-PN+TR-INS	1.09 (1.04 - 1.15)	.001	0.70 (0.65 - 0.75)	<.001

[a]Reference: engaged; Model 1: n=169,647; Model 2: n=38,490; Model 3: n=34,204; Model 4: n=72,694.

[b]Reference: click on persistent general resource; Model 2: n=20,939; Model 3: n=18,198; Model 4: n=39,137.

[c]OR: odds ratio.

[d]Not applicable.

[e]TR-D: tailored resources to demographics.

[f]TM-PN: tailored message to perceived need.

[g]TR-INS: tailored resources to intended next steps.

[h]TM-PN+TR-INS: tailored message to perceived need + tailored resources to intended next steps.

[i]Includes participants in both the demographics survey and Next Steps survey conditions (Level 1) who were subsequently randomized to the nontailored condition (Level 2).

TR-D Reduced Disengagement and Increased Clicks on Featured Resources

Among participants who viewed the screening results page after submitting the demographics survey, those who received resources tailored to demographics had a 10% decrease in the odds of disengaging (OR 0.90, 95% CI 0.87 - 0.94; *P*<.001) compared with participants in the nontailored condition. Participants in the TR-D condition had a 90% increase in the odds of clicking a featured resource versus a persistent general resource (OR 1.90, 95% CI 1.79 - 2.01; *P*<.001) compared with participants in the nontailored condition.

TR-INS and TM-PN+TR-INS Increased Clicks on Featured Resources

Among participants who viewed the screening results page after submitting the Next Steps survey, there were no significant differences in the odds of disengaging for participants in the TM-PN (*P*=.33), TR-INS (*P*=.51), and TM-PN+TR-INS (*P*=.52) conditions compared with the nontailored condition. However, there were statistically significant differences in the odds of

XSL•FO
RenderX

clicking a featured resource versus a persistent general resource among those who engaged. Compared with the nontailored condition, those in the TR-INS condition had a 25% increase in the odds of clicking a featured resource (OR 1.25, 95% CI 1.14 - 1.37; *P*<.001), and those in the TM-PN+TR-INS condition had a 34% increase in the odds of clicking a featured resource (OR 1.34, 95% CI 1.23 - 1.47; *P*<.001). There was no significant difference in the odds of clicking a featured resource between the nontailored and TM-PN conditions (*P*=.11).

Tailoring to Demographics Was the Optimal Tailoring Strategy in This Study

Tailoring resources to demographics yielded the best engagement outcomes compared with the remaining Level 2 conditions. Compared with participants shown resources tailored to demographics, those in the remaining conditions had 8%-13% greater odds of disengaging (*P*≤.004) and, among participants who engaged, had 30%-52% fewer odds of clicking a featured resource versus a persistent general resource on the screening results page (*P*<.001).

Discussion

Principal Findings

This study examined whether personalizing content increased engagement with a self-guided mental health website. There was a small but statistically significant cost to engagement from adding tailoring questions assessing perceived need and intended next steps, and tailoring resources to demographics was the most effective strategy used in this study. Appealing to perceived need alone via tailored messages, as chosen in this study based on HAPA theory, did not improve engagement. We speculate that this may be the case because although perceived need may be associated with intent to take action, intent is not necessarily associated with taking health actions (ie, the intention-behavior gap) [26]. Individuals with a perceived need to act may not be ready to do so immediately after viewing their screening results, and it is possible that increased cognitive load due to the additional text of tailored messages discouraged further engagement [27]. However, we also observed that while tailored resources to intended next steps increased the odds of clicking a featured resource by 25%, combining a tailored message to perceived need with tailored resources to intended next steps further increased those odds to 34%. It is possible that there was an interaction effect, such that tailored messages to perceived need may have facilitated engagement when individuals were also provided with resources relevant to their needs. Moreover, the HAPA has been used to describe behaviors that change over periods of days to weeks [18]. Whether the HAPA or other frameworks of health behavior change apply to long-term engagement with mental health websites remains unknown.

Design Implications

Our findings have important generalizable design implications for implementing tailoring on websites to enhance engagement:

1. Defining engagement: we used indicators for disengagement and clicks on web-based resources to assess the impact of tailoring on early engagement. It is important that the operationalization of engagement aligns with the context of each study. For example, research questions related to long-term engagement may be better addressed by engagement outcomes such as total number of clicks, length of time spent on each web page, and whether visitors return to the website.
2. Selecting tailoring variables: tailoring variables may include, but are not limited to, any number of demographics, screening results, behavioral characteristics, and theoretical constructs of behavior change. Our preliminary MRTs identified variables that may be related to engagement specific to the MHA website. However, it is likely that engagement with websites that offer different types of resources or that are targeted toward specific populations is associated with variables not used for tailoring in this study. We recommend conducting pilot studies to identify potential tailoring variables related to engagement unique to each website. Researchers are also advised to consider the production costs of tailoring (eg, whether existing materials can be used or if new materials and design elements will need to be developed).
3. Acceptability of tailoring: researchers must also consider the acceptability of tailoring to demographics without suggesting that those characteristics are causal factors of visitors' mental health problems [28]. For example, while tailoring to demographics was an effective strategy in this study, tailoring solely to LGBTQ+ status may have an inadvertent stigmatizing effect by implying to visitors that their depressive symptoms stem from their LGBTQ+ identity. Alternatively, researchers may ask participants about what they believe contributes to their mental health issues and tailor content accordingly.
4. Balancing costs and benefits: it is critical to identify the appropriate threshold for the number of tailoring questions to add to a website such that the costs of tailoring (ie, in this study, disengagement due to the addition of tailoring questions) do not outweigh the benefits. However, what constitutes costs and benefits depends on the goals of each website. For example, in some contexts, research questions may be better answered by retaining visitors who are willing to invest time and energy into answering many tailoring questions.
5. Randomization procedures: in the current study, participants were allocated to a Level 1 condition through simple randomization on the PHQ-9 web page, on which a link to the appropriate postscreening survey was generated. In addition, MHA does not retain screening data from visitors who do not submit a postscreening survey. Allocations to Level 1 conditions among participants who viewed a postscreening survey were slightly imbalanced (51.7% versus 48.3%) due to when randomization was triggered. To ensure balanced allocation to experimental conditions, future studies may use a 1:1 allocation among participants who meet inclusion criteria while taking existing data saving procedures into account.

Strengths and Limitations

Our study was a large-scale randomized trial in an ecologically meaningful setting with a help-seeking population. Additional

XSL•FO
RenderX

strengths include the use of objective measures of engagement and our design implications for implementing tailoring on websites. The generalizability of our findings may be limited to self-guided mental health websites, as opposed to other digital mental health formats (eg, apps and interventions).

One limitation of the study was that content could only be tailored for participants who responded to tailoring questions. By necessity, we could not assess the impact of tailoring for individuals who did not provide tailoring data. In addition, both featured resources and persistent general resources may have varied in appeal regardless of visitors' personal characteristics and preferences. Nevertheless, our approach used MHA's existing resources to align with the research questions as closely as possible in a real-world setting.

Another limitation was the use of IP addresses to identify individual website visitors. This method may not reliably distinguish between responses from multiple individuals accessing the website from within the same household or from visitors connected to a shared public network. However, MHA's internal data cleaning procedures exclude entries from IP addresses of known public spaces (eg, libraries and schools; see Multimedia Appendix 1). Our analyses retained only the first entry from each unique IP address, which may have excluded data from additional visitors accessing the website from the same IP address. Nonetheless, our approach was a practical means of tracking website activity at a large scale, minimizing duplicate entries, and preemptively excluding responses from potential bots before analyses.

Future Directions

This study focused on identifying strategies to enhance immediate engagement outcomes and was not designed to assess health behavior change over the long term. Tailoring to perceived need based on HAPA theory was effective in increasing the odds of clicking featured resources only when paired with tailored resources to participants' intended next steps on the website. It is possible, however, that these decision processes are not well-suited for HAPA theory and that other guiding frameworks are needed for future research in this area. For example, other theoretical frameworks that have been used to tailor web-based interventions (eg, the theory of planned behavior [29], the transtheoretical model [30], and social cognitive theory [31]) may further guide research toward establishing optimal tailoring strategies on mental health websites. Future research may also test tailored messages that incorporate stronger calls to action intended to shift ambivalence (eg, via motivational interviewing language [32]). Given our evaluation of a restricted set of tailoring strategies, our findings provide an indication toward an optimal tailoring strategy for mental health websites. It is possible that other strategies not examined in this study, such as mode tailoring [33] or psychographic targeting [11], may also increase engagement in similar contexts. In addition, personal contexts and barriers can be assessed through open-ended questions to better understand contextual factors that may impact engagement with mental health websites, and long-term engagement patterns may be explored by identifying optimal times for re-engaging visitors when they are ready to access mental health resources.

Conclusion

Mental health websites have the potential to serve millions of people with mental health concerns, particularly those who face barriers to treatment, yet their resources are underutilized. This study addresses the critical need for empirical research on effective strategies for connecting mental health website visitors with digital mental health resources. Our findings provide evidence that personalizing resources to demographic characteristics can enhance engagement with mental health websites: in this study, visitors who were shown resources tailored to demographics had 10% fewer odds of disengaging and, among those who engaged, 90% greater odds of clicking a featured versus a persistent general resource. We provide design implications for future research, which may explore alternative frameworks of behavior change, test different tailoring variables and strategies, and evaluate engagement over repeated visits. Researchers are encouraged to continue to address these gaps to improve engagement with mental health websites and better support individuals seeking web-based mental health information.

Abstract

Background: Mental health–related artificial intelligence (MH-AI) systems are proliferating across consumer and clinical contexts, outpacing regulatory frameworks and raising urgent questions about safety, accountability, and clinical integration. Reports of adverse events, including instances of self-harm and harmful clinical advice, highlight the risks of deploying such tools without clear standards and oversight. Federal authority over MH-AI is fragmented, leaving state legislatures to serve as de facto laboratories for MH-AI policy. Some states have been highly active in this area during recent legislative sessions. Yet, clinicians and professional organizations have mainly remained absent or sidelined from public commentary and policymaking bodies, raising concerns that new laws may diverge from the realities of mental health care.

Objective: To systematically analyze recent state-level legislation relevant to MH-AI, categorize bills by relevance to mental health, identify major regulatory themes and gaps, and evaluate implications for clinicians and patients.

Methods: We conducted a systematic analysis of bills introduced in all 50 US states between January 1, 2022, and May 19, 2025, using standardized searches on the legislative research website (LegiScan). Bills were screened and categorized using a custom 4-tier taxonomy based on their applicability to MH-AI. Bills passing threshold review were coded by topic using a 25-tag system developed through iterative consensus. Legally trained reviewers adjudicated final classifications to ensure consistency and rigor.

Results: Among 793 state bills reviewed, 143 were identified as potentially impactful to MH-AI: 28 explicitly referenced mental health uses, while 115 had substantial or indirect implications. Of these 143 bills, 20 were enacted across 11 states. Legislative efforts varied widely, but 4 thematic domains consistently emerged: (1) professional oversight, including deployer liability and licensure obligations; (2) harm prevention, encompassing safety protocols, malpractice exposure, and risk stratification frameworks; (3) patient autonomy, particularly in areas of disclosure, consent, and transparency; and (4) data governance, with notable gaps in privacy protections for sensitive mental health data.

Conclusions: State legislatures are rapidly shaping the regulatory landscape for MH-AI, but most laws treat mental health as incidental to broader artificial intelligence or health care regulation. Explicit mental health provisions remain rare, and clinician and patient perspectives are seldom incorporated into policymaking. The result is a fragmented and uneven environment that risks leaving patients unprotected and clinicians overburdened. Mental health professionals must proactively engage with legislators, professional organizations, and patient advocates to ensure that emerging frameworks address oversight, harm, autonomy, and privacy in ways that are clinically realistic, ethically sound, and supportive of flexible—but responsible—innovation.

Introduction

The use of mental health–related artificial intelligence (MH-AI) is rapidly expanding, both in consumer and clinical domains. In this paper, MH-AI is broadly defined as any artificial intelligence (AI) system used in the delivery, facilitation, or simulation of mental health services. In April 2025, the Harvard Business Review reported that therapy and companionship had

XSL•FO
RenderX

become the most frequently cited use cases for generative AI systems mentioned online [1]. Tens of millions of individuals are already engaging with AI systems as human-like companions, so-called "emotional support tools," to ask mental health-related questions, or even as stand-in therapists [2-4]. On the clinical side, in one study, 33% (45/138) of psychiatrists recently reported using OpenAI's ChatGPT to assist with clinical care, and—in the same study—75% (104/138) believed that patients are likely to consult generative AI before seeking a medical provider [5]. Practitioners, health systems, researchers, and other stakeholders are increasingly exploring the use of AI in various applications, including administering mood scales, diagnosis and treatment, risk stratification, administrative support, drug design, and the detection and monitoring of severe mental illnesses, with varying degrees of success [4,6-8].

These advances, however, are not without risk. While the authors identified no systematic review of harms related to MH-AI, numerous high-profile reports in the media of troubling adverse events—including alleged suicidal [9,10] and homicidal [11] acts—have been documented, contributing to the development of a dedicated "AI Incident Database" aimed at raising public awareness of the potential dangers of AI [12]. Further illustrating the risks, the Center for Countering Digital Hate recently found that generative AI tools produced harmful eating disorder information in 41% (74/180) of reviewed samples, such as recommending hiding uneaten food from parents and, with even the most restrictive AI tested, offering the advice of swallowing a tapeworm egg to lose weight under certain easily achieved conditions [13]. Such examples highlight how easily MH-AI tools can shift from supportive to harmful, particularly when deployed without clear standards, safeguards, or human oversight.

Multiple federal agencies and laws, including the Food and Drug Administration, Federal Trade Commission, Department of Health and Human Services, and the Health Insurance Portability and Accountability Act (HIPAA), exercise limited oversight over MH-AI technologies. However, federal authority in this space is constrained by the specific mandates and domains of each agency or statute, a fuller discussion of which can be found in studies by Kahane et al [14,15]. As a result, many MH-AI tools fall into regulatory gray zones or remain exempt from rules governing other medical technologies, particularly so-called "wellness" products and other technologies not specifically marketed as medical or therapy products [7,14-17]. In the absence of a comprehensive federal framework, there is little unified guidance for states or stakeholders. Consequently, states have become de facto policy laboratories, with state legislatures proposing hundreds of AI-related bills since 2022.

Despite the growing legislative interest in AI, public commentary from clinicians on specific proposed state MH-AI laws remains muted. Even major professional organizations, such as the American Psychiatric Association and the American Psychological Association, have issued mainly limited position statements, stopping short of offering detailed practice guidelines or public policy recommendations [16,17]. This absence of public clinical input is troubling given the complexity of regulating mental health care, where risks to patient safety, autonomy, professional ethics, and standards of care are profound. As explored throughout this paper, most proposed and enacted state laws lack meaningful integration of clinical insight and fail to address mental health use cases, thereby raising the risk that future norms (both regulatory and clinical) will be misaligned with the realities of patient care. In response, this paper synthesizes findings from a comprehensive review of state-level MH-AI legislation to identify emerging legislative trends and crucial gaps, as well as highlights the urgent need for clinician and patient engagement in shaping the future of MH-AI policy.

Methods

The authors conducted a systematic analysis of state legislative activity across all 50 US states between January 1, 2022, and May 19, 2025, to identify bills relevant to the intersection of AI and mental health. The year 2022 was chosen as the start of the range due to both the lack of significant bills related to MH-AI before this year on initial review and the first public release of OpenAI's ChatGPT in November 2022, which marked a turning point in legislative activity on this front. The search was conducted on May 19, 2025. The search was limited to this date to allow the reviewers to conduct a cross-sectional analysis of bills without needing to account for changing bill status. This search was conducted on the LegiScan website to ensure that querying methods were consistent across states, regardless of variations in individual legislative website design and search functionality [18]. Boolean search queries that paired AI-related terms with mental health-related terms were used in order to narrow results to bills plausibly implicating MH-AI, while excluding bills referencing AI or mental health in isolation and unrelated contexts. The following process was used: (1) navigate to LegiScan, (2) set sessions to "all," and (3) for each state, the following query was used: intro:20220101..20250519 AND ("artificial intelligence" OR "predictive model" OR chatbot OR LLM OR "language model" OR "machine learning" OR "deep learning") AND (mental OR behavioral OR psych OR healthcare OR "health care").

Each retrieved bill was screened for initial relevance by 1 of 4 authors, each responsible for approximately a quarter of the bills. Furthermore, 2 authors were legally trained (JNS and CAL), and 2 had undergone multiple rounds of training to achieve rating reliability (ER and MF). All bills were then reviewed a second time by the first author (JNS), also a legally trained individual, to make a final adjudication. Bills determined to have no plausible bearing on MH-AI were coded as Not Relevant (NR) and excluded from further analysis. Companion bills with versions in both state legislative chambers and bills continued from a previous legislative session were excluded if a more recent version was available.

Bills passing the threshold screen were then independently reviewed by 2 research assistants (ER and MF) using a 4-tiered coding taxonomy developed by the study team (Table 1). This taxonomy distinguished bills based on the specificity and relevance of their relationship to MH-AI systems and clinical practice. A legally trained researcher (CAL) reviewed these codings and provided an opinion on any that lacked complete

XSL•FO
RenderX

consensus. Any bills that received consensus from the majority of reviewers were labeled accordingly. The first author (JNS) reviewed all bills without a majority consensus and made a final determination for taxonomy coding purposes.

Following taxonomy coding, each of the remaining bills was independently reviewed by 2 research assistants (CH and WX) using a set of 25 predefined topic tags, as described in Table 2. These tags were developed through an iterative consensus process based on terms and provisions found in the collected bills during the initial relevance threshold review. Tags were selected for their topical significance to the intersection of AI and mental health. Tag assignment was descriptive rather than qualitative, signaling only that the tag's specific topic was addressed in the bill in some form. A second pair of research assistants (ER and MF) subsequently reviewed and reconciled any discrepancies in tagging. Final review and quality control were conducted by a legally trained member of the research team to ensure consistency and interpretive rigor.

Table . Four-tier coding taxonomy for classifying state artificial intelligence bills by relevance to mental health applications, with code labels, definitions, and inclusion criteria.

Code	Category	Definition	Inclusion criteria
E[a]	Explicit	Bills that explicitly reference mental health, behavioral health, psychotherapy, or related services in the context of AI[b] development, regulation, or application.	The bill directly names mental health uses of AI, specific clinical applications, or mental health contexts as targets of regulation, policy, or oversight.
SR[c]	Substantively relevant	Bills that govern MH-AI[d] in ways that have direct, foreseeable implications for mental health services or stakeholders, even if mental health is not explicitly or substantively discussed in the bill's text.	The bill regulates MH-AI in a way that predictably impacts mental health uses, delivery, or providers, regardless of whether mental health is explicitly mentioned.
II[e]	Incidentally implicative	Bills that are broadly written and might include MH-AI, but only in a general or indirect way. Clinical impact is uncertain or minimal.	MH-AI falls or could fall under the bill's scope, but direct mechanisms or practical effects at the clinical level are not apparent or minimal.
NR[f]	Not relevant	Bills with no meaningful relationship to MH-AI services, even under expansive interpretations.	The bill does not touch on mental health services.

[a]E: explicit.

[b]AI: artificial intelligence.

[c]SR: substantively relevant.

[d]MH-AI: mental health–related artificial intelligence.

[e]II: incidentally implicative.

[f]NR: not relevant.

XSL•FO
RenderX

Table . Definitions of the 25 topic tags and their frequency among included mental health–related artificial intelligence bills (n=143); counts indicate presence of a topic, not strength or quality.

Tag	Number of bills	Definition
Civil penalties	100	Applies any kind of civil penalty to violators (eg, noncriminal penalties such as system suspension, civil fines, creation of private right of action to sue, profit disgorgement, suspension of noncompliant systems, punitive monitoring, or application of a separate civil enforcement statute).
Disclosure or consent	96	Implements any requirement to disclose use or features of the AI[a] system (including disclaimers), consent to the use of such systems or features, or the ability to revoke consent.
Transparency	90	Implements requirements involving public or patient rights to access AI system data (eg, requests to obtain data, public inventories of AI systems, publication, or transparency requirements).
Consumer protection	84	Provisions concerning fraudulent, manipulative, or deceptive use of MH-AI[b] systems, including in advertising.
Monitoring	80	Applies any kind of monitoring requirements for MH-AI (eg, live supervision, submission to audits or documentation processes, generation of reports, or postmarket surveillance).
Data protection	77	Implements any requirements for data privacy, data security, or data retention or deletion (eg, encryption requirements, secure storage, or data purging policies).
Discrimination or bias	68	Implements any requirement regarding discrimination, bias, or fairness.
Postmarket review	66	Implements requirements for any level of scheduled or routine review after the AI product has been marketed or implemented (eg, postmarket surveillance, auditing, risk assessments, and efficacy reviews), subject to regulatory oversight.
Safety standards	50	Pertains to safety standards for MH-AI (eg, human overrides, emergency protocols, or prohibitions on high-risk uses) or safety-based exceptions to other requirements (eg, bypassing procedures when delays risk harm and allowing immediate protective actions).
Vulnerable populations	50	Creates any responsibilities related to vulnerable populations (eg, older adults, children, disabled, and foreign-language speakers), such as mandated reporting requirements, accessibility requirements, or parental controls.
Human-in-the-loop	49	Explicitly requires a human to monitor, approve, or participate in an essential part of the provision of the MH-AI service.
Meta or biometric data	46	Regulates biometric data, behavioral data, or metadata used by MH-AI systems.
Research	45	Pertains to or would affect mental health research (eg, data collection, consent requirements, ethical guidelines, and exemptions for legitimate research use).
Practitioner responsibilities	37	Applies any kind of requirements on practitioners—or waivers or exemptions—related to their use of AI systems.

XSL•FO
RenderX

Tag	Number of bills	Definition
Risk classification	34	Implements or defines the scope of the law by a risk classification system (eg, "high risk" AI system, consequential decisions, and similar frameworks).
Premarket review	34	Implements requirements for any level of regulatory review before the AI product being offered or implemented (eg, state commission approval, FDA[c] approval, and submission of risk assessments).
Event reporting	29	Creates a system for reporting adverse events, near misses, or other safety events involving MH-AI.
Special purpose entities	22	Creates or assigns committees, subcommittees, task forces, or similar special-purpose bodies pertaining to MH-AI.
Opt out	18	Provides for the ability to opt out of AI services in favor of receiving equivalent human-delivered health services.
Licensing board oversight	17	Applies any kind of oversight by state professional licensing boards (eg, requiring board approval of MH-AI systems used in diagnosis and treatment or allowing boards to discipline individuals or systems).
Malpractice or liability	16	Pertains to medical malpractice involving AI, including liability allocation for AI-related harm (eg, standards of evidence, assigning responsibility to deployers, developers, practitioners, or manufacturers, liability shields or limitations, and use of MH-AI records and data in litigation).
Criminal penalties	11	Applies any kind of criminal penalty to violators (eg, criminal fines, incarceration, and misdemeanor or felony designations).
Pilot or sandbox	11	Provides for regulatory pilot programs or sandbox systems, allowing AI products to be tested and receive feedback from regulators prior to full marketing.
Payments or insurance	10	Regulations on insurance coverage, reimbursement, and payment models.
Prescribing	2	Applies any requirements or waivers regarding prescriptions.

[a]AI: artificial intelligence.

[b]MH-AI: mental health–related artificial intelligence.

[c]FDA: Food and Drug Administration.

Results

The search yielded 793 total bills, of which 523 were excluded after initial threshold review as NR, and 124 were excluded as companion bills or superseded versions. The 146 bills remaining underwent complete taxonomy coding. Following consensus determination and final review, 3 additional bills were recoded as NR, leaving 143 bills in the final analytic sample. Among these, 28 were classified as Explicit, 79 as Substantively Relevant (SR), and 36 as Incidentally Implicative (II). Notably, of these bills, 20 had been enacted into law at the time of this analysis.

A state-by-state summary of the distribution of these codes has been illustrated in Figure 1 and Appendix S1 in Multimedia Appendix 1. Clear outliers include California with 19 bills meeting inclusion criteria and the 12 states with no bills meeting the inclusion criteria: Oregon, Michigan, Kansas, Tennessee, Idaho, Iowa, Delaware, Arizona, Wisconsin, West Virginia, Wyoming, and South Dakota.

