In 2019, the first symposium on the DTA took place in Melbourne [37]. The event addressed various forms of digital mental health care, including web or mobile apps, teletherapy, and AI-based therapy agents [12]. Some researchers emphasized the role of human-computer interaction (HCI) in establishing standards for DTA, identifying key HCI knowledge that could shape the formation of DTA: namely, persuasive system design, positive computing, and affective computing [38]. Canonical measures for TA were revised to measure the DTA: mobile ARM (mARM) through the lens of HCI [38]. HCI further contributed to understanding DTA by presenting methods for developing and integrating therapeutic content into digital interventions and evaluating their effectiveness [8,39,40]. Though DTA shows promise for improving digital mental health interventions, its concept remains underdeveloped, with limited research exploring its definition and predictive value [37,41]. Addressing this gap, Malouin-Lachance et al [42] conducted

XSL•FO
RenderX

an integrative review that synthesized 28 studies to propose a conceptual framework for the DTA, highlighting core components such as goal alignment, task agreement, therapeutic bond, and user engagement. Their review underscores the potential of AI-driven tools—particularly chatbots—to replicate certain relational mechanisms found in traditional therapy, while also noting ongoing challenges related to personalization, ethical use, and long-term engagement. This framework provides a theoretical basis for understanding user-chatbot relationships and informs this study's exploration of how people perceive and articulate emotional bonds in real-world interactions with mental health chatbots.

Past research on DTA has primarily relied on adapted or newly developed instruments to evaluate alliance quality in technology-mediated interventions. One widely used tool is the Working Alliance Inventory (WAI)-Short (WAI-S), which assesses the traditional therapeutic bond between clients and therapists across task, goal, and emotional connection dimensions [23]. To evaluate alliance in technology-mediated therapy, the Digital WAI (D-WAI) extends the original WAI framework to digital contexts. It includes two items each for task agreement, goal alignment and emotional bond, rated on a 7-point scale (1=strongly agree to 7=strongly disagree), with lower scores indicating stronger alliance [7,43]. In contrast, mARM was developed for unguided app-based interventions. It comprises 25 items across five dimensions: bond, partnership, confidence, openness, and client initiative, each rated on a 7-point Likert scale. A score of 4 represents a neutral stance, with higher scores reflecting a stronger perceived alliance [25].

While these tools offer structured and standardized assessments, they may not fully capture the early-stage, dynamic, or moment-based relational states typical of fully automated, memory-limited chatbot interactions. These limitations suggest the need for complementary approaches that more directly capture lived experiences and nuanced perceptions of alliance in chatbot-mediated contexts. In this study, rather than applying standard alliance instruments, we adopted an inductive, qualitative approach to explore how users describe and interpret relational dynamics over time. This allowed us to examine how therapeutic relationships emerge, fluctuate, and at times remain ambiguous in short-term interactions with unguided mental health chatbots.

Mental Health Chatbots and Human-Chatbot Relationship

Chatbots are now widely used for mental health support. A scoping review identified 41 chatbots across 53 studies, including Woebot and Wysa, which are used for various purposes such as delivering therapy (eg, cognitive behavioral therapy for depression and anxiety), training social skills, and screening for conditions like depression and dementia [2]. Most of these chatbots were rule-based, using written language for input and combining written, spoken, and visual outputs [2]. There is growing evidence for the positive effectiveness of mental health chatbots in psychological treatment [1,3,17,44,45].

To better understand the aspects influencing relationships with mental health chatbots, we review literature on human-chatbot relationships, particularly in the context of nonclinical social chatbots. Key aspects such as trust [46], self-disclosure [47,48], diverse interaction [49], human-like conversations [50,51], and interactivity [52,53] enhance subjective experiences of the relationship. Studies suggest that longer and more intense interactions with chatbots lead to stronger feelings of social connectedness [54]. These aspects may also be relevant in clinical domains, yet health care chatbots remain understudied [54].

Although few studies on mental health chatbots directly consider the impact of relationships, they have identified elements that contribute to positive user experiences, such as usefulness, ease of use, responsiveness, understandability, and acceptability [55], as well as trust and enjoyment [14]. These elements help build intimacy with chatbots, boosting satisfaction and reuse intentions [15,55]. Multiple studies and a recent systematic review [16] have identified several design features that foster connectedness in AI-driven mental health chatbots. These include diverse content (eg, videos and games) [1,56], empathetic and friendly communication styles [1,56-58], a nonjudgmental tone [3,48], therapeutic tools like mindfulness and bibliotherapy [58-60], and personalized responses [57].

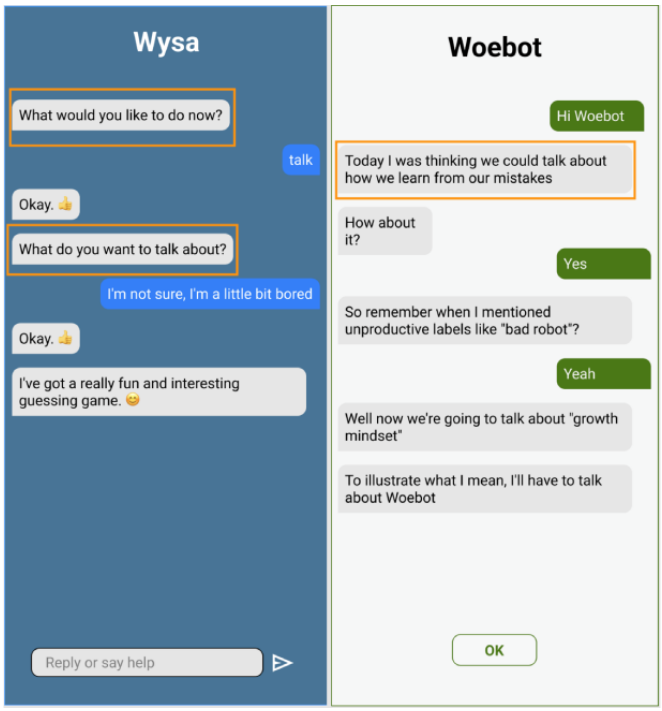
While existing literature sheds light on experiences with mental health technologies, less is known about how such experiences contribute to therapeutic relationships. A recent qualitative study of the DTA examined fully automated apps (including meditation tools and mental health chatbots) and identified five dimensions shaping connection: emotional resonance, perceived safety, goal alignment, on-demand availability, and the user's own role in sustaining engagement [18]. These dimensions apply across non–dialog-based apps and provide a general jumping-off point to focus on how conversational interactions affect relational development. This study builds on this work by focusing specifically on mental health chatbots capable of two-way communication. By examining how conversation style, preferences, and interaction design influence DTA over time, we extend the understanding of relational mechanisms in more conversational, dialogue-based systems.

Research Question

This research seeks to deepen our understanding of the relationship that forms between humans and digital mental health chatbots. Specifically, it aims to explore the nature of these bonds and how individuals perceive them. To achieve this, the study gathers participants' perspectives on their interactions with mental health chatbots, examining whether they subjectively feel a sense of relationship with the chatbot. Additionally, it identifies key themes that shape and influence the development of these connections. The research question leading this study is the following: What are the themes in people's perceptions about developing relationships with mental health chatbots? By addressing this question, the study aims to reveal the elements that foster human-chatbot relationships in the context of mental health care.

XSL•FO
RenderX

Methods



Chatbot Selection

Two well-established mental health apps, namely Woebot and Wysa, were selected for investigation. Both chatbots, based on cognitive behavioral therapy, an evidence-based approach, provide guided self-help treatments that typically range from 2 to 12 weeks [61-64]. Woebot has proven effective in alleviating symptoms of anxiety and depression while supporting overall well-being [1,3]. Wysa is a responsive chatbot with empathetic support and encourages users to delve deeper into their feelings [17]. Wysa also demonstrated efficacy in promoting well-being, exhibiting high engagement, and garnering positive acceptability [17,44,45]. This study used the publicly available versions of Woebot and Wysa between September 2022 and May 2023. At the time of this study, both Woebot and Wysa operated mainly with predefined decision pathways and natural-language classifiers, rather than open-ended generative AI [1,3,17].

As previous studies have shown, a sense of control plays a key role in shaping patients' relationships with therapists [31-34]. Similarly, Wysa and Woebot represent two distinct approaches to conversation control. Wysa, with its free-text input and minimal guidance, allows users greater control over topics. In contrast, Woebot, with its predefined reply options and structured conversation flow, provides users with less control, potentially influencing how they perceive their relationship with the chatbot. Wysa adopts a more passive role, engaging minimally and waiting for users to initiate conversations. It primarily listens, encourages users to express themselves, and refrains from interrupting, steering discussions, or offering unsolicited advice. In contrast, Woebot takes a more proactive approach, frequently initiating conversations and greetings. It introduces topics, guides discussions in its own direction, provides advice, and shares more about itself. These differences resemble two distinct counseling styles.

As shown in Figure 1, when users engage with Wysa, the chatbot prompts them to decide what they want to do, encouraging them to take the lead in conversations. In contrast, Woebot typically provides predefined topics and directs users to follow its guidance. Wysa adopts the role of a listener, fostering self-expression, while Woebot acts more like a coach, leading users through structured interactions. Additionally, Wysa offers a free-text input field with fewer prompts, allowing for open-ended conversations. Woebot, on the other hand, relies on structured responses, requiring users to select from preset options. As seen in Figure 2, Wysa provides both multiple-choice options and an open-text box, creating a more flexible conversational experience. In contrast, Woebot limits responses to predefined options—when users cannot find a suitable response, they must request additional options until they find a close match or exit the conversation. This demonstrates Woebot's closed-ended conversation style. Beyond conversation style, the chatbots also differ in their design. Visually, Wysa incorporates cute illustrations, while Woebot uses more humorous and lighthearted visuals. Wysa embeds videos and resources directly within the app, allowing users to access them seamlessly, whereas Woebot provides external links that require users to open a separate web page. Further design differences exist in areas such as how user reports and questionnaires are presented. These variations offer a variety of experiences and relationship dynamics, enabling analysis of features that influence bond formation.

Figure 1. Comparison of chatbot communication styles: a more passive tone (left, Wysa) versus a more directive tone (right, Woebot). Yellow callouts highlight contrasting conversational roles—Wysa invites users to choose what to do and fosters self-expression, while Woebot guides users through predefined topics with a coaching tone. Simplified interface depictions by authors.

XSL•FO
RenderX

Figure 2. Comparison of chatbot input options: flexible free-text choices (left, Wysa) versus predefined responses (right, Woebot). Yellow callouts highlight interface differences—Wysa supports open-ended input alongside multiple-choice prompts, whereas Woebot requires users to select from fixed options, limiting conversational flexibility. Simplified interface depictions by authors.

Study Design

Overview

This study used a 4-week diary study methodology, a short-term longitudinal qualitative approach designed to capture participants' lived experiences in real-world contexts. This method is particularly suitable for studying human-chatbot interaction in naturalistic settings, allowing for rich, ecologically valid data collection on emotions, behaviors, and reflections over time [65,66]. Diary studies can involve various forms of data collection, including screenshots, voice memos, and participant annotations [66-69]. We adopted a similar approach, asking participants to document moments of emotional significance—such as engagement, disconnection, or expressiveness—while using the chatbot.

Participants engaged with two mental health chatbots—Woebot and Wysa—each for a 2-week period. Given that prior research has shown meaningful mental health improvements can occur within 2 weeks of chatbot use [1], this duration was selected as sufficient to observe the emergence of relational dynamics. Participants were not forced to engage daily but were encouraged to interact regularly based on their preferences and needs. They were also invited to capture screenshots and brief notes during emotionally salient moments.

To assess changes in emotional well-being, the World Health Organization—Five Well-Being Index (WHO-5) was administered at baseline and biweekly. This tool measures mood, vitality, interest, and general life satisfaction on a scale from 0 to 100, with a threshold of ≤50 indicating possible depression [70,71]. In this study, if scores fell below this threshold, participants were provided with information about support resources, such as University Health and Counseling services. Weekly semistructured interviews were conducted to collect qualitative data on participants' experiences. These interviews provided opportunities to discuss emotional reactions, interpret chatbot behaviors, and reflect on relational developments.

Participant Recruitment and Eligibility

Participants were recruited through university-wide advertisements and mailing lists. Eligibility criteria included (1) current university enrollment, (2) aged 16 years or older, (3) ability to understand and respond in English during chatbot interactions and interviews, (4) interest in interacting with mental health chatbots, and (5) willingness to complete weekly interviews over 4 weeks. No prior relationship was established between the researcher and participants before the study began. We limited participation to currently enrolled students to streamline recruitment and ensure alignment with ethics protocols for low-risk university populations. In addition, access to support services (eg, University Health and Counseling) was contingent on student enrollment, enabling us to provide participants with appropriate resources if needed.

Prior to participation, eligible individuals attended a web-based onboarding session that outlined the study's aims, procedures, confidentiality measures, and participants' rights. Written informed consent was obtained after reviewing an information sheet. Participation was voluntary, and individuals could withdraw at any time without penalty. Because the lead researcher is bilingual in Mandarin and English, some bilingual participants were offered the option to conduct their interviews in Mandarin to facilitate more comfortable and nuanced verbal expression when reflecting on emotionally sensitive topics. This arrangement was intended to support deeper insight during interviews. Nonetheless, all participants met the proficiency requirements for university study in English as required for their

XSL•FO
RenderX

enrollment, and thus met the study's eligibility criteria of sufficient English proficiency to engage with the chatbots and participate in the study.

Initially, 34 individuals enrolled in the study. After excluding 8 participants due to withdrawal or incomplete WHO-5 data, the final sample included 26 participants (15 women and 11 men), aged 17 to 35 years (mean age 23, SD 4.66 y). Participants were recruited from computer science (n=16) and psychology (n=10) disciplines and received NZ $50 (US $30) upon completing the 4-week protocol, which included weekly surveys and interviews.

At baseline, participants' WHO-5 scores ranged from 32 to 80 (mean 54.77, SD 13.42). In total, 12 individuals scored below the clinical threshold of 50, which is indicative of poor well-being. Table 1 displays the total WHO-5 score distribution, while Figure 3 shows item-level response patterns across the 5 questions (rated on a 5-point Likert scale from 1=none of the time to 5=all of the time). Red dashed lines indicate the mean response for each item. Although most participants scored above the threshold, the item-level data suggest generally moderate emotional well-being.

Interview data further revealed that participants across the full range of WHO-5 scores expressed a strong interest in improving their mental health and exploring digital support tools, despite most having no prior experience with mental health apps.

Study Procedure

A visual overview of the study timeline and components—including chatbot use periods, weekly interviews, and WHO-5 assessments—is presented in Figure 4. The study took place over 4 weeks. During an initial onboarding session, researchers also guided participants through chatbot installation and conducted short test interactions (1-2 min) to ensure usability. Participants were randomly assigned to two groups in a crossover design: Group A used Woebot for the first two weeks, followed by Wysa, while Group B followed the reverse order. This design controlled for potential order effects.

Figure 4. Study procedure. WHO-5: World Health Organization—Five Well-Being Index.

Participants were encouraged to use each chatbot for 5-10 minutes per day or to complete 1-2 conversations per session, where one conversation referred to a person-initiated interaction that continued until the chatbot completed its suggested activity or dialog flow. They were asked to take screenshots of interactions that felt emotionally relevant and to annotate them with reflections or reactions. They were encouraged to blur any sensitive information to maintain privacy and were not required to capture a specific number of screenshots. All participation was individual, with no interaction between participants.