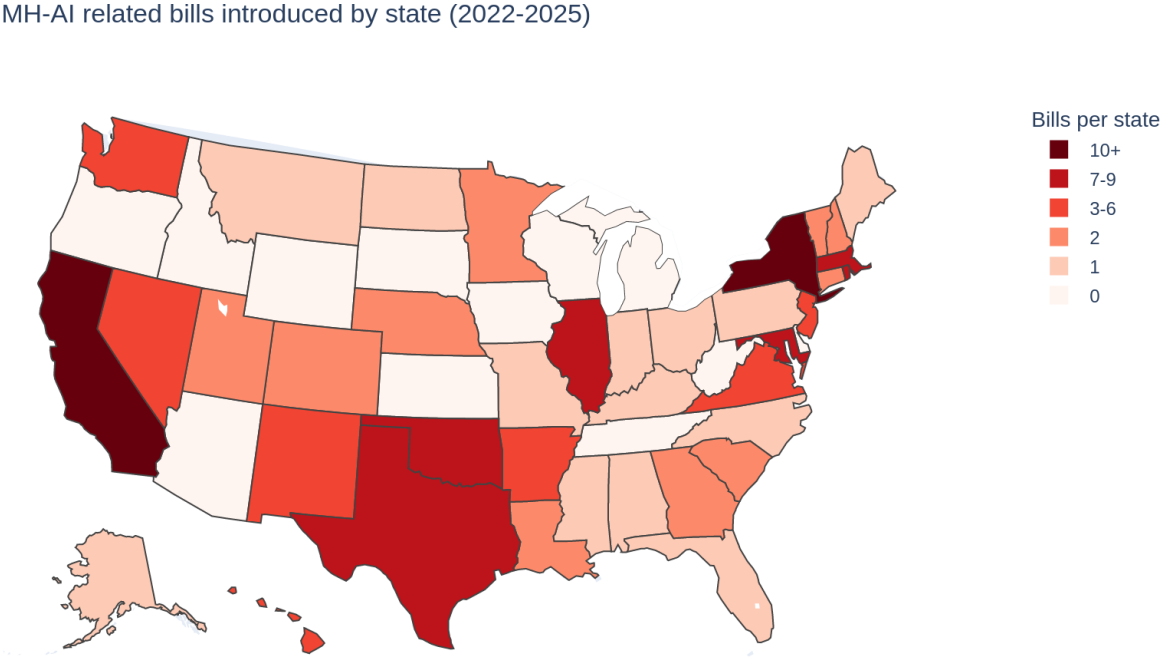
Tagging across these 143 bills revealed instances of all 25 tags with variable incidence (Table 2 and Figures 2,3).

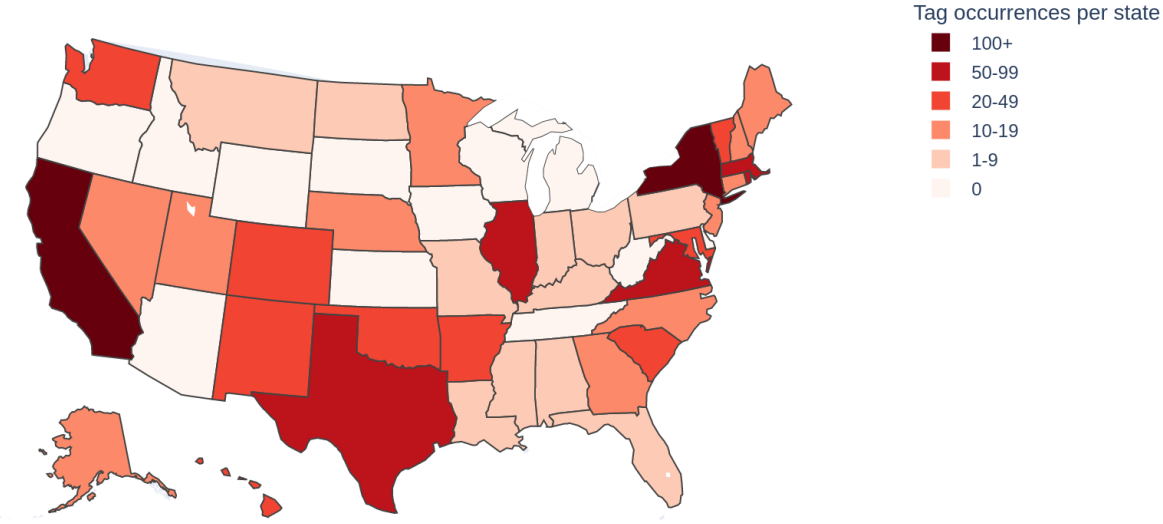
Individual analysis of taxonomy-coded bills and their tags revealed hundreds of variations of provisions potentially or explicitly impacting MH-AI. California, Texas, New York, and Virginia were notable outliers in the breadth of distinct tags

XSL•FO
RenderX

addressed by their proposed laws. Several notable policy directions and gaps also appeared, as described in Table 3 (sorted into significant areas of legal and clinical relevance).

Figure 1. State counts of mental health–related artificial intelligence–relevant bills introduced January 1, 2022-May 19, 2025, displayed as a choropleth (bins: 0, 1, 2, 3 - 6, 7 - 9, 10+). Counts exclude not relevant bills and deduplicate companion or superseded versions. MH-AI: mental health–related artificial intelligence.





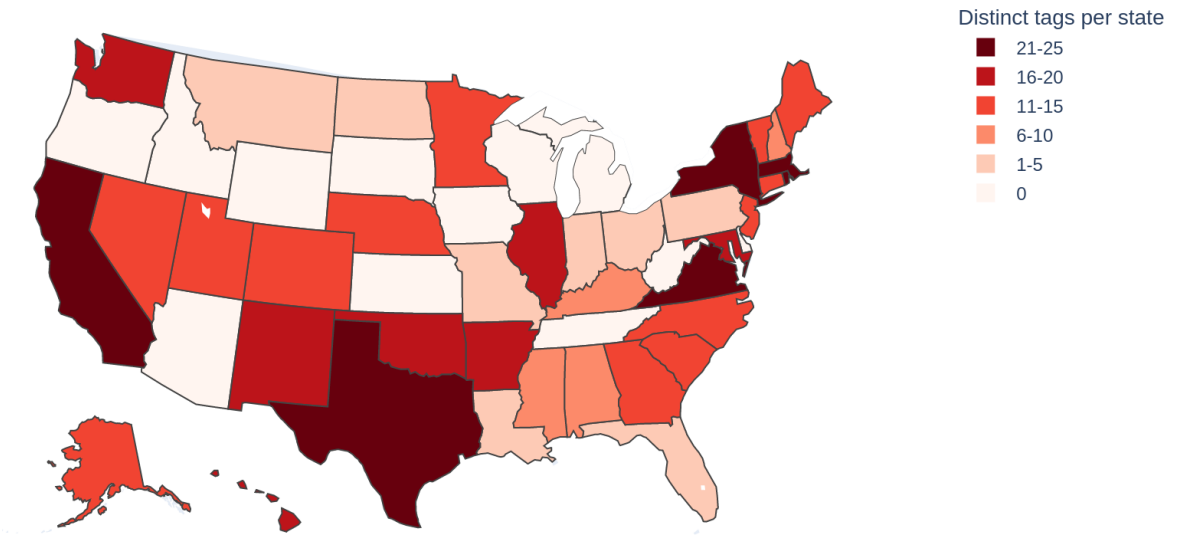


Figure 2. Total tag incidence by state. The sum of all tag occurrences across included bills (tags may appear in multiple bills; categories are nonmutually exclusive). Differences between tag density here and bill density in Figure 1 likely reflect individual bills that carry many tags, fragmented drafting that spreads topics across multiple narrower bills, and presence-based coding in which a single bill can receive multiple tags. MH-AI: mental health–related artificial intelligence.

XSL•FO
RenderX

Figure 3. Tag breadth by state: the number of unique topic tags (out of 25) represented in included bills introduced January 1, 2022-May 19, 2025. Each tag is counted once per state regardless of how many bills contain it; not relevant and companion or superseded bills are excluded. Higher values indicate wider topical coverage, not the strength or effectiveness of a state's mental health–related artificial intelligence framework (contrast with Figure 2's tag incidence). MH-AI: mental health–related artificial intelligence.

XSL•FO
RenderX

Table . Notable policy domains in mental health–related artificial intelligence state legislation: number of bills touching each domain (nonmutually exclusive; n=143).

Policy domain	Number of bills, n (%)
Professional oversight and responsibilities	
Explicit oversight by licensed mental health professionals required	6 (4.2)
Authorization for oversight by professional licensing boards	17 (11.9)
Governance and ethical standards	
Formation of special task forces, committees, or relevant entities with jurisdiction overlapping with MH-AI[a]	10 (7)
Ethical frameworks referenced to guide AI[b] use	12 (8.39)
Alignment with National Institute of Standards and Technology (NIST) or other national best-practice standards	14 (9.79)
Consumer protection and enforcement	
Violations explicitly tied to existing state consumer protection laws	39 (27.27)
Explicit creation of private right of action for AI-induced harms	30 (20.98)
Assignment of punitive or super-compensatory damages or penalties	11 (7.69)
Violations tied directly to professional disciplinary actions	12 (8.39)
Allocation of malpractice liability or responsibility for MH-AI harms, including strict liability, immunities, and affirmative defenses	11 (7.69)
User protections and disclosures	
Explicit informed consent requirements for MH-AI use	4 (2.8)
Mandated disclosure of AI interactions, including continuous or repeated disclosures	33 (23.08)
Restrictions on AI systems simulating professional licensure or impersonating clinicians	6 (4.2)
Restrictions on advertising	14 (9.79)
Right to human review of AI-decision appeals	17 (11.89)
Allows for users to opt out of AI services in favor of human-provided services	9 (6.29)
Crisis response and safety	
Mandated crisis response planning for suicidal ideation or threats	8 (5.59)
Exemptions from certain requirements (eg, data privacy) when compliance could result in harm	15 (10.49)
Special populations and agency-specific provisions	
Specific protections designated for children	39 (27.27)
Application exclusively to state agencies and organizations	9 (6.29)
Transparency and accountability	
Public registry or inventory of AI systems mandated	19 (13.29)
Exemptions for entities or data covered under HIPAA[c]	22 (15.38)

[a]MH-AI: mental health–related artificial intelligence.

[b]AI: artificial intelligence.

[c]HIPAA: Health Insurance Portability and Accountability Act.

No attempt was made to analyze the variance between enacted bills and unenacted bills, as such analysis would likely be arbitrary and misleading when the data were collected midlegislative session. However, an additional table and figures compiling tags associated only with enacted bills are provided in Appendix S2 in Multimedia Appendix 1**,** offering an interesting point of comparison. In keeping with the most rigorous legal data transparency methods described by Pepin et al [19], all legal mapping methods are described herein, and all results were integrated into a single publicly available database discussed below.

Discussion

Principal Findings

Despite growing interest in the use of AI in health care, few state laws explicitly address its application in mental health. This analysis reveals a fragmented policy environment in which mental health–specific considerations are often overlooked or subsumed under broader AI or health care regulations. In the sections that follow, the authors examine trends in legislative activity and identify 4 key policy domains—oversight, harm, autonomy, and privacy—that warrant closer attention. These domains are likely to shape how enacted legislation is interpreted, implemented, and enforced. Illustrative examples of bill provisions are presented alongside a discussion of critical regulatory gaps. Together, these findings suggest the need for more targeted policymaking to ensure that MH-AI technologies are developed and deployed in a manner that protects patients and supports mental health professionals in delivering effective and innovative clinical care.

Taxonomy Analysis

Of the 143 bills identified, only 28 explicitly address MH-AI, while 115 regulate MH-AI either substantially or incidentally. State-level patterns reveal an even sharper contrast. Only 13 states had proposed bills specifically mentioning mental health (or related terms), and, of these, only 3 had been enacted by the close of the study window. By comparison, 34 states had proposed laws that substantially or incidentally affected MH-AI regulation through provisions aimed at adjacent areas such as data privacy, general health care, or other regulatory domains. Of those, 17 were enacted. In total, only 2 states had enacted any explicit-coded laws from the sample (Utah [20] and New York [21]), 7 states enacted an SR-coded law, and 11 states enacted an II-coded law (Multimedia Appendix 1) at the time of data collection.

An explicit-coded bill example would include New Jersey's Senate Bill (SB) 4463, which explicitly prohibits AI systems from being advertised as licensed mental health professionals [22]. An example of an SR-coded bill is Rhode Island's SB 627, which aims to regulate "high-risk" AI systems making "consequential decisions," including those related to health care, and likely encompasses MH-AI systems [23]. However, the bill does not explicitly mention mental health or tailor its scope for mental health–related systems or services. It is possible that Rhode Island case law or agency guidance already interprets "health care" broadly enough to include mental health; however, such a consideration falls outside the scope of this study. In contrast, Missouri's House Bill (HB) 1462, an II-coded bill, establishes general legal definitions and liability rules for AI systems without addressing health care [24]. Although not designed with MH-AI in mind, its provisions could still influence the regulatory context in which these technologies operate.

This jumbled distribution of MH-AI legislation underscores significant disparities in regulatory attention and preparedness. States with little or no relevant legislation may be relying on outdated or overly broad frameworks ill-suited to address the unique risks of MH-AI tools [25,26]. Conversely, states enacting broad AI or health care laws without mental health–specific provisions may inadvertently leave gaps in oversight, particularly for technologies operating at the margins of existing legal and clinical frameworks. In either case, there is a strong argument that mental health practitioners should take an active role in shaping these rapidly evolving laws.

Trends and Themes

A closer analysis of the sampled bills reveals substantial variation in how states regulate MH-AI, with most efforts reflecting fragmented provisions rather than cohesive regulatory frameworks. Despite this heterogeneity, at least 4 prominent thematic domains emerge that require clinicians' attention. The following section organizes these themes and highlights illustrative examples that reveal consequential divergences in scope, emphasis, and implementation strategies relevant to MH-AI. Equally important, this paper also discusses some of the ways in which state legislation has failed to engage with MH-AI, leaving prominent gaps that carry implications for both practice and oversight.

Oversight

This section examines how a subset of state legislation addresses clinician oversight in MH-AI, focusing on 3 key areas: requirements for professional supervision, the integration of AI use into licensure and disciplinary frameworks, and the role of licensing boards in regulating state MH-AI.

A notable subset of legislation directly ties the use of AI to clinician responsibilities and professional licensure. For example, bills in Oklahoma, Texas, Rhode Island, and Massachusetts propose real-time professional supervision or continuous monitoring of MH-AI services [27-31]. Similarly, bills in Illinois, Louisiana, and Nevada would require clinicians to verify AI-generated outputs used in care delivery or communications (eg, Illinois HB 5649, Illinois HB 1806, Louisiana HB 114, Louisiana HB 916, Nevada Assembly Bill [AB] 406) [32-36]. Some states propose less stringent human oversight, mandating availability on request rather than continuous intervention (eg, Texas HB 4455) [37].

Several bills explicitly link compliance failures to professional disciplinary actions, effectively integrating AI use into the existing licensure framework (eg, Rhode Island HB 6285, Illinois HB 5649) [30,32,33,36,38-47]. Meanwhile, states such as Louisiana (HB 916), Georgia (HB 887), and Illinois (SB 2259) involve professional licensing boards directly, either to promulgate MH-AI rules or to explicitly approve clinical use (Massachusetts HB 1974, Rhode Island HB 6285) [30,31,35,38,47]. California's SB 813 takes a distinctive approach by proposing voluntary certification by multidisciplinary stakeholder groups, which may potentially include clinicians [48]. Such board-based oversight offers potential advantages, including clinically informed standards, regulatory flexibility, and alignment with existing safety and ethical frameworks.

However, shifting oversight to licensing boards or individual licensed professionals also raises important concerns. Licensed clinical professionals may lack the expertise and resources to validate algorithmic reliability or effectively detect bias,

XSL•FO
RenderX

potentially exposing them to disproportionate liability (as exemplified by North Carolina HB 934, discussed below) [49]. In addition, laws targeting only licensed clinicians (whether directly or through their licensing bodies) risk creating regulatory gaps by leaving MH-AI use among unlicensed actors—such as life coaches, wellness influencers, peer support groups, and AI-driven self-help platforms—as well as AI system developers and deployers who fall outside traditional professional licensing requirements, underregulated. This could paradoxically compromise public safety while imposing undue and anticompetitive burdens on licensed practitioners (eg, Illinois SB 2259, Georgia HB 887, California SB 503, Arkansas HB 1816, Virginia HB 916; Texas SB 1188, Rhode Island HB 6285, Oklahoma HB 1915) [28,29,32,33,37,38,44,46,47,50-53]. If a developer or deployer can bypass meaningful oversight and safety regimes by marketing their product as a wellness tool or companion chatbot and avoid the labels used by a state's laws, then the laws may both be ineffective and stifling of innovation in the professions most likely to use them responsibly.

Although these legislative efforts deserve attention, they remain the exception. Only 11 states propose bills involving clinician oversight or licensure frameworks in this sample, underscoring a striking lack of regulatory engagement with the clinical dimensions of MH-AI. While many laws regulate AI in abstract or consumer-oriented terms, most fail to incorporate clinical or patient input to reflect the realities of therapeutic deployment. To address these challenges, MH-AI policy must move beyond treating clinicians as the default point of oversight and instead develop layered governance models that include professional boards, technologists, patient advocacy groups, and public regulators in shared accountability structures.

Key lessons to take away are that effective MH-AI oversight should (1) be layered and role-based with developers, deployers, clinicians, and boards each carrying defined duties calibrated to risks; (2) account for unlicensed consumer platforms and practitioners; (3) involve in some degree licensing boards and invest them with real authority; and (4) avoid offloading unworkable validation standards onto the point-of-care and instead determine the best point in the process for capability-appropriate audits.

Harm

A small number of state legislatures have begun to confront the potential harms of MH-AI, introducing proposals focused on liability allocation, harm prevention and crisis response standards, safeguards for vulnerable users, fraud protections, and limited exemptions for research and therapeutic use.

For example, most states have yet to clarify how malpractice and liability laws specifically apply to MH-AI, leaving uncertainty about how courts might classify such technologies, whether as products, clinical tools, or services subject to standard-of-care analysis. Only a few states, most notably California and New York, explicitly proposed legislation that establishes specific claims for damages related to AI-induced harms, such as self-harm or suicide [54-57], although a few other states propose a more general AI-harm liability framework (eg, Missouri HB 1462, "Any direct or indirect harm caused by an AI system's operation, output, or recommendation…shall be the responsibility of the owner or user who directed or employed the AI.") [24]. New York and Rhode Island both introduce strict liability (ie, liability regardless of negligence or intent) for harm under certain circumstances [56,58]. Both California and Rhode Island also introduce affirmative defenses (ie, a defense even if one is legally responsible for the harm): California SB 813 provides an affirmative defense linked to compliance with certification standards, while Rhode Island SB 358 grants an affirmative defense to strict liability if the model "satisfied the standard of care applicable to humans who perform the same function" [48,58]. Conversely, North Carolina's HB 934 immunizes developers entirely, assigning liability solely to clinicians—a concerning policy that places disproportionate responsibility on providers who may lack sufficient technological expertise to foresee or mitigate AI failures, including those introduced through problematic automatic software updates [49]. An emerging concern, then, is not simply a lack of liability rules but the effect of their asymmetry: inconsistent provisions risk overassigning responsibility to clinicians while underspecifying developer and deployer duties.

Only 16 of the 143 reviewed bills directly addressed malpractice and liability allocation, with just one enacted within the study period (Appendix S2 in Multimedia Appendix 1). This scarcity signals significant policy gaps, increasing risks of inconsistent liability outcomes. Oklahoma's HB 1915 illustrates another liability-related challenge by mandating that developers track and document clinicians' overrides of AI recommendations, thereby creating potential evidence in malpractice litigation [28]. Such provisions underscore the need for more transparent standards and clinician engagement regarding the acceptable use of AI in clinical practice, as well as how that use will influence both the standard of care and associated medicolegal risks.

Regarding safety standards, 52 bills addressed harm prevention, of which 8 bills pertained to crisis response protocols and 15 bills addressed exemptions to other provisions (eg, data privacy restrictions) to prevent imminent harm. California SB 243 and New York AB 6767, for example, explicitly mandate crisis intervention plans for detecting suicidal ideation, though incident reporting mechanisms remain uncommon [24,54,57,59-68]. California's SB 243 notably requires annual reporting on suicidal ideation incidents but without mandating public disclosure, thus limiting transparency [54]. Missouri's HB 1462 requires specifically "owners or developers" of AI systems involved in incidents resulting in bodily harm or death to "promptly notify the relevant authorities," but creates no special system for doing so [24].

Risk stratification frameworks proposed in several states significantly influence MH-AI oversight, typically centering on "high-risk" AI systems used in "consequential decisions" impacting fundamental services, legal rights, and health care. Oklahoma's HB 1916 introduces a formally tiered risk categorization, labeling health care AI as high-risk and subjecting it to stringent oversight [27]. However, definitions of scope remain unclear, raising questions about how specific applications (eg, cognitive behavioral therapy chatbots) should be categorized. At least 33 bills reviewed suggest a potential growing consensus around heightened scrutiny for MH-AI

XSL•FO
RenderX

systems by placing them in the highest risk categories, although practical definitions remain ambiguous, and only 5 had been enacted at the time of the sample. In short, a few states aspire toward "high-risk" frameworks and crisis protocols, but even in those cases, rarely define operational triggers, minimum controls, or reporting expectations. Absent concrete thresholds (eg, suicide-risk detection, human-override requirements, and postmarket surveillance), "high-risk" may come to embody a simple administrative hurdle or—more concerningly—a label rather than a true safety regime.

One of the most common harms addressed in these bills was the threat of deceit, fraud, or abuse in a consumer protection context, with 84 of the bills identified addressing these topics, whether directly by creating new standards or incorporating AI systems with existing state consumer protection laws (39 bills). Bills out of Nevada, New Jersey, California, and Utah explicitly prohibit AI systems from impersonating licensed clinicians or advertising without clear disclosures (Nevada AB 406, New Jersey SB 4463, California AB 489, and Utah HB 452) [22,36,45,66], joining a total of 14 bills addressing advertising related to covered AI systems [22,33,36,66,69-78].

Protections for vulnerable populations also remain uneven. Although 50 bills addressed responsibilities toward vulnerable groups generally, the vast majority (n=39) appear focused on protections for minors (eg, California AB 1064 [79] and Nevada AB 406 [36]), with none explicitly considering risks to users with limited English proficiency, cognitive impairments, or severe mental illnesses. However, some of these categories might fall under otherwise protected disability categories. Similarly, only 1 of the 143 bills reviewed addresses mandatory reporting obligations for MH-AI operators upon detecting signs of abuse or neglect, highlighting a potentially significant oversight and underscoring the tension between patient safety and practical feasibility for AI developers [29].

This may illustrate that the immediate legislative impulse has been to regulate impersonation and deception while leaving untouched more difficult problems concerning manipulative designs, biased recommendations, undisclosed commercial influence, and misuse targeting vulnerable populations. For example, it is not difficult to imagine an AI-supported chatbot, diagnostic tool, report generator, or other MH-AI system that systematically makes recommendations or uses language in support of a particular product or service. Simultaneously, protections cluster around minors while leaving other at-risk users (eg, limited English proficiency, cognitively impaired, and severely mentally impaired) thinly served.

Finally, despite 45 bills containing provisions exempting or touching on aspects of legitimate research use, all bills sampled appear to lack clear protections or exemptions for the legitimate use of MH-AI in research and treatment involving techniques such as behavioral influence or limited disclosure. By contrast, the European Union's AI Act (Article 5) includes targeted exemptions for approved uses involving forms of persuasion, manipulation, or partial information to achieve clinically valid outcomes [80]. Without similar carve-outs, well-intentioned bills like Montana HB 178, which broadly prohibit "cognitive behavioral manipulation of a person or group," may unintentionally limit future innovation and care in the mental health space [81].

Key lessons to take away are that durable harm prevention in MH-AI requires (1) balanced liability that reaches developers, deployers, and clinicians; (2) specified safety baselines for high-risk uses (eg, detection, escalation, human-in-the-loop, and incident reporting) and populations; and (3) safeguards that target manipulative or biased design without foreclosing clinically legitimate influence in treatment or research.

Autonomy

As MH-AI systems increasingly intersect with patient care, user autonomy has emerged as a critical regulatory and ethical priority, with state legislation primarily addressing transparency, disclosure, and informed consent.

Legislative efforts around transparency remain limited, with relatively few states proposing public registries or disclosure standards specifically targeting MH-AI systems. Of the 91 bills identified addressing transparency broadly, 19 explicitly mandate public-facing inventories or similar public registry reporting requirements (eg, Pennsylvania HB 290, Georgia HB 988, Delaware HB 333, Illinois HB 3529, and Illinois HB 3720) [82-86]. California's SB 813 uniquely integrates transparency benchmarks within its voluntary certification system [48]. Despite these initiatives, transparency mandates tailored specifically for MH-AI remain uncommon, leaving clinicians and patients reliant on proprietary technologies that are not required to provide training or safety data, validation or outcome data, or other information arguably necessary for meaningful disclosure and consent.

Disclosure requirements are among the most frequently proposed regulatory strategies, with 96 bills addressing disclosure or consent in some form. Many explicitly mandate clear notification to users interacting with AI systems (eg, California AB 410, Indiana HB 1620, Massachusetts HB 1975, Utah SB 226, and Illinois HB 5649), and a few states, such as Nevada (SB 186) and New York (AB 6767), propose continuous or repeated disclosures in interactive settings [20,32,39,40,57,87,88]. California's AB 3030 creates an exemption to some disclosure requirements if a licensed provider has reviewed the AI-generated output [46]. Explicit informed consent requirements for MH-AI are considerably rarer; only a small number of bills, namely Texas HB 1265, Pennsylvania SB 631, and Rhode Island HB 6285, directly require informed consent specifically for MH-AI services [29,30,89]. Notably, bills such as Massachusetts HB 1975 and Illinois HB 5649 propose providing users with the option of non-AI alternatives for services, although such provisions remain exceptions [32,39].