At the end of each week, participants joined a 30- to 90-minute web-based Zoom (Zoom Video Communications, Inc) interview, conducted in English or Mandarin based on preference. These semistructured interviews explored their weekly experiences with the chatbot. Participants also reviewed their screenshots and reflected on why they had captured those particular moments. The number and content of interview questions varied

XSL•FO
RenderX

depending on how many weeks they had used the chatbots. Interview content was audio-recorded and later transcribed. Participants completed the WHO-5 survey at Weeks 0, 2, and 4 to monitor changes in well-being. The interview guide is provided in Multimedia Appendix 1.

Ethical Considerations

This study was approved by the University of Auckland Human Participants Ethics Committee (24040). All participants provided informed consent prior to participation, and they were informed that they could withdraw from the study at any time without penalty. To ensure privacy, no personally identifiable information was collected, and all data were anonymized before analysis. Participants received NZ $50 (US $30) as compensation for their time. All procedures complied with institutional regulations and the principles outlined in the Declaration of Helsinki.

Data Analysis

We used reflexive thematic analysis as outlined by Braun and Clarke [72,73] to explore how participants formed relationships with mental health chatbots over time. This approach acknowledges that meaning is coconstructed between researchers and participants. Rather than seeking coding consensus or interrater reliability, it prioritizes interpretive depth, reflexive engagement, and theoretically informed reading of participants' accounts. In line with this approach, our analysis was primarily inductive and semantically grounded in participants' explicit descriptions rather than pre-existing theory or latent interpretation. This study followed the COREQ (Consolidated Criteria for Reporting Qualitative Research) guidelines to enhance transparency and reporting rigor (Multimedia Appendix 2) [74].

The dataset included weekly semistructured interviews and annotated chatbot screenshots from 26 participants, yielding over 110 hours of audio data and more than 1500 images. We observed data saturation [75] after analyzing material from approximately 21 participants, when no new themes or conceptually novel insights emerged, supporting the sufficiency of the sample size and analytic scope.

All interviews were conducted by a bilingual doctoral researcher in computer science, with a focus on HCI and digital mental health. Two additional researchers—one with a background in psychology and the other in computer science—each joined approximately half of the sessions to support data collection. All researchers took detailed field notes and memos during and after interviews to support reflexive analysis. Interview protocols were adapted over time: during the first 2 weeks, questions focused on participants' immediate experiences using the chatbots (eg, "How did you feel using the chatbot this week?"). In weeks 3 and 4, the same core prompts were retained to support continuity, while additional questions were introduced to explore emerging relational dynamics and invite comparisons between the two chatbots. In the final interview sessions, themes that had emerged earlier in the study were lightly introduced as flexible prompts when participants did not raise them spontaneously. This approach aimed to support reflection without narrowing the conversation, allowing participants to respond freely based on their own perspectives. Screenshots submitted by participants were used as contextual prompts to elicit deeper reflections on their interactions. These visual records were particularly helpful in surfacing moments of connection, misunderstanding, or disengagement that might not have been captured through verbal recall alone. Field notes taken during and after interviews provided additional contextual cues and helped interpret participants' reactions to specific exchanges, particularly when screenshots conveyed ambiguous or emotionally nuanced content. This integration of multiple data sources aligns with reflexive thematic analysis, which emphasizes researcher subjectivity and iterative interpretation grounded in participants' evolving accounts.

In addition to developing experiential themes inductively, we conducted a complementary deductive content analysis [76] to classify how participants described their overall relationship with the chatbots: Bond, Light Bond, and No Bond. This analysis drew on responses to recurring interview questions, such as "How would you describe the relationship between you and this chatbot?" and how participants described their overall relational experience, often in the context of emotional support, a feeling of being collaborative, and perceived understanding. Based on participants' accounts, we categorized participant-chatbot relationships into one of the three categories of relational experience, typically based on the consistent presence of these elements. Ambiguous cases were reviewed collaboratively by the research team to ensure consistency.

Thematic development proceeded iteratively and reflexively over 5 months. The analysis team included the three researchers involved in data collection, as well as two senior researchers with expertise in digital mental health and HCI. The lead researcher began by identifying early patterns of meaning across transcripts and screenshot narratives. The other two researchers independently engaged with selected interview sessions and screenshots to provide alternative readings, challenge assumptions, and bring in varied disciplinary perspectives. Themes were initially explored separately for interview and screenshot data to preserve the nuances of each modality. Across the team, this process resulted in approximately 20 initial themes. In team discussions, we refined these themes by merging similar ideas, removing those that were unrelated to relationship development, and developing clearer definitions. These meetings also allowed us to reflect on how our own backgrounds and assumptions shaped the way we interpreted the data. Through this process, we arrived at a final thematic structure that all team members agreed captured both the conceptual clarity and the range of participant experiences observed in the data.

Although most participants spoke primarily in English, several incorporated Chinese in their annotations or interviews. These excerpts were translated by the bilingual lead researcher and reviewed for cultural nuance and accuracy by a second bilingual team member. Minor ambiguities in culturally specific expressions were discussed and resolved. Reflexivity remained integral throughout: the core team, comprising researchers from Chinese, bicultural, and North American backgrounds, regularly reflected on how their own positionalities shaped theme development, especially in interpreting relational norms and

XSL•FO
RenderX

emotional expression in cross-cultural contexts of human-chatbot interaction.

Results

Overview of Themes and Bond Formation

This study identifies six major themes that shape and influence the relationship between humans and mental health chatbots. We describe these along with illustrative quotes.

Among participants who scored below the WHO-5 threshold (n=12), 7 reported forming either a strong or light emotional bond with at least one chatbot. Similarly, 11 of the 14 participants who scored above the threshold also described such relational experiences. These findings indicate that the capacity to perceive a bond with a mental health chatbot does not appear to be limited by one's mental health status at the time of participation. Thematic analysis of interviews revealed that participants from both groups, regardless of WHO-5 score, discussed similar types of relational experiences. All six themes drew responses from participants across both WHO-5 groups (at times for only a single chatbot), as presented in Table 2, reflecting that these relational aspects were widely encountered, even if experienced and interpreted in varied ways.

Table 2. Participant distribution across six themes by WHO-5[a] group (<50 vs ≥50)[b].

Theme	Below the WHO-5 threshold, n (%)	Participant IDs below threshold	Above the WHO-5 threshold, n (%)	Participant IDs above threshold
Theme 1	11 (92)	5, 8, 10, 13, 14, 16, 20, 23, 24, 25, 26	13 (93)	2, 3, 4, 6, 7, 9, 11, 12, 17, 18, 19, 21, 22
Theme 2	12 (100)	5, 8, 10, 13, 14, 15, 16, 20, 23, 24, 25, 26	14 (100)	1, 2, 3, 4, 6, 7, 9, 11, 12, 17, 18, 19, 21, 22
Theme 3	11 (92)	8, 10, 13, 14, 15, 16, 20, 23, 24, 25, 26	13 (93)	1, 2, 3, 4, 6, 7, 9, 11, 12, 18, 19, 21, 22
Theme 4	10 (83)	5, 8, 10, 13, 15, 16, 20, 23, 24, 26	13 (93)	1, 2, 3, 4, 6, 7, 9, 11, 12, 17, 18, 21, 22

[a]WHO-5: World Health Organization—Five Well-Being Index.

[b]Percentages reflect the proportion of participants within each WHO-5 category who contributed any quote coded under the corresponding theme. Because some contributions were brief, tangential, or neutral—and some reflect experiences with only one chatbot—100% does not indicate full or consistent endorsement across participants.

Based on participants' interview data, we identified three categories of relational experience: Bond (B), Light Bond (LB), and No Bond (NB). Participants categorized as Bond (B) described forming a clear emotional connection and bonding with one chatbot, often likening it to "talking to a friend" or "talking to a coach or therapist." For instance, Participant #2 shared, "Woebot made me feel like it was a friend who was encouraging you to complete a task as you are so close." Those categorized as No Bond (NB) did not perceive any relationship with the chatbots, describing them as "just a tool," "like a stranger," or "acquaintance," or simply stating there was "no relationship." A subset of participants reported a more neutral or tentative connection, categorized as Light Bond (LB), often describing the chatbot as "a friend but not too close," "a long-distance coach," or expressed that they felt a little bit bonded with the chatbot. For example, Participant #1 noted, "I think after stopping using Woebot, I actually kind of missed it. So I definitely felt a bit of a bond with Woebot."

To present participants' perceived bonding levels with the two chatbots, we use a standardized shorthand notation in the format N#BondLevel–WB|BondLevel–WY (eg, N11LB–WB|NB–WY), where bond levels are abbreviated as B (Bond), LB (Light Bond), and NB (No Bond). The app order is fixed as WB|WY, referring to Woebot and Wysa, respectively. For readability, the simplified notation N#LB|NB is used throughout the paper, with the WB|WY order assumed. For example, N11LB|NB indicates that Participant 11 reported a Light Bond with Woebot and No Bond with Wysa. In total, 18 participants reported perceiving a bond or light bond with at least one chatbot, while 8 participants did not perceive any bond with either chatbot (NB). In the following themes, we begin with findings related to Woebot, followed by those on Wysa. To illustrate how participants experienced emotional connection and relationship development with the chatbots, we include participant identifiers (N#LB|NB) alongside representative quotes from those who reported varying levels of bonding. Table 3 further summarizes the types of bonds participants reported, grouped by their WHO-5 well-being scores. Participants were categorized as either above or below the threshold score of 50. As shown, both groups included individuals who experienced a bond, a light bond, or no bond with the chatbots. This distribution indicates that the ability to perceive a relational connection with a mental health chatbot is not strictly dependent on one's current level of psychological well-being.

XSL•FO
RenderX

Table 3. Distribution of bond types among participants categorized by WHO-5[a] scores.

WHO-5 group	Bond type distribution (N)	Participant IDs
Below threshold	• Woebot: B (3), LB (3), NB (6) • Wysa: B (3), LB (1), NB (8)	N5LB|NB, N8B|NB, N10B|NB, N13NB|NB, N14NB|NB, N15B|B, N16LB|NB, N20NB|NB, N23NB|NB, N24NB|LB, N25NB|NB, N26LB|B
Above threshold	• Woebot: B (6), LB (6), NB (2) • Wysa: B (7), LB (0), NB (7)	N1LB|NB, N2B|B, N3LB|NB, N4LB|B, N6LB|B, N7LB|NB, N9NB|NB, N11LB|NB, N12B|B, N17NB|NB, N18NB|NB, N19B|B, N21B|B, N22B|NB

[a]WHO-5: World Health Organization—Five Well-Being Index.

Theme 1: The Desire to Lead or Be Led in Conversation

Overview

Participants had varying preferences for managing conversations with mental health chatbots, influenced by their need for control or their desire to cede control. Participants reported that their control over interactions impacted their connection and relationship quality. Some preferred leading conversations by themselves, while others appreciated chatbot-led discussions that introduced new topics or timely interruptions, which some found helpful for keeping the conversation moving. Participants suggested that a dynamic approach, where the chatbot adapts to a person's needs, would provide a better balance of autonomy and guidance.

Person-Led Conversations

Some participants preferred to lead conversations themselves, finding it more engaging and tailored to their needs. But Woebot does not support a person-led conversational style, which led some participants to feel disconnected and constrained during their interactions. N6LB|B described feeling disconnected when they were unable to redirect the conversation, highlighting how Woebot's rigid flow limited their sense of control—despite the exchange initially seeming open-ended:

> *It got really boring and mundane. I didn't want to talk about(...), and now I have to talk about it for ages. I felt very disregarded because I didn't have a choice.* [N6LB|B]

Participants praised Wysa for offering them the freedom and control to guide the conversation, which contributed to the development of a bond. For instance, one participant explained their perception of a light bond with Wysa:

> *I like to start the chat by myself because it's like a tool for my emotions. I need to share and talk about more.* [N24NB|LB]

Moreover, this feeling was echoed by another participant, who shared a screenshot capturing a moment of perceived connection during the interaction, even though they ultimately did not feel a sustained bond with Wysa:

> *It can let me take charge of the conversation by saying what I want to say.* [N23NB|NB]

Additionally, N23NB|NB further reflected that the sense of bond was disrupted by interactions that felt impersonal, overly scripted, and overly focused on promoting services, ultimately breaking the illusion of a genuine connection.

However, Wysa's conversation style sometimes posed challenges for those who struggled to initiate or direct conversations. A participant shared:

> *I didn't want to start chatting and didn't have much to share. It left me feeling frustrated.* [N5LB|NB]

Chatbot-Led Conversations

Some participants appreciated when chatbots took the initiative in conversations, especially when they are in a bad mood or need guidance. They valued Woebot's ability to lead discussions and introduce new topics. N8B|NB built the bond with Woebot and remarked:

> *Even though Woebot usually takes charge of the chat most of the time, I can stay very focused during our chat.*

This indicates that a chatbot-led approach can be effective for people who benefit from a structured dialogue. N11LB|NB further highlighted the benefits of this approach by stating the following statement. This proactive topic introduction helps maintain engagement and stimulates ongoing conversation:

> *It shares new topics every day, I feel curious and want to keep chatting with it.* [N11LB|NB]

In contrast, Woebot's tendency to drive the topics of the conversation led to frustration. One participant expressed concern with Woebot's lack of conversational control, said:

> *It brings up a topic and then just keeps talking to itself. It gives you stuff to think about, but you can't really have a chat with it—you're just sitting there taking it all in.* [N9NB|NB]

These responses highlight a gap between expectations and the chatbot's style in managing the dialogue, underscoring the need for more balance in conversational control.

On the other hand, Wysa does not support a chatbot-led conversational style. Participants who preferred Woebot's more structured and directive approach compared it to Wysa's, noting that they appreciated having clearer guidance and direction in the interaction, as shared by one participant:

> *Woebot usually starts with a topic, which makes it easier for me to follow and want to open up. I kinda like how Woebot starts the conversation—feels more natural.* [N12B|B]

XSL•FO
RenderX

Dynamic Control in the Conversation

Participants also expressed a preference for dynamic conversational control, where the chatbot adapts to their needs. One participant explained:

> *If I have a particular problem, then leading the conversation can be quite a lot more useful. If I don't really have that or if I don't understand my own problems, then having it lead the conversation can be quite helpful.* [N22B|NB]

N11LB|NB echoed this view, describing how their preference shifted based on emotional state:

> *If I was feeling down that day, I wanted to start the chat myself. But on a normal day, I preferred the chatbot to suggest the topic.*

This feedback indicates a desire for flexibility, where the chatbot can switch between leading and following based on the person's needs. This dynamic approach allows for a more tailored interaction, potentially enhancing the relationship. Other participants, including N18NB|NB and N14NB|NB, also supported this flexible control, suggesting that a responsive chatbot can better meet their needs and improve their relationship with chatbots.

Theme 2: The Match Between the Ability and Desire to Self-Express: Open-Ended Style (Free-Text) or Closed-Ended Style (Provided Prompts)

Overview

Participant communication preferences, such as open-ended versus closed-ended conversation style, showed influence on their relationship with chatbots. Woebot uses prompts, such as a handful of one-word mood options that the user can select in response to the question "How are you feeling today?" which provides a structured conversation flow. Wysa offers free-text input, which allows users to open up and talk about their own topics.

Preference for Free-Text Input

Many participants valued free-text input for its ability to facilitate self-expression, which they felt strengthened their connection with the chatbot. In some instances where Woebot allowed free-text input, participants often recorded these moments and described feeling a sense of connection with the chatbot during these less restricted exchanges, suggesting that even brief opportunities for free-text input contributed to perceived bonding. For instance, one participant echoed this sentiment, stating:

> *Woebot shares its own stuff (...) When I can type my own thoughts, it makes me want to open up more. [explaining the moment they felt a bond].* [N11LB|NB]

Wysa's support for free-text input was frequently cited by participants as a key interaction contributing to moments of perceived bonding. Many participants emphasized this during interviews, noting that the ability to express themselves in their own words made interactions feel more personal and meaningful. For instance, N20NB|NB recalled a moment of connection, as illustrated in the quote below, even though they ultimately did not feel a sustained bond with Wysa. This highlights how open-text input can enhance connection and support the development of relational closeness with the chatbot:

> *Typing whatever I want, it is kind of like chatting with a friend.*

However, free-text input did not always suit every situation. N11LB|NB also shared why they did not feel a bond with Wysa, saying:

> *When I chat with it at night, I'm usually exhausted and don't want to think too hard. So, I'd rather just pick from options than type out my own stuff.*

This view was consistent with N18NB|NB's opinion, noting that while free-texting can enhance bond, it may be less practical during times of fatigue.

Preference for Predefined Options

While many participants favored free-text input, predefined options were useful in some circumstances. Predefined options helped participants initiate conversations more easily and maintained the flow of interaction. One participant, who did not build a relationship with Woebot but shared the moment when he felt the bond with it, stated:

> *I think the options are really easy to use. I actually prefer using them ... it feels relaxing and there's no pressure. I don't have to come up with what to say, and it's easy to just go with the flow and move on to the next topic.* [N13NB|NB]

This view was echoed by N16LB|NB, who also appreciated the convenience of predefined choices. Participants who formed connections with Woebot valued platforms that adapted to their preferences. As N12B|B shared:

> *I'm not super expressive, so if the options don't match exactly how I feel, I'm fine picking something close enough. It doesn't really bother me.*

On the flip side, limited options sometimes led to frustration, as one participant expressed:

> *It gives me prompts instead of actual input. It feels like I'm pressing buttons instead of typing, so it kind of takes away from the experience. I'm disappointed.* [N23NB|NB]

Regardless of their preferred expression methods, all participants emphasized the importance of chatbots accurately understanding their input to maintain engagement. Frustration arose when chatbots failed to comprehend free-text input, leading to a decrease in motivation to express themselves. As N1LB|NB explained why they lost the bond with Wysa:

> *It's obviously not interpreting correctly what I'm typing in. So it's kind of pointless.*

XSL•FO
RenderX

Theme 3: Expectations for Caring and Nurturing From the Chatbot

Overview

Participants expressed strong expectations that chatbots could act as emotionally supportive figures, providing comfort, empathy, and reassurance. This theme focuses on the emotional depth and relational quality participants sought in chatbot interactions—expecting to feel heard, comforted, and emotionally understood, much like with a caring human companion.

Fostering Bond Through Empathy and Emotional Depth

Participants sought attachment and closeness with mental health chatbots, emphasizing the need for emotional understanding and empathy. They believed that for chatbots to provide effective emotional support, demonstrating empathy was essential, as participants expected varying levels of understanding and kindness.

First, participants valued the basic comfort and care provided by chatbots, especially during moments of distress. Acts of reassurance, concern, and empathy—such as attentive listening and validating emotions—were key in strengthening the human-chatbot bond. Both Woebot and Wysa demonstrated these supportive behaviors, which contributed to building emotional rapport. This sense of comfort was reflected by one participant, who described a subtle feeling of connection with Woebot:

> *I felt like I was being looked after by Woebot. It seemed to care about me. I felt relieved knowing it's okay to do nothing. It showed caring and empathy. I felt a little bit of a bond, like with a friend.* [N8B|NB]

A similar feeling was expressed by participants who interacted with Wysa. For instance, another participant noted:

> *When it said, "I heard you, and noted at all." I felt (...) it was actually listening, not just taking a bunch of data from what I was saying.* [N15B|B]

This sense of being genuinely heard was also echoed by N2B|B and N21B|B, who described the responses as attentive and emotionally validating.

Second, participants expressed a desire for emotional support that went beyond surface-level engagement. They wanted chatbots not only to display empathy but also to engage in meaningful dialog that explored deeper emotional issues. This kind of support involved thoughtful prompts, reflections, and a willingness to address the root causes of distress. Wysa, in particular, was noted for facilitating such depth by encouraging participants to open up. As a participant shared:

> *The only difference is when they ask me about deeper feelings or emotions, I open up more and am more exposed.* [N21B|B]

However, this pursuit of emotional depth was a double-edged sword. When chatbots probed too directly or failed to convey sensitivity, participants could feel uncomfortable or even overwhelmed. As N9NB|NB reflected:

> *I felt uncomfortable because it kept asking about my problems.*

Providing Consistent Emotional Support

To foster lasting emotional bonds, chatbots needed to strike a delicate balance between being empathetic listeners and offering practical guidance. Participants emphasized that while comfort and emotional support were crucial, they also appreciated actionable suggestions—so long as these were delivered with empathy. This balance, however, was not always easy to maintain. When the chatbot's tone or approach shifted too abruptly, it could disrupt the emotional connection and reduce the sense of being understood. As one participant, who felt a light bond with Woebot, reflected:

> *I was surprised by how comforting and empathetic it could be. But it needs to be consistent. One day it was really comforting, but the next day it just felt like it was teaching and didn't bring empathy.* [N26LB|B]

A similar sentiment was echoed by Wysa users. When chatbots failed to demonstrate empathy, participants described feeling disconnected or even dismissed. Without emotional resonance, the interaction risked becoming cold or mechanical. For instance, N12B|B shared a moment when the bond with Wysa broke down:

> *I told it I was in a bad mood and hoped it would continue to give me some comfort and suggest things I could try. But it just sent me a bunch of hotlines.*

Theme 4: Relevance of the Chatbots' Psychoeducation and Joint Activities

Overview

Participants reported that interactions needed to feel regularly "valuable," including engaging through diverse types of content such as text-based reflections, digital exercises, and professional psychoeducational resources. Repetitive activities and unrefined content were found to disrupt the process of building a relationship.

Sustained Use and Meaningful Engaging Activities

Participants emphasized that regular daily use, offered by both chatbots, contributed positively to relationship-building. Routines, predictability, and consistent check-ins helped establish a sense of familiarity and structure, which was reassuring over time, as one participant described the impact of these regular interactions with Woebot:

> *The bond is developing well [by using daily check-ins], but it's not strong enough.* [N8B|NB]

After participants established familiarity through regular use of chatbots, their relationships with the chatbots were further strengthened by joint activities, games, and exercises. Engaging activities like goal-setting tasks, breathing exercises, workouts, and meditation, offered by both chatbots, kept participants motivated and fostered a deeper connection, making interactions more beneficial and fulfilling, as one participant highlighted:

> *I really enjoyed a lot of activities. It felt friendly and was easy to navigate. I definitely felt engaged by the*

XSL•FO
RenderX

> *app. And it was quite helpful, supportive, and warm. And it made me feel empowered.* [N24NB|LB]

Moreover, collaborative exercises offered by both chatbots fostered a sense of bonding by creating shared experiences. These activities encouraged participants to reflect on positive aspects of their lives, helping to deepen their emotional connection with the chatbot and enhancing feelings of support and understanding. As N6LB|B described, this sense of "doing it together" contributed to feeling emotionally supported—a sentiment echoed by N15B|B, N8B|NB, and N22B|NB:

> *I could say there was a connection there because it was telling me that "we all" kind of do it as a team, instead of just me, and it was like helping me out, it was like "we'll figure it out together." So this one made me feel quite understood, supported.*

Professional Advice

Both chatbots provide constructive suggestions and psychological insights that enhance support and bonding. By offering practical tips and professional knowledge in relatable terms, they foster connection and make interactions educational and supportive. Positive reinforcement and helpful guidance strengthen the bond between the person and the chatbot, as one participant shared:

> *It uses psychological terms, which is pretty cool. It helps people who might not know things like CBT and guides them to explore their thoughts and solve problems.* [N21B|B]

On the contrary, excessive and impersonal advice could undermine the supportive nature of the interaction. When chatbots overwhelmed participants with too much information or presented advice in a detached manner, participants reported feeling annoyed or disengaged. As N18NB|NB noted:

> *I was reading quite a bit [with it], providing quite a bit of information. It was quite annoying to read. Sometimes I just don't want to.*

Moreover, repetitive or generic responses, unpolished content, and overwhelming follow-ups also led to frustration and emotional disconnect, as N3LB|NB shared:

> *The chat keeps asking the same mood question every day, and if I pick "OK, I guess," it just gives me the same reply every time. It gets kind of boring and makes me feel a bit lonely.*

Theme 5: Appreciation for Human-Like Colloquial Communication

Unlike Theme 3, which focuses on expectations for emotional empathy and support, and Theme 1, which centers on preferences for directing the flow of conversation, this theme highlights how colloquial communication styles and replies that demonstrated awareness of prior exchanges shaped participants' sense of bond—by making interactions feel more natural, responsive, and attractive.

Participants largely appreciated chatbots that exhibited human-like qualities and demonstrated awareness of previous conversations, finding that these elements fostered connection. Participants emphasized the importance of a human-like colloquial communication style. The use of engaging features like emojis and shared stories created a sense of empathy and understanding. Conversely, scripted or irrelevant responses that lacked tailored understanding weakened the bond, making interactions feel impersonal and ineffective.

For example, some participants described feeling "noticed" when the chatbot remembered past exchanges or picked up on previously shared content. These follow-ups made the interaction feel more like a continuing relationship than a series of isolated conversations. As N12B|B shared—and a sentiment echoed by N10B|NB and N3LB|NB about Woebot:

> *It said that I'd said (…) before and suggested starting a new topic based on what I'd said. It made me feel like he remembered and cared about what I'd shared, which made me feel that our relationship was deepening.*

Participants also valued when the chatbot's language and emotional tone felt personally relevant and emotionally attuned, which enhanced their sense of being seen and understood. Moreover, when chatbots demonstrated the ability to recognize emotions and respond with empathy, sometimes even sharing similar experiences, participants felt genuinely understood, which helped deepen the connection. As N26LB|B explained, a key reason they formed a bond with Wysa was the chatbot's replies that built on their earlier conversations:

> *[I felt the bond because] the replies that were given were tailored to my response.*

Similarly, N8B|NB, who ultimately did not form a strong bond with Wysa, still recalled a moment of connection when the chatbot demonstrated emotional recognition:

> *It seemed to understand me and shared the exact same experience I had. It made me feel much more understood and closer.*

Conversely, when chatbots delivered generic responses, interactions often felt impersonal and one-sided. This made the chatbot seem disconnected and uncaring, reducing its perceived bond, as one participant explained:

> *If it just talks about what it wants to say without considering my feelings, it feels like it doesn't really understand me. The advice ends up being generic and not helpful for my specific situation, which makes it feel pretty pointless and perfunctory.* [N9NB|NB]

Finally, visuals or jokes that seemed irrelevant or overly scripted diminished the appeal, making interactions feel robotic. Some participants expressed frustration over mismatched tones, noting that these elements detracted from their overall experience.

Theme 6: Valuing a Private and Nonjudgmental Conversation

Trust played a central role in building relationships with mental health chatbots, and this theme gathers evidence on how trust was established and the elements that could undermine it. Participants discussed how their trust in chatbots developed over time. Key elements for building trust included creating a

XSL•FO
RenderX

safe, nonjudgmental environment, ensuring technological reliability, and protecting privacy.

Participants felt trust grew when chatbots provided a safe space where they could express their thoughts without fear of judgment. Both Woebot and Wysa received praise for fostering nonjudgmental environments, making participants feel comfortable sharing their emotions and personal issues. This sense of safety encouraged deeper engagement, as participants felt they could open up more freely. As N21B|B noted:

> *I trust it [Woebot]. It will not speak out about what I said.*
>
> *I trust it [Wysa] a lot. It always gives the neutral side of ideas rather than personal ideas.*

Additionally, privacy played a pivotal role in trust-building. Participants were more willing to share personal details when they believed their data were secure and confidential. As N25NB|NB highlighted the importance of privacy:

> *It seems like it's [Woebot] very private, and I wouldn't worry about any like information leakage.*

Conversely, certain beliefs and behaviors eroded trust and hindered relationship development. Participants felt disconnected when chatbots appeared to have profit-driven motives or when they feared their information might be misused. Such concerns created barriers to open communication and reduced the chatbot's effectiveness. As one participant explained the moment they lose the bond:

> *It makes you step back and realize, oh, you know, at the end of the day, this is just an app [Wysa] with a developer, and they need to get good ratings in the app store. It sort of breaks the natural flow of the conversation.* [N2B|B]

Discussion

Principal Findings

The study identified six key themes that impact the relationship between humans and mental health chatbots. First, preferences for leading or being led in conversations influenced the relationship with the chatbot, with some preferring more control while others value guidance. Second, the match between communication preferences—whether through free-text input or predefined options—and the chatbot's style affected engagement and expression. Third, people sought emotional support that is empathetic and consistent. Fourth, participants valued meaningful, engaging activities and professional advice from chatbots, but repetitive or generic content hindered relationship development. Fifth, human-like communication, such as referencing past conversations, sharing stories, using colloquial language, and providing replies that demonstrated awareness of previous exchanges, supported relationships, while overly scripted or irrelevant content detracted. Finally, trust was essential for relationship building, with participants emphasizing the importance of privacy, nonjudgmental environments, and the chatbot's perceived motives.

While each of the six themes reflects a distinct aspect of how people build relationships with mental health chatbots, we also observed meaningful overlaps between them. For example, emotional resonance often appeared alongside perceived human-likeness, suggesting that people were more likely to feel emotionally connected when the chatbot's language and tone felt more natural or human. Likewise, conversational control was frequently mentioned together with expressiveness, indicating that people felt more in control when they could express themselves freely. These patterns suggest that relationship-building is shaped not by isolated factors, but by the interaction of multiple experiences. Future research could explore how these elements work together over time to influence how people relate to mental health chatbots.

Comparisons With Prior Research

This study contributes to the DTA framework by examining interactions with mental health chatbots over a 4-week period, focusing on subjective experiences and the perceptions of relationship development with chatbots. Our findings contribute to the ongoing efforts to define and operationalize the DTA, as proposed in recent reviews, such as Malouin-Lachance et al [42]. While their work outlines key theoretical components of DTA, including goal alignment, task agreement, therapeutic bond, and user engagement, this study offers empirical insights into how these dimensions are experienced and interpreted during real-world interactions with mental health chatbots. It also helps clarify the scope of DTA, which holds potential for enhancing digital mental health interventions but remains underdefined [37,41]. Prior studies, including one that explored DTA across a range of mental health apps, have identified several factors impacting it [18]; our work validates their findings that beliefs about digital conversations being safe and nonjudgmental support relationship building, and that meaningful emotional interactions also play a key role. We extend DTA research by connecting it to work on two-way communication in social contexts, an important aspect in physician-patient relationships [31-34]. Additionally, we further the DTA framework with communication-related themes such as leadership in conversation topics, the impact of input modes on self-expression, and the role of colloquial communication style. Our theme on perceived effectiveness aligns with previous work on goal alignment, but also introduces the concept of "being" and "doing" together, linking our findings to those suggesting that diverse interactions foster relationship development [49].