Without detailed statutory or professional guidelines, clinicians are left with unanswered practical questions, particularly regarding the level of understanding required of AI systems to meet disclosure and informed consent obligations. For example, should clinicians review and communicate error rates, data sources, or regulatory status in a manner comparable with how they communicate the risks, benefits, and limitations of medications or other clinical interventions? If the law protects such information as proprietary or fails to promote transparency

XSL•FO
RenderX

or external validation of clinical MH-AI, it also raises the question of where responsibility—and liability—for harm should fall. Without clear legislative or professional guidelines, clinicians face potential liability risks, and patient autonomy remains inadequately protected.

Key lessons include that effective MH-AI autonomy protections should yield usable choices through (1) plain-language disclosure of AI use, limitations, and provenance; (2) consideration of rights to human review or non-AI pathways for consequential decisions; (3) development of scaling consent requirements based on risk; and (4) accounting for point-of-care limitations in expertise by facilitating policies that appropriately distribute transparency requirements.

Privacy and Data

Despite the uniquely sensitive nature of mental health data, few states propose tailored privacy protections for MH-AI systems. Legislative efforts remain limited, focusing primarily on addressing gaps in existing privacy frameworks, ensuring user control over AI-generated data, and establishing exceptions for crisis-related interventions.

Traditional mental health records, such as psychotherapy notes and substance use treatment records, receive specialized privacy protections under HIPAA and 42 Code of Federal Regulations Part 2 [90,91]. However, none of the reviewed state bills explicitly extend similar protections to MH-AI–generated content, such as therapy-like transcripts, emotional disclosures, or sensitive behavioral metadata (excepting, perhaps, Illinois HB 1806, which brings such records under the state's Mental Health and Developmental Disabilities Confidentiality Act, but analysis of this separate law is outside the scope of this review) [33]. Of the 77 bills addressing data protection, the lack of specialized protections may be particularly pertinent for non–HIPAA-covered entities, such as app developers and commercial platforms, creating a potential regulatory gap that leaves clinicians and patients vulnerable to data misuse and potential reidentification. Perhaps compounding the issue, several bills specifically exclude HIPAA-covered entities from their protections, relying on a federal statutory framework that also does not consider many MH-AI uses and products (eg, Rhode Island S0627 exempts HIPAA-covered entities providing health care recommendations that "are not considered to be high risk") [23,68,69,78,92-108]. Therefore, within this snapshot of legislation, the present privacy posture is mainly entity-centric when the risk is data-centric. MH-AI generates unique data products that are sensitive regardless of who holds them.

Few state bills meaningfully address users' rights to control their mental health data within MH-AI systems. Notable exceptions include California AB 1018 and Colorado SB 24‐205, which grant users access rights to data involved in high-risk AI decisions [72,95]. In contrast, North Carolina's SB 624 uniquely mandates a 30-day self-destruction timeline for MH-AI chat data and imposes enhanced encryption and data reuse restrictions for such applications [60]. However, these data control provisions introduce practical challenges related to clinical documentation, adverse event review, and compliance with existing medical record retention laws—placing them in tension with clinicians' ethical and legal obligations.

Alongside the safety exemptions mentioned above, several bills aim to strike a balance between data privacy and immediate patient safety concerns, such as Colorado SB 24‐205 and Virginia HB 747, which permit the temporary suspension of privacy rules during emergencies [95,109]. While potentially critical in crises involving self-harm or suicide risk, such exceptions raise serious concerns about intervention protocols, accountability for misuse, and access by law enforcement or the legal system. Without well-defined protocols and robust oversight, these exemptions risk undermining patient trust and clinical integrity and could disproportionately impact communities already experiencing heightened surveillance or systemic mistrust.

Key lessons include that effective MH-AI privacy frameworks should (1) be data-centric; (2) govern data lifecycle use throughout collection, inference, retention, and sharing; and (3) integrate bounded emergency exceptions, auditable controls, and rights that are workable in clinical settings.

The goal is not maximal secrecy or maximal access, but accountable use.

Limitations

This review should be interpreted with several limitations in mind. First, the analysis represents a cross-sectional snapshot of policy content in legislation as it existed on May 19, 2025, regardless of whether each bill was later amended, enacted, or failed. This study's intent was to characterize what states were proposing for MH-AI, but not to systematically evaluate political feasibility, legislative trajectories, or implementation effects.

Second, legislation was collected from a single source, LegiScan, a database that aggregates bills from all 50 states and presents them in a standardized format. This approach ensured consistent capture of bill texts at a defined point in time, regardless of legislative status. Such consistency was necessary given the highly dynamic nature of the legislative process: bills may exist in multiple versions in different legislative chambers, undergo repeated committee revisions, fail, and later be reintroduced under different identifiers, and are subject to state-specific procedural rules. By using a centralized platform, the analysis minimized the effects of procedural variation across states. It also enabled more direct comparisons, although it necessarily depended on the integrity and coverage of the LegiScan service. Relatedly, companion bills were treated as a single legislative item to reduce redundancy; however, this simplification may obscure substantive differences between House and Senate versions of some bills.

Third, the search strategy relied on keyword-based retrieval. Multiple candidate terms were evaluated, but a refined set was ultimately adopted to balance 2 objectives: narrowing the dataset to legislation (plausibly relevant to clinical AI) while excluding a large volume of unrelated bills. This compromise inevitably excluded some relevant measures, particularly those using indirect or atypical terminology. For example, North Carolina's HB 934, noted earlier, was omitted despite its substantive relevance because it did not include qualifying keywords. More broadly, statutory frameworks are often fragmented and depend heavily on cross-references to agency regulations, definitional

XSL•FO
RenderX

clauses, and related instruments. Even with comprehensive protocols, such complexity limits the ability to capture all relevant legislation. In the future, computational methods such as natural language processing might be used instead to identify relevant legislation beyond keyword-based retrieval. Nevertheless, the bills analyzed provide meaningful insight into emerging policy patterns and legislative concerns across US states.

Fourth, simple counts of bills or tags are activity metrics, not quality metrics. They do not capture scope, enforceability, or implementation (eg, funding, effective dates, sunset clauses, and exemptions). One omnibus statute can cover more policy areas than several narrow bills, while some tags reflect incidental mentions rather than operative provisions. Counts also reflect drafting style and calendar differences across states, so higher numbers may indicate legislative fragmentation rather than greater comprehensiveness or effectiveness.

Future Directions and Recommendations

Future research should move beyond cataloging and classifying bills to more fully interrogate the substantive policy directions emerging from state legislatures. The tagging system developed for this study could be used to trace specific themes across jurisdictions over time. Such a unified approach will enable comparative analyses that highlight both convergence and divergence in state approaches, providing evidence to inform potential federal policymaking or the development of national standards.

The current findings suggest that mental health remains one of the most consequential yet least prepared frontiers of AI regulation. Legislative activity is marked by rapid growth but fragmented execution, with critical gaps in professional oversight, liability frameworks, privacy protections, and safeguards for vulnerable populations. Furthermore, clinicians are frequently assigned responsibilities without corresponding guidance or resources, effectively shifting complex regulatory burdens to the point of care. The limited inclusion of mental health practitioners or patients in legislative task forces and advisory bodies underscores the risk of policymaking that diverges from clinical realities.

Addressing these gaps will require greater engagement from mental health professionals, institutions, and professional associations. Active collaboration with policymakers and patient advocacy groups is necessary to ensure that regulatory frameworks are clinically informed, ethically grounded, and practically feasible. To facilitate this process, the authors provide (1) Appendix S3 in Multimedia Appendix 1, which proposes a scoring framework for interpreting state engagement across key legal domains relevant to MH-AI and is less reliant on the simple counting scheme used in this analysis with its previously mentioned limitations; and (2) access to the tagging database of MH-AI related bills created for this study [110]. By raising awareness of MH-AI policy issues and providing practical tools, this work lays the groundwork for more active clinician engagement in shaping the next generation of AI regulation, whether through direct advocacy or further research. Clinician and patient involvement at this juncture will be pivotal in determining whether MH-AI governance advances care, safety, and innovation.

Conclusion

This 50-state review demonstrates that while legislative activity related to MH-AI is widespread, it remains uneven. Although hundreds of AI-related bills have been introduced since 2022, only a small fraction explicitly address mental health, and enacted provisions remain limited in scope. Where regulation exists, it is fragmented across states and typically incorporates mental health incidentally rather than as a distinct policy focus.

Across jurisdictions, 4 recurring domains emerge: professional oversight, harm prevention, patient autonomy, and data governance. These domains reflect central questions raised by MH-AI but are addressed inconsistently, with significant variability in scope and emphasis. Gaps remain evident within each domain, such as how liability is allocated between developers and clinicians, how adverse events are reported, and how sensitive data are protected. In addition, while this review highlights proposed provisions of law, omissions may carry equal or greater significance.

Taken together, these findings demonstrate that state legislatures are actively shaping the regulatory environment for MH-AI, but in fragmented and incomplete ways. This evolving regulatory landscape is characterized by sporadic attention to mental health, limited integration of clinical perspectives, and reliance on broadly framed statutes that may fail to capture the realities of psychiatric practice. This analysis establishes a baseline for tracking future policy development and assessing whether subsequent legislation achieves greater coherence, specificity, and responsiveness to the complexities of mental health care.

Abstract

Background: Trauma exposure is highly prevalent and associated with various health issues. However, health care professionals can exhibit trauma-related diagnostic overshadowing bias, leading to misdiagnosis and inadequate treatment of trauma-exposed populations. Generative artificial intelligence (GAI) models are increasingly used in health care contexts. No research has examined whether GAI demonstrates this bias in decision-making and how rates of this bias may compare to mental health professionals (MHPs).

Objective: This study aimed to assess trauma-related diagnostic overshadowing among frontier GAI models and compare evidence of trauma-related diagnostic overshadowing between frontier GAI models and MHPs.

Methods: MHPs (N=232; mean [SD] age 43.7 [15.95] years) completed an experimental paradigm consisting of 2 vignettes describing adults presenting with obsessive-compulsive symptoms or substance abuse symptoms. One vignette included a trauma exposure history (ie, sexual trauma or physical trauma), and one vignette did not include a trauma exposure history. Participants answered questions about their preferences for diagnosis and treatment options for clients within the vignettes. GAI models (eg, Gemini 1.5 Flash, ChatGPT-4o mini, Claude Sonnet, and Meta Llama 3) completed the same experimental paradigm, with each block being reviewed by each GAI model 20 times. Mann-Whitney *U* tests and chi-square analyses were used to assess diagnostic and treatment decision-making across vignette factors and respondents.

Results: GAI models, similar to MHPs, demonstrated some evidence of trauma-related diagnostic overshadowing bias, particularly in Likert-based ratings of posttraumatic stress disorder diagnosis and treatment when sexual trauma was present (P<.001). However, GAI models generally exhibited significantly less bias than MHPs across both Likert and forced-choice clinical decision tasks. Compared to MHPs, GAI models assigned higher ratings for the target diagnosis and treatment in obsessive-compulsive disorder vignettes (r_b=0.43 - 0.63; P<.001) and for the target treatment in substance use disorder vignettes (r_b=0.57; P<.001) when trauma was present. In forced-choice tasks, GAI models were significantly more accurate than MHPs in selecting the correct diagnosis and treatment for obsessive-compulsive disorder vignettes (χ^2_1=48.84 - 61.07; P<.001) and for substance use disorder vignettes involving sexual trauma (χ^2_1=15.17 - 101.61; P<.001).

Conclusions: GAI models demonstrate some evidence of trauma-related diagnostic overshadowing bias, yet the degree of bias varied by task and model. Moreover, GAI models generally demonstrated less bias than MHPs in this experimental paradigm. These findings highlight the importance of understanding GAI biases in mental health care. More research into bias reduction strategies and responsible implementation of GAI models in mental health care is needed.

KEYWORDS

generative artificial intelligence; trauma; mental health professionals; diagnosis; treatment

Introduction

Trauma exposure is associated with a range of health-related issues, including physical health problems [1,2] and mental health problems [3,4]. Owing to the potential impact of trauma exposure on individual health and well-being, assessing trauma exposure history is an essential part of mental health assessment [5,6]. Trauma exposure is quite common, with some estimates suggesting that around 90% of individuals experience trauma during their lifetime. However, the incidence of trauma-related mental health problems following trauma exposure is much less common [3]. As a result, many individuals seeking mental health

XSL•FO
RenderX

care are likely to report a history of trauma, even if they are not presenting with trauma-related symptoms.

Previous research has indicated that trauma-related diagnostic overshadowing bias occurs when health care professionals prioritize an individual's trauma history in diagnostic and treatment decision-making, rather than focusing on the individual's primary symptoms [7,8]. Experimental research has shown that mental health professionals (MHPs) are more likely to provide a posttraumatic stress disorder (PTSD) diagnosis and recommend PTSD-specific treatment for individuals with a trauma history, even when the trauma exposure occurs after the onset of primary symptoms and those symptoms do not warrant a PTSD diagnosis or PTSD treatment [7,8]. The consequences of trauma-related diagnostic overshadowing bias are likely to be significant and far-reaching for both trauma-exposed individuals and the mental health care system. By prioritizing trauma history over current symptoms, MHPs risk misdiagnosing and providing inadequate treatments to trauma-exposed individuals. This can lead to individuals receiving diagnoses and treatments that do not address their presenting concerns, potentially delaying their ability to receive optimal care and exacerbating their primary symptoms [9,10].

An increasing body of research has used generative artificial intelligence (GAI) models to assist with health care, including the use of GAI for diagnosis [11], treatment planning [12,13], treatment delivery [14,15], and other clinical care tasks [16]. Although GAI has existed for some time, the development of more advanced models has led to greater proliferation of GAI technologies in health care. There is a growing body of literature that not only evaluates the use of GAI in clinical decision-making but also compares clinical decision-making across MHPs and GAI models in a variety of tasks [17]. For example, a recent clinical trial demonstrated higher rates of diagnostic accuracy between large language models and physician samples in response to clinical vignettes [17]. Additional research has shown that GAI can be used to support and improve clinical decision-making among health care professionals [18]. Within the context of mental health, several studies have compared the clinical decision-making across MHPs and GAI [19-22]. These studies have found that GAI models can perform comparably to, and in some cases better than, MHPs in identifying diagnoses and recommending evidence-based treatments [19-22]. While GAI may demonstrate a high level of performance on clinical decision-making tasks, research has also raised important concerns about bias and limitations in GAI clinical decision-making [21,23].

Errors in clinical decision-making from GAI models in health care applications can be quite harmful [24,25]. Recent research indicates that individuals may use GAI to "help manage their emotional and mental health" [26]. As GAI models are increasingly scaled for diverse health care contexts, greater attention is being paid to the potential biases and limitations associated with their use in health care [25,27-29]. As GAI is developed and trained using inherently biased data, this may result in biased clinical decision-making being scaled to real-world environments [27,29]. For example, previous work has demonstrated significant biases in GAI responses related to clinical decision-making, including gender-related bias in diagnosing comorbid mental health conditions [21] as well as racial biases in diagnosis [29] and emergent clinical decision-making for individuals experiencing mental health crises [30]. Assessing the potential for bias in decision-making by GAI models is critical for reducing potential harms associated with this technology. However, there is a dearth of research focused on examining bias and other errors in clinical decision-making involving trauma-exposed populations by GAI models.

This study aimed to fill this gap by conducting a secondary data analysis of a prior study on trauma-related diagnostic overshadowing bias among MHPs [8]. Specifically, the study assessed trauma-related diagnostic overshadowing among GAI models and compared evidence of trauma-related diagnostic overshadowing between GAI models and MHPs. This study supports the growing body of literature focused on evaluating bias in artificial intelligence, as it relates to mental health care. The results from this research may help inform the development, evaluation, and implementation of GAI in mental health care for trauma-exposed populations.

Methods

Participants

Mental Health Professionals

In the initial study, the sample of MHPs was recruited from professional listservs and networks [8]. MHPs (N=232) reported a mean (SD) age of 43.73 (15.95) years (71.98% female-identifying). The sample mostly comprised doctoral-level (n=115, 53.99%) and master's-level (n=90, 42.25%) professionals, primarily in the fields of clinical psychology (n=129, 60.56%) and social work (n=67, 31.46%). MHPs had a mean (SD) of 15.41 (13.73) years of experience.

GAI Models

A total of 4 large-scale GAI models were used, that is, Llama 3.0 [31], ChatGPT-4o mini [32], Gemini 1.5 Flash [33], and Claude Sonnet [34], to assess trauma-related diagnostic overshadowing among GAI models (each model is hereafter referred to by the name of the model developer). These models were selected as they had demonstrated high-level performance across a range of diverse benchmarks focused on general knowledge, reasoning, instruction following, and language comprehension (eg, Massive Multitask Language Understanding) [35,36]. These models have been used in past research to assess clinical decision-making capabilities [18,20,37-39].

Procedures

In the initial study, MHPs were randomized to 1 of 8 experimental blocks in which each block contained 2 brief vignettes. Trauma exposure was present in only 1 of the vignettes. The first vignette depicted an adult experiencing obsessive-compulsive disorder (OCD), and the second vignette depicted an adult experiencing substance use disorder (SUD) (Multimedia Appendix 1). Cases contained enough information to support the target diagnoses and treatment of OCD and SUD but did not contain information to warrant diagnosis or treatment

XSL•FO
RenderX

of PTSD (Multimedia Appendix 2). Furthermore, when trauma exposure was present, it was explicitly indicated to have occurred following the onset of the primary presenting symptoms. For the vignettes containing trauma exposure, the type of trauma exposure was counterbalanced across conditions such that vignettes presented either physical trauma exposure (ie, single incident of a "serious" motor vehicle accident with lingering physical injuries) or sexual trauma exposure (ie, single incident of sexual assault by a coworker during a business trip). The sex of the individual in the vignette was also counterbalanced (ie, a female-identifying individual was the focus of a vignette and a male-identifying individual was the focus of the other vignette).

To ensure reliability, each GAI model was queried 20 times using the same experimental vignettes delivered to MHPs (ie, 8 experimental blocks containing 2 vignettes each) [22]. To make it as similar as possible to that delivered to MHPs, each iteration was performed in 1 prompt that combined the vignettes and questions for each experimental block. Across cases, this resulted in a total of 160 responses to vignettes containing sexual trauma, 160 responses to vignettes containing physical trauma, and 320 responses to vignettes containing no trauma. Previous work has demonstrated that GAI models do not update model weights during inference, resulting in little carryover of memory from session to session [40]. To reduce the potential impact of model memory on output, all prompts were entered into each GAI model through the web-based implementations of each GAI model using a new instance of a Google Chrome incognito browser for each iteration and model. Prompts were limited to vignettes, questions, and prompt instructions alone to match as closely as possible the information presented to MHPs. Prompts, containing the vignettes, questions, and instructions, were entered once per session for each model. All vignettes and prompts can be found in Multimedia Appendix 1. To mirror the paradigm completed by MHPs, hyperparameters (such as temperature, which can affect the randomness of model responses, or maximum length, which can affect the length of responses) were not manipulated. All GAI models were prompted in January 2025.

After reviewing each vignette, both MHPs and GAI models responded to diagnostic and treatment questions related to the vignettes. For GAI models, each question included additional prompt information to ensure that the corresponding response matched the format of the question (eg, "please select the most clinically appropriate treatment model and include that below with no other information" for forced-choice questions).

Measures

After reviewing each vignette, respondents rated the likelihood that the individual would meet diagnostic criteria for a range of mental health disorders using a 7-point Likert scale (1="not at all likely," 7="extremely likely"). Diagnostic options included OCD, adjustment disorder, major depressive disorder, generalized anxiety disorder, PTSD, and SUD. Trauma-related diagnostic overshadowing for these likelihood ratings was defined as lower ratings for the target diagnosis (ie, OCD or SUD) or higher ratings for a PTSD diagnosis when trauma exposure was present versus absent. Respondents were then asked to select the primary diagnosis they would assign from the list of diagnoses. Trauma-related diagnostic overshadowing in diagnosis selection was indicated when respondents were less likely to select the target diagnosis (OCD or SUD) or more likely to select a PTSD diagnosis in trauma-present vignettes compared to trauma-absent vignettes.

Next, respondents rated the clinical appropriateness of specific mental health treatments for the individuals using a 7-point Likert scale (1="extremely inappropriate", 7="extremely appropriate"). Treatment options included dialectical behavior therapy, cognitive processing therapy (CPT), exposure and response prevention (ERP), motivational interviewing (MI), and psychodynamic psychotherapy, with the option to enter an alternative treatment. Trauma-related diagnostic overshadowing for these treatment ratings was defined as lower appropriateness ratings for the target treatment (ERP for OCD case; MI for SUD case) or higher ratings for a PTSD-specific treatment (CPT) when trauma exposure was present versus absent. Finally, respondents selected the most appropriate treatment from the list of treatments. Trauma-related diagnostic overshadowing in treatment selection was indicated when respondents were less likely to select the target treatment (ERP or MI) or more likely to select the PTSD treatment (CPT) in response to vignettes where trauma exposure was present, compared to when trauma exposure was absent.

Data Analysis

Normality in Likert-based data was assessed using *z* tests based on skewness and kurtosis values. These tests indicated deviations from normality across Likert-based response variables for both cases. Therefore, to establish whether GAI models demonstrated bias (Aim 1), Mann-Whitney *U* tests were used to compare Likert ratings for target diagnosis, target treatment, PTSD diagnosis, target treatment, and PTSD treatment across no trauma and trauma conditions (ie, no trauma vs physical trauma, no trauma vs sexual trauma) as well as physical trauma versus sexual trauma conditions for each case (ie, OCD and SUD). Chi-square analyses were used to compare forced-choice selection of target diagnosis, PTSD diagnosis, target treatment, and PTSD treatment across no trauma and trauma conditions (ie, no trauma vs physical trauma, no trauma vs sexual trauma) as well as physical trauma versus sexual trauma conditions for each case. To compare the rates of bias across GAI models and MHPs (Aim 2), Mann-Whitney *U* tests were used to compare Likert ratings for target diagnosis, PTSD diagnosis, target treatment, and PTSD treatment for vignettes including trauma (ie, vignettes including physical trauma or sexual trauma) across each case. Chi-square analyses were used to compare forced-choice selection of target diagnosis, PTSD diagnosis, target treatment, and PTSD treatment for vignettes including trauma (ie, vignettes including physical trauma or sexual trauma) across each case. Effect sizes were calculated for comparison of Likert data using rank-biserial correlations [41]. Bootstrapped CIs are provided for rank-biserial correlations. Effect sizes (r_b) are interpreted using Cohen's conventions: small ≥0.10, medium ≥0.30, and large ≥0.50 [42]. A Bonferroni correction was applied to adjust for the number of tests, resulting in an adjusted α value of .001. All analyses were performed using R version 4.3.1 [43].

XSL•FO

Ethical Considerations

Procedures for the initial study received approval from the Institutional Review Board (IRB) at the University of California, Irvine (IRB #448). Mental health professionals provided informed consent as part of the initial study. More information on the initial study can be found in past work [8]. No additional approval was required for secondary data analysis.

Results

Do GAI Models Demonstrate Bias?

Results From Likert Ratings

Likert ratings of diagnosis and treatment options from GAI models, as well as results from Mann-Whitney *U* tests comparing within-model Likert ratings for each response choice can be found in Table 1.

Table . Likert ratings of diagnosis and treatment options by GAI models[a].

	Target[b]			PTSD[c]		
Model	No trauma, mean (SD)	Physical trauma, mean (SD)	Sexual trauma, mean (SD)	No trauma, mean (SD)	Physical trauma, mean (SD)	Sexual trauma, mean (SD)

Llama	6.99 (0.11)[e]	7.00 (0.00)	6.95 (0.22)[e]	2.26 (0.47)[e]	4.63 (0.59)[f]	5.10 (0.44)[g]

[a]Values for target diagnosis and treatment closer to a score of 7 and values for PTSD diagnosis and treatment closer to a score of 1 reflect less trauma-related diagnostic overshadowing bias. Mann-Whitney *U* tests could not be conducted when there was no variance in responses.

[b]The target column reflects mean ratings for target diagnosis or treatment for each case.

[c]The PTSD column reflects mean ratings for PTSD diagnosis or treatment for each case.

[d]Different superscripts (ie, e, f, and g) denote significantly within-model differences in ratings at the Bonferroni-corrected significance level ($P < .001$) through a Mann-Whitney *U* test

The mean ratings for the target diagnosis (range 6.28 - 7.00) and target treatment (range 6.68 - 7.00) were quite high across all models, regardless of case type and presence of trauma exposure. This reflects evidence that GAI models tended to

XSL•FO
RenderX

demonstrate minimal to no bias in target diagnosis and treatment ratings. Llama provided significantly lower ratings of OCD diagnosis and OCD treatment when sexual trauma was present in the OCD case compared to when no trauma was present (Table 1), indicating evidence of bias. Unexpectedly, Gemini demonstrated significantly greater ratings of OCD diagnosis in the OCD case when sexual trauma was present, compared to when it was absent (Table 1). However, the overall magnitude of difference in ratings was small (less than 1 point on the scale) for both Llama and Gemini across cases, indicating slight evidence of bias in within-model target diagnosis and target treatment ratings.

The mean ratings for PTSD diagnosis (range 1.00 - 6.20) and PTSD treatment (range 2.26 - 6.00) varied across all models. There was consistent evidence of bias in comparing Likert ratings of PTSD diagnosis and treatment in vignettes with and without trauma exposure, such that all models across both cases demonstrated significantly higher ratings of PTSD diagnosis and PTSD treatment when trauma exposure was present, compared to when it was absent (Table 1). Furthermore, evidence of bias was stronger for vignettes containing sexual trauma versus physical trauma, as all models tended to assign greater ratings of PTSD diagnosis and PTSD treatment when sexual trauma was present, compared to when physical trauma was present (Table 1). Notably, the magnitude of differences in PTSD diagnosis ratings across vignettes with and without trauma was substantial (range of 2.33-5.00 points on the 7-point Likert scale), providing a clear indication of bias. The magnitude of differences in PTSD treatment ratings across vignettes with and without trauma was smaller (range of 0.37-3.35 points on the 7-point Likert scale), yet still indicative of bias.

Results From Forced Choice Ratings

Forced-choice selection of diagnosis and treatment options can be found in Multimedia Appendix 3. ChatGPT, Gemini, and Claude demonstrated no evidence of bias by correctly selecting the target diagnosis and treatment 100% of the time. Llama correctly selected the target diagnosis and treatment in 95% of vignettes for the SUD case. However, Llama demonstrated evidence of bias in the OCD case, selecting the target diagnosis and treatment 62.50% and 65% of the time, respectively, and the PTSD diagnosis and treatment 37.50% and 35% of the time, respectively. Notably, the evidence of bias in diagnosis and treatment selection in Llama responses was present only in OCD vignettes that contained sexual trauma (Multimedia Appendix 3).

Do GAI Models Demonstrate Less Bias Than MHPs?

Results From Likert Ratings

Results from the analysis of Likert-based ratings of diagnosis and treatment from GAI and MHPs are found in Table 2.

XSL•FO
RenderX

Table . Likert ratings of trauma vignettes from GAI models and mental health professionals[a].

Outcome	Physical trauma				Sexual trauma			
	MHP[b], mean (SD)	GAI[c], mean (SD)	*U*	r_b (95% CI)	MHP[b], mean (SD)	GAI[c], mean (SD)	*U*	r_b (95% CI)

[d]OCD: obsessive-compulsive disorder.

[e]*P*<.001

[f]not available.

[g]PTSD: posttraumatic stress disorder.

[h]*P*<.05.

[i]SUD: substance use disorder.

[j]*P*<.01.

Compared to MHPs, GAI models tended to exhibit less bias by assigning significantly greater target diagnosis and target treatment ratings for both the OCD case and SUD case when trauma exposure was present (Table 2). Across both cases, effect sizes for comparisons of target diagnosis and treatment ranged from moderate to large (Table 2). There were no significant differences between MHPs' and GAI models' ratings of PTSD diagnosis and PTSD treatment for both cases using the Bonferroni-corrected significance level (*P*=.001), with the exception that compared to MHPs, GAI models provided significantly lower ratings of PTSD diagnosis in the SUD case when physical trauma was present (Table 2).

Results From Forced Choice Ratings

Percentages of forced-choice selections of diagnosis and treatment are included in Table 3.

[a]Values of 100% for target diagnosis and treatment and 0% for PTSD diagnosis and treatment reflect less trauma-related diagnostic overshadowing bias.

[b]MHP: mental health professionals.

[c]GAI: generative artificial intelligence.

[d]OCD: obsessive-compulsive disorder.

[e]*P*<.001.

[f]PTSD: posttraumatic stress disorder.

[g]SUD: substance use disorder.

[h]*P*<.01.

For the OCD case, there was consistent evidence that GAI models demonstrated less bias than MHPs across all outcomes (Table 3). MHPs selected the correct OCD diagnosis and treatment approximately 64% and 63% of the time in the physical trauma vignettes and approximately 46% and 43% of the time in the sexual trauma vignettes. In contrast, GAI models selected the correct OCD diagnosis and treatment 100% of the time in physical trauma vignettes and 91% of the time in sexual trauma vignettes. For the SUD case, GAI models consistently demonstrated less bias than MHPs in all outcomes for the sexual trauma vignettes (Table 3). In SUD vignettes including physical trauma, GAI models demonstrated less bias only in selecting the target treatment (Table 3). In the SUD case, there were no significant differences between MHPs' and GAI models' selection of target diagnosis, PTSD diagnosis, or PTSD treatment in physical trauma vignettes (Table 3). MHPs selected the correct SUD diagnosis and treatment approximately 93% and 64% of the time in the physical trauma vignettes, respectively, and 84% and 38% of the time, respectively, in the sexual trauma vignettes. GAI models assigned the correct diagnosis and treatment 100% of the time in physical trauma vignettes and approximately 99% of the time in sexual trauma vignettes.

Discussion

This study is the first to evaluate trauma-related diagnostic overshadowing among GAI models and the first to compare rates of trauma-related diagnostic overshadowing between health care professionals and GAI models. From these results, it is clear that GAI models show some evidence of bias. However, the degree to which GAI models demonstrated bias in this study appears to depend on the specific task and model. Specifically, evidence of bias was more apparent when GAI models were asked to rate the likelihood of assigning a PTSD diagnosis and treatment but showed almost no bias when asked to select a primary diagnosis and treatment. Furthermore, there were some notable differences in the rates of bias across GAI models. This was most apparent for forced-choice diagnostic and treatment decision-making, as Llama was responsible for all evidence of bias in forced-choice diagnosis and treatment selection, whereas ChatGPT, Gemini, and Claude correctly selected the appropriate diagnosis and treatment across all vignettes. This suggests that the ways in which GAI models are engineered and trained can affect whether they exhibit bias. Our findings align with past research showing that GAI models demonstrate evidence of a variety of biases that may impact health care [19,21,24,44,45]. Given that GAI is increasingly being used in health care settings [26,46], understanding the conditions that increase biased diagnostic and treatment decision-making and what prompting strategies can be used to reduce bias is an important direction for future research.

Although GAI models were not bias-free, they demonstrated less bias compared to MHPs under many conditions. Past research has demonstrated more accurate clinical decision-making among GAI models, compared to MHPs, across a range of diagnoses [20-22]. In this study, GAI models were

XSL•FO
RenderX

more accurate in rating the likelihood of selecting the target diagnosis and treatment across both cases and trauma types. They were also more accurate when selecting a primary diagnosis and treatment for the OCD cases and the SUD case when sexual trauma was present. Though differences were not found in selecting a primary diagnosis and treatment for the SUD case when physical trauma was present (with the exception of target treatment), this is because MHPs showed minimal bias in this case. While these findings may suggest that GAI models may be useful in supporting MHPs engaging in clinical decision-making tasks with trauma-exposed populations, it is critically important to further understand the potential consequences of scaling GAI to support clinical decision-making in mental health care.

Similar to MHPs [7,8], GAI models produce greater bias in decision-making when sexual trauma exposure was present compared to when physical trauma was present. Future research should thoroughly evaluate diagnostic and treatment decisions in response to trauma-exposed populations experiencing a range of different clinical presentations and coming from different demographic backgrounds. In addition, our findings showed that the type of question asked (eg, Likert vs forced-choice) impacted the degree of bias. GAI models can demonstrate significant variability in response to different prompts, and more work is needed to identify and examine how different prompting strategies produce errors in GAI responses (eg, GAI model "hallucinations" or when GAI models produce inaccurate or fabricated information in response to prompts).

While the precise training data and methods used by developers of large-scale GAI models largely remain proprietary, several plausible explanations exist for why GAI models may demonstrate patterns of bias such as trauma-related diagnostic overshadowing. GAI models are trained on vast amounts of internet-based data, which includes both data related to (eg, clinical case vignettes, diagnostic standards, treatment best practices) and unrelated to clinical decision-making (ie, misinformation, pseudoscience) [27]. As noted in prior research, GAI often demonstrates factual knowledge similar to many professionals across various contexts, including in mental health, yet it simultaneously demonstrates difficulties with clinical decision-making, particularly in nuanced or complex situations [21,23]. Furthermore, past research has demonstrated evidence of a range of biases in GAI decision-making as it relates to mental health, including racial bias [30] and gender bias [21]. Given that GAI models are not explicitly taught to engage in the steps of clinical decision-making (eg, differential diagnosis) but instead are trained to predict likely completions of text based on patterns in their training data, they may default to overemphasizing trauma-related outcomes when trauma is mentioned. This aligns with literature indicating that LLMs can exhibit particular cognitive biases (eg, anchoring) [47], particularly when exposed to emotionally salient information such as trauma [48]. Consequently, trauma-related diagnostic overshadowing in GAI models may stem from these models making decisions probabilistically based on the available context and its training data rather than through logic. For example, elevated Likert ratings for PTSD diagnosis and treatment in response to vignettes with sexual trauma reflect the well-established finding that sexual trauma is particularly traumatogenic [49].

Prior research has demonstrated that GAI models may be helpful in supporting physician decision-making [18]. However, there has been little research on how GAI models can support clinical decision-making for mental health care [50]. Given that a portion of MHPs already use GAI models in their work [26], it is particularly important to not only understand if these tools may be helpful in supporting clinical decision-making, but also it is important to understand how these tools may be helpful in supporting clinical decision-making. Research has indicated that artificial intelligence (AI)–assisted diagnosis has affected clinical decision-making processes in other areas of health care, such that health care professionals use AI-derived diagnostic information as a first step, then "work backward" to confirm whether the diagnostic prediction matches available information from other sources (eg, patients, experts, and existing guidelines) [51]. Although GAI has the potential to serve a similar function in mental health care, there are numerous important considerations for using GAI in supporting clinical decision-making in a mental health context. Research has demonstrated that humans are often overconfident in the accuracy of GAI model responses [52], which may potentially result in greater bias in clinical decision-making in instances where GAI models make biased decisions. Past research has indicated that bias from AI can negatively impact individual decision-making both in specific tasks and beyond, as there is evidence that humans "inherit" and "generalize" AI-derived bias to new situations [53]. Given the potential negative consequences of bias in clinical decision-making, it is incredibly important to not just examine the extent of bias in GAI responses but also to develop and implement strategies to reduce bias in GAI. Importantly, bias in decision-making by GAI models, including evidence of trauma-related diagnostic overshadowing, is likely driven by bias in data used to train GAI models [24,25,27].

Bias reduction strategies are especially critical in clinical contexts, where biased outputs could lead to misdiagnosis or ill-fitting treatment recommendations for trauma-exposed populations. GAI models are trained on biased data, including data that may reflect societal stereotypes or clinical misconceptions [24,25,27,29,44]. Approaches to bias reduction in GAI are particularly important and may include improved dataset curation, debiasing during model fine-tuning, prompt engineering techniques, human oversight methods, and post hoc bias correction mechanisms [29,44]. Educational strategies that help users recognize and mitigate model bias, such as bias demonstrations, feedback-based training, and consolidation of outputs across multiple models, have also shown promise [38,54,55]. Moreover, bias reduction must be considered across the full lifecycle of model development and deployment, including continuous auditing and version monitoring [55]. As GAI becomes increasingly integrated into mental health work, bias identification and mitigation are essential to ensure safe and effective outcomes. It is also particularly important to improve knowledge regarding GAI among professionals. Given the increasing integration of GAI in health care settings, it is imperative that health care professionals are equipped to

XSL•FO
RenderX

understand, use, and evaluate these technologies as it relates to their practice. Improving health care professionals' literacy around GAI can help mitigate risks associated with bias in clinical decision-making. Emerging work on AI literacy may provide a framework for evaluating and promoting essential knowledge for using GAI across domains [56]. As GAI becomes increasingly integrated into health care, it is essential that health care professionals are equipped not only to use these technologies but also to educate patients, laypeople, and other providers about their limitations.

There are significant ethical concerns related to the integration of GAI into mental health care. Although GAI systems offer potential benefits, such as enhancing accurate clinical decision-making, these systems also pose risks [28,29]. GAI models can inadvertently reinforce harmful stereotypes or produce misleading recommendations due to inherent biases in their training data, particularly when applied to trauma-exposed, minoritized, or otherwise vulnerable populations. Given that GAI lacks human judgment and contextual understanding, relying too heavily on its outputs without clinical oversight could lead to inappropriate treatment decisions or reduced patient trust [57]. Furthermore, overreliance on GAI for clinical decision-making may erode providers' abilities to engage in these tasks. As these tools become more integrated into mental health settings, ethical guidelines must be developed to ensure responsible deployment, including greater involvement of providers in model training and testing, transparency in how models are trained, clear delineation of clinical responsibility, and safeguards to protect clinical populations [29,55-57]. Furthermore, as GAI continues to be scaled into health care technologies, it is increasingly important to embed intentional design choices in these technologies to minimize the risk of inaccurate, biased, or otherwise harmful decisions [57].

A few limitations should be noted. Primarily, research on trauma-related diagnostic overshadowing to date has been experimental. The vignettes in our study were brief and may not provide as much information as would be available in real-world clinical care settings. The specific prompting strategies used in this study may not reflect how clinicians interact with GAI tools in real-world practice. Clinicians are unlikely to use fixed Likert-based or forced-choice questions when using these tools and the context in which prompts are given can vary considerably. More research is needed to understand how MHPs may prompt GAI in real-world contexts [57]. Although standardized prompts were used in this study, slight variations on these prompts may result in different responses, including responses that may contain hallucinations or inaccurate responses. To match the paradigm for MHPs, prompts were not counterbalanced across trials, which is a limitation given the sensitivity of GAI models to prompt order and phrasing. While this fixed prompt order was necessary to mirror the methodology for MHPs, future work should explore how alternative or counterbalanced prompting strategies influence responses as it relates to clinical decision-making with trauma-exposed populations.

Furthermore, past work has shown that previous versions of specific GAI models can struggle to provide appropriate and safe guidance in response to complex clinical information [19,58]. As such, more research incorporating different streams of information, clinical presentations, and experimental methodologies is necessary to understand how GAI models can best support clinical decision-making with trauma-exposed populations. Moreover, more research is needed to understand how this bias contributes to decision-making in real-world contexts. In doing so, it may be important to understand if and how MHPs may be currently using GAI to support clinical decision-making with trauma-exposed populations. Only a few diagnostic presentations were considered for this research, and GAI models as well as MHPs may demonstrate differences in trauma-related diagnostic overshadowing in response to different symptom presentations, as shown in this work. This research also used a structured experimental paradigm, limiting our understanding of how GAI models may respond to less-structured prompts (eg, prompts in which diagnoses and treatment options are not provided). Ultimately, GAI models are often updated quickly, resulting in differences in their capabilities and outputs. As a result, findings from this study may not generalize to future versions of these models or to different applications of GAI within mental health care. More work may be needed to evaluate this bias in future versions of GAI models.

Despite these limitations, our study is the first to examine whether GAI models demonstrate trauma-related diagnostic overshadowing bias. Findings indicated that GAI models are not free of bias and the degree of bias is specific to the task and model. Notably, GAI models demonstrated less evidence of trauma-related diagnostic overshadowing than MHPs. GAI may be able to provide significant support to clinical decision-making in mental health care; however, there are important considerations for doing so. Future research should aim to further examine and develop strategies to address the presence of trauma-related diagnostic overshadowing among GAI models. In addition, research should aim to understand how best to use GAI to support MHPs to facilitate optimal clinical decision-making for trauma-exposed populations.

Abstract

Background: The uptake of digital mental health tools (DMHTs) in mental health services is suboptimal, limiting key avenues to facilitate personalized and measurement-based care. This misses critical opportunities for enhanced patient-clinician communication, improved assessment, and early intervention.

Objective: This paper aims to understand young people's experiences and perceptions of engaging with a DMHT to support their care in a real-world setting over time.

Methods: This study is part of a larger randomized controlled trial, where an added human support, the digital navigator (DN), provided technological and engagement assistance for young people to use a DMHT as part of usual care. The DN conducted 118 semistructured interviews with 73 young people (mean age 22.7, SD 2.7 y) at baseline and 3-, 6-, and 12-month follow-up visits.

Results: We found that the majority of young people were enthusiastic about incorporating a DMHT into their care when they understood its potential to facilitate shared decision-making and enhance self-awareness of their mental health. Notably, the DN's support was effective in fostering this understanding at the initial stages of implementation. However, it was evident that the lack of clinician buy-in for using the DMHT posed a risk of disillusionment to young people's sustained engagement with the tool. Young people perceived that clinician uptake of the tool was poor, limiting its perceived value addition and sustainability.

Conclusions: Young people want to use DMHTs in their care and DNs can effectively facilitate implementation through ongoing engagement and technical support. However, successful implementation of DMHTs also depends on broader systemic factors, particularly on clinician and service engagement. Future research should examine how to address these contextual barriers and optimize DN support for implementation and sustained engagement of DMHTs.

KEYWORDS

youth mental health; digital navigator; digital mental health; measurement-based care; digital mental health tools; health services research

Introduction

Youth mental health has emerged as a global crisis [1], with mental disorders affecting more than 1 in 10 individuals aged between 5 and 24 years and accounting for the highest disease burden in this age group [2]. Despite the widespread use of psychotherapies and pharmacotherapies, their overall effectiveness remains modest [3,4], highlighting the need to enhance personalization and precision in treatment [5].

Measurement-based care (MBC) offers a promising solution by systematically collecting standard measurements to inform and guide mental health care. It involves 2 main components, routine collection and review of client-reported outcomes, to monitor progress, evaluate treatment plans, and inform shared decision-making [6]. Digital mental health tools (DMHTs) have been introduced in services to facilitate MBC, increasing accessibility to multidimensional measures and assisting with data interpretation by visualizing symptom progress [7,8]. Such

XSL•FO
RenderX

DMHTs are able to detect at-risk clients [9,10], support client-clinician communication [11], and improve treatment engagement and outcomes [12-14]. Given the challenges associated with accurately predicting clients who are more likely to deteriorate in care [15], the iterative process of symptom tracking and review using DMHTs ensures that treatment is data-informed [16] and personalized to individuals' changing needs [17]. This is particularly beneficial for young people who often present with complex and heterogeneous symptoms that do not fit into specific diagnostic criteria [18,19].

Despite its potential, implementation of DMHTs in mental health services remains challenging. Meaningful engagement and complete integration of DMHTs into services are crucial factors for success [20-22]. Yet, barriers to client, clinician, and organizational uptake are complex. These challenges are closely tied to various aspects of service capacity: high service demand can limit the time for adoption, insufficient education and training reduces clinician confidence in effectively using these tools, and a lack of leadership support undermines organizational commitment to integrating DMHTs into routine care [23-25]. Furthermore, conflicting reports exist on the feasibility and acceptability of DMHTs. For example, while some clinicians perceive regular monitoring as overly time-consuming for their clients [26,27], a meta-analysis demonstrates high adherence and acceptability rates even among people with severe mental illnesses [28]. This discrepancy, along with the suboptimal uptake of DMHTs [29,30], indicate a need for a deeper understanding of the factors that influence young people's experience of and engagement with these tools, especially over time.

A potential solution to address these barriers is the introduction of a digital navigator (DN) role into health services [31]. A DN can optimize the value of DMHTs to clinical teams by being the conduit between the client, the clinician, and services. By providing technical and engagement support, they facilitate the implementation and adoption of these digital innovations in clinical settings [31,32]. They are responsible for improving accessibility, helping services to integrate new tools into clinical governance, and enhancing client engagement through regular support [33,34]. Furthermore, a DN with lived experience can provide an added benefit of peer support, fostering trust and accountability for clients using DMHTs in care [35].

Therefore, this study aims to assess young people's experiences and real-time changing perceptions of integrating a DMHT (Innowell, Innowell Pty Ltd), designed to facilitate highly personalized, measurement-based care and symptom data review into their routine care, with the support from a DN. The DN conducted semistructured interviews at 4 time points (baseline and 3-, 6-, and 12-month follow-ups) to understand their evolving engagement patterns and perceived value-add of the DMHT in a real-world clinical setting over time.

Methods

Study Context

This study is part of a larger, multisite, 24-month randomized controlled trial examining the clinical effectiveness of highly personalized MBC for young people (15 - 25 y) engaged in mental health services [36]. The ongoing trial is being conducted at the University of Sydney's Brain and Mind Centre (Australia) and affiliated youth centers that treat young people with mental illnesses. While the broader trial involves multiple sites, the qualitative data presented in this paper were collected from a single site: Mind Plasticity, a private, specialist consortia based in inner-city Sydney that provides multidisciplinary care to individuals requiring mental health support. Participant recruitment, screening for eligibility, and obtaining informed consent are facilitated by the trial research team, per the trial protocol published elsewhere [36].

Both treatment arms have access to the DMHT—Innowell—and receive ongoing support from a DN. Innowell is a DMHT that seeks to promote better mental health outcomes by facilitating access to comprehensive multidimensional assessment and real-time results to inform clinical care [37]. The DN role focuses on providing peer support to participants, aiding their understanding of how to use the tool in their care. This includes motivating them to use Innowell, developing strategies to enhance their engagement, resolving technical issues experienced by participants, carers, and clinicians, and performing data collection.

The Digital Navigator

The DN (author CG) was embedded in the service as part of the trial design. The DN's previous professional experience in a public youth mental health service, where she was involved in a service redesign that resulted in the implementation of Innowell, was instrumental to her approach to the DN role. Lived experience is a key factor of this role and this expertise was crucial to forming rapport with participants to share information about their current care and how Innowell can enhance it [38]. As the DN had previous professional experience with Innowell, her training was more practical as part of a pre-trial phase, which focused on optimizing the role for the specific service [32].

Within the trial, the DN's duties were to regularly interact with all participants, while tracking Innowell engagement data only for those in the intervention arm. The DN's focus was to monitor the frequency of Innowell use among the intervention arm participants, to ensure their consistent symptom tracking. When the DN noticed that a participant had not entered symptom data for more than 21 days, this was marked as a risk of disengagement. Subsequently, this prompted the DN to contact the participant to address any concerns regarding the use of Innowell. This peer support aimed to encourage participants to resume using Innowell.

Data Collection

The trial protocol [36] details the full set of data items and collection processes, which includes a structured clinical interview for *Diagnostic and Statistical Manual of Mental Disorders* [39], standardized clinical assessments, and ongoing data collected via Innowell. Relevant data collected and analyzed here includes research observations and field notes recorded by the DN during 4 "study visits" with young people conducted at key time points: baseline and 3-, 6-, and 12-month follow-ups.

XSL•FO
RenderX

A final visit will occur at the trial's end (24 months). Study visits were initiated by a research assessor, that is, a member of the research team who conducted clinical assessments with participants. After that, the DN had a brief follow-up discussion (approximately 5 min) with participants to provide ongoing support and complete data collection.

Textbox 1 details the discussion topics that guided the study visits between the DN and participants, and Multimedia Appendix 1 collates the most common questions asked by the DN. The discussion topics and questions were adapted to ensure a natural conversational flow and account for various other factors, including, for instance, a participant's current level of care, previous experience of using Innowell in care, and mental health status. Study visits were conducted in-person, over the phone, or via Zoom teleconferencing software (Zoom Communications), and ranged between 5 and 30 minutes. Multiple participation modalities were offered to enable young people to participate via their preferred method to maximize safety, comfort, and scheduling. In-person study visits were conducted at the Brain and Mind Centre to provide participants with a safe, comfortable, and private environment, with a nearby supporting mental health clinician made readily available. Similarly, as an equal member of a participant's care team, a crucial factor in encouraging engagement with Innowell [32], the DN is well positioned to inspire a safe and comfortable environment, open feedback, and familiarity among participants as a data collector. All semistructured interviews were conducted with risk protocols in place for the DN, ensuring clear boundaries between the DN's peer support role and clinical responsibilities, and escalation protocols when required. These were established as part of the trial to ensure the safety of both the DN and the participants.

- Improving accessibility.

Data collected included research observations (eg, participant behavior and environmental factors during interviews) and field notes (eg, interviewer reflections and interpretations during interviews). Interviews were not recorded and transcribed, instead the research observations and field notes were combined to form the interview data, which documents views on how the DN role functions (from the participant's and DN's perspective); participant experiences with their care and Innowell (eg, Innowell onboarding completion and duration of use); contextual information (eg, participant demographics, trial enrolment status and time point, changes in participant's care delivery and life circumstances, regularity of clinical appointments, etc); and verbatim responses to questions during the discussion. Field notes and research observations enable researchers to collect rich contextual information about the participants' lives and study engagement [40], and thus are suitable for constructing rich descriptions of the study visits, participant responses, and researcher reflections as data for thematic analysis [41,42]. Interview data was later deidentified, collated, and organized by individual participants in question-response format for data analysis.

Data Analysis

This study used reflexive thematic analysis to develop and report themes based on patterns of shared meaning in the interview data [43,44]. Established thematic techniques reported by Braun and Clarke [45] guided this study, informing 6 iterative, flexible phases: familiarizing yourself with the data, generating initial codes, searching for themes, reviewing potential themes, defining and naming themes, and producing the report. The data was interpreted using an inductive approach. NVivo 14 (Lumivero) was used to collate and code interview data.