Previous research on face-to-face therapy has shown that managing control dynamics in physician-patient interactions enhances communication and strengthens relationships in clinical settings [31-34]. Our first theme aligns with these insights, suggesting that similar dynamics are important in building therapeutic relationships with mental health chatbots. Previous studies recognized free-text input as enhancing user experience [48], but they did not link it to relationship development. Our findings do this and reveal that while free-text input contributes to positive experiences, this does not account for all communication needs—matching people's preferred methods for self-expression is what helps to build relationships with chatbots.

XSL•FO
RenderX

Empathic interaction makes people feel cared for, understood, and connected when they receive emotional support [1,18,56-58]. Our research extends this with the specific types of emotional support that people expect, bringing up relevant aspects of previous conversations, consistent demonstrations of empathy, and balancing the role of empathetic listener and proactive coach. This study highlighted that the perceived effectiveness of the chatbot's advice and proposed activities was linked to relationship development. This echoes previous findings within a social chatbot context [49], which mentioned chatbots' ability to participate in a variety of interactions pushed the relationship toward attachment. Across the board, our participants appreciated human-like colloquial communication style and replies that demonstrated awareness of prior conversations, which aligns with past research [1,3,57]. In contrast to previous work, this study revealed that one specific aspect of a human-like colloquial style—recalling past conversations in future interactions—was particularly important for fostering a consistent connection and ongoing relationship development with chatbots.

While previous work found that specific therapeutic approaches and techniques [58-60] and diverse content [1,56] contributed to positive user experiences, these were not connected to mental health chatbot relationship development in this study. Our findings had a shifted focus toward perceptions of professionalism and diverse content for perceived effectiveness. We also found that creating a routine can help develop familiarity, which is in line with previous work showing that longer and more intense interactions with chatbots are associated with increased social connectedness [54]. Our research links routine interaction, increasing feelings of familiarity, with deepening relationships with chatbots.

Trust emerged as a fundamental aspect influencing initial willingness to use a chatbot, a point widely discussed in previous literature [3,46,48]. We also found that trust plays a foundational role in relationship development. Trust has been linked to a nonjudgmental environment, which has been linked to positive user experiences [3,48]. Our research further suggests that such an environment not only fosters trust but also encourages openness, allowing people to share their thoughts more freely. Privacy concerns were also highlighted in our findings as an important aspect of trust-building. The belief in a nonjudgmental and privacy-respecting environment fosters trust and a bond with mental health chatbots.

Although we did not directly apply structured instruments such as the WAI-S, D-WAI, or mARM, our categories (Bond, Light Bond, and No Bond) show meaningful alignment with these tools. For example, participants in the Bond group described experiences of collaboration, emotional support, and feeling understood—core features also emphasized in WAI and mARM frameworks. No Bond cases reflected disengagement and lack of emotional resonance, suggesting parallels with low alliance scores. Light Bond, meanwhile, captured more mixed experiences: participants described moments of connection or responsiveness, but without the consistency or emotional investment typically associated with full alliance. These cases reflect the kind of early-stage or partial alliance that structured tools may not always capture well. Importantly, our findings suggest that Light Bond may not simply represent a transitional stage toward a stronger alliance, but rather a distinct and meaningful relational state—emotionally real, yet fragile and easily disrupted. While low TA in traditional therapy is often associated with treatment dropout or reduced treatment efficacy [77], the Light Bond observed in chatbot contexts does not always lead to disconnection. Instead, some continued to use despite only a minimal sense of bond. This divergence highlights a key distinction between chatbot-mediated and human-delivered care: in digital contexts, even tenuous relational bonds may be sufficient to sustain engagement. These findings underscore the need for DTA frameworks to more explicitly account for the variability and fluidity of alliance formation in chatbot settings.

While many participants reported feeling bonded to the chatbot, they also emphasized that this sense of bond needed to be paired with therapeutic relevance. When interactions felt generic or failed to address their concerns, some questioned the chatbot's purpose, suggesting they might prefer a general-purpose agent instead. This highlights an important distinction: general chatbots may offer companionship or entertainment, but mental health chatbots are expected to provide emotionally attuned support and help people work through personal challenges. In this context, participants' expectations aligned more closely with the goals of a DTA—one that includes empathy, goal-setting, and responsive guidance. Without these elements, even warm or friendly interactions were seen as superficial, underscoring the need for design approaches that integrate both emotional connection and therapeutic intent.

Rather than relying on predefined rating scales, we show how alliance-related perceptions emerge through specific types of interaction, such as empathetic responses, collaborative tasks, and feeling remembered. These insights may inform future refinements of DTA theory and the development of hybrid measurement approaches that combine structured tools with narrative-based indicators of relational quality.

In addition, although our analysis did not specifically track changes over time, participants' weekly reflections suggested that their sense of relationship with the chatbot often shifted. Some described initial curiosity that faded as conversations became repetitive, while others reported growing connection as they discovered useful or emotionally attuned features. These patterns highlight that DTA is dynamic—shaped by evolving expectations and experiences—underscoring the need for designs that support relationship development over time. Future longitudinal studies could further explore how such temporal dynamics influence relationship formation and sustainability.

Drawing from our findings, we propose three design suggestions to support early-stage DTA in mental health chatbots. First, chatbots should balance emotional support with actionable guidance, ensuring both are tailored to evolving emotional states and concerns. Participants valued empathy and advice, but only when responses felt relevant and attuned to their needs—generic replies often led to a lack of relational bond. Second, offering flexible input methods (eg, switching between free text and structured options) can accommodate communication preferences and enhance their sense of agency. Finally, continuity mattered: when chatbots recalled prior conversations

XSL•FO
RenderX

or followed up on earlier topics, people felt seen and supported. Simple memory mechanisms that highlight relevant past exchanges may deepen trust and foster a more sustained relational connection. In addition, logging adaptive responses to user input—such as changes in tone or content—could support transparency and auditability, aligning with Article 22 of the European Union (EU) AI Act [78]. This design practice not only helps ensure accountability in automated decision-making but also builds trust by allowing users and regulators to understand how and why a chatbot responded in particular ways.

Limitations and Future Work

This study has several limitations. First, while participants were encouraged to interact with the chatbots daily, some struggled to maintain consistent engagement due to busy schedules, declining interest, or perceived repetitiveness. This inconsistency highlights a challenge in sustaining real-world use and suggests that longer-term studies may be needed to capture how relationships with chatbots evolve over time. We therefore describe this as a short-term longitudinal study that primarily reflects early-stage dynamics of DTA formation. Second, during the study period, more advanced conversational agents—such as GPT—capable of understanding language in more flexible and adaptive ways, were beginning to attract public attention. Some participants drew informal comparisons between the chatbots they used and these emerging systems, highlighting a growing expectation for interactions that demonstrated awareness of prior exchanges. While generative AI systems promise more adaptive support, they may misinterpret distress or provide inaccurate guidance, raising concerns about safety, reliability, and clinical oversight. Regulatory frameworks such as the EU AI Act (Regulation [EU] 2023/1114) emphasize transparency, explainability, and safeguards against algorithmic bias—particularly under Article 22, which highlights the importance of traceability and meaningful explanation of automated decisions [78]. These principles could inform how memory and relational language are implemented in future mental health chatbots, ensuring agency and ethical accountability. Third, although participants engaged with the chatbots for 4 weeks, the intensity and depth of bonding varied across individuals. We did not conduct a formal quantitative analysis linking relationship types or specific themes to changes in participants' well-being, such as WHO-5 scores. Future studies could combine qualitative analysis with outcome measures to examine whether certain relational patterns are associated with better emotional well-being or greater benefit over time. Fourth, our sample primarily consisted of university students and young adults in New Zealand, many of whom had backgrounds in psychology or computer science. This may have influenced their perspectives due to prior exposure to mental health concepts or AI technologies. Most of whom were digitally literate and relatively well-educated, which limits the generalizability of findings to broader or less digitally fluent populations. Cultural expectations, clinical needs, and access to technology may differ across age groups, education levels, and geographic regions. Future research should include more diverse participants, such as individuals from clinical populations, older adults, or communities outside of urban Western and Asian settings. Finally, participants also mentioned elements such as tone of voice, color schemes, emojis, and overall visual design. However, these features were not consistently linked to how users perceived their relationship with the chatbots. Most participants did not view these aspects as playing a significant role in building or deepening the bond. Therefore, this study focused on relational dimensions—such as empathy, responsiveness, and autonomy—which appeared more directly tied to a sense of bonding. Future research could further explore how design aesthetics and interaction style might support or hinder relationship development in different contexts.

Conclusions

The potential effectiveness of the DTA is promising. But what aspects influence its success, and how do people perceive it? Our research explored the human relationship with mental health chatbots and identified six key themes that shape relationship-building. Diverse preferences for conversational control impact the bond: some preferred to lead, others to be led, and there is a desire for a more dynamic balance of both. While many favored free-text input, our findings highlighted the importance of matching input methods to preferences and adapting them to different situations. In this study, people sought not just basic empathetic care, but deeper, more consistent emotional support. Relationships began to form through routine check-ins and became stronger with supportive activities, especially those that involve collaboration. Recalling past conversations made interactions feel more personal and human-like, further enhancing the bond. Our findings expand the DTA framework by providing new insights into how relationships with mental health chatbots develop. These findings have implications for the design of chatbots that foster stronger connections.

Acknowledgments

We sincerely thank all the participants who generously shared their experiences and time, making this study possible. We also extend our appreciation to the volunteer students who supported the study through participant interviews, data cleaning, and analysis. Special thanks to Associate Prof Danielle Lottridge for her outstanding mentorship, insightful guidance, and continuous support throughout the research process. We are deeply grateful to Associate Prof Yi-Chieh Lee for his intellectual leadership and invaluable feedback, which significantly shaped the direction of this work. We also thank Prof Jim Warren for his detailed review and constructive comments, and Associate Prof Karolina Stasiak for her encouraging feedback and helpful input during the study development. Finally, we acknowledge the University of Auckland for providing the academic environment in which this study was conducted, as part of Zian Xu's doctoral research.

Abstract

Background: Participating in leisure and social activities can alleviate depression symptoms, yet effective strategies to enhance enjoyment and maintain long-term engagement remain scarce. Gaining insight into the reward subcomponents that influence daily experiences and drive behavior could uncover novel targets for intervention.

Objective: This study examines the role of anticipation and motivation in predicting enjoyment and engagement in leisure activities and socializing among young people, and how these relationships are moderated by depression severity, using intensive longitudinal ecological momentary assessments.

Methods: Participants (N=80; mean age 20, SD 2.3 years) used the Psymate2 smartphone app to report mood, enjoyment, current and anticipated activities, and social company 7 times daily for 6 days. Activity categories were relaxation, exercise, other leisure, work or school, studying, chores, shopping, hygiene, eating or drinking, and traveling, and company categories were partner, friends, family, colleagues, acquaintances, strangers, and nobody. Anticipation (anticipatory pleasure and expectation) and motivation (interest and preference) for upcoming activities were rated on Likert scales. Participants were grouped by depression severity, measured using the Mood and Feelings Questionnaire (MFQ): high (HD, MFQ ≥27, N=42), moderate (MD, MFQ 16 - 27, N=16), and low, that is, controls (C, MFQ ≤16, N=22). Totally, 2316 assessments met inclusion criteria.

Results: Leisure activities (relaxation, exercise, and other leisure) and social company (partner, friends, and family) were rated most enjoyable across all groups. Higher depression symptoms were associated with reduced enjoyment of studying (β=−.03; *P*=.005), eating or drinking (β=−.02; *P*=.02), and other leisure activities (β=−.02; *P*=.02), as well as lower engagement in work or school (β=−.26; *P*=.02) and hygiene (β=−.08; *P*=.03), and increased inactivity (β=.17; *P*=.03). Time-lagged multilevel analyses showed that anticipatory pleasure predicted greater enjoyment across all activities (β=.12; *P*<.001) and social contexts (β=.33; *P*<.001), with consistent effects in controls and the high depression group. However, the more an activity was expected to happen, the less enjoyment was experienced in the whole sample (β=−.006; *P*=.001) and high depression group (β=−.008; *P*=.001) but not controls. Anticipatory pleasure and motivation (preference) predicted leisure engagement in the whole sample (β=.19, *P*=.003; β=.11, *P*<.001) and controls (β=.43, *P*=.005; β=.17, *P*=.048) but not the depression groups. Anticipatory pleasure predicted only leisure engagement in the high depression group when predictors and outcomes were matched for the same event (β=.22; *P*=.001). Anticipatory pleasure predicted social engagement in the whole sample (β=.095; *P*=.047) and controls (β=.34; *P*=.003), but not in the depression groups.

Conclusions: These findings highlight the importance of anticipatory pleasure and intrinsic motivation in shaping young people's engagement and enjoyment of daily activities. Structured or externally driven contexts may dampen enjoyment—especially among those with depression—underscoring the need for novel interventions targeting anticipation and motivation to enhance sustained participation in rewarding activities, leading to improved well-being in individuals with depression.

Introduction

Major depressive disorder is a leading cause of disease burden among young people worldwide, yet current treatments offer only moderate effectiveness [1,2]. A key challenge in depression treatment is that individuals with depression engage less in rewarding activities, likely due to anhedonia—a diminished ability to anticipate and experience pleasure [3-5]. Furthermore, depression also encompasses deficits in the motivation to engage in rewarding experiences [6]. These deficits in reward function could lead to inactivity, which is particularly problematic as reduced engagement in physical and social activities perpetuates symptoms, reinforcing a cycle of low mood and withdrawal. Additionally, loneliness not only increases depression risk [7,8] but also predicts future antidepressant use [9] underscoring the urgent need for interventions that promote sustained participation in mood-boosting activities [10-14].

A growing body of research highlights the protective role of leisure activities—those that are inherently enjoyable and recreational—in reducing depression rates in the general population [15-19] and in patients [20,21], compared with functional activities such as work or chores. Similarly, social interactions, particularly with close friends and family, appear to be more effective in alleviating depression symptoms than solitary activities or interactions with acquaintances [22]. These findings support the rationale for interventions such as behavioral activation, which encourages individuals to increase engagement in pleasurable activities to enhance positive reinforcement [21,23]. However, despite its effectiveness, behavioral activation does not outperform other treatments, likely due to an incomplete understanding of the reward mechanisms that drive sustained engagement [24,25].

To optimize interventions, a more nuanced understanding of reward function is needed. Reward processing involves distinct subcomponents, including anticipation, motivation, and enjoyment, which collectively influence approach behavior [26,27]. According to the Temporal Experience of Pleasure model, anticipation plays a crucial role in shaping motivation, which then drives behavioral engagement [28,29].