Here, the following thematic analysis processes were completed. First, 3 co-authors (CG, MKC, and AP) independently reviewed 5 interviews and generated initial codes. Following thematic analysis best practice, generating codes involved the 3 co-authors "closely reading the data, considering what is interesting and important, and then assigning a code label that captures your understanding of the meaning of a segment of the data" [46]. Codes were not predetermined before analysis, were subject to evolve as understanding deepens, and were labeled with descriptions of why some data are relevant to the research question [46]. Following that, in discussion, the initial codes were reviewed, combined, and revised, and new codes were developed. Importantly, noting an adaption of the reflexive thematic analysis method here [47], a mutable coding framework was created collaboratively to be used as a flexible guide for the remaining analysis to ensure that the multiple co-authors could independently code using a shared language. After that, using the flexible coding framework, 4 co-authors (CG, MKC, AP, and AT) each independently reviewed and coded a part of the total remaining interview data. After that, in group discussion, variability between coauthors' codes was resolved to ensure that codes were mutually agreed upon, and the final set of codes were consistently applied across the combined dataset. Then, on 2 occasions, the 4 coauthors (CG, MKC, AP, and AT) met to iteratively develop, review, and label the themes in consultation with the senior author (FI). Multimedia Appendix 2 shows an in-depth description of how specific themes were finalized. Through this collaborative and iterative process, consensus was reached on the final set of codes and themes, ensuring coherence and consistency.

Following best practices for thematic analysis, the principle of information power is preferred to data saturation in determining

XSL•FO
RenderX

whether data provides a sufficient basis for the proposed analysis [46]. As per the information power principle, a study needs fewer participants when the study primarily addresses a narrow aim (ie, young people's experiences and perceptions of engaging with Innowell), the participants represent similar experiences and knowledge (ie, young people), the study is grounded in existing theory (ie, MBC), an experienced interviewer conducts it, and it addresses a single case analysis [48]. The sample size here adequately satisfies the typically expected 15‐30 participants range for single case studies [48], and thus, the study holds ample information power to develop new knowledge.

Ethical Considerations

This clinical trial was approved by the Human Research Ethics Committee of the Sydney Local Health District (HREC X22-0042 and 2022/ETH00725)" and all participants gave informed consent for their qualitative data to be used for research purpose. All data had been de-identified. Participants received a AUD$50 Coles/Myer gift voucher at the completion of the baseline assessment and a further AUD$50 voucher at the completion of the 12th assessment.

Results

Participants

A total of 73 young people aged between 15 and 25 years participated in this study. A total of 118 interviews were conducted: 73 at baseline, 5 at 3-month, 29 at 6-month, and 2 at 12-month follow-up visits. The mean age of participants was 22.7 (SD 2.7) years and 51 (69.9%) participants were female. Table 1 shows the mental health diagnoses of participants.

Table . Demographic and clinical presentation of participants.

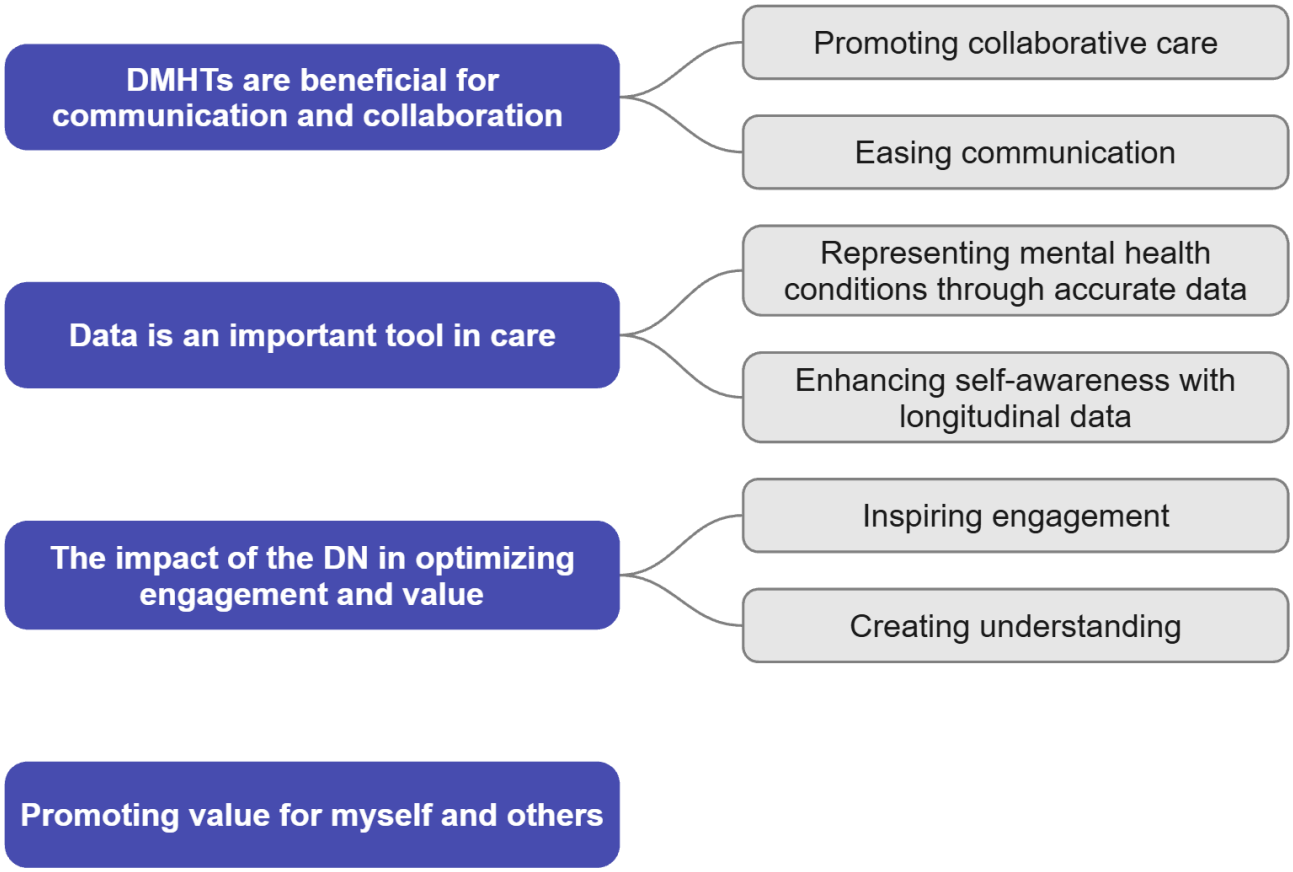
Lifetime diagnosis of mental disorders	Participants (N=73), n (%)
Major depressive disorder	53 (72.6)
Anxiety disorder	60 (82.2)
Bipolar I disorder	4 (5.5)
Bipolar II disorder	7 (9.6)
Substance use disorder	1 (1.4)

Thematic Analysis

A total of 4 themes and 6 subthemes were developed based on patterns of shared meaning in the data using reflexive thematic analysis (see Table 2). The themes (and subthemes) include: "DMHTs are beneficial for communication and collaboration" (subthemes: promoting collaborative care and easing communication), "Data is an important tool in care" (subthemes: representing mental health conditions through accurate data and enhancing self-awareness with longitudinal data), "The impact of the DN in optimizing engagement and value" (subthemes: inspiring engagement and creating understanding), and "Promoting value for myself and others."

Table . Theme names and descriptions.

Theme name	Theme description
DMHTs[a] are beneficial for communication and collaboration	Relationships and communication in care and the introduced role of DMHTs.
Data is an important tool in care	How data is impactful and used by young people and clinicians in care.
The impact of the DN[b] in optimizing engagement and value	Key roles of the DN for improving understanding and engagement of DMHTs and to advance toward personalization.
Promoting value for myself and others	Meaningful ways DMHTs can be used to add value to oneself and for the broader community via informing service provision change.



[a]DMHT: digital mental health tool.

[b]DN: digital navigator.

Figure 1 visualizes the final thematic map, indicating the 4 themes developed during analysis. Per best practices for reporting thematic analysis [45], Multimedia Appendix 2 shows the complete process of thematic development.

XSL•FO
RenderX

Figure 1. Final thematic map. DMHT: digital mental health tool; DN: digital navigator.

DMHTs Are Beneficial for Communication and Collaboration

Promoting Collaborative Care

Participants experienced a positive change in the quality of their care when their multidimensional assessment data was collaboratively discussed with clinicians. They found that the DMHT, Innowell, effectively coordinated care between various health professionals (eg, general practitioner, psychologist, and psychiatrist), tracked medication response, and informed care plans based on individual progress. The collaborative use of collected symptom data with clinicians heavily influenced participants motivation, engagement, and ability to have meaningful experiences with Innowell.

Notably, participants' perceived value of Innowell increased when their data was used by clinicians to inform and modify treatment plans in response to their changing needs. For example, a participant found Innowell "most helpful" when it allowed them to "bring it up with [psychiatrist] and use it as a tool to review data together". They knew "from Innowell that this is how [they've] been and being able to pull it up and show [their psychiatrist]" led them to go into "immediate damage control" (Participant 1, 3-month visit). Similarly, participants liked that collaboratively reviewing their data with clinicians could facilitate proactive care. Before using Innowell, they were hopeful that regular symptom data input and review will allow clinicians to detect changes in their mental health early, so that they could be "addressed now, rather than later when it's too late or missed it" (Participant 2, baseline visit). Multimedia Appendix 3 shows additional quotes that illustrate participants' emphasis on the impact of the collaborative nature of Innowell.

However, most participants expressed that their clinicians did not deeply incorporate Innowell in their care. At baseline visits, most participants were enthusiastic to use Innowell as they learnt about its potential to enhance collaborative care with their clinicians. However, their initial motivation quickly diminished when neither Innowell nor their data was acknowledged or discussed with clinicians during their therapy sessions. The following feedback from a participant at 2 study time points illustrates this view:

> *I want to talk more about myself, share my emotions more during the therapy. I feel Innowell will help me communicate this to [my psychiatrist].* [Participant 3, baseline visit]

> *[My psychiatrist] never talked about it [Innowell] but I'm just doing it because of this trial… but it's not that helpful. Talking with a real person, like now, would be inherently better. It's just a website now, so I'm just inputting the data, like on auto-mode.* [Participant 3, 6-month visit]

In addition, participants wanted greater initiative from clinicians to drive collaborative care. At the 12-month follow-up, 1 participant recalled:

> *If I turned up at a session and (my clinician) was like "You didn't use Innowell, we have to do it now to get more out of your appointment," that would be more*

XSL•FO
RenderX

> *motivating for me. It really needs to be used with your clinician.* [Participant 9, 12-month visit]

Participants expected the use of Innowell to be also "valued by clinician[s]." However, when this expectation was not met during care, a participant expressed feeling "cheated" (Participant 43, 6-month visit) by their clinicians.

Easing Communication

Innowell was an effective communication tool for participants who carried guilt and shame around their mental health. Participants usually found it challenging to overcome these emotions and openly communicate their deteriorating mental health to their clinicians. During these periods, showing their symptom data on Innowell made "it a lot easier to communicate how [they were] feeling. [It was] really helpful for [them] to tell the truth about [their] emotions" and it was "easier to answer the questionnaires without feeling the guilt and shame to bring it up to [clinicians]" (Participant 4, 12-month visit).

In addition, the symptom data collected between sessions helped participants to effectively communicate important mental health changes during their appointments. Having data that illustrates their changes in mental health gave them confidence. A participant who used Innowell consistently for few months said that it allowed them to "actually [be] able to voice, and [feel] confident to voice [symptom changes to clinician] because all the information was there" (Participant 1, 3-month visit). They felt that Innowell helped them to feel more prepared for appointments because their data provided "a point of reference for [psychiatrist] but also a very good point of reference for [themselves]." (Participant 5, 6-month visit). They reported that this sense of readiness and made the sessions more efficient.

Data Is an Important Tool in Care

Representing Mental Health Conditions Through Accurate Data

Participants expressed different and sometimes contrasting perspectives on the value of standardized assessments for tracking treatment progress. Some participants expressed that they could "trust the answers more because [they knew] it was legitimate" (Participant 6, 3-month visit). Furthermore, the multidimensional measures allowed participants to break down and "differentiate those components that make up [their] mental health and better identify where that underlying feeling [they are] having lies" (Participant 6, 3-month visit) and helped them to "conceptualize what's going on for [them]" (Participants 7, 3-month visit).

Some contrasting views about standardized assessments were also reported. Although a quantitative representation of mental health provided insights into their symptom trajectories over time, this was not always useful as "some of those questions feel imprecise [to their diagnosis]" and "[it] doesn't necessarily capture things as deeply" (Participant 8, 6-month visit). Participants believed that their answers to the assessment were "a lot more of a complicated issue [and the assessment on Innowell] maybe doesn't go into enough detail" (Participant 5, 6-month visit). The inability to provide the additional context to these assessments made participants question "the accuracy in terms of what the data is looking at" (Participant 8, 6-month visit).

Enhancing Self-Awareness With Longitudinal Data

Participants found the longitudinal symptom data on Innowell to be insightful for self-reflection. In particular, the visual presentation enhanced participants' understanding of their mental health trajectory over time (see Figure 2). This data-driven self-awareness empowered them to identify "slightest of dips on the graph" and take proactive steps to "help manage [their] symptoms by catching it in time" (Participant 9, 6-month visit).

XSL•FO
RenderX

Figure 2. Graph summary of a client's Innowell.

The insights gained from their personal mental health trajectory served as a motivational factor for some participants. They reported feeling hopeful even during difficult periods of poor mental health because they understood its dynamic nature from previous symptom data. It served as a reminder that positive periods would return. For example, one participant who consistently used Innowell recalled that:

> *I've never had the opportunity to look back and see when things have been good. In my head, I think you focus on the times you've been bad so that becomes all you see in yourself, but it's nice to look at it [the graphs] and be able to go "hey, I was pretty good there."* [Participant 10, 6-month visit]

Furthermore, longitudinal symptom data was used as an extension to their care, particularly for those who had irregular or infrequent appointments (eg, every 3 or 6 months). For these participants, access to Innowell helped them to "keep engaged in [their] mental health" between appointments and meant they "don't have to check-out completely" (Participant 6, 6-month visit). In addition, using Innowell as a personal record keeping tool was useful when explaining their condition to new health professionals.

The Impact of the DN in Optimizing Engagement and Value

Inspiring Engagement

One of the key responsibilities of the DN within the trial was to routinely encourage participants to complete questionnaires on Innowell to ensure routine outcome monitoring. Participants' feedback indicated that the DN played a critical role in galvanizing young people to use Innowell from the beginning and sustaining their engagement throughout the trial.

The rapport that formed between participants and the DN through regular contact served as a strong motivator for engagement. The genuine empathy, compassion and lived experience of the DN made participants feel that the DN "actually care[d] about [them] using the technology as part of [their] appointments" (Participant 7, 6-month visit). The importance of human support is exemplified by a participant's feedback stating that the DN's personalized text reminders for Innowell completion were "honestly the most helpful" for ongoing use of Innowell and "very useful in terms of helping [them] feel supported to use it" (Participant 11, 6-month visit). In addition, another participant described that it was "a relief to know that a DN is looking at it and monitoring [their] Innowell when updated" and "nice knowing that there's someone there to support [them] with it if [they] ever need it" (Participant 12, 6-month visit).

Beyond providing engagement support, the DN helped participants to alleviate technical barriers of using Innowell, although the approach and outcome differed case by case. Exemplary approaches revolved around offering in-person support where possible, providing accessibility tips, and supporting creative problem-solving. These are examples from different participants at the 6-month follow-up visits, who initially were not using Innowell regularly due to difficulties with access. These quotes illustrate the added value of the DN in collaborating with young people to find individualized solutions to alleviate barriers and inspire engagement:

> *[Innowell] only really works for me when it's in person…Every time I've been in the clinic, [the DN] has been really good at motivating me to do it…In-person support [from the DN] is absolutely the way to go.* [Participant 13, 6-month visit]

> *[After the DN explained how to access the log in page of Innowell] That's much better. Now I'll be able to access it easier. I can see myself doing the questions more consistently now.* [Participant 14, 6-month visit]

However, there were limitations to alleviating barriers that extended beyond the control of the DN. In most cases, these barriers revolved around clinician engagement and uptake with integrating DMHTs into clinical practice, appointment

XSL•FO
RenderX

frequency, duration and type of care, and external technological factors. Multimedia Appendix 3 shows participant quotes that illustrate this.

Creating Understanding

For participants, understanding the benefits of Innowell and practical implementation strategies as part of their care were important drivers for ongoing engagement. Informed by their lived experience, the DN had a substantial understanding of participants' needs and challenges within the mental healthcare system. Therefore, the DN was effective in communicating how participants' current needs can be addressed through Innowell. Providing explanation on complex concepts such as MBC, self-advocacy and shared decision-making further supported participants' understanding of the benefits of the tool. Establishing this understanding made the implementation of Innowell "[make] a lot more sense…behind why I should do it and knowing when to do it too" (Participant 15, baseline visit). The tailored suggestions of the DN on how participants could "use Innowell in a way that aligned with my goals for using it in my care" (Participant 1, 6-month visit) were deemed especially helpful.

An exemplary scenario demonstrates the role of the DN in creating understanding of Innowell to motivate engagement. A participant, initially hesitant to use Innowell due to a negative experience at a different mental health service, discussed their concerns with the DN. Recognizing that Innowell had previously been misused with this participant, the DN allayed their reluctance by explaining its purpose and how it could be effectively integrated into their care. The following is a segment from that conversation:

> *Explaining the intent of it was really helpful. It [Innowell] was never explained to me how it should be used. It's really helpful to know not just how I'm meant to use it but also knowing how a clinician is supposed to use it. I can see that when your clinician understands this intent too, it has the potential to be really helpful for the person…I can see how Innowell can work when it's used properly.* [Participant 16, baseline visit]

Promoting Value for Myself and Others

Participants often expressed a broad, altruistic perspective on the potential of DMHTs when discussing their expectations and goals for using Innowell as part of their care. Many felt that Innowell could catalyze meaningful and essential transformations across all levels of the mental health care system—from organizational change to empowering themselves and other young people to shape the improvements they seek in their care.

Multiple participants reported to the DN that they were actively seeking ways to improve their current care, explaining that "the therapeutic relationship hasn't evolved with the needs that [they] have as [they've] grown up…even though [they] would like something different" (Participant 17, baseline visit). They even went so far as to say "[The clinician] thinks I'm okay, but actually no, I'm not" (Participant 17, baseline visit). Participants welcomed the integration of DMHTs, seeing it as a way to address perceived limitations in their current care. They felt that "Innowell can help [them] to advocate for what [they] really need" (Participant 17, baseline visit), and it "could make care more well-rounded, more progressive" by "break[ing] down a lot of barriers for young people who receive care" (Participant 18, baseline visit).

However, across different time points, participants voiced concerns about the potential for DMHTs to be implemented poorly by clinicians and services. When Innowell was not incorporated into their sessions, one participant expressed that they would "like the Innowell platform to be seen as part of [their] care. It needs to be seen as an integral component to how clinicians and a service operate." The participant wanted to "see the platform be more driven and encouraged by clinicians" (Participant 19, 6-month visit). The delay and reluctance of services and clinicians to integrate DMHTs in care was seen as a sign that the healthcare system needs to adapt to young people's needs and views.

On a broader level, participants viewed their involvement in the trial as an opportunity to create meaningful change in mental healthcare delivery, benefiting future help-seeking young people. They expressed a desire "to be involved in helping develop mental health systems that can better support others" (Participant 15, baseline visit). They believed that "this kind of stuff makes things better for people in the future" (Participant 1, 6-month visit) and that "change will only happen when [their] needs and voices are represented in research, that is linked to empirical evidence to support that change that needs to happen" (Participant 20, baseline visit).

Discussion

Principal Findings

This study explores young people's real-world experiences and evolving engagement with using a DMHT, Innowell, as part of their ongoing care in a real-world, clinical setting in Sydney, Australia. Particularly, the repeated observations and interviews conducted throughout care provided enriched understanding of their evolving perspectives in real time. The findings reveal that young people were enthusiastic about integrating the DMHT in their care when they understood how it can facilitate self-reflection, ease communication burdens, and enhance shared decision-making with their clinicians. The 4 themes developed here demonstrate the value of DMHTs for improving communication and collaboration in care, the usefulness of data as a tool, the significance of promoting its value, and the DN's role in translating the utility of DMHTs into practical applications. Overall, this study shows that most young people were motivated to adopt the DMHT to improve their mental health care. Notably, although most young people initially expressed interest in integrating the DMHT into their care, their sustained engagement and regular use of Innowell appeared to depend on the level of clinician involvement and its collaborative use in care. Furthermore, the study indicates that young people recognize the crucial role that services play in establishing the infrastructure required for the genuine, holistic adoption of DMHTs, highlighting the importance of proactive service-wide implementation in maximizing their benefits.

Young People Want to Use Technology

Contrary to views of some mental health professionals [26,49], this study demonstrates that young people are eager to use DMHTs as an integral component of their care. Participants reported that using the data collected from the validated measures in Innowell helped them feel more prepared for therapy sessions, provided an objective overview of their symptoms, and reduced feelings of guilt, shame, and anxiety associated with discussing changes in their mental health with their clinicians. In this way, the DMHT facilitated more open and honest conversations, and therefore, were willing to continue inputting their data. For young people, the primary value-add of using a DMHT was that it gave them an equal voice and enhanced self-advocacy, thereby supporting shared decision-making with clinicians and leading to more efficient, highly-personalized appointments that proactively addressed their real-time changing needs.

Similarly, positive experiences with tracking multidimensional data served as a motivator for sustained engagement with the DMHT. Some young people leveraged their data to gain accurate insights into their mental health trajectories, ultimately inspiring self-driven engagement [50]. A self-reinforcing loop developed for those who consistently used Innowell over a prolonged period: they entered their symptom data, gained insights, and continued tracking due to their positive experiences. Interestingly, these individuals exhibited an inherent drive to continue monitoring their own symptoms by using the DMHT regardless of their clinician's involvement. However, as observed from the qualitative interviews with the DN, mainly at 6- and 12-month follow-ups, there was a substantial decline in engagement with using Innowell shortly after the participants entered the trial. Therefore, this experience of benefiting from self-tracking their data was only reported among a minority of participants. Many participants disengaged from using Innowell regularly before they could discover the benefits of tracking their data over time. Hence, the study suggests that without these positive experiences during the early stages of using the DMHT in care, its prolonged use is at risk of being limited.

Collaboration is Key for Meaningful Engagement

A total of 2 interdependent factors were identified as enhancing sustained engagement with Innowell and creating understanding of DMHTs: the support of a DN with lived experience and collaborative use with clinicians. In this study, incorporating a DN provided young people with both personalized engagement and technological support alongside their regular care teams. The DN offered continuous communication about the rationale and the value of using Innowell through frequent check-ins, engaged in meaningful discussions regarding the young people's care and health priorities, and subsequently developed tailored, highly-personalized plans for using Innowell in their care. Supporting previous studies that emphasize on client's understanding on the rationale of DMHTs [51,52] for successful implementation, our findings show that young people's misunderstandings or concerns about using a DMHT as part of care were alleviated when its purpose and functionality were clearly explained (eg, advising that the technology is not a substitute for in-person clinical care, how to access the login page correctly, and best practices for questionnaire response frequency). Notably, these positive benefits of the DN depended on their ability to build a strong rapport with the participants. These findings suggest that a DN's experience, empathy, and compassion may be essential characteristics that could determine the effectiveness of the role. Therefore, to ensure scalability and consistency of this role, standardized training protocols should be developed for future DNs, with a particular focus on interpersonal skills, which are crucial for effective client engagement in mental health settings [34].

In addition to the DN's support, clinicians' collaborative use of the collected data was essential for fostering young people's meaningful engagement with the DMHT. Clinician feedback, open communication, and shared decision-making are established motivators for continued engagement and improved treatment outcomes [20,52-54]. Conversely, when data collection is not paired with the use of the data with clinicians, this has been reported to limit clients' engagement with such DMHTs [25,55].

The findings of this study align with previous research, as clinicians' use and reviewing of data during sessions emerged as a critical element in helping young people to appreciate the DMHT and its relevance in their care, particularly for contextualizing and monitoring their tracked symptoms. When clinicians did not discuss or review collected symptom data in Innowell during appointments, therefore, reducing the opportunity for collaborative care and communication, this then decreased the perceived clinical relevance of symptom tracking among young people. As a result, this led to disengagement from using the DMHT. It is important to also note that, some factors, such as infrequent appointments (eg, every 3 or 6 months) or discharge from the service, also contributed to reducing the perceived clinical value of Innowell and disengagement from using the technology. However, echoing previous findings, the reluctance of clinicians and services to review progress from routine outcome monitoring data were perceived as a lack of concern for, or indifference to clients' needs [56,57]. In contrast, collaboratively reviewing longitudinal data enabled proactive responses to young people's changing needs, such as re-evaluating medication and expediting appointment schedules.

Young people highlight the critical need for collaboration between clinicians and DNs in using DMHTs as part of care. For instance, at baseline visits with the DN, young people were initially enthusiastic about engaging with Innowell to achieve their goals. However, most became more sporadic in their engagement, especially as their clinicians showed reticence to incorporate Innowell into their sessions. The majority of their frustrations came from clinicians not utilizing Innowell effectively or not meeting young people's expectations for using it. This reiterates established systematic challenges including inadequate training for clinicians and service staff, and lack of supportive environments with clear protocols, strong leadership, and resources such as DNs [57,58]. Further research should focus on extending the DN's role to support communication between the client-clinician dyad and help clinicians to make effective use of the DMHT to facillitate collaborative care. [32,59].