Reward dysfunction is well documented in depression (Ma X, Sahni A, McCabe C, unpublished data, 2024) [30,31]. For example, higher depression symptoms in adolescents and college students are shown to be associated with lower social pleasure using the Domains of Pleasure Scale [32], and lower consummatory pleasure using the Snaith-Hamilton Pleasure Scale [33] and the Fawcett-Clark Pleasure Capacity Scale [34]. We have also found lower anticipatory and consummatory pleasure in young people with depression using the Temporal Experience of Pleasure Scale [35,36]. Furthermore, studies find that depressed adolescents have reduced pleasure and motivation for hobbies, food or drinks, social activities, and sensory experiences using the Dimensional Anhedonia Rating Scale [37]. The recently developed Positive Valence System Scale [38] incorporates nearly all the reward subprocesses, such as anticipatory pleasure, consummatory pleasure, and motivated behavior and effort, and has shown that deficits in all subprocesses correlate with depressive symptoms in a college student sample [38].

Laboratory-based tasks have found lower motivation to exert effort for rewards with increasing depression symptoms in young people [36]. Similarly, studies find that anhedonia is associated with a lower frequency of high-effort choices in a young community sample [39-41] and in young people with subthreshold depression [42]. Taken together, there is evidence for reward subcomponent-processing deficits in young people that could underpin their depression symptoms. However, surveys and experimental tasks still fail to capture the dynamic real-world nature of reward-driven behavior (Ma X, Sahni A, McCabe C, unpublished data, 2024) [30,43], leaving critical gaps in our understanding of how anticipation and motivation influence engagement in daily activities in real time.

Ecological momentary assessment (EMA) offers a powerful solution to this limitation by tracking real-time experiences within natural environments using smartphone-based assessments [44-47]. EMA studies have demonstrated that social and physical activities protect against depression [48] and that individuals with depression experience fewer positive daily events and social interactions, predicting lower well-being even a decade later [49]. Critically, while one study has shown that anticipatory pleasure predicts subsequent enjoyment of an activity [50] and another found that depressive symptoms weaken the link between anticipation and behavior [51], these findings remain incomplete. Existing EMA studies have yet to examine motivation as a predictor of activity engagement, despite its central role in approach behavior. Furthermore, it is unknown whether anticipation and motivation specifically predict engagement in key mood-boosting activities such as leisure and socializing—activities known to be crucial for mental health [52,53].

To address these gaps, this study investigates how anticipation and motivation influence enjoyment and engagement in leisure activities and social contexts using EMA. Adopting a methodological approach similar to the work on schizophrenia by Edwards et al [54], we hypothesize that individuals with higher depressive symptoms will exhibit weaker associations between anticipation, motivation, and subsequent engagement. By providing real-world evidence on the role of reward subcomponents in shaping behavior, this study could identify novel targets for reward-based interventions aimed at improving mental health outcomes.

Methods

Power Analysis

We conducted a priori power analysis using PowerAnalysisIL designed for EMA [55] using data provided by Li et al [50] (Table S1 and Figure S2 in Multimedia Appendix 1). Analysis suggested that 80% power could be achieved with a sample size of 50, consistent with estimates from multilevel logistic [56] and linear models [57] using our design.

XSL•FO
RenderX

Recruitment

Young people (N=95), aged 16‐25 years with varying depression symptoms, were recruited from local schools and universities.

Patient and Public Involvement and Piloting

Based on feedback from piloting sessions with young people, we revised the activity categories and allocated time for app troubleshooting in our study briefing sessions. We also assessed completion time for questionnaires and participant feedback. We found the daily burden manageable, supporting our decision to retain the questionnaire structure.

Baseline Demographics

Participants completed the Mood and Feelings Questionnaire (MFQ; ≥27 cut off for clinical depression) [58]. Higher scores indicate higher depression symptoms. The 33-item questionnaire has been shown to have excellent internal reliability in adolescents (Cronbach α=0.91-0.93) [59]. It is a widely used and validated questionnaire to examine depressive symptoms in young people.

EMA Assessments

Similar to an EMA study in schizophrenia [54] at each assessment (beep), participants rated their mood (negative affect and positive affect) and then selected their current activity from categories and rated their enjoyment. They then selected current company from a selection of categories and rated their enjoyment. Next, they selected their future activity from the same categories and rated their anticipatory pleasure, expectation (likelihood of activity happening), and motivation (interest and preference). They then selected future company from categories and rated their anticipatory pleasure. The motivation questions were posed indirectly so as not to intervene or influence, and this style of questioning limits the potential for the participants to change their behavior in response to the question [54] (Table 1).

Table . Description of the ecological momentary assessment questionnaires, showing the questions used to capture the reward subprocesses and categories of activities and company, and how they were rated.

Reward subprocess	Question	Categories and ratings
Mood	"Right now I feel…"	• Cheerful, ashamed, annoyed, enthusiastic, relaxed, anxious, satisfied, lonely, insecure, down, guilty. • 1 = Not at all to 7 = Very much
Current physical	What were you doing just before the beep went off? (*Select one*)	• Relaxing, work or school, studying, chores, shopping, hygiene, eating or drinking, traveling, social media, exercising, other leisure activity, nothing.
Enjoyment	How much are you enjoying this activity?	• 1 = Not at all to 7 = Very much
Current company	Who are you with? (Select one)	• Partner, friends, family, colleagues, acquaintances, strangers, nobody.
Enjoyment	How much are you enjoying being in this company?	• 1 = Not at all to 7 = Very much
Future physical	What activity will you be doing after this one? (Select one)	• Relaxing, work or school, studying, chores, shopping, hygiene, eating or drinking, traveling, social media, exercising, other leisure activity, nothing.
Anticipatory pleasure	How much do you think you will enjoy this activity?	• 1 = Not at all to 7 = Very much
Expectation	What do you think are the chances this activity will occur?	• Rated from 0% to 100%.
Motivation (interest)	How interested are you in this activity?	• 1 = Not at all to 7 = Very much
Motivation (preference)	Would you prefer to do something else?	• 1 = Not at all to 7 = Very much
Future company	Who will you be with? (Select one)	• Partner, friends, family, colleagues, acquaintances, strangers, nobody.
Anticipatory pleasure	How much do you think you will enjoy this company?	• 1 not at all to 7 = Very much

Procedure

The experimenter met with each participant to brief them on the app. Participants were then required to log on and fill in their age, gender, ethnicity, and the MFQ. EMA assessments began the next day. Participants were asked to respond to each assessment as soon as possible; otherwise, they would expire.

We collected data 7 times a day, between 8:30 AM and 10 PM, for 6 days, during the period July 2022 to October 2023. There was at least a 45-minute delay between each semirandom assessment, which took approximately 1 minute to complete and expired after 20 minutes. This sampling frequency and questionnaire design has been shown to encourage compliance and reduce burden in young people and those with mood disorders [56,57,60,61]. We contacted participants on days 2 and 5 to check that they were receiving notifications and to troubleshoot any problems.

At the end of the study, we collected app user experiences (Table S2 in Multimedia Appendix 1), and participants were debriefed and advised to contact their general practitioner or the mental health charity, the Samaritans, if they were concerned about their mood.

Data Analysis

Fisher exact tests, ANOVAs, and chi-square statistics were used to examine group differences in the demographic data. We prepared the EMA data using *esmpack* in R (version 4.4.1; R Core Team, 2024) [62]. Activity and company enjoyment and engagement were calculated across participants and ranked from highest to lowest.

To check for potential confounds, we ran multilevel regression models using the lme4 package in R with mood (negative affect and positive affect), assessment time (1-7), and assessment day (1-6) as predictors of anticipation, motivation, and enjoyment. Predictors were subject-mean centered and represented at level 1 and symptoms were level 2 fixed effects. All multilevel models were represented by a subject-level random intercept. As assessment time and mood covaried, they were added to all multilevel analyses as covariates (Table S3 in Multimedia Appendix 1).

We next ran multilevel models with depression as a continuous variable (MFQ) as a predictor of anticipation, motivation, and enjoyment across all activity, then specifically leisure (relaxing, other leisure, and exercise) and functional activity (work or school, studying, chores, shopping, hygiene, eating or drinking, and traveling). We also ran multilevel models with depression as a continuous variable as a predictor of anticipatory pleasure and enjoyment across all company and then specifically social (partner, friends, and family) and nonsocial company (nobody). We then examined the effects of depression symptoms on enjoyment and engagement for each specific activity and specific company, using separate standard linear regression models.

The Temporal Experience of Pleasure cycle shows that anticipation and motivation are temporally predictive of enjoyment and engagement in activities [28,29]. This is the basis of our theoretical framework (Figure S1 in Multimedia Appendix 1) for examining the temporal dynamics using time-lagged analyses. Using anticipation and motivation as predictors at ($t-1$), we modeled activity enjoyment and engagement (0 = functional, 1 = leisure) as outcomes at (t) using multilevel linear and logistic models, respectively. Similarly, using anticipation at ($t-1$), we modeled company enjoyment and engagement (0 = nonsocial, 1 = social) as outcomes at (t). We reported data for the whole sample (WS) and participants by depression symptom severity; controls (C, score of ≤16 on MFQ), moderate (MD, score of >16 and <27 on MFQ), and high depression symptoms (HD, score of ≥27 on MFQ). Splitting the sample into groups, similar to Li et al [50], allows us to compare the 4 main predictors (anticipatory pleasure, interest, preference, and expectation) in the same model while controlling for each other, across each of the 4 groups.

As participants may anticipate doing something but then do something else, we also examined the data when the predictors (anticipation and motivation) and outcomes (enjoyment and engagement) were matched for the same events, for example, anticipatory pleasure for exercise predicting enjoyment of exercise. However, matched data can mean much fewer assessments and possible model overparameterization.

Ethical Considerations

The study adhered to ethical standards (Revised Declaration of Helsinki 2008) and was approved by the University of Reading Psychology Department ethics committee (REC number 2021 - 120-CM). All participants provided written informed consent after reviewing the information sheets. To preserve participant privacy, no identifiable features were included in the manuscript and supplementary materials. After completion, participants were compensated by SONA credits [63].

Results

Overview

A total of 2426 questionnaires were collected from 95 participants. We excluded participants who had <30% threshold of assessments (N=15) [64,65], and the mean compliance rate was 69%, similar to previous EMA studies [66]. About 1.5% of assessments were incomplete and therefore removed from analysis.

Demographics

The final sample consisted of 2316 questionnaires. Participants self-identified as White (63/80, 78.8%), Black (4/80, 5%), Asian (9/80, 11%), Mixed (2/80, 2.5%), and Other (2/80, 2.5%). The depression groups differed on symptoms as expected and also for age and assessment period but not for gender, ethnicity, compliance, or assessment delay (Table 2).

[g]MFQ: Mood and Feelings Questionnaire.

[h]Not applicable.

What Activity Do Young People Enjoy and Engage With?

The leisure activities "exercising," "relaxing," and "other leisure" were rated most enjoyable (Table S4 in Multimedia Appendix 1). Young people engaged most frequently in "relaxing" and "other leisure" activities, followed by "eating or drinking" and then "work or school" and "studying" (Multimedia Appendix 2).

What Company Do Young People Enjoy and Engage With?

Being with "friends," "family," and "partner" was rated highest for enjoyment (Table S5 in Multimedia Appendix 1). Although young people spent more time alone than with others, they were mostly with "friends," "family," and "partner" when socializing (Multimedia Appendix 2).

Dimensional Analyses

Are Depression Symptoms Associated With Reduced Anticipation, Motivation, and Enjoyment of Activity?

As depression increased, anticipation (anticipatory pleasure and expectation), motivation (interest and preference), and enjoyment decreased across all activities (Table S6 in Multimedia Appendix 1). When examining data for leisure and functional activity, enjoyment and expectation also decreased as depression increased (Table S7 in Multimedia Appendix 1).

Are Depression Symptoms Associated With Anticipation and Enjoyment of Company?

As depression increased, anticipatory pleasure and enjoyment decreased across all company (Table S8 in Multimedia Appendix 1). Anticipatory pleasure and enjoyment of social company (friends, family, and partner) and enjoyment of non–social company (nobody) decreased as depression increased (Table S9 in Multimedia Appendix 1).

XSL•FO
RenderX

Are Depression Symptoms Associated With Enjoyment and Engagement in Specific Activities and Specific Company?

As depression increased, enjoyment for "studying," "eating or drinking," and "other leisure" activities decreased (Table S10 in Multimedia Appendix 1), and as depression increased, young people reported doing more "nothing," less "work or school," and "hygiene" (Table S11 in Multimedia Appendix 1). Depression did not predict enjoyment or engagement with any specific company.

Categorical Analyses

Time-Lagged Analyses

Using multilevel time-lagged linear regressions, anticipatory pleasure positively predicted enjoyment across all activity categories in the WS, controls, and in those with high depression symptoms (HD) (Table 3). Expectation negatively predicted enjoyment across all activity categories in WS and HD (Table 3).

Predicting Activity Enjoyment and Company Enjoyment

Anticipatory pleasure positively predicted enjoyment across all company categories in all groups (Table 4). Results were similar when predictors and outcomes were matched for the same events (Table S12 in Multimedia Appendix 1).

Table . Reward predictors of activity enjoyment[a].

	Whole sample (n=1514)			C[b] (n=389)			MD[c] (n=275)			HD[d] (n=850)

Predicting Leisure Enjoyment and Social Company Enjoyment

When looking specifically at leisure (exercising, relaxing, and other leisure activity), we found that motivation (interest) positively predicted leisure enjoyment at trend in the WS (*P*=.06) (Table S13A in Multimedia Appendix 1). Anticipatory pleasure positively predicted enjoyment of social company (friends, family, and partner) in both the WS and HD groups and at trend in the MD group (*P*=.055) (Table S13B in Multimedia Appendix 1).

Predicting Leisure Engagement and Social Company Engagement

Using multilevel time-lagged logistic regressions, anticipatory pleasure and motivation (preference) positively predicted engagement in leisure in the WS and controls (Table 5). When predictors and outcomes were matched for the same leisure events, anticipatory pleasure positively predicted engagement in leisure activities in the WS and HD group (Table S14A in Multimedia Appendix 1). Expectation negatively predicted engagement in leisure in the WS, controls, and HD groups (Table 5).

Anticipatory pleasure positively predicted engagement in social company in the WS and controls and in the matched condition (when predictors and outcomes were for the same social company) (Table 6 and S14B in Multimedia Appendix 1). Anticipatory pleasure did not predict engagement in social company in the MD or HD groups.

Table . Reward predictors of leisure activity engagement (leisure vs functional activity engagement)[a].

Discussion

Principal Results

To our knowledge, this is the first study to demonstrate in real-world settings that anticipatory pleasure reliably predicts future enjoyment across various physical activities and social contexts in young people. Anticipatory pleasure and motivation (preference) predicted leisure engagement, and anticipatory pleasure predicted social engagement in the WS and controls but not in individuals with depression symptoms. However, when measured for the same specific event, anticipatory pleasure does predict leisure engagement in those with higher depression symptoms, indicating a potential target for intervention.

Comparison With Prior Work

While prior research has established that depression blunts reward-related processes (Ma X, Sahni A, McCabe C, unpublished data, 2024), most studies rely on retrospective reports or laboratory tasks that fail to capture the temporal dynamics of reward processing in daily life. By leveraging EMA, this study provides novel insights into how anticipation and motivation dynamically shape behavior in real-world contexts. Consistent with prior work [50,67], we found that individuals with higher depression symptoms reported less enjoyment across various activities. However, our study extends these findings by showing that depression is also linked to a broader dampening of anticipation and motivation across functional, leisure, and social experiences. This supports the idea that depression is associated not only with reduced momentary pleasure but also with a diminished ability to anticipate and seek out rewarding experiences.