Implementation Implication

A plethora of research demonstrates the multifaceted challenges associated with the uptake of DMHTs by mental health clinicians and services. At the clinician level, barriers to implementation include time and resource burdens [60], performance anxiety [61], difficulties integrating with existing electronic systems [60], and insufficient training and leadership support [25,61,62]. At the service level, structural challenges, such as the need for systematic changes and lack of funding, remain significant obstacles to widespread adoption [25,63]. However, the growing evidence of its effectiveness [64-66] and young people's willingness to adopt this model calls for a concerted effort from all stakeholders to integrate DMHTs effectively into mental health services [67]. Findings from this study indicate that DNs play a key role in alleviating barriers to engagement with DMHTs among young people. Emerging recommendations for DN-driven approaches to address these barriers and support engagement are collated in Textbox 2. Future research should explore longitudinal systematic integration of DMHTs in services. Beyond initial deployment, studies should explore how the adoption of DMHTs can be effectively sustained in services over time. Future research is needed to understand the long-term sustainability of DNs in services and examine how the role can be integrated successfully to reduce the clinical barriers to implementation. Previous research has shown a variety of methods of implementation [31,32], but long-term studies with a DN in a service, measuring their impact, the engagement rate of clinicians, and the outcomes of young people using a DMHT, would significantly improve the current body of research. Of particular note is if there is a "silver bullet" implementation strategy that can be scaled amongst a significant population of services.

Textbox 2. Textbox 2. Recommendations for how digital navigators (DNs) can support engagement with digital mental health tools (DMHTs) in youth mental health.

1. Provide hands-on onboarding support: assist young people with setting up accounts and completing initial assessments.
2. Explain the purpose and benefits of DMHTs: ensure young people understand how DMHTs can enhance their care (eg, through enhanced communication, progress monitoring, and personalized care coordination).
3. Support symptom tracking integration: help young people to interpret and use their longitudinal data during appointments.
4. Foster ongoing engagement: maintain regular communication with young people (eg, sending reminders for completing questionnaires).
5. Facilitate collaboration for meaningful use: alert clinicians or managers of deteriorations and assist young people's progress feedback during case review.

Limitations

Despite the strengths of this study, including longitudinal observation and interviews, the results should be interpreted in consideration of its limitations. First, the study focuses solely on young people's perspectives, leaving the perspectives of clinicians and services unknown. Examining clinicians' perspectives may reveal different ways they engage with DMHTs, such as Innowell, that may not be apparent to young people using the DMHT. Second, the study lacks quantitative measurements of young people's use of Innowell, such as the frequency of questionnaire completion and their symptom trajectories over time. Such metrics could have complemented the qualitative data by characterizing the type of individuals who are more likely to benefit from using DMHTs in their care. Third, qualitative data indicates that the study sample consisted primarily of young people who were familiar with care. While this may limit the generalizability of the findings to those who are new to care, these participants' previous experiences provided deeper insights into how DMHTs could be better integrated into care. Fourth, the data were collected from young people at a single site (Mind Plasticity), a private mental health service in inner-city Sydney, which likely influenced the socio-economic and cultural profile of participants. This context may not represent the experiences of young people from other diverse backgrounds, those accessing other types of services in different geographical locations, or other age groups with different technology preferences and care needs. As the multi-site clinical trial is ongoing, future analysis of data from other sites will address this limitation by providing insights from more diverse service contexts. Fifth, while the longitudinal design is a strength for this study, the smaller sample size for the follow-up interviews does reduce the impact of these longitudinal findings. The follow-up interviews tended to be opportunistic and are not reflective of dropout of the study itself (beyond the scope of reporting of this study). While the sample size might be limited at follow-up, sufficient information power was reached as no new information was generated between the 6- and 12-month interviews, and so we expect that the 29+ longitudinal interviews provide us with enough detail to understand how views differ over time. Future studies will focus on understanding longitudinal changes in views further by using a more robust sample size. Nevertheless, the data collected from the 6-month interviews had reached sufficient information power and demonstrated young people's experience of engaging with Innowell as part of usual care. Finally, wider evaluation across multiple clinical settings and contexts would be useful in the future to investigate how different service characteristics and settings shape user experiences, how DN support needs to be adapted for different populations to ensure equity in implementation, and the impact of DNs on implementation of DMHTs across diverse health care environments.

Conclusion

The implementation of DMHTs has the potential to significantly transform mental health services. Young people recognize the value of using DMHTs in their care, and DNs play an important role in its implementation by reinforcing the rationale behind using the tools and providing engagement and technical support. However, the fidelity of DMHTs and young people's sustained

XSL•FO
RenderX

engagement are contingent on wider contextual factors, including clinician and service engagement. Therefore, it is essential to explore how these factors can be addressed and how DNs can further support services to use DMHTs and long-term engagement.

Acknowledgments

The funding sources of this study have had no input into the design and conduct of the study; collection, management, analysis, and interpretation of the data; preparation, review, or approval of the manuscript; and decision to submit the manuscript for publication. This study was part of the investigator-initiated trial funded by the National Health and Medical Research Council (NHMRC) – 2020 Clinical Trials and Cohort Studies (application ID: 2001568). CG was supported by the Ainsworth 4 Foundation. IBH is supported by a NHMRC Leadership L3 Fellowship (GNT2016346); FI is funded by a NHMRC Emerging Leadership Fellowship (GNT2018157). SM is supported by the Cottle Family Fellowship in Youth Mental Health. MKC was supported by the Australian Government Research Training Program (RTP) Scholarship.

Authors' Contributions

CG and MKC are joint co-lead authors. CG, MKC, and FI conceptualized and designed the study. AP and AT assisted with conceptualization. CG was the digital navigator and collected the data. CG, MKC, AP, AT, and FI analyzed and interpreted the data. AP designed and developed the thematic map. MKC and CG wrote the manuscript. AP, AT, and FI substantively edited and revised the manuscript. All authors (CG, MKC, AP, AT, HML, SM, EMS, IBH, and FI) edited and revised the manuscript, and approved the final version of the manuscript.

Conflicts of Interest

EMS is principal research fellow at the Brain and Mind Centre (BMC), University of Sydney. She is discipline leader of Adult Mental Health, School of Medicine, University of Notre Dame, and a consultant psychiatrist. She was the medical director, Young Adult Mental Health Unit, St Vincent’s Hospital Darlinghurst until January 2021. She has received honoraria for educational seminars related to the clinical management of depressive disorders supported by Servier, Janssen and Eli-Lilly pharmaceuticals. She has participated in a national advisory board for the antidepressant compound Pristiq, manufactured by Pfizer. She was the national coordinator of an antidepressant trial sponsored by Servier. IBH is the co-director, Health and Policy at the BMC, University of Sydney. The BMC operates an early-intervention youth services at Camperdown under contract to headspace. He is the chief scientific advisor to, and a 3.2% equity shareholder in, Innowell Pty Ltd, which aims to transform mental health services through the use of innovative technologies.

Abstract

Background: Mental health concerns have become increasingly prevalent; however, care remains inaccessible to many. While digital mental health interventions offer a promising solution, self-help and even coached apps have not fully addressed the challenge. There is now a growing interest in hybrid, or blended, care approaches that use apps as tools to augment, rather than to entirely guide, care. The Digital Clinic is one such model, designed to increase access to high-quality mental health services.

Objective: To assess the feasibility, acceptability, and potential efficacy of the Digital Clinic model, this study aims to conduct a nonrandomized open trial with participants experiencing depression, anxiety, or both, at various levels of clinical severity.

Methods: Clinicians were trained in conducting brief transdiagnostic evidence-based treatment augmented by a mental health app (mindLAMP); digital navigators were trained in supporting participants' app engagement and digital literacy while also sharing app data with both patients and clinicians. Feasibility and acceptability of this 8-week program were assessed against a range of benchmarks. Potential efficacy was assessed by calculating pre-post change in symptoms of depression (Patient Health Questionnaire-9; PHQ-9), anxiety (7-item Generalized Anxiety Disorder; GAD-7), and comorbid depression and anxiety (Patient Health Questionnaire Anxiety and Depression Scale; PHQ-ADS), as well as rates of clinically meaningful improvement and remission. Secondary outcomes included change in functional impairment, self-efficacy in managing emotions, and flourishing.

Results: Of the 258 enrolled participants, 215 (83.3%) completed the 8-week program. Most were White (n=151, 70.2%) and identified as cisgender women (n=136, 63.3%), with a mean age of 41 (SD 14) years. Feasibility and acceptability were good to excellent across a range of domains. The program demonstrated potential efficacy: the average PHQ-9 score was moderate to moderately severe at baseline (mean 13.39, SD 4.53) and decreased to subclinical (mean 7.79, SD 4.61) by the end of the intervention (t_{126}=12.50, P<.001, Cohen d=1.11). Similarly, the average GAD-7 score decreased from moderate at baseline (mean 12.93, SD 3.67) to subclinical (mean 7.35, SD 4.19) by the end of the intervention (t_{113}=13, P<.001, Cohen d=1.22). Participation in the program was also associated with high rates of clinically significant improvement and remission.

Conclusions: Results suggest that the Digital Clinic model is feasible, acceptable, and potentially efficacious, warranting a future randomized controlled trial to establish the efficacy of this innovative model of care.

Introduction

Background

Common psychiatric disorders, such as depression and anxiety, are prevalent and costly. Recent nationally representative data suggest that approximately 1 in 3 adults—and 1 in 2 young adults—in the United States struggles with anxiety or depressive symptoms [1]. Although efficacious mental health treatments exist [2], demand for care outpaces its availability, leaving more than half of those with unmet mental health needs unable to access care [3]. Barriers include cost, inadequate insurance coverage, a shortage of clinicians, geographical challenges, stigma, and inadequate health care provider diversity, according to national data [4]. Alongside long-term health care system reforms, there is a need for immediate, scalable solutions to increase access to care.

Digital mental health interventions (DMHIs), delivered via smartphones or the internet, offer one promising solution. DMHIs can disseminate evidence-based interventions at scale and at low cost, and their inherent privacy can mitigate stigma. However, existing DMHIs have not yet fully realized their potential.

Problems With Efficacy, Engagement, and Trust

DMHIs range from unguided (ie, self-help apps and electronic learning modules) to guided (those that include varying degrees of human support). As unguided DMHIs offer greater scalability at lower cost, they have been touted as ideal solutions to access problems. However, challenges with efficacy, engagement, and trust have undermined their utility in addressing access problems [5,6]. In contrast, guided DMHIs have stronger evidence of efficacy, engagement, and trust.

First, meta-analytic evidence suggests that unguided (vs guided) DMHIs have lower effect sizes and are less effective for those with more severe psychopathology [7,8]. In addition, when given a choice between using a mental health app as stand-alone treatment or to augment in-person therapy, people with moderate and severe (vs mild) psychopathology prefer the latter [9]. Even internet-delivered cognitive behavioral therapy (iCBT) with minimal human support tends to be less acceptable than individual cognitive behavioral therapy (CBT) for people with higher clinical severity [10]. These findings suggest that the lack of human support may lower perceived quality and acceptability for many, especially those with higher clinical severity.

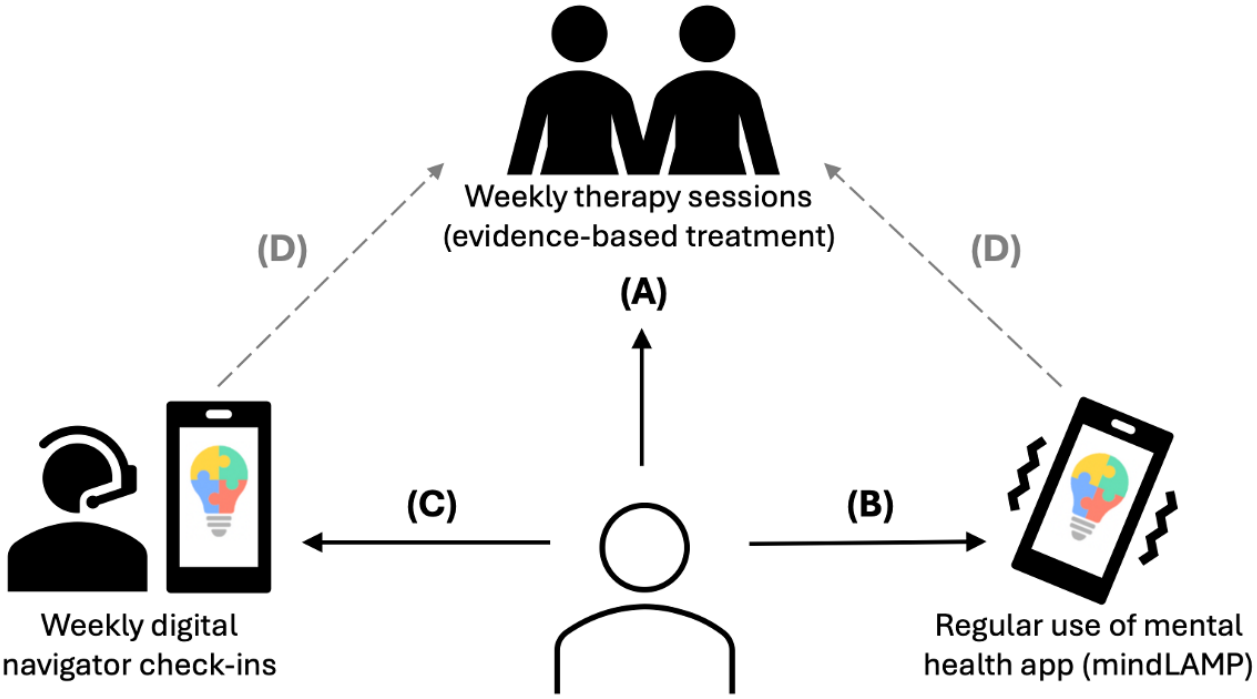
Second, unguided DMHIs suffer from low real-world engagement. Despite demonstrating efficacy in reducing depression and anxiety in randomized controlled trials (RCTs) [11], many stand-alone mental health apps fail to sustain engagement after just 10 days in real-world settings [12]. Similarly, the dropout rates of iCBT are as high as 80%, despite iCBT's demonstrated efficacy [13]. A recent systematic review found that DMHI engagement facilitators include greater digital literacy, more structured training in DMHI use, perceived DMHI relevance, and DMHI integration into daily life [14]. Because guided DMHIs can directly address such factors, they may be more capable of facilitating engagement [15]. Indeed, studies comparing unguided and guided versions of the same app show that the latter has better engagement and outcomes [16,17].

Third, mistrust of data handling hinders DMHI uptake [18]. Most DMHIs operate outside health care regulation and lack data use protections and transparency [18]. Examples of problematic data sharing practices and opaque privacy policies abound [19] and have, at times, led to high-profile privacy violations [20]. Such incidents undermine trust [21], contributing to low DMHI engagement [18].

Taken together, these findings suggest that sacrificing human support for scalability can lower quality and acceptability. To reach people with mental health problems that range in clinical severity, it is key to retain human support, design trustworthy DMHIs, and use scalable engagement strategies (eg, support that enhances DMHI use, relevance, and digital literacy). However, the challenge remains: how can this all be done without sacrificing scalability?

Guided DMHIs: More Viable Solutions?

While guided DMHIs have stronger evidence, they have also been incomplete solutions for addressing barriers to access. Many simply add digital components to the existing face-to-face care [22-26], which neither lowers cost nor impacts the workforce shortage. To address these barriers, some guided DMHIs have replaced clinicians with less costly supporters (eg, coaches and nonprofessionals) [27]. While the effect sizes of those DMHIs are higher than those of unguided DMHIs [28], it remains unclear when and for whom support is best provided by a clinician, coach, or nonspecialist [29]. Until it is known, retaining a trained clinician in care remains an important ethical consideration in DMHIs.



In addition, a key implementation challenge inherent to guided DMHIs remains unresolved: As DMHIs differ from traditional in-person services, they do not readily fit within traditional clinician workflows; as such, the addition of digital tools and data can feel burdensome to clinicians [30]. As a result, when DMHIs transition from RCTs to real-world settings, uptake tends to be low, and these tools are quickly abandoned [31]. Minimizing the added workload for clinicians is essential for the successful implementation of guided DMHIs. However, examples of effective DMHI integration into health care settings remain scarce [30].

A Practical Solution: Ensuring Scalability, Quality, Engagement, and Trust

A more comprehensive solution is that of the Digital Clinic, an innovative guided DMHI that combines brief clinician-delivered treatment via telehealth with between-session support from an app and a nonspecialist called a digital navigator [32,33], as seen in Figure 1. Each of the model's components addresses leading access barriers while supporting effectiveness.

XSL•FO
RenderX

Figure 1. The Digital Clinic. In the Digital Clinic, (A) the patient receives brief therapy sessions of evidence-based transdiagnostic treatment, provided via telehealth by a trained clinician. (B) The mindLAMP app is integrated into care, enabling real-world skills practice and measurement-based care, including digital phenotyping data collection. (C) Brief weekly check-ins are also held via telehealth with a digital navigator, who provides technology support, shares key data insights, and encourages sustained app engagement. (D) The Digital Navigator also shares data highlights from the app with the clinician, who then uses app data to inform clinical decision-making and enhance patient care in subsequent sessions.

First, to ensure both scalability and quality, the model offers brief evidence-based transdiagnostic treatment by a trained clinician (Figure 1A). Brief evidence-based interventions are more efficacious than treatment as usual for depression and anxiety [34-36]. Their brevity addresses the workforce shortage by freeing up clinicians faster; retaining the clinician in care increases the likelihood of reaching people with higher clinical severity.

Second, for greater scalability and impact, the mental health app mindLAMP is integrated into care to facilitate real-world skills practice and enable measurement-based care (Figure 1B). Recent meta-analytic evidence suggests that supplementing standard interventions with an app has additive effects [7], possibly increasing therapeutic dose without taking up additional clinical resources [23]. In addition, measurement-based care is a well-established yet underutilized approach to increasing care quality [37-39]. To facilitate measurement-based care, mindLAMP streamlines questionnaire administration and data visualization; data are discussed in sessions, informing clinical decision-making. The app's digital phenotyping capacity also enables the collection of behavioral data, offering additional insights for clinical care [33].

Third, to support patient app engagement and clinician data integration into care, a digital navigator is included in this model (Figure 1C). Designed to support innovative technology-enhanced care models, the broad purpose of the digital navigator role is to make technology usable and useful for patients and clinicians [40-42]. In the Digital Clinic, digital navigators support patients during weekly check-ins in several ways: they explain data use and privacy policies to facilitate trust in mindLAMP (which is already designed with the highest privacy and security standards). They also provide technical support and app use training, as needed, share data highlights with patients, and encourage them to use the app in ways their clinician has recommended. Digital navigators also offer data insights to clinicians that can inform patient care so that data enhances care without adding to clinician workloads [43]. As digital navigators do not need clinical expertise, the addition of this feature preserves the model's scalability and cost-effectiveness.

Finally, remote delivery methods are prioritized to enhance scalability and mitigate stigma, with therapy sessions and digital navigator check-ins conducted via telehealth. Telehealth is acceptable to patients [44], and brief evidence-based treatment via telehealth is noninferior to its in-person equivalent [45]. In addition, some data suggests that digital approaches can address stigma [46].

Prior research has not focused on or evaluated the feasibility and acceptability of a comprehensive care model incorporating all of these components to address leading access barriers. An earlier report on the development of the Digital Clinic showed that this model is promising [32]. In this study, we conducted an open trial to evaluate the Digital Clinic model's feasibility, acceptability, and potential efficacy in treating patients with common mental health problems ranging in clinical severity.

Methods

Participants

A total of 10 clinicians were involved in this study (5 master's and 3 doctoral mental health counseling students from local colleges, a postdoctoral-level clinical psychologist, and a licensed psychiatrist). Clinicians identified as White (n=6), Asian (n=3), and Black (n=1), and had a background in evidence-based treatment. In addition, 16 nonclinician volunteers with an interest in digital interventions were involved as digital navigators in the study [41,43]. Digital navigators were either college students (n=8) or had recently earned bachelor's degrees (n=8). They had no prior clinical experience, as the digital navigator role does not require clinical expertise but rather active listening skills, which can be taught in a curriculum [42].

Procedures

Recruitment and Enrollment Procedures

Individuals were screened on the basis of the inclusion and exclusion criteria shown in Textbox 1.

Textbox 1. Participant inclusion and exclusion criteria.

Inclusion criteria

- Aged at least 18 years
- Able to speak English
- Ownership of an Android or Apple phone

Exclusion criteria

- Severe intellectual or attentional deficits that would interfere with participation in therapy
- Acute suicidality requiring a higher level of care
- Current enrollment in a more intensive care program (ie, inpatient treatment, partial hospitalization, or detox rehabilitation program)

For potential participants who were in higher levels of care, we recommended transitioning to the Digital Clinic after discharge, allowing it to serve as a step-down, transitional care option. Participants with subclinical anxiety or depression severity scores were not screened out to avoid denying care to those whose distress may not have been captured by these measures, but they were later excluded from the analyses.

Participants were recruited primarily through referrals from primary care at 2 hospitals in the eastern region of Massachusetts, Beth Israel Deaconess Medical Center and Beth Israel Deaconess Hospital—Needham. A psychiatrist and member of the research team held informational sessions twice a year for primary care doctors from these 2 hospitals. These sessions focused on describing the Digital Clinic, its offering, eligibility criteria, and how to introduce it to potentially eligible patients. Referrals were then made directly from primary care providers (PCPs) to the psychiatrist on the research team, with no direct outreach or recruitment of primary care patients. Recruitment began in August 2022. Upon referral receipt, participants were sent a web-based screening questionnaire via email. Once this form was completed and potential eligibility was confirmed, participants were invited to attend a virtual appointment with a trained digital navigator, who would offer details about the intervention and all of its components. If a participant chose to enroll in the clinic during this appointment, the digital navigator scheduled their first therapy appointment and administered a baseline questionnaire.

Intervention Procedures

Enrolled participants were offered 8 weeks of brief app-augmented treatment based on the Unified Protocol (UP) for Transdiagnostic Treatment of Emotional Disorders [47], as further described in the Intervention section below. Treatment was provided free of charge and involved weekly therapy sessions with a trained clinician, weekly check-ins with a digital navigator, and regular use of the mental health app mindLAMP. All sessions and check-ins were conducted via telehealth.

Training and Competency

A brief therapy manual based on the UP was created for this study. This manual contained session-by-session guides, including guidance for clinicians to integrate the app and its data into care. Clinicians were first given several in-person training sessions in evidence-based treatment. These sessions, led by a licensed clinical psychologist, amounted to approximately 8 hours of training. The focus of the training was on understanding UP principles and on conducting therapy based on the manual. Once clinicians began seeing participants, their adherence and competency was monitored closely in weekly supervisions. Individual supervision (with a psychologist or psychiatrist) focused on conceptualizing patient problems within the UP and conducting treatment in line with evidence-based principles.

Digital navigators were offered 4 training sessions in person that amounted to a total of 10 hours of training. The lead digital navigator of the research team led these training sessions, which included didactic information and experiential learning through role plays. Topics covered included how to conduct the introductory session and the weekly check-ins with participants, how to troubleshoot technical issues that may arise along the way, how to understand digital phenotyping data collected via mindLAMP, and how to support digital literacy by helping participants interpret and understand their own data. Digital navigators were also trained to handle special considerations that could arise in their support meetings with clients: if a participant expressed suicidal thoughts or intent, for example,

XSL•FO
RenderX

the digital navigator was trained to escalate the concern to a designated clinical supervisor. Similarly, if a client sought therapeutic advice, digital navigators were trained to encourage the participant to direct those inquiries to their clinician in the next session and to use the app for support between sessions. Upon the completion of this 10-hour training curriculum, digital navigators completed 2 supervised live appointments with participants before being approved to conduct appointments on their own. These training guidelines have been described and are published elsewhere [42,43].

Intervention Description

The Digital Clinic is a blended care program that offers brief evidence-based treatment augmented by a mobile app (mindLAMP) [48] and a digital navigator. The purpose of integrating mindLAMP into care is 2-fold: to help patients acquire and generalize new skills and to collect psychosocial insights that inform treatment. The role of the digital navigator is to support app use, helping to resolve any difficulties (technological or motivational) that may interfere with the patient's ability to benefit from app use. The digital navigator role has been integrated into this model in light of research showing that app engagement often correlates with clinical improvement yet tends to decline when patients are given a stand-alone app without support [18]. The digital navigator was also introduced into the model to avoid overburdening clinicians with app and data management tasks in addition to their therapy-related responsibilities.

The Digital Clinic intervention has 2 phases. Phase 1 involved app use with digital navigator support. Participants begin the 8-week program with 2 weeks of app use supported by brief weekly check-ins with a digital navigator. The goal of this period is to help participants become accustomed to completing daily and weekly self-report measures on the app, and for the app to begin collecting digital phenotyping data. Digital phenotyping data is defined as the "individual-level human phenotype in-situ using data from smartphones and other personal digital devices" [49] and in this study included several behavioral metrics: steps, movement, screentime, and a sleep estimate. Highlights of this and other data from the app were shared with participants during the digital navigator check-ins, where digital navigators also offered support for continued app use. Phase 2 involved therapy sessions and continued app use along with digital navigator support. In this phase, participants met weekly for 6 weeks with a clinician, who provided transdiagnostic treatment based on the UP. Sessions lasted between 45 and 50 minutes, with an hour-long intake. In each session, mindLAMP data were reviewed with the participant, and UP skills were discussed and assigned as home practice through the app. Therapists shared their screen at key points in each session to review mindLAMP data together with the participant, including week-by-week symptom fluctuation graphs and home practice data.