Our study also provides a nuanced perspective on real-world activity deficits in depression. Individuals with higher depression symptoms reported lower enjoyment in activities such as studying, eating or drinking, and other leisure activities, as well as reduced engagement in work or school and hygiene. Importantly, depression was associated with doing more "nothing," a behavioral pattern consistent with wearable-monitor studies showing reduced activity in depression [68,69]. However, our results go beyond previous findings by contextualizing these activity deficits within specific daily-life behaviors. The reduction in work or school and hygiene aligns with known risk factors for depression, such as academic underachievement [70] and self-neglect [71]. These findings suggest that ecological momentary interventions (EMIs) could be developed to support goal setting, progress tracking, and real-time encouragement for maintaining daily routines [47,72].

Crucially, we demonstrate for the first time that anticipatory pleasure significantly predicts future enjoyment across all physical activities and social contexts. Anticipatory pleasure and motivation (preference) predicted leisure engagement, and anticipatory pleasure predicted social engagement in the WS and controls but not in individuals with depression symptoms. However, anticipatory pleasure did predict leisure engagement in those with high depression symptoms, when assessed for the same specific event. This suggests that while individuals with depression may struggle to generalize anticipation across contexts, if they can be encouraged to anticipate specific leisure activities, they may be more likely to engage in them, which could strengthen the anticipation-engagement link over time.

Our findings support the development of interventions that could exploit the time-lagged relationships such as episodic future thinking (EFT) [73], a cognitive exercise that uses mental imagery to anticipate the feelings associated with future positive activities. Preliminary data suggest that EFT can increase anticipatory pleasure using both traditional scales [74-76] and EMA [77] in healthy controls and those with major depressive disorder. Therefore, we propose that an EFT-based EMI could be developed and tested to see whether it could increase engagement in leisure and social activities in young people with depression symptoms.

A striking finding was that higher expectation (likelihood of activity happening) was associated with lower enjoyment, especially in those with high depression symptoms. This aligns with our finding that the least enjoyable activities were work or school and studying, activities that are usually scheduled and therefore highly expected. Consistent with this, we found that enjoyment for activities such as studying decreased as depression increased and that higher expectation predicted more engagement with functional versus leisure activities across groups. These findings are supported by previous reports that show that activity scheduling reduces enjoyment, potentially due to diminished spontaneity [78].

Our findings could be explained by Self-Determination Theory [79], whereby activities that are externally imposed (such as school or studying) and extrinsically motivated (to pass examinations) tend to be less enjoyable, especially if autonomy is low, contrasted with activities that are intrinsically motivated such as leisure (inherently enjoyable). In depressed individuals, the lack of intrinsic reward and reduced agency may amplify the negative experience of expected, scheduled tasks. As the least enjoyable activities in this study are the ones most likely scheduled—this aligns with the Self-Determination Theory that autonomy is key to enjoyment and well-being. Moreover, as individuals with depression tend to hold negative core beliefs and cognitive distortions [80], negative biases could lead to negative perceptions of predictable activities, such as school or work, sustaining low enjoyment.

Taken together, highly expected activities are often externally imposed, reducing autonomy and intrinsic motivation. For youth with depression, these activities—especially when perceived as unpleasant—could confirm negative schemas about being powerless or trapped [80], which could lead to lower enjoyment and possibly deeper anhedonia. Future research should explore whether EMIs that promote spontaneous enjoyable activities, while addressing negative cognitive biases, could enhance activity engagement in depression.

Limitations

While our study offers significant contributions, several limitations must be acknowledged. First, although EMA captures real-time experiences, self-report measures remain subject to bias. Future studies could integrate passive-sensing data (eg, activity trackers and voice recordings) to objectively assess engagement [81]. Second, our sample consisted of young adults,

XSL•FO
RenderX

limiting generalizability to older populations. In future studies, time-lagged relationships should be investigated in a broader demographic. Third, while we demonstrated the predictive role of anticipation and motivation, causality remains uncertain. Experimental studies using reward-training interventions could further elucidate these mechanisms.

Conclusions

Our results support anticipation and intrinsic motivation as novel intervention targets for real-time, technology-driven approaches to managing depression. By leveraging digital tools to enhance anticipation and motivation, future interventions could empower individuals to engage with rewarding experiences, ultimately improving mental health outcomes.

Acknowledgments

The authors would like to thank Karel Borkelmans and Nele Volbragt for their invaluable guidance on study design and data acquisition and Wolfgang Viechtbauer for his guidance in data analysis from the PsyMate team. The authors would also like to thank their MSc students, Tarun Vermani and Manasa Veluvali, who helped in recruiting and briefing participants. The authors are really grateful to Dr. Xu Li for providing them with data from their study [51] to assist the authors with their power analysis. This work was funded by a University of Reading Research Fellowship for Prof. Ciara McCabe.

Data Availability

The data that support the findings of this study are available from the corresponding author upon reasonable request.

Abstract

Background: Cross-sector collaboration is increasingly recognized as essential for addressing complex health challenges, including those in mental health. Industry-academic partnerships play a vital role in advancing research and developing health solutions, yet differing priorities and perspectives can make collaboration complex.

Objective: This study aimed to identify key principles to support effective industry-academic partnerships, from the perspective of industry partners, and develop this into actionable guidance, which can be applied across sectors. Mental health served as a motivating example due to its urgent public health relevance and the growing role of digital innovation.

Methods: Using a 3-stage, mixed-methods approach, we conducted a web-based survey of UK-based digital mental health companies (N=22) to identify key barriers and facilitators to industry-academic partnerships. This was followed by 2 focus groups (n=5) that explored emerging themes from the survey using thematic analysis. Finally, we conducted a workshop with industry representatives, researchers, clinicians, and PPI members to co-develop the Principles of Industry-Academic Partnerships (PIP) guidance.

Results: Survey findings highlighted that industry partners valued academic collaboration for enhancing credibility, facilitating knowledge transfer, and gaining access to PPI networks. However, key barriers included high costs, slow academic timelines, and complex contracting processes. The 4 major themes that emerged from the focus groups were: advantages of collaboration, cultural differences between organizations, collaboration models, and structural barriers within universities. Through informed discussions in the workshop, these themes were explored, leading to the development of 14 actionable strategies. These strategies reflect industry perspectives and formed the PIP guidance, categorized under project initiation, defining the scope and agreements, project execution, and promoting sustainability.

Conclusions: The PIP guidance provides a practical framework to support more effective and mutually beneficial collaborations between industry and academia. Developed through the lens of mental health research, the strategies identified are broadly applicable across disciplines where cross-sector partnerships are essential. Industry partners valued academic collaborations for their credibility and scientific rigor, but highlighted persistent structural and cultural barriers within universities. Addressing these challenges by aligning expectations and timelines, adopting flexible collaboration models, and streamlining operational processes can help foster impactful and sustainable partnerships in mental health and beyond.

Introduction

Mental health disorders constitute a global public health challenge, with growing demands for more effective treatments, interventions, and policy solutions [1,2]. The integration of expertise, resources, and diverse perspectives from both academic institutions and industry partners is increasingly essential to address the complex biological, psychological, and societal dimensions of mental health [3]. While here we focus on digital mental health as a motivating case example, the challenges and opportunities identified are broadly relevant to other sectors where interdisciplinary and cross-sector collaboration is critical. Despite the potential benefits, forming successful and sustainable industry and academic partnerships remains a challenge. Between 2016 and 2017 and between 2018 and 2019, the National Health Service (NHS) in the United Kingdom received £9000 ($12,156) per patient enrolled in commercial trials and saved £5800 ($7834) per patient in drug costs, generating £355 million ($471,520) in income and £28.6 million ($38,632) in savings [4]. However, patient recruitment to industry-funded research has halved over the past 5 years, costing the NHS around £360 million ($486,274) [5].

In this study, we refer to the "industry sector" as organizations involved in the development, commercialization, and delivery of digital mental health technologies, including start-ups, small to medium enterprises (SMEs), and larger corporations. The "academic sector" refers to university-based researchers and research institutions engaged in the evaluation, design, and theoretical advancement of mental health interventions. While these roles can sometimes overlap, particularly in collaborative or spin-out models, we use these definitions to distinguish the differing priorities, structures, and operational cultures that shape partnership dynamics. Improving industry and academic partnerships in mental health research could accelerate the development of new treatments, digital health tools, and public health strategies to help address the United Kingdom's mental health crisis [3]. Recent advances in artificial intelligence, big data analytics, and precision medicine present an opportunity for new forms of partnership that can leverage the industry's technological capabilities and access to resources with academia's research expertise. However, across areas of study (ie, not specific to the mental health field), academia and industry have traditionally been viewed as having different and often contrasting priorities [6,7]. Traditionally, academia has played a central role in advancing foundational knowledge in mental health, focusing on epidemiology, neuroscience, and therapeutic approaches. Academic researchers often prioritize long-term studies, driven by a commitment to high-quality scientific inquiry, resulting in high-impact outputs (eg, academic publications) with an emphasis on data sharing and transparency. Industry, on the other hand, excels in translating research into practical applications, with a focus on commercialization, rapid innovation, and the scalability of interventions. Industry partners are often concerned with protecting intellectual property. These differences can lead to mistrust and misaligned priorities or reluctance from either side to engage fully, which can hinder the development of impactful, patient-centered mental health solutions [6,8-10].

Despite growing interest in exploring the motivations, barriers, and facilitators to industry-academic partnerships [6,8-10], there is a lack of UK-based research and a lack of research specific to mental health collaborations. Further investigation is needed to understand the specific challenges facing the mental health field, and a solution-focused approach is required to develop actionable insights. A recent paper identified that clear guidance for industry-academic collaborations in the field of mental health is lacking, but may support successful collaborative practice [11]. Although the authors of this paper noted that such guidance may include the importance of supporting shared values around a commitment to ethical principles and patient and public involvement (PPI), as well as data sharing, specific details, and strategies were not provided. There is a time-critical need for collaborations to be better developed to ensure transparency in partnerships' accessibility of data and to support independent verification of results [11]. Indeed, there are calls to action to improve awareness of each partner's needs and the barriers and facilitators to successful partnerships [12-14].

This study aimed to identify key principles to support effective industry-academic partnerships from the perspective of industry partners and develop actionable guidance to support such partnerships. With the aim of developing this early-stage guidance, we conducted a web-based survey and focus groups to explore common barriers and facilitators and hosted a workshop to translate the learning from these into actionable guidance statements. Due to the pressing societal relevance and growing role of digital innovation, mental health served as the motivating context to develop this guidance. However, the study did not focus on any single diagnostic category. Instead, it examined collaboration across the broader digital mental health sector, which could also be applied more broadly to other health sectors. The resulting guidance addresses cross-cutting structural and relational factors that influence collaboration, offering insights that are applicable across a range of disciplines where interdisciplinary and cross-sector partnerships are critical.

Methods

Patient and Public Involvement

PPI was embedded throughout the project and reported according to the GRIPP2-SF (Guidance for Reporting Involvement of Patients and the Public-Short Form) [15]. The aim of including PPI was to ensure that the guidance was not just shaped by institutional or commercial priorities but was anchored in the real-world needs, values, and concerns. Two PPI members, with lived experience of participating in mental health research with industry partners, contributed throughout the study. They participated in iterative piloting of the survey before launch (Stage 1), informed the development of the focus group topic guide through discussions and interpretation of survey findings (Stage 2), and were invited to an online workshop to collaboratively review and agree on the key statements forming the final guidance (Stage 3).

XSL•FO
RenderX

Stage 1: Survey

Recruitment and Participants

We aimed to recruit 20 - 25 participants to a web-based survey to provide an initial understanding of the benefits and challenges that industry partners experience when considering evaluating their product through an academic partner research study or trial. Participants were recruited to the survey through targeted email invitations to UK commercial mental health companies, identified through the study teams' contacts, through internet searches, and through disseminating study adverts at the Giant Health London 2024 conference. All participants who completed the consent form completed the survey. Inclusion criteria included:

1. Industry professional: individuals who were currently employed or contracted in a professional capacity within the mental health, technology, or health care sectors and not via an academic institution.
2. Working in digital mental health: participants must have been actively involved in work related to digital mental health, defined as the use of digital tools, platforms, or services aimed at supporting mental health care, prevention, or well-being. This includes work on apps, web-based therapy platforms, digital interventions, AI-based mental health tools, or related infrastructure.
3. Have a UK base: participants must be based in the United Kingdom, either through their primary place of work or residence, to ensure relevance to the UK digital mental health landscape.

There were no exclusion criteria.

Survey Design

The survey consisted of a mix of closed (eg, Likert scale) response and open-ended (eg, free text box) style questions. The survey was an "open" web-based survey hosted on Research Electronic Data Capture (REDCap; Vanderbilt University Medical Center), a secure web application for building and managing web-based surveys and databases and open from November 12, 2024, to January 9, 2025. The survey was iteratively piloted through multiple rounds of feedback and revision before its launch. No changes were made after being launched. The survey was conducted according to the CHERRIES (Checklist for Reporting Results of Internet E-Surveys) checklist [16] (see Appendix B in Multimedia Appendix 1). Cookies or intellectual property (IP) checks were not used to assign unique identifiers. Participants' email addresses were checked to assess duplication (there was no duplication).

Instruments

A survey comprised 30 - 37 items (depending on whether they had or had not collaborated with academics previously), including 10 background questions relating to their organizations, 2 questions on collaboration with health care professionals, 3 questions on working with PPI, 15 questions on their experiences collaborating with academics, or alternatively 22 questions if they had not previously worked with academics. Items are presented in Appendix C in Multimedia Appendix 1, but typically asked participants to rate how strongly they agreed with negative and positively worded statements. All items had to be completed to allow submission of the survey.

Procedure

The study advert provided with a brief description alongside a website link and QR code, which linked to the survey REDCap database. Participants who clicked on this link were directed to the participant information sheet detailing the study aim, expected duration, data storage, and the named investigators. Participants were also informed on the information sheet that any personal data would only be accessible by approved members of the study team and deleted in accordance with the data policy outlined in the information sheet. After reading this, the database hosted the consent form, which had to be fully completed before access to the survey questions was granted via the REDCap system. Completion of consent and the survey was voluntary. At the end of the survey, participants were given the opportunity to be entered into a prize draw to receive either a possible £50 voucher (US$68; 1 was available) or £25 voucher (≈ US$34; 2 were available). They were also asked if they would like to be contacted to participate in a further focus group. Participants could not review their answers or log back in and change them. Only the named study investigators had log-in details to the REDCap survey to protect data privacy. Downloaded data were password-protected and only available to the study team.

Analysis

Descriptive statistics were reported for individual survey items. Free text items were analyzed using an inductive approach to identify key themes surrounding participants' experiences and perceptions of industry-academic partnerships [17].

Stage 2: Focus Group

Recruitment and Participants

Survey participants who indicated interest in participating in further group discussions about the survey findings and the barriers and facilitators to industry-academic partnerships were invited to join a web-based focus group. Those who selected "yes" to this question received a personalized email containing a link to a participant information sheet and consent, providing them with the opportunity to take part. Consent forms had to be completed before the focus group started.