The UP was selected as the basis of care in the Digital Clinic because its transdiagnostic approach aligned with the clinic's primary aim of increasing access to care. This approach enhances scalability by training clinicians to deliver a single therapy that can be applied to a wide range of presentations. The UP is an emotion-focused CBT that targets reactivity and avoidance, 2 underlying mechanisms that perpetuate distress across various forms of psychopathology. The therapy begins with conceptualization of the patient's problems within the UP framework. The therapist then offers emotion psychoeducation on the adaptive function of emotions and helps the patient learn to self-monitor their mood and identify the 3 components of emotional experiences (ie, cognitive, physiological, and behavioral). The goal is to help the patient begin to tolerate and understand, rather than habitually react to, unpleasant emotions. Core UP interventions include mindfulness, cognitive flexibility, countering avoidance, and exposure (including interoceptive, emotional, and situational). A termination session consolidates learning and assists patients in creating a plan to independently practice skills and thus continue making gains after termination. The brief treatment manual designed for the Digital Clinic offers guidance on all of these topics, as seen in Table 1.

Table 1. Topics covered in the Digital Clinic manual[a].

Session	Focus	mindLAMP home practice module
Intake	• Problem assessment, history, goals • Collaborative approach to case conceptualization based on the Unified Protocol • Psychoeducation on link between 3 parts of emotional experiences (emotions or sensations, thoughts, behaviors)	• Self-monitoring emotional experiences
Mindfulness	• Psychoeducation on function of emotions • Role of aversive reactions in maintaining emotional disorders • Mindfulness practice	• Mindfulness audio • Anchoring in the present
Cognitive flexibility	• Impact of thoughts on emotions and behavior • Common thinking traps • Examining automatic thoughts • Practice thinking more flexibly	• Thinking more flexibly
Countering avoidance	• Link between emotions and behavior • Avoidance and emotion-driven behaviors • Opposite action practice	• Act opposite
Exposure	• Rationale for exposure • Conduct exposure • Discussion of exposures as home practice	• Exposure
Termination	• Progress review • Plan generation for continued skills practice to maintain gains	—[b]

[a]The Digital Clinic manual focuses on emotion-focused cognitive behavioral therapy–based skill-building interventions that support adaptive coping. The manual is based on the Unified Protocol. Therapists are trained to adhere to its core principles but deliver it flexibly—that is, by slowing down the pace, emphasizing certain interventions more than others or adding an adjunctive module to tailor treatment to the patient's needs.

[b]Not applicable, given that it is the last session, where participants were encouraged to continue practicing all skills learned during their time in the Digital Clinic.

Materials

mindLAMP App and Dashboard

mindLAMP is an open-source mental health app that is designed to be easily customizable to meet the needs of different populations and to be integrated into care. mindLAMP comes with an accompanying dashboard that can be accessed on desktop by both patient and clinician. LAMP stands for the app's 4 prominent navigation tabs: Learn (contains psychoeducation modules), Assess (self-report measures), Manage (interactive modules for skills practice), and Portal (visualizations of patient data). mindLAMP also has digital phenotyping capabilities and can automatically collect various types of behavioral data (eg, steps and screentime) without the patient having to enter it. mindLAMP has a wide variety of sensors available, including access to metrics derived from Apple Sensorkit that patients can opt in to share data from. The sensors used in the Digital Clinic are accelerometer, ambient light, nearby devices (detected through proximity to Bluetooth), and screen state. mindLAMP has been described in more detail elsewhere [32,43].

Digital Clinic Manuals

Clinicians were trained with the Digital Clinic manual for conducting brief, app-augmented UP-based therapy via telehealth. The manual was written by a licensed clinical psychologist and includes guidance for integrating the app and its data into care. Digital navigators were trained with the Digital Navigator manual, which details the protocol for the digital navigator role. Protocols for digital navigator sessions were previously published as part of the Digital Clinic Implementation Manual [41], along with detailed descriptions of how the digital navigator role can be adapted for different clinical settings [42].

Measures

Feasibility

Feasibility of recruitment was assessed in 2 ways. First, we calculated the proportion of approached participants who enrolled in the clinic. Approached participants were those we first confirmed to be eligible upon referral and thus invited to an introductory informed consent meeting. Second, we calculated the proportion of participants who agreed to participate after understanding what is involved in the Digital Clinic program during the introductory meeting. For both metrics, a feasibility rate of at least 70% was considered good, with at least 36% considered acceptable for the first metric, given that 36% is the rate of treatment initiation upon receiving a new depressive episode diagnosis in primary care, according to large-scale research [50].

Feasibility of retention was determined by calculating the proportion of participants who completed the entire 8-week program. A feasibility rate of 70% was considered good, based on large-scale research that found a 30% attrition rate for in-person therapy in high-income countries [51]; a feasibility

XSL•FO
RenderX

rate of 76% was considered ideal, based on recent RCT findings showing a 24% attrition rate for blended CBT [52] (ie, CBT that blended in-person treatment and iCBT components).

Adherence to mindLAMP home practice was determined by the frequency of activities completed in mindLAMP. Adherence was deemed good if at least 70% of participants used the app on at least half the days of their total time in the clinic (ie, 8 weeks) to complete home practice (ie, self-monitoring and UP-based skills practice). Therapist adherence to the manual was closely monitored in ongoing supervision and was deemed good if at least 75% of a random selection of 40% of all clinical notes described session content that was in line with the Digital Clinic therapy manual (ie, in line with UP core principles and interventions). Digital navigator adherence to the digital navigator protocol was assessed via checklists that each digital navigator submitted after each digital navigator meeting with a patient. Preexisting templated checklists for each check-in covered such topics as introducing the clinic structure, setting up and demonstrating the app, reviewing data highlights, and troubleshooting technology issues. Adherence was considered good if at least 75% of a random selection of 10% of all-digital navigator meeting checklists completed showed perfect adherence.

Feasibility of quantitative measures was deemed acceptable if 80% completed questionnaires at each time point. Finally, feasibility of the digital format of the program was assessed with 1 question in the postintervention questionnaire regarding hurdles to digital access ("What was the biggest hurdle you encountered regarding access to the Digital Clinic?"). Feasibility was deemed good if at least 75% endorsed "No significant hurdles encountered" rather than the other options (ie, "difficulty getting stable Wi-Fi," "difficulty finding a quiet place for clinician sessions," "difficulty using mindLAMP," or other self-reported hurdles).

Acceptability

Satisfaction with key aspects of the intervention was evaluated using several questions in the postintervention questionnaire. For *clinician satisfaction*, participants were asked to rate "How supported did you feel by your clinician?" on a scale of 1 (not supported at all) to 5 (very supported). *Digital navigator satisfaction* was assessed with 4 items ("What was the quality of time you spent with your Digital Navigator?" "What was the quality of information provided by the Digital Navigator?" "The Digital Navigator was willing to understand my questions and concerns," and "The Digital Navigator explained things in a way I understood.") on a scale of 1 to 5, with 1 indicating low satisfaction and 5 high. These 4 items were averaged to create a composite digital navigator satisfaction score. *App satisfaction* was assessed with "How would you rank the mindLAMP user experience?" rated from 1 (very difficult to use) to 5 (very easy to use). Acceptability was deemed good if these components of the Digital Clinic were rated at least a 4, on average.

A total of 2 additional indicators of acceptability were assessed: *therapeutic alliance* with the clinician (measured via the Working Alliance Inventory-Short Revised; WAI-SR [53] and *digital working alliance*, or the perception of the app as a helpful therapeutic tool (Digital Working Alliance Inventory; DWAI] [54]. Both measures were administered weekly via mindLAMP, and the scores closest to the midpoint (ie, +10 or –10 days) were used in this study. For the WAI-SR, which has demonstrated good validity and reliability [55,56], participants rated 12 items (eg, "What I am doing in therapy gives me a new way to look at my problem") from 1 (seldom) to 5 (always), summed to yield a total score ranging from 12 to 60. For DWAI, which follows the same structure as the WAI and has also shown good reliability and validity [57], participants rated 6 items (eg, "I believe the app tasks will help me to address my problem") from 1 (strongly disagree) to 7 (strongly agree), yielding a summed total score. Although normative data for determining cutoffs for these scales are not available, it has been suggested that a score of at least a 42 is considered positive or high on the WAI-SR [58]. Our benchmarks for good acceptability thus became a minimum score of 42 on the WAI-SR and a corresponding minimum score of 30 on the DWAI, on average.

Potential Efficacy

Depressive symptom severity and anxiety symptom severity were assessed with the 9-item Patient Health Questionnaire (PHQ-9) [59] and the 7-item Generalized Anxiety Disorder (GAD-7) scale [60], respectively. Participants completed these measures at the pre-post and 3-month follow-up time points via a web-based questionnaire and weekly via mindLAMP during the intervention period. On each measure, participants rated from 0 (not at all) to 3 (nearly every day) how much each symptom bothered them over the past 2 weeks. Scale items were then summed to yield a total PHQ-9 score (0-27) and GAD-7 score (0-21). The PHQ-9 has demonstrated construct and criterion validity, and excellent internal reliability (α=.89) [59], as has the GAD-7 (α=.92) [60]. Scores on these 2 scales were also summed together to derive the Patient Health Questionnaire Anxiety and Depression Scale (PHQ-ADS), a measure of comorbid depressive and anxiety symptom severity with strong convergent and construct validity and high internal consistency reliability (α=.88) [61]. This measure was included as our treatment is transdiagnostic and targets comorbid disorders.

Secondary Clinical Outcomes

Emotion regulation self-efficacy, the hypothesized mechanism of treatment [62], was measured via the Patient Reported Outcomes Measurement Information System (PROMIS) Item Bank (version 1.0)—Self-Efficacy for Managing Emotions Short Form 8a [63], which contains 8 items rated from 1 (I am not at all confident) to 5 (I am very confident). These items are summed to yield a total score from 8 to 40, with higher scores indicating higher levels of self-efficacy for managing negative emotions. This brief scale has good psychometric properties, including high internal consistency (α=.90-.95) [63]. *Flourishing*, a measure of psychosocial functioning, was measured with the 8-item Flourishing Scale [64]. Rated from 1 (strongly disagree) to 7 (strongly agree), items on this scale are summed to yield a total score from 8 to 56, with higher scores representing greater psychological resources [65]. This scale also has good psychometric properties and high internal consistency (α=.86). *Functional impairment* was measured with the Sheehan Disability Scale, a 5-item assessment of impairment in 3 domains: work or school, social life, and family life. A total

XSL•FO
RenderX

of 3 items assessing these 3 domains are rated from 0 (not at all) to 10 (extremely) and yield a total summed score of 0 (unimpaired) to 30 (highly impaired). The Sheehan Disability Scale is a psychometrically sound instrument, with good internal consistency (α=.83) [66].

Data Analytic Plan

Analyses were conducted using R (version 4.2.1). In line with, and guided by, guidelines for feasibility studies [67], we computed descriptive statistics to assess feasibility and acceptability, and then conducted paired samples *t* tests (2-tailed, with Cohen *d* effect sizes) to examine within-group pre-post differences as a marker of potential efficacy. As commonly reported in the therapy outcomes literature, we also computed clinically significant improvement and remission rates to further assess potential efficacy. Clinically significant improvement was determined by the proportion meeting the minimum clinically important difference (MCID) thresholds established in prior empirical research, which is 4 points for the PHQ-9 and GAD-7 [61] and 6 points for the PHQ-ADS [61]. Per published guidelines, remission was defined as <8 on PHQ-9 [68] and <8 on GAD-7 [69,70], which corresponds to <16 on the PHQ-ADS.

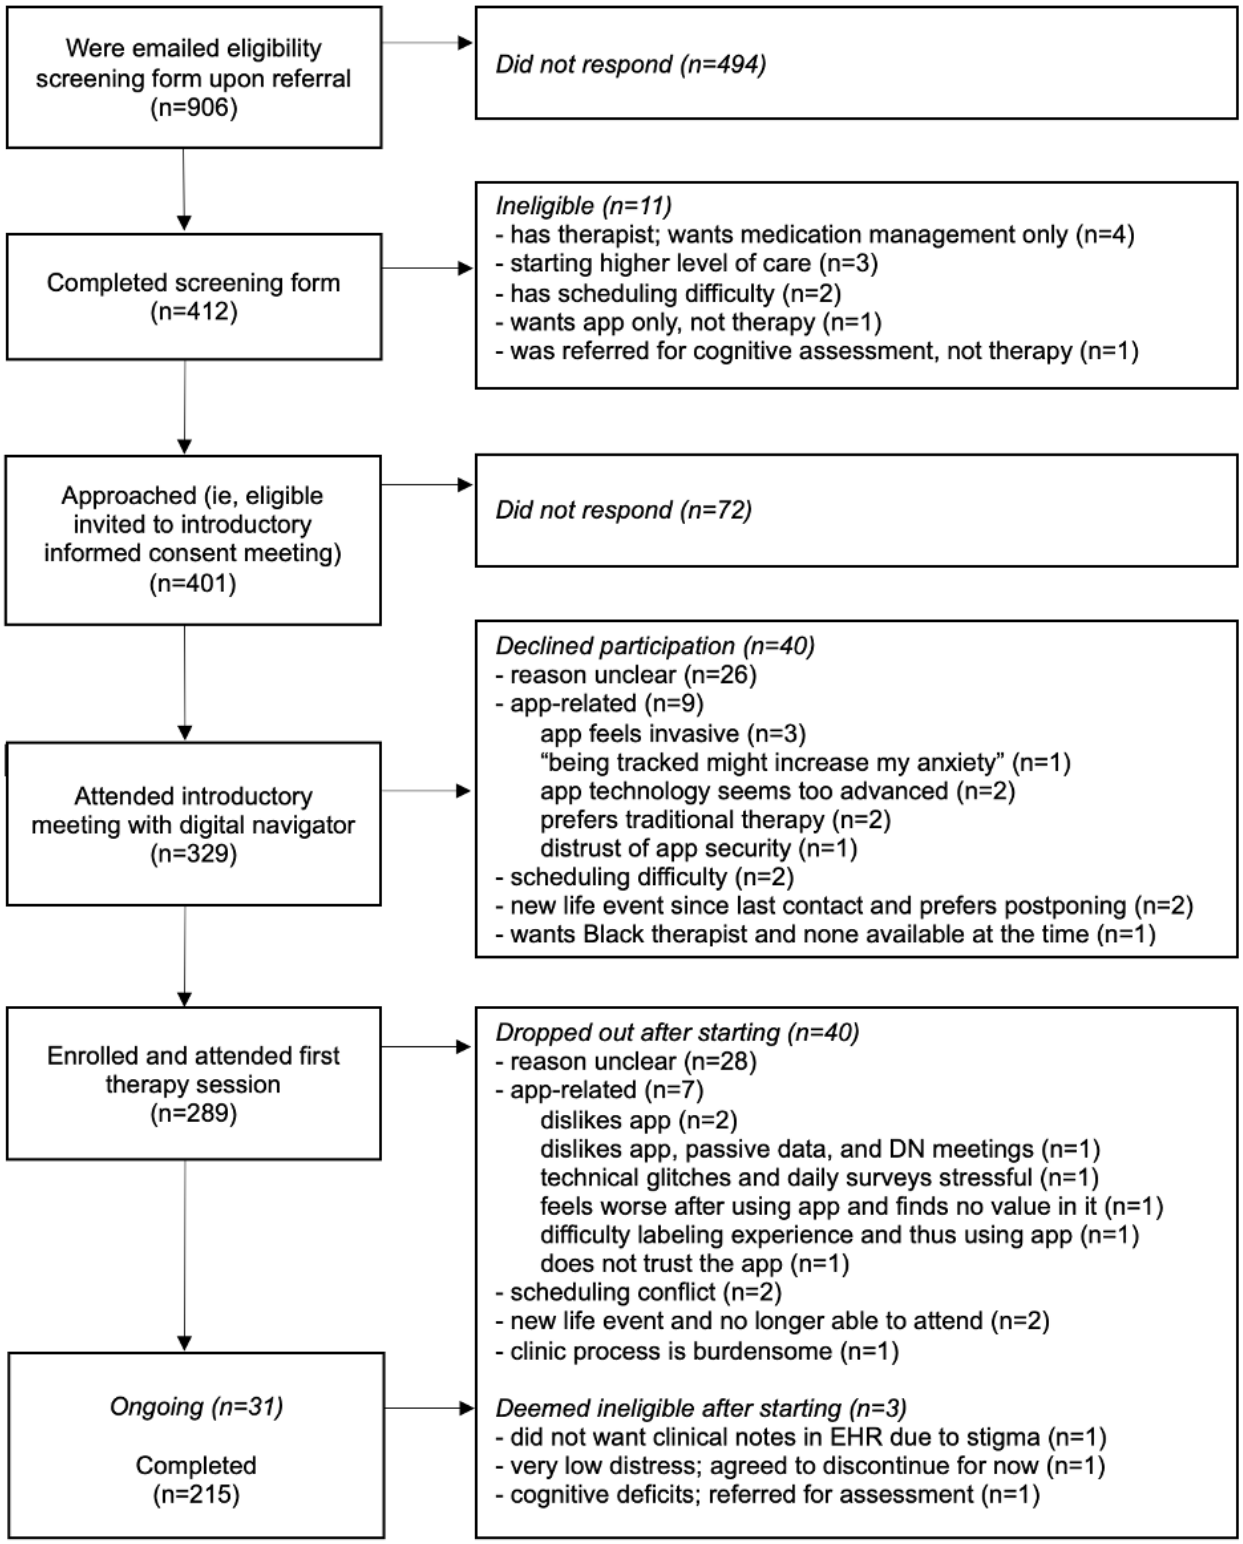
In preparation for conducting the analyses, for participants who did not complete the questionnaire at the end of the intervention (n=36), we obtained PHQ-9 and GAD-7 scores from mindLAMP if they had completed these measures in the app within 10 days of their last therapy session (n=27). Before conducting each type of potential efficacy analysis, we excluded data from participants with baseline subclinical scores on the PHQ-9 (n=74), on the GAD-7 (n=89), or on the PHQ-ADS (n=81). A total of 7 participants experienced significant life events during the 8-week period, including the death of a close loved one (n=5, 71%) and homelessness due to eviction (n=1, 14%) or fire (n=1, 14%). Although we offered these individuals care, nonetheless, we also excluded their data from analyses as these events would have prevented adequate participation in and response to brief treatment. We also excluded data from 1 individual who was wrongly referred to the clinic for a physical rather than a psychological condition.

Ethical Considerations

This study was reviewed before being conducted by the Beth Israel Deaconess Medical Center institutional review board and was approved as a quality improvement project (reference #2022D000016). All participants provided consent as part of the introductory meeting to the Digital Clinic, where a digital navigator informed them on all aspects of the clinic, including the collection of data and its use in the clinic and afterward. As part of the baseline questionnaire, participants signed an informed consent and acknowledgment of services form, which outlined the use of data and limits of confidentiality in treatment and asked participants for their explicit consent to have their deidentified data be used in aggregate with others' data for research purposes. Data were collected in Health Insurance Portability and Accountability Act (HIPAA)–compliant systems. Participants did not receive compensation for participating in the Digital Clinic.

Results

Participants



The total number of participants who completed the Digital Clinic program was 215 (n=136, 63.3% cisgender women, n=73, 34% cisgender men, and n=6, 2.8% nonbinary), with a mean age of 41 (SD 14) years. Approximately 70.2% (151/215) identified as White, 10.7% (23/215) Asian, 9.3% (20/215) Black or African American, 7% (15/215) Hispanic or Latinx, 2.8% (6/215) Middle Eastern or North African, 0.5% (1/215) Native Hawaiian or Pacific Islander, and 0.5% (1/215) biracial.

Feasibility of Recruitment

Of the 401 individuals approached after initial eligibility was confirmed, 289 decided to enroll in the clinic—a 72.1% (289/401) recruitment rate (good, per the 70% benchmark). The proportion of participants who agreed to enroll after understanding all of the components of the Digital Clinic during their first introductory meeting was 87.8% (289/329; excellent, per the 70% benchmark). The recruitment and enrollment flowchart is shown in Figure 2.

XSL•FO
RenderX

Figure 2. Recruitment and enrollment flowchart. Data for this study comes from a clinic with a constant flow of patients. "Ongoing" in this flowchart thus refers to participants who were still receiving treatment at the Digital Clinic at the time that data collection ended for this particular study. "Completed" refers to participants who completed a full course of care (ie, phase 1 and phase 2, as described in the Intervention Description section of the Methods section). DN: digital navigator; EHR: electronic health record.

Feasibility of Retention

After excluding 31 participants still in progress from the 289 enrolled, 83.3% (215/258) completed the 8-week program, an excellent retention rate (given benchmarks of 70%-76%).

Adherence to mindLAMP Home Practice

Results indicated that 73.5% (158/215) of participants used the app on at least half the days of their total time in the clinic (benchmark 70%).

XSL•FO
RenderX

Therapist Adherence

A review of clinical notes from a random selection of 51 cases revealed that 86.6% (265/306) of all session notes closely adhered to UP core principles and interventions described in the Digital Clinic manual. The average adherence rate within each participant's course of care was 87% (SD 17%), indicating that adherence was present in at least 5 of the 6 sessions, on average. Regarding the 4 core UP interventions, 98% (50/51) of cases focused on mindfulness practice, 78% (40/51) on cognitive flexibility, 76% (39/51) on countering avoidance, and 41% (21/51) on exposure. The Digital Clinic manual permits the use of non-UP adjunctive evidence-based interventions as needed, provided they align with the case conceptualization; session notes describing adjunctive interventions most often focused on assertive communication skills practice (ie, the DEARMAN [Describe, Express, Assert, Reinforce, Mindful, Appear Confident, and Negotiate] skill from dialectical behavior therapy), additional assessment and problem solving, relaxation (eg, progressive muscle relaxation and deep breathing), gratitude practice, and values clarification.

Digital Navigator Adherence

A review of a random selection of 22 cases' digital navigator meeting checklists showed that 98.9% (196/198; benchmark 75%) had perfect adherence.

Feasibility of Quantitative Measures

For the 215 who completed the intervention, questionnaire completion rates were 100% (215/215) at baseline, 83.3% (179/215) at the end of the intervention, and 39.1% (84/215) at 3-month follow-up. (After excluding those with baseline subclinical scores on all three symptom measures [PHQ-9, GAD-7, and PHQ-ADS; n=52], the 3-month follow-up rate was still low; 68/163, 41.7%). While the baseline and postintervention questionnaire feasibility rates met and exceeded our 80% benchmark, the follow-up rate did not.

Feasibility of the Digital Format

Regarding hurdles to digital access, 72.1% (129/179) endorsed no significant hurdles, falling slightly below the 75% benchmark. Regarding challenges, 11.2% (20/179) reported difficulty using mindLAMP, 10.6% (19/179) difficulty finding a quiet place for clinician sessions, 3.4% (6/179) difficulty getting stable Wi-Fi, 2.2% (4/179) challenges remembering to do home practice on the app, and 0.6% (1/179) other self-reported challenges.

Acceptability

The average clinician, digital navigator, and mindLAMP user experience satisfaction rates were 4.81 (SD 0.52), 4.61 (SD 0.62), and 4.18 (SD 0.79), respectively (benchmark: at least a 4). The average midpoint WAI-SR and DWAI scores were 50.15 (SD 7.86) and 32.10 (SD 6.74), respectively, exceeding the benchmarks of 42 (WAI-SR) and 30 (DWAI).

Potential Efficacy

For those who entered the clinic with depression severity in the clinical range, the average baseline PHQ-9 score was in the moderate to moderately severe range (mean 13.39, SD 4.53) and fell to the subclinical range (mean 7.79, SD 4.61) by the end of the intervention, a statistically significant mean reduction of 5.61 (95% CI 4.72-6.49; t_{126}=12.50; P<.001), with a large effect size (Cohen d=1.11). Gains were maintained at the 3-month follow-up for those who completed the follow-up questionnaire and had an end-of-intervention PHQ-9 score (n=55, 43%), with scores still in the subclinical range (mean 7.42, SD 4.60) and not significantly different from scores at the end of the intervention (t_{54}=1.38; P=.17).

For those who entered the clinic with anxiety severity in the clinical range, the average baseline GAD-7 score was in the moderate range (mean 12.93, SD 3.67) and fell to the subclinical range (mean 7.35, SD 4.19) by the end of the intervention, a statistically significant mean reduction of 5.58 (95% CI 4.73-6.43; t_{113}=13; P<.001), with a large effect size (Cohen d=1.22). Gains were maintained at 3-month follow-up for those who completed the follow-up questionnaire and had a postintervention GAD-7 score (n=48, 42%), with scores still in the subclinical range (mean 6.88, SD 4.65) and not significantly different from scores at the end of the intervention (t_{47}=0.62; P=.54).

For those who entered the clinic with comorbid depressive and anxiety symptoms in the clinical range, the average baseline PHQ-ADS score was in the moderate range (mean 25.51, SD 7.05) and fell to the subclinical range (mean 15.01, SD 8.30) by the end of the intervention, a statistically significant mean reduction of 10.50 (95% CI 8.95-12; t_{121}=13.40; P<.001), with a large effect size (Cohen d=1.21). Gains were maintained at 3-month follow-up for those who completed the follow-up questionnaire and had a postintervention PHQ-ADS score (n=52; 43%), with scores still in the subclinical range at 3-month follow-up (M 14.56, SD 8.77) and not significantly different from scores at the end of the intervention (t_{51}=1.09; P=.28).