Instruments

The focus group topic guide was informed by the survey findings, PPI discussions, and the relevant literature in this field [6,10]. Prompts were developed for the key topic areas, to be used if needed to promote discussion. Prompts were developed based on themes emerging from earlier survey responses and relevant literature, with open-ended questions such as "What would motivate your organization to consider collaborating with academic researchers in the future?" designed to encourage reflection and dialog.

XSL•FO
RenderX

Procedure

The focus groups were conducted and recorded using Microsoft Teams, during standard UK working hours. Participants were contacted before the focus group with a short description of each member of the study team who would be attending the focus group as a way of introduction. The focus groups were led by author SSH (PhD), who has experience in conducting remotely delivered focus groups and has completed training courses in qualitative research. SSH is a female researcher who was employed as a Senior Research Fellow at the University of Nottingham at the time of data collection. SSH has 12 years of experience working in academic research and trials. KMP (BA Hons), a female Senior Project Manager employed by the University of Nottingham, assisted with initiating and following up on discussion points where needed. KMP has 17 years of experience working in the industry. OH, a female Research Assistant at the University of Nottingham, supported note-taking throughout the focus group discussions. Focus groups lasted approximately 90 minutes.

Analysis

Focus groups were recorded and transcribed using the built-in function in Microsoft Teams. Transcripts were reviewed by OH for accuracy and cross-checked against written notes and the recording of the discussions, where necessary. Transcripts were independently analyzed by 2 researchers (SSH and OH) using an inductive approach, with decisions reviewed, and disagreement resolved through discussion. The researchers conducted open coding to identify recurring concepts and patterns. These initial codes were then grouped into broader categories through discussion, allowing themes to emerge organically from the data rather than being imposed a priori. The researchers met regularly to compare coding decisions, resolve discrepancies, and refine the thematic structure. A third researcher (CLH) oversaw this process and supported discrepancy resolution. This process led to the identification of key themes. A coconstructivist epistemology was operationalized through engagement with participants, allowing for clarification and expansion of ideas, and through collaborative analysis involving multiple researchers. This approach supported the emergence of insights through thematic synthesis rather than predefined coding. For instance, when one participant described inefficiencies in academic meetings, others built on this by sharing contrasting experiences, which collectively shaped the theme “Collaboration Models”.

Stage 3: Workshop

Recruitment and Participants

Nine experts, with varying experience working with mental health industry partners, researchers, clinicians, and PPI members were sent a personalized email invitation to participate in a workshop to review and reach agreement on the key statements to form the Principles of Industry-Academic Partnerships (PIP) guidance. The experts were selected by the study team (authors of this paper) based on the individual’s experience and relevance to the study aims. Selection criteria included: (1) recognized expertise in digital mental health (eg, through innovations, publications, or leadership roles), (2) professional or lived experience in the UK context, and (3) to ensure representation across clinical, academic, public, and industry sectors. Consent was not required to participate in the workshop since there was no formal data collection or analysis procedures and recordings were not taken. This was approved by the ethics committee.

Instruments

Before the workshop, the study team drafted the PIP guidance statements based on the findings from the survey and the focus group. The draft statements were circulated to the workshop attendees for review and familiarization 2 weeks before the meeting.

Procedure and Analysis

The half-day workshop was conducted using Microsoft Teams software. The workshop was co-facilitated by the study leads (CLH, SSH). Each guidance statement was presented and discussed in turn. The workshop was not recorded with key discussions minuted (OH). No formal analysis procedures were implemented. Discussions in the workshop were centered around making minor refinements to the guidance statements, with no polarizing opinions. Notes from the discussions were used to refine and finalize the PIP guidance statements.

Integration of findings across the 3 stages was achieved through a sequential process. Insights from the survey (Stage 1) were used to inform the focus group topic guide (Stage 2), ensuring that qualitative discussions were built directly on the quantitative findings. Themes emerging from the focus groups were then synthesized and used to draft preliminary guidance statements. These statements were reviewed and refined during the workshop (Stage 3), where participants validated, expanded, or restructured them based on their collective expertise. This triangulated approach ensured that the final PIP guidance was grounded in both empirical data and stakeholder consensus.

Ethical Considerations

Ethical approval for the study was granted by the University of Nottingham, Faculty of Medicine and Health Sciences Research Ethics Committee, FMHS 298 - 0924 approved on October 4, 2024. Informed consent was obtained by a consent form hosted on RedCap before undertaking any study activities. The consent form included a statement on privacy and confidentiality of participant data. Participants in the focus group and workshop were given a £50 (US $68) voucher to compensate for their time.

Results

Results of Patient and Public Involvement

PPI input led to a more accessible and relevant survey, with improved clarity and framing of questions. Their contributions shaped the focus group topic guide to better reflect public concerns and lived experience. Through the coproduction workshop, PPI members helped refine and agree upon the final statements, ensuring the guidance was grounded in values relevant to a mental health population.

Stage 1: Survey Findings

Sample Characteristics

The sample characteristics are described in Table 1. A total of 22 people completed the survey. It is not possible to know the exact response rate as study flyers were posted in the conference center at the 2024 Giant Health Conference. However, 62 people were approached to complete the survey directly via email, 26 of whom were contacts known to the study team.

Table . Demographic and background characteristics of the company (N=22).

Demographic and background items	Count, n (%)
Type of organization	
Small-medium enterprise (SME)	14 (64)
Start-up	7 (32)
Large corporation	1 (5)
Location	
London	8 (36)
North West England	3 (14)
East of England	3 (14)
North East England	2 (9)
East Midlands	2 (9)
Yorkshire and the Humber	1 (5)
South West England	1 (5)
Wales	1 (5)
Other (remote company)[a]	1 (5)
Role within company	
Founder or cofounder	8 (37)
Marketing or sales lead	5 (23)
CEO or executive	4 (18)
Research and development lead	3 (14)
Product manager	1 (5)
Other (chief of staff)	1 (5)
Years in operation (years)	
More than 10	9 (41)
7 - 10	2 (9)
4 - 6	8 (36)
1 - 3	3 (14)
Length of time in mental health industry (years)	
More than 10	4 (18)
7 - 10	2 (9)
4 - 6	9 (41)
1 - 3	6 (27)
Less than 1 year	1 (5)

[a]A remote company is a company where employees work in other locations rather than a traditional office space, such as in their own home or coworking spaces.

The majority of the sample was made up of SMEs, accounting for 64% (14/22), with only one company identifying as a single large corporation (1/22, 5%). The companies were primarily based in London (8/22, 36%) but included representation from various regions in England. Founders or cofounders make up the largest role category (8/22, 36%), with marketing and sales leads and CEOs and executives also significantly represented. Most companies had been in operation for over 10 years (9/22, 41%) or between 4 and 6 years (8/22, 36%). In terms of experience in the mental health industry, 41% (9/22) had been

XSL•FO
RenderX

involved for 4 - 6 years, with smaller proportions having over 10 years or less than 1 year of experience.

Companies primarily offered digital mental health interventions for both adults and children (11/22, 50%). Most products were in the postmarket or scaling stage (12/22, 55%) and funding was predominantly from grants (16/22, 73%), followed by revenue and sales (12/22, 55%) and venture capital (11/22, 50%). The most addressed mental health conditions were anxiety (18/22, 82%) and depression (15/22, 68%). The characteristics of the interventions are summarized in Table 2.

Table . Characteristics of the main digital mental health intervention (N=22).

Product characteristic	Count, n (%)
Target age for the product	
Both adults and children and young people	11 (50)
Adult	8 (36)
Children and young people	3 (14)
Stage of product readiness[a]	
Post market or scaling	12 (55)
Prototype	6 (27)
Market Launch	6 (27)
Beta-testing phase	3 (14)

Other-functional neurological disorder	1 (5)

[a]denotes participants could tick more than one box and thus answers will not add up to 100% or N=22.

Collaborating With Health Care Professionals, Patients, and Public Members

All our participants reported collaborating with health care professionals at least once, with half (11/22, 50%) stating they had collaborated over 6 times, and the remaining half reported collaborating less than 6 times. The majority of the participants reported feeling completely or very confident in collaborating with health care professionals (17/22, 77%), with the remainder reporting moderate (2/22, 9%) or slight confidence (3/22, 14%).

Only one of the participants reported having never worked with PPI members. The rest of the respondents reported having engaged with PPI as part of their product development (14/22, 64%), evaluation (15/22, 68%), or implementation (10/22, 46%).

Participants were asked to leave free text comments to explain how they had been involved in PPI. Responses included involvement in focus groups or workshops (7/22, 32%), testing the product (2/22, 9%), developing and piloting the product (2/22, 9%), and involvement in trials (2/22, 9%), although they

XSL•FO
RenderX

did not clarify the exact tasks or purpose of this involvement. Participants were also asked to describe the benefits of PPI; answers included to validate the product and innovation (8/22, 36%), support real-world understanding of the product (6/22, 27%), to aid product development (5/22, 23%), and to improve the product or service (2/22, 9%).

Collaborations With Academics

Only one participant had never collaborated with academics previously. This participant was directed to a different set of questions via survey logic (see Appendix C for survey items in Multimedia Appendix 1). This one participant was asked further questions about why they had not engaged with researchers. They noted that the key barrier was a lack of clear benefits, concerns of intellectual property, and their eagerness to publish results. They also reported that the high costs associated with trials were a barrier to engagement, as well as the complex and time-consuming nature of academic collaboration.

Out of the remaining 21 participants, 10/21 (47%) had collaborated with academics one to two times, 6 (29%) had collaborated between 3 and 5 times, and 5/21 (23%) had collaborated 6 or more times.

The majority 14/21 (67%) reported seeking support from external organizations to initiate a collaboration with academics. Sources of this support included the National Institute for Health Research MindTech, a national center focusing on the development, adoption, and evaluation of new technologies, and Health Innovation Networks, a UK-based government-funded infrastructure that brings together the NHS, industry, academic, third sector, and local organizations to support early adoption of innovations into practice. Other sources of support included Innovation UK; Wellcome Trust, who are UK-based research funders; and more broadly, responses included “NHS” and “Universities.”

Most respondents reported positive experiences of collaborating with academics, with 19/21 (90%) agreeing that their experience was positive and 18/21 (86%) feeling communication was clear and effective. Similarly, 17/21 (81%) found the process valuable for developing the intervention. Expectations alignment was slightly lower, with 14/21 (67%) agreeing that expectations aligned. Just over half of the participants (11/21, 52%) felt that the pace at which academic evaluation is conducted hindered their business. Despite this, the same number of participants, 11/21 (52%), felt that cultural differences between academia and industry were not a barrier to collaboration, and the sample was divided as to whether regulatory and ethical procedures had caused challenges for their product’s evaluation.

The majority of participants (18/21, 86%) reported being satisfied with the outcome of their academic collaborations, while 3/21 (14%) felt neutral about their experiences. However, all 21 respondents said that they would be willing to engage in future collaborations with academic researchers again.

Participants were asked 3 open-text questions to understand challenges and advantages to collaborating with industry. The primary purpose of these questions was to inform the topic guide for the focus groups. However, for completeness, we summarize the key findings from these.

With reference to challenges, the key barriers were centered around costs (such as overheads and on-costs) and timeframes (20/21, 95%). Participants noted that university procedures and bureaucracy often meant delayed timelines, with one participant noting that this is not the same with private companies.

> *Private companies tend to be more flexible and wish some modifications to planned projects based on preliminary outcomes and business needs while academic researchers wish to stay on initial plans understandably.* [Participant ID 71]

Noted key advantages of collaboration included support on study designs and ethics (7/21, 33%), and evidence that the product works, including increased reputation and credibility (10/21, 48%).

When asked what support would be needed to support academic collaborations, responses included more funding (8/21, 38%), support in finding academic experts (6/21, 29%), universities having a better understanding of how to work with industry (4/21, 19%), and better PPI support (3/21, 14%).

Randomized Controlled Trials

Participants were also asked if they had conducted a randomized controlled trial for their product partnering with an academic. Three respondents had not engaged in a randomized controlled trial. Out of the remaining 18, all (18/18, 100%) reported strongly agreeing or agreeing that their organization was adequately involved in the design of the trial and trial process. The majority (17/18, 94%) reported that the outcome measures used in the trial were relevant to the product’s real-world application, with one responding “neutral.”

Stage 2: Focus Groups Findings

A total of 5 participants took part in the focus groups. Participants in both the first focus group (n=3) and the second focus group (n=2) had experience of engaging in industry-academic research partnerships.

Four major themes were evident in the first focus group. The second focus group provided further enrichment to this, but no additional themes were identified. The themes formed the basis of study team discussions to develop recommendations to support industry-academic partnerships, which were evaluated in the workshop stage of the project.

The 4 major themes evidenced in the focus groups were: Advantages, Industry versus academic culture, Collaboration models, and Structural issues within the universities. These themes and their subthemes are reported below.

Advantages

This theme was comprised of 3 subthemes: quality and credibility; knowledge transfer and talent development; and patient and public involvement, access, and management.

Academic work was perceived as offering a different kind of quality and credibility with more theoretical rigor and scrutiny, as well as offering an independent form of evaluation.

> *It’s a different kind of quality, right? It comes from a place of theory and a place of scrutiny, as opposed*

XSL•FO
RenderX

> *to industry, which is a different kind of high quality* [P01]

Industry partners value the "academic stamp of approval" for enhancing the credibility of their products.

> *It may be that we need we kind of need their logo or we need the university, especially in the US it's like we need an academic stamp of approval from a certain university and that's how it works* [P03]

Partnerships with universities provide opportunities for knowledge transfer and talent development.

> *So by design there's an element of upskilling of other people within the team to learn more about these kind of, you know, academic methods for example* [P02]

Industry-academic partnerships support talent development, allowing researchers to experience industry environments and vice versa. This can benefit individual career development as well as positively contribute to the wider partnership in terms of providing a go-to person who can act as a translator and/or mediator between the 2 partners. Identification of this individual was also noted to improve the longevity of industry-academic partnerships. Participants discussed the benefits of Knowledge Transfer Partnerships (KTPs), a scheme in which a graduate works at both a company and university to share knowledge and facilitate company development.

> *Just in terms of like different speaking different languages, I think that's something that we've really valued, KTPs for is that in some way the person working on the KTP is an interpreter between academia and like industry.* [P02]

Partnering with academics was deemed valuable in terms of providing access to and support from PPI groups. Participants recognized that PPI was important to product development, but that the industry often lacked the resources in terms of connections, as well as the face value trust which is needed to engage patients and the public.

> *I definitely think this is where the university plays into its strengths because ultimately, you know, a patient is much more likely to engage with stakeholder meetings with a university than they might be a small business just because. There's an element of trust there or an element of reputation there.* [P01]

Industry vs Academic Culture

This theme was comprised of 3 subthemes: incentives and drivers, differences in timescales and decision making, and rigid versus dynamic mindsets.

Participants commented that the different incentives and drivers for industry and academic partners can create tension in the relationship, particularly in terms of the fact that industry partners may need to "fail fast" to cut their losses, whereas academic partners are in for the long haul to the pursuit of knowledge acquisition.