From baseline to the end of the intervention, approximately 68.5% (87/127), 76.3% (87/114), and 70.5% (86/122) of those who completed the intervention experienced at least a 25% symptom decrease in PHQ-9, GAD-7, and PHQ-ADS, respectively. Rates of clinically significant improvement (ie, a reduction equal to or greater than the MCID) were 63.8% (81/127), 66.7% (76/114), and 73% (89/122) in terms of PHQ-9, GAD-7, and PHQ-ADS, respectively. Remission rates were 52.8% (67/127), 59.6% (68/114), and 55.7% (68/122) on the PHQ-9, GAD-7, and PHQ-ADS, respectively. These per protocol rates along with the intent-to-treat rates are shown in Table 2 and the rates calculated separately by baseline severity level are shown in Table 3.

RenderX

Table 2. Rates of overall clinically significant improvement and remission (N=215).

	Values, n (%)	T1[a], mean (SD)	T2[b], mean (SD)	Clinically significant change[c] (%)	Remission[d] (%)	Remission or mild at T2[e] (%)
Dep[f] (PP[g]; n=134)	127 (95)	13.39 (4.53)	7.79 (4.61)	64	53	66
Anx[h] (PP; n=120)	114 (95)	12.93 (3.67)	7.35 (4.19)	67	60	73
Comorb[i] (PP; n=127)	122 (96)	25.51 (7.05)	15.01 (8.30)	73	56	70
Dep (ITT[j,k] MI[l])	161 (100)	13.55 (4.52)	7.86 (4.16)	66	55	73
Anx (ITT MI)	148 (100)	13.25 (3.78)	7.44 (3.74)	73	59	79
Comorb (ITT MI)	155 (100)	26.08 (7.23)	15.26 (7.50)	77	56	77
Dep (ITT BOCF[m,n])	161 (100)	13.55 (4.52)	9.11 (5.27)	50	42	53
Anx (ITT BOCF)	148 (100)	13.25 (3.78)	8.92 (5.08)	53	47	57
Comorb (ITT BOCF)	155 (100)	26.08 (7.23)	17.82 (9.78)	57	44	55

[a]T1: baseline time point.

[b]T2: end-of-intervention time point.

[c]Clinically significant improvement, also known as clinically meaningful change.

[d]Remission: rates of remission at T2.

[e]Remission or mild at T2: proportion of participants whose T2 symptoms were mild or in remission if baseline symptoms were moderate or severe, or in remission if baseline symptoms were mild.

[f]Dep: depressive symptoms, measured by the 9-item Patient Health Questionnaire scale.

[g]PP: per protocol sample (ie, participants with a baseline clinical-range score who completed the intervention and had a T2 score). Percentages represent the proportion of PP participants out of all completers with a baseline clinical-range score, regardless of T2 questionnaire completion).

[h]Anx: anxiety symptoms, measured by the 7-item Generalized Anxiety Disorder scale.

[i]Comorb: comorbid symptoms of depression of anxiety, measured by the PHQ-Anxiety and Depression Scale.

[j]ITT: intent-to-treat.

[k]ITT: intent-to-treat sample, which includes those with missing T2 scores either due to dropout or T2 questionnaire noncompletion.

[l]ITT MI: missing T2 scores were imputed using the mean imputation method (ie, the PP T2 mean of the severity subgroup to which the participant belongs).

[m]BOCF: baseline observation carried forward.

[n]ITT BOCF: missing T2 scores were imputed using the baseline observation carried forward method, a conservative worst-case scenario approach that assumes participants with missing T2 scores would have had no improvement.

Mild (ITT MI)	26 (100)	8.46 (0.51)	4.68 (2.23)	88	88	—
Moderate (ITT MI)	72 (100)	11.83 (1.39)	7.27 (3.30)	72	67	83
Severe (ITT MI)	50 (100)	17.78 (1.96)	9.11 (4.07)	86	34	68
Mild (ITT BOCF)	26 (100)	8.46 (0.51)	5.10 (2.54)	77	77	—
Moderate (ITT BOCF)	72 (100)	11.83 (1.39)	8.36 (3.93)	51	44	61
Severe (ITT BOCF)	50 (100)	17.78 (1.96)	11.72 (5.97)	58	34	40
Comorbid depressive and anxiety symptoms (PHQ-ADS[p])						
Mild (PP)	30 (100)	17.53 (1.07)	9.93 (5.57)	80	80	—
Moderate (PP; n=58)	56 (97)	24.02 (2.90)	15.09 (6.62)	66	48	71
Severe (PP; n=38)	36 (95)	34.87 (4.09)	19.11 (10.20)	86	47	61
Mild (ITT MI)	34 (100)	17.56 (1.08)	9.93 (5.57)	80	80	—
Moderate (ITT MI)	71 (100)	24.06 (2.91)	15.09 (5.87)	70	59	77
Severe (ITT MI)	50 (100)	34.76 (4.27)	19.11 (8.62)	90	34	72
Mild (ITT BOCF)	34 (100)	17.56 (1.08)	10.85 (5.83)	71	71	—
Moderate (ITT BOCF)	71 (100)	24.06 (2.91)	17.01 (7.10)	52	38	56
Severe (ITT BOCF)	50 (100)	34.76 (4.27)	23.70 (11.65)	62	34	44

[a]T1: baseline time point.

[b]T2: posttreatment time point.

[c]Clinically significant improvement, also known as clinically meaningful change.

[d]Remission: rates of remission at T2.

[e]Remission or mild at T2: proportion of participants whose T2 symptoms were either at least in the mild range (if moderate or severe at baseline) or in remission (if mild at baseline).

[f]PHQ-9: 9-item Patient Health Questionnaire.

[g]Per-protocol sample (ie, participants who completed the intervention and had a T2 score).

[h]Not applicable.

[i]ITT: intent-to-treat.

[j]Intent-to-treat sample, which includes those with missing T2 scores (either due to dropout or questionnaire noncompletion).

XSL•FO
RenderX

[k]MI: mean imputation.

[l]ITT MI: missing T2 scores were imputed using the mean imputation method (ie, the PP T2 mean of the severity subgroup to which the participant belongs).

[m]BOCF: baseline observation carried forward.

[n]ITT BOCF: missing T2 scores were imputed using the baseline observation carried forward method, a conservative worst-case scenario approach that assumes participants with missing T2 scores would have had no improvement.

[o]GAD-7: 7-item Generalized Anxiety Disorder Scale.

[p]PHQ-ADS: PHQ-Anxiety and Depression Scale.

Secondary Clinical Outcomes

Emotion regulation self-efficacy significantly increased from baseline (mean 20.42, SD 4.99) to the end of the intervention (mean 26.97 SD 5.61; t_{133}=–13.13; P<.001). Flourishing significantly rose from baseline (mean 39.90, SD 9.06) to the end of the intervention (mean 44.43, SD 8.28; t_{83}=–6.06; P<.001). Functional impairment significantly decreased from baseline (mean 18.72, SD 6.41) to the end of the intervention (mean 13.24 SD 8.30; t_{134}=8.94; P<.001). Gains were maintained at 3-month follow-up (mean 9.86, SD 7.68), with scores significantly lower at the follow-up time point (t_{59}=3.86; P<.001).

Discussion

Overview

This study was an initial evaluation of the Digital Clinic, an innovative model of care designed to mitigate leading mental health care access barriers by offering brief, clinician-delivered evidence-based treatment via telehealth that is augmented by an app and a digital navigator [34,71]. The aim of this study was to assess the feasibility, acceptability, and potential efficacy of this model by conducting a nonrandomized open trial. Results suggest that this model is feasible, acceptable, and has the potential to be an effective solution for increasing access to high-quality, evidence-based mental health intervention.

Principal Findings and Comparison With Prior Work

The open trial showed good to excellent feasibility and acceptability across most metrics. Results indicated that it is feasible to recruit and retain patients. About 87.8% (289/329) of the participants chose to continue after the introductory meeting, which suggests that many patients were not discouraged by the clinic's all-digital format or its various innovative components (ie, app, digital phenotyping data collection, and integration of a digital navigator into care). Moreover, the Digital Clinic's completion rate met and exceeded rates seen in other guided DMHIs (eg, blended CBT [52]) and in-person therapy [72]. It also improved on attrition rates of unguided DMHIs, which reach nearly 50% when accounting for publication bias [73].

Therapist, digital navigator, and mindLAMP adherence were also all high. That therapists were not all highly experienced suggests that the training procedures and clinic manual effectively enabled delivery of brief, transdiagnostic, evidence-based treatment by clinicians with a range of experience, supporting the scalability of the model. That digital navigator adherence was also high suggests that checklists helped facilitate smooth check-ins and should be used in future studies. Finally, mindLAMP adherence among participants was high, with app use between sessions potentially extending the impact of treatment to their daily lives. In addition, these 3 components of the clinic (app, clinician, and digital navigator) appeared to be acceptable to patients, based on high satisfaction ratings with each one.

In terms of the potential efficacy of the Digital Clinic, the results yielded promising findings. The average depression, anxiety, and comorbid depression and anxiety symptom scores fell to the subclinical range by the end of the intervention, suggesting the potential of the DMHI in making a meaningful clinical impact in a short time. Moreover, overall rates of clinically significant improvement (67% and 64% for anxiety and depressive symptoms, respectively) and remission (60% and 53% for anxiety and depressive symptoms, respectively) were high, meeting and exceeding those typically observed in traditional treatment (ie, 51% remission for anxiety disorders [74] and 33% for depression [75], according to recent meta-analyses of primarily evidence-based treatments). However, this feasibility study was not designed to establish efficacy and thus did not use a control group. Nevertheless, these outcomes are promising and warrant a future RCT to establish the efficacy.

Lessons Learned

While the feasibility of quantitative measures was high for baseline and end-of-intervention time points, completion rate of the 3-month follow-up measures fell below our benchmark. This suggests room for improvement, with our current method of simple email outreach 3 months after the intervention being insufficient. Alternative strategies for a future study include offering participants payment or scheduling a study appointment for the 3-month follow-up questionnaire upfront.

Further room for improvement was suggested in terms of the feasibility of aspects of the digital format. Overall, 72.1% (129/179) endorsed that they encountered no significant hurdles, slightly below our 75% benchmark. Most hurdles reported were around finding a quiet place for therapy sessions (19/179, 10.6%) and difficulty using mindLAMP (6/179, 3.4%). To mitigate the first barriers, in future studies, it will help to build in protected time at the introductory meeting to discuss and resolve practical barriers with each patient around finding privacy for therapy sessions. Regarding the second hurdle, it is likely that difficulty reported around mindLAMP use was resolved in digital navigator meetings. Nevertheless, a future study analyzing the qualitative feedback obtained in this study will help shed light on this question and inform refinements.

XSL•FO
RenderX

Finally, a key lesson about DMHI implementation came out of this study: Partnering with primary care substantially helped with the successful implementation of the Digital Clinic. For one, it eased the burden of delivering mental health care on PCPs—a task that increasingly falls on them due to limited access to specialty mental health care [76]. In addition, PCPs reported that strongly endorsing the Digital Clinic directly to their patients rather than referring them to an external resource seemed to increase patients' willingness to start care at the Digital Clinic. These PCPs noted that having the Digital Clinic embedded into the health care system may have felt like a natural extension of patients' primary care received at the hospital, rather than being viewed as a separate mental health program. Thus, partnering with primary care can solve provider problems and increase patient engagement and access to mental health care.

Strengths and Limitations

Strengths of this study include its evaluation of a program designed to be both highly scalable and effective, offering a promising solution to increase access to care. Several components increase scalability, including brief therapy, the creation of standardized manuals for the clinician and digital navigator roles, and the use of an open-source smartphone app. The focus on transdiagnostic evidence-based treatment enhances the program's ability to reach individuals with a wide range of clinical presentations. That the program was effective for a majority of this patient sample without the need for highly experienced clinicians supports the potential for its widespread adoption and implementation in various health care settings.

Despite these strengths, several limitations are also worth considering. First, although valid and reliable instruments were used for all outcomes, the PHQ-9 and GAD-7 measures do not adequately capture distress for some clinical presentations (eg, someone with social anxiety disorder, whose distress is only apparent in specific situations they may generally avoid). Future studies should consider a fuller breadth of outcome measures. Second, the low ethonoracial diversity of our sample may limit the applicability of the findings to more diverse populations. In addition, this study focused entirely on English-speaking participants, and the experiences and outcomes discussed in this study may not be fully reflective of those of non-English speakers. These factors should therefore be considered when interpreting the generalizability of this study's findings. Third, because this was a feasibility study [77] designed to primarily examine whether this model is feasible and acceptable to patients and providers (and secondarily whether it is *potentially* efficacious), no control group was used. The lack of a control group precludes definitive conclusions about clinical improvement resulting from the intervention itself rather than the passage of time or other factors. Fourth, we did not track treatment fidelity in a traditional manner, relying instead on supervision meetings and the subsequent examination of clinical notes to assess clinician adherence. This method could be strengthened in a future study by using a checklist system as done with digital navigators, or by obtaining session recordings coded for adherence. Fourth, although data integration into care was a frequent topic of discussion in supervision meetings, we did not formally track the extent to which clinicians regularly incorporated data into care. This limitation paves the way toward fruitful avenues for further enhancing clinician training in the future and implementing a process of actively measuring the extent of data incorporation into care. Finally, we did not formally track whether patients were concurrently receiving other therapies or medications. We inquired about these factors at intake, and in the few cases in which participants were in concurrent outpatient therapy, we recommended that they start in the Digital Clinic after their current treatment. However, we still accommodated those on medications. As a result, for some patients, pre-post clinical improvements may not be solely due to the Digital Clinic intervention. This aspect will need to be more rigorously tracked and addressed in a future RCT.

Future Directions

Results of this study suggest that this model of care shows promise as a solution for mitigating barriers to quality mental health intervention access. This model was informed by research that shows that digital interventions offered with (vs without) human support are more effective [7], especially for people with higher clinical severity [31]. The inclusion of support in terms of clinicians and digital navigators appears to be effective in increasing access and quality in care for people with a range of clinical severity. Results suggest that the Digital Clinic warrants a future efficacy RCT.

Another future direction is to conduct a dismantling study to isolate the additive effects on outcomes of the brief clinician-delivered therapy, the digital navigator, and mindLAMP app integration. Research suggests that the digital components of guided DMHIs may independently contribute to outcomes [78] and that mindLAMP enhanced by a digital navigator alone can have its own beneficial effects [79]. The extent of each component's impact on efficacy can inform future model adaptation and lead to a more cost-effective, stepped-care version of the Digital Clinic, where more clinical resources are offered first to those with higher severity. Recent research supports such models, as they use limited clinical resources in ways that maximize efficacy and are cost-effective [80].

Related, continuing to focus on the implementation and therapeutic effect of incorporating digital phenotyping data versus actively collected data into care is an important future direction. We observed that some clinician-patient dyads embraced both types of data more readily than others, with some patients also benefiting more from digital phenotyping aspects of the data than others. We also observed that some clinicians required further training to feel more confident in integrating all kinds of data into care. This is not surprising, as most training programs do not prioritize the development of skills in conducting measurement-based care. Addressing these implementation and knowledge gaps may enhance both clinician readiness and patient outcomes.

Finally, a still unanswered question in the field is whether gains obtained from participating in brief, guided DMHIs are sustained in the long term. In this study, clinical improvement was sustained for the 41.7% (68/163) of participants with baseline clinical scores who completed the 3-month follow-up questionnaire. This finding once again suggests that this

XSL•FO
RenderX

intervention may be potentially efficacious in the short and long term, but it warrants more research to confirm this possibility.

Conclusions

Guided DMHIs that offer brief, evidence-based treatment may reduce the cost of care and alleviate the provider shortage; integrating an app into treatment that provides between-session support and enables measurement-based care can increase the impact of care delivered in a short time. The digital navigator supports app engagement and can lower the burden of data collection and technology use on the clinician. Results from this study suggest that the Digital Clinic model is feasible, acceptable, and potentially efficacious, warranting a future RCT.

Data Availability

The datasets generated and analyzed during this study are not available due to the clinical nature of this project.

Authors' Contributions

NM was responsible for conceptualization, formal analysis, investigation, methodology, project administration, supervision, visualization, writing the original draft, and writing, review and editing. KC and EL were responsible for formal analysis, project administration, writing the original draft, and writing, review and editing. NN and JP were responsible for resources, project administration, and writing, review and editing. SY was responsible for methodology and writing, review and editing. JT was responsible for conceptualization, investigation, methodology, supervision, writing the original draft, and writing, review and editing.

Conflicts of Interest

JT is the editor-in-chief of JMIR Mental Health, and he recused himself from editorial handling of this manuscript during the peer review process.

Abstract

Background: As artificial intelligence (AI) tools are integrated more widely in psychiatric medicine, it is important to consider the impact these tools will have on clinical practice.

Objective: This study aimed to characterize physician perspectives on the potential impact AI tools will have in psychiatric medicine.

Methods: We interviewed 42 physicians (21 psychiatrists and 21 family medicine practitioners). These interviews used detailed clinical case scenarios involving the use of AI technologies in the evaluation, diagnosis, and treatment of psychiatric conditions. Interviews were transcribed and subsequently analyzed using qualitative analysis methods.

Results: Physicians highlighted multiple potential benefits of AI tools, including potential support for optimizing pharmaceutical efficacy, reducing administrative burden, aiding shared decision-making, and increasing access to health services, and were optimistic about the long-term impact of these technologies. This optimism was tempered by concerns about potential near-term risks to both patients and themselves including misguiding clinical judgment, increasing clinical burden, introducing patient harms, and creating legal liability.

Conclusions: Our results highlight the importance of considering specialist perspectives when deploying AI tools in psychiatric medicine.

Introduction

The use of artificial intelligence (AI)—"a machine-based system that can, for a given set of human-defined objectives, make predictions, recommendations, or decisions influencing real or virtual environments" [1]—in psychiatric medicine has been of much interest to clinicians, researchers, and developers, with potential to support areas such as pharmacological treatment [2] and psychotherapy [3]. Particularly, machine learning—"a set of techniques that can be used to train AI algorithms to

XSL•FO
RenderX

improve performance at a task based on data" [1]—methods combining clinical, sociodemographic, and biomarker data (eg, pharmacogenomics) to predict treatments, prognoses, and diagnoses have been proposed for psychiatric care [4,5]. Similar methods have been used to develop screening tools that identify psychiatric disorders such as major depressive disorder (MDD) and generalized anxiety disorder, while AI tools using natural language processing aim to provide access to therapy and mental health guidance [6-8].

Despite the potential of these AI tools, there is varying evidence supporting their adoption in clinical practice. For instance, digital mental health applications have proliferated in consumer marketplaces and yet have mixed evidence supporting [9] and disputing [10] their therapeutic efficacy. In addition, AI-enabled clinical prediction tools for precision psychiatry, while having improved over the last decade, face challenges in clinical translation related to bias and overfitting, generalizability, and clinical use [11]. In addition to these evidentiary considerations, there are ethical concerns related to patient safety, transparency, data privacy, bias, and responsibility that present additional implementation challenges [12,13]. While these tools are not yet standard of care, they are gaining acceptance and likely to impact psychiatric medicine in a variety of ways in the future [14,15].

It is unclear how physicians treating patients with psychiatric conditions will respond to these new AI tools. Health systems are experiencing resource constraints amid great demand for psychiatric services [16,17], with AI increasingly being viewed as an opportunity for providing support [18,19]. These technologies may change practices by altering conventional workflows, training, and decision-making for physicians [20]. As with applications of AI in other clinical specialties, accounting for physician perspectives in psychiatric medicine will be critical for addressing their specific needs as practitioners and primary end users of these tools. Key considerations for acceptability and integration of AI may involve physicians' assessments of the benefits and risks that will be introduced to both themselves and their patients [21,22].

Prior studies have examined physician attitudes broadly toward AI often focusing on general acceptability [23-26]. In addition, some psychiatry-focused research has begun to characterize physician use of AI-enabled clinical support tools or clinical decision support systems for depression [27,28], as well as physician perspectives on AI in adolescent care [29] and generative AI [30]. In this paper, we report results from a qualitative research study that sought to characterize physician perspectives on applications of AI in psychiatric medicine. Drawing on several emerging real-world applications of AI in psychiatry, our study offers insight into perceived benefits and challenges that specialists are likely to consider in the adoption of AI tools. This study aims to advance the understanding of AI tools in psychiatric care by leveraging in-depth interviews to uncover the nuanced ways frontline physicians perceive and anticipate impacts of AI in their clinical practice.

Methods

Participant Recruitment

Physicians were recruited from a single health care system in the Upper Midwest of the United States. We identified eligible participants by searching the health system's enterprise health record database for physicians in family medicine or psychiatry who met the following criteria: (1) prescribed selective serotonin reuptake inhibitors for depressive disorders and (2) diagnosed patients using *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*) codes relevant to MDD (F32, F33, F34.1, N94.3, F32.8, and F32.9). MDD was relevant to several of our case scenarios and served as a suitable entry point for discussing broader psychiatric conditions and accompanying AI tools with physicians. Family medicine practitioners were included in addition to psychiatrists given the high incidence of psychiatric conditions that are diagnosed and treated in the specialty [31,32]. Participants must have made a minimum of 1 prescription and 15 or more diagnoses during their tenure. This ensured that participants had some experience with the clinical subject matter discussed in the interviews. Physicians returned in the search were randomized and recruited via email invitation. Interviews were conducted between February 1, 2022, and April 28, 2022.

Ethical Considerations

This study was approved by the Mayo Clinic institutional review board (protocol 21-006191). All participants consented orally to participation in the study and to have their interviews recorded. All data reported have been deidentified. Participants voluntarily enrolled in the study. No compensation was provided.

Data Collection

Case Scenarios

Four hypothetical clinical case scenarios were provided that described various AI tools in psychiatric medicine settings [33]. The cases included depictions of AI tools that (1) assisted a physician in prescribing medications based on patient pharmacogenomic information, (2) provided adjunct cognitive behavioral therapy to a patient via a chatbot interface, (3) assisted a physician with providing a differential diagnosis and associated disease risk scores, and (4) identified patients at risk for suicide based on population health characteristics. Initial cases were constructed based on a review of commercially available tools and academic literature. The depicted technologies were chosen to highlight varying health conditions and use cases for psychiatric AI tools. In accordance with methodological best practices, cases were subsequently revised and finalized in consultation with subject matter experts in psychiatry to confirm their relevance to clinical practice [34]. Cases were also evaluated during interviews with direct questions posed to participants: "Did the cases presented to you seem like something you might encounter in your practice?" "Did any of the cases seem implausible for any reason?"

XSL•FO
RenderX

Interviews

We conducted in-depth interviews following a case-based approach [35,36]. All interviews were conducted virtually over Zoom (Zoom Video Communications) with 2 study team members present. One primary interviewer (SHC) led the interviews, and 1 of 2 secondary interviewers (AMS and JJS) took notes and asked follow-up questions. The interviews began with questions that explored participant understanding, familiarity, and experience with health care AI such as "Can you briefly tell me about your familiarity with the idea of using AI tools in healthcare?" A formal definition of AI was not provided to participants. Cases were introduced after these general questions along with several structured questions gauging physician perceptions of the AI tool such as "What do you think the benefits of this tool could be?" and "What potential risks or concerns does this tool pose?" Due to time constraints, not all cases were discussed in each interview. Interviewers selected cases to ensure that each one was presented in interviews throughout the study. Additional questions focused on physicians' assessments of AI and included questions such as "What risks and benefits do you think AI could bring to your practice?" This approach allowed us to explore specialist attitudes toward AI in psychiatric medicine and in health care generally. Questions and probes were designed to be open-ended to encourage exploration of participant viewpoints. Throughout data collection, the study team met regularly to refine interview questions and address gaps in the data, helping to support thorough data collection.

Interviews were audio-recorded and externally transcribed by a professional transcription firm. Transcripts were subsequently deidentified and edited by the study team for any typographical errors or other transcription inaccuracies by reviewing the transcript alongside the original audio.

Data Analysis

Interview data were analyzed following an inductive approach. A field note was created summarizing general themes after each interview [37]. Upon completing the set of 42 interviews, a synthetic field note was created to summarize emerging themes across interviews. A preliminary codebook was then created from the individual field notes, synthetic field note, and interview guide. This preliminary codebook was applied to a subset of the transcripts that varied in length, interview number, cases used, and physician specialty. The performance of the preliminary codebook was discussed by the study team including reflective assessments of intercoder agreement as well as the codebook's coverage, consistency, and clarity. After these study team discussions, the codebook was revised into a final version that was applied to the set interviews. Throughout coding, the final codebook was iteratively revised and applied as themes emerged in the dataset [38]. The coding team consisted of 1 primary coder who analyzed the full set of transcripts (IBW) and 2 secondary coders who each coded a subset of transcripts (AMS and SHC). Transcripts were coded independently and in duplicate using NVivo (release 1.7.2; Lumivero, LLC). After independently coding, primary and secondary coders subsequently met to reach consensus [39]. Once interview data were fully coded, the study team discussed and refined several emerging themes related to potential benefits and risks of AI tools.