> *In our kind of setting, you know, you might want to fail fast if something isn't going to work out. You want to find that out quickly and stop working on it and move on. And that's maybe a bit of tension within an academic partnership where it might be something that you have set up that we're going to run for a number of years* [P02]

> *It takes a fair degree of patience on both sides and there's this inherent tension. I think we've noticed between the different incentives that each party is operating under in that stands to risk jeopardising the relationship, or it certainly puts tension on the relationship at various moments throughout the life of that partnership.* [P05]

Cultural differences were also discussed frequently in terms of differences in timescales and decision making. Participants commented that academics operated over months and years as opposed to days and weeks, and that setting deadlines was important for achieving a positive working relationship.

> *We're working companies who are reactive all the time. So we're constantly getting answers from our team about what's happening and we're working in an immediate culture. So it's the contrast then where you might e-mail someone and it might be, you know seven days before you get a reply and it so it's so it's like a feels quite jarring.* [P04]

Academics were viewed as being rigid in their approach to an evaluation, with a clear start and end point. In contrast, industry is often more dynamic and used to adapting to situations as they arise, even if that means making substantial changes to the project plan (protocol).

> *Do they (industry partners) understand that it will be a bit more rigid usually like once we start it's quite like we're going down the same kind of road, there are some kind of like pivot points that if you've missed those you've pretty much kind of you're going to continue down that road……I think there's needs to be a bit of balancing of like actually what would work so they (academics) need to be quite pragmatic and balancing their expectations with that can be a bit challenging.* [P03]

Collaboration Models

This theme was comprised of 3 subthemes, efficiency and key people, initial challenges and establishing relationships, and the role of facilitators. The theme focuses on ways of working between academia and industry.

Participants reflected on the number of academic staff that are involved in meetings and collaboration in relation to efficiency and key people, with current academic practice considered an often inefficient and ineffective model of collaboration. Whereas academics often encompass a more inclusive model in their way of working, industry feels only key people are required, and that involving too many people can slow down progress.

> *Industry has become very good at only having the people that need to be in the room in the room. And I think that's one of the key things is the more hands you have on this, the slower things that just get generally going* [P01]

XSL•FO
RenderX

Interestingly, participants felt that more senior academics were often not required. This is in contrast to a traditional academic collaboration, whereby senior academics, such as Professors, have a higher status and are typically considered critical in key meetings. Conversely, the industry placed more emphasis on having attendees who would be able to action tasks, which they noted might be more junior staff.

> *If you go kind of too senior, it means that they just don't have enough time, they're not really responding. You're chasing things from them and that's when it breaks down.* [P03]

Participants reported that establishing relationships with academics was often the hardest part of collaboration. Some noted that initial relationships are often formed by industry reaching out to individuals, or via networking and conferencing events.

> *I think actually getting to a point where you can work with researchers is often the hard part when working with academia, the researchers are typically very easy to work with once we've kind of established the working arrangement.* [P01]

The importance of selecting the right partnership was mentioned, with emphasis placed on having visions and goals that aligned with each other. Industry representatives acknowledged that there are likely to be times in research where honest communication is required, and it's important to have academic partners with whom you are able to have open conversations.

> *Is there a good like personality fit because you're going to need to work with them and you're going to have difficult conversations.* [P03]

The importance of the role of facilitators in brokering that early relationship and continuing to support throughout the collaboration was also noted. Most respondents noted the importance of networks such as the Health Innovation Network or KTPs. KTPs, although different in remit and scope to the HIN, also connect businesses with academic experts to support innovation.

> *The HIN has been fundamental…they're a nice broker in that relationship* [P01]

Participants noted that these facilitators are particularly useful in interpreting academic language.

> *In terms of speaking different languages, that's something we've really valued KTPs for…the KTP is an interpreter between academic and industry* [P02]

The importance of also having proacademic employees within the industry business was also noted, with participants also noting having an academic champion from within can be useful, particularly if other members have had negative experiences of partnering with academia.

> *Definitely had situations in the past with people who are quite negative about academic relationships… so having someone in the in the company, that's a good bridge would be useful.* [P03]

Structural Issues Within the Universities

This prominent theme highlighted core structural issues with the university that resulted in significant barriers to collaboration, including cost barriers and bureaucratic inefficiencies.

Participants noted cost barriers, with SMEs often operating on small budgets without the capital to invest significantly in research. They noted that the costs of academia often precluded the ability to collaborate and that more competitive pricing was often offered by consultants. Although consultants were considered to still offer many of the advantages associated with academic institutions, including good networks and knowledge of study design and publication.

> *And our experiences that has just blown out the water in terms of what we can afford. So we have to go to someone else, a consultant that's working privately* [P04]

Even when industry and academics partnered to fund the work through external grants, there was still a feeling of resentment toward the costs associated with academic partnership, most notably, the staff overheads.

> *the overhead spend on academic resources is outrageous. We're working on another project and half of it [THE COSTS] went on university overheads. I just think that is unacceptable* [P01]

University bureaucratic inefficiencies contributed to inefficient processes and decision-making, which led to delays in initiating collaborations and applying for grants.

> *from a company perspective, we would turn a grant around a grant application around in two to three weeks…the universities we've tried to collaborate with can't work in that sort of time scale.* [P01]

It was noted that this was at least in part driven by the large-scale nature of university organizations, alongside the nature of universities to be "risk averse" and requiring the approval and sign-off from multiple people, slowing decision-making and project initiation.

Challenges with contracting and IP were prominent issues in the focus groups, which were partially driven by lengthy and complex internal governance structures. The contracting discussions can take months due to back-and-forth negotiations over templates, agreements, and responsibilities.

> *academia is often very slow in contracting. The governance is complicated* [P05]

Issues with IP were considered to contribute to this, and it was noted that, particularly, smaller universities, or those not used to industry collaborations, may not be as adept at navigating IP.

> *I think ultimately universities get tied up in IP…. whereas actually it's not often that complicated* [P01]

Participants also noted that there is often confusion and tension when determining which templates to use for drafting these agreements on IP and contracts. This lack of clarity can create

XSL•FO
RenderX

delays and frustration, especially when different teams have different expectations about the terms.

> *there's like a little bit of a back and forth between whose agreements do we use? Whose templates do we use for the IP? Are we all agreeing on that and it's and the actual our team and the researchers aren't that bothered. It's just the two entities that are kind of battling back and forth sometimes* [P03]

Stage 3: Workshop Findings

The workshop members reviewed and provided feedback on 15 guidance "action" statements, which were developed by the study team based on the survey and focus group findings. The action statements were initially separated under the themes derived from the focus groups.

Discussions in the workshop included whether implementing this guidance would result in meaningful change and the feasibility of implementation. As a result of these discussions, the 15 action statements were modified. These modifications included separating the statements into broader headings, which were more reflective of the research roadmap (project initiation, defining the scope and agreements, project execution, and promoting sustainability). As well as making minor alterations to the wording of the action statements, some were merged together and/or segmented into separate actions. This resulted in a final PIP guidance document, comprised of 14 key actions (See Appendix D in Multimedia Appendix 1). The PIP guidance is presented in a text and infographic version to provide both detailed and rapid (eg, an aide-mémoire) support to teams depending upon the situation or context.

The PIP guidance document provides a structured framework to supporting effective industry-academic partnerships in mental health research. Key actions are organized into 4 phases: project initiation, defining the scope and agreements, project execution, and promoting sustainability. The guidance emphasizes early engagement, cost-effective funding models, streamlined contracting, and clear intellectual property agreements to facilitate smoother partnership setups. It also highlights the importance of structured project management, effective communication strategies, and fostering long-term sustainability through knowledge exchange and talent development. By addressing common challenges such as balancing speed with rigor or navigating cultural differences, the PIP guidance aims to improve collaboration and maximize research impact.

Discussion

Overview

We used the digital mental health field as a case example to explore how industry-academic partnerships can be improved, from the perspective of industry partners. We conducted a web-based survey and focus groups to examine digital mental health companies' experiences and perceptions of collaborating with academics to evaluate their products. Insights from these activities informed the development of practical guidance to support more effective partnerships. Our findings revealed that overall, the industry valued academic partnerships, particularly for the credibility, rigor, scientific knowledge, and access to PPI that they provide. However, significant barriers to engagement were noted, particularly around the financial costs of collaboration with academics and the differences in timescales for delivery. Through discussions with our experts (including people with lived experience of mental health conditions and those working in mental health through a clinical and industry-focused role), these challenges were positioned into principles for supporting positive industry-academic collaborations. These principles have been developed based on experiences of digital mental health industry partners (see Textbox 1) but are likely to apply more broadly outside of the field of mental health.

Textbox 1. Case study illustrations.

Case Example 1. One small to medium enterprise (SME) in our sample developed a digital CBT (Cognitive Behavioral Therapy) app for adolescents with anxiety. They partnered with an academic team to conduct a feasibility trial. The collaboration benefited from academic expertise in safeguarding and ethics, and access to a university-affiliated patient and public involvement (PPI) group that helped adapt the app's language and content. However, delays in contracting and differing expectations around trial timelines created tension. Applying the Principles of Industry-Academic Partnerships (PIP) guidance, particularly around early alignment of expectations and streamlined governance, could have mitigated these challenges.

Case Example 2. A company that was developing a digital intervention for stress management partnered with an academic team to evaluate the intervention's feasibility and acceptability. While the collaboration was productive overall, the company noted inefficiencies in academic meeting structures, where large numbers of attendees slowed decision-making and diluted accountability. In contrast, the company's internal culture prioritized lean teams and rapid iteration. This mismatch led to frustration and delays in progressing the evaluation. The PIP guidance's emphasis on defining collaboration models early—particularly around team roles, decision-making authority, and meeting structures—could have helped align expectations and improve operational efficiency. This example illustrates how differences in working culture can impact progress, and how structured guidance can support smoother, more agile partnerships in mental health research.

Principal Findings

The focus group discussions identified 4 major themes—Advantages, Industry versus academic culture, Collaboration models, and Structural issues within the universities—each highlighting key factors influencing industry-academic partnerships.

Industry partners recognized the value of academic collaborations in enhancing credibility, facilitating knowledge transfer, and supporting talent development. However, cultural differences, particularly in incentives, decision-making timelines, and flexibility, often created tensions. Industry operates with a "fail fast" mindset, whereas academia prioritizes long-term knowledge generation, leading to challenges in aligning expectations. Efficient collaboration models were seen as crucial, with industry favoring smaller teams and actionable

XSL•FO
RenderX

engagement, while academia often involved broader participation. Establishing partnerships was noted as a key hurdle, emphasizing the role of facilitators such as KTPs in bridging communication gaps. Structural barriers within universities, including high costs, bureaucratic inefficiencies, and intellectual property disputes, further complicated partnerships. These findings underscore the need for universities to streamline administrative processes, adopt more flexible collaboration models, and enhance support mechanisms to foster stronger, more efficient industry-academic relationships. Addressing these challenges could lead to more impactful partnerships that better translate academic research into real-world applications. In addition, issues with IP indicate the importance of having a department within a research institution, such as a Technology Transfer Office. These departments manage the IP generated by researchers and support the commercialization of research findings. Such roles are critical to ensure fair agreements on revenue sharing, IP rights, and protecting the assets of partners.

Survey respondents commonly reported involving PPI in their research and design, primarily through focus groups or meetings. However, fewer described engagement in product testing, development, or trials, suggesting a limited understanding of what constitutes meaningful PPI. A one-off focus group, for instance, does not equate to fully integrating PPI contributors as active members of the research and development team, an approach more consistent with coproduction. This highlights the need for clearer guidance and support for industry partners on effective PPI implementation and best practices. These findings are especially pertinent to sectors where trust, safeguarding, and stigma are critical considerations, such as in mental health. In this field, meaningful PPI is not just a methodological enhancement but a necessity for ensuring interventions are acceptable, ethical, and responsive to the needs of vulnerable populations. Industry partners in our study valued academic collaboration for access to established PPI networks, which can play a vital role in shaping mental health research that is both inclusive and impactful.

Comparison With Prior Work

These findings support a recent systematic review in this area which highlighted issues with communication (collaboration models) and identified some cultural differences, particularly in terms of goals of the partnership [6]with industry-academic partnerships in general (not specific to the mental health field). However, unlike the previous research [6], the PIP guidance is the first co-developed guidance, shaped by the lived experiences of industry partners. Although small scale, by combining quantitative (survey) and qualitative (focus groups and workshops) research methods and talking directly with industry partners, we can better understand how to support positive industry-academic collaborations. Developed within the context of digital mental health, the guidance addresses cross-cutting structural and relational factors that are broadly applicable across sectors. Its emphasis on actionable strategies and stakeholder co-creation distinguishes it as a practical tool for enhancing the impact and sustainability of cross-sector partnerships.

Strengths and Limitations

Given the early stage of inquiry in this area, our findings provide valuable insights into industry-academic collaborations which will not only directly inform practice, through implementation of our proposed PIP guidance, but also inform future research efforts in this area. Our study is strengthened by our coproduced approach to survey and focus group item generation. We sought opinions from industry engagement experts, as well as patient and public involvement members who had lived experiences of mental ill health and supporting industry partners in evaluating their products. Our mixed-methods approach, combining quantitative responses from a broader survey sample and in-depth qualitative responses, enabled us to explore experiences in more detail, which is important given the early stage of inquiry in this field.

Nonetheless, our findings should be interpreted in line with the limitations of our relatively small sample, which prevents us from making subgroup comparisons, and how this sample was recruited. Although we advertised the study via social media, including via the Health Innovation Network, the Institute of Mental Health, and the work accounts of our team, we did not receive any uptake from these methods. The lack of uptake via social media may demonstrate the difficulties that academics might face when engaging with the digital mental health industry and highlight the importance of having a personal connection and being flexible to trying novel methods of recruitment. Our sample was primarily comprised of individuals who were emailed by members of the National Institute of Health Research (NIHR) MindTech Health Research Centre (HRC) team, the study authors, and the Center for Healthcare Equipment and Technology Adoption (CHEATA). This may also reflect that most of the sample had previously collaborated with academics, which is unlikely to accurately reflect the real percentage of digital mental health companies that have partnered with academics. However, we were also successful in recruiting participants via snowballing (encouraging participants to forward survey links to their peers and competitors) and also by networking at a national conference “Giant Health” in December 2025, a conference aimed at industry and NHS health care innovation in the United Kingdom.

To mitigate the potential responder bias, focus groups were held by members of the study team that had not previously worked with the industry partners. Participants were also informed that their personal or identifiable information would be removed before wider sharing within the team; however, we cannot rule out that this may have influenced responding. That aside, the focus groups did reveal significant barriers to collaboration, which may indicate that participants were responding candidly.

Most of our sample identified as an SME, which potentially reflects the status of most of the digital mental health industry; however, our findings may not be generalizable to other companies, particularly large corporations, which were poorly represented in our sample. In addition, while our sample included companies working across a diverse range of mental health areas, the guidance developed in this study is intended to address overarching structural and relational factors in industry, academic partnerships. Future research may be needed

XSL•FO
RenderX

to adapt and tailor these principles to specific mental health contexts or diagnostic categories. Furthermore, our participants were drawn from the United Kingdom, and further research across different countries is required to understand the cultural context of these findings. Despite these limitations, our study provides a novel insight into a currently overlooked area. We hope the findings presented here and our guidance document will be useful to generate further research, including exploring the perceptions of academics, larger corporations, and those who have not engaged with academics, and facilitate research with larger sample sizes. Given the guidance was developed from the viewpoint of the industry partner, we believe at this stage in its development academic partners are likely to gain the greatest benefit from it. Future investment in this area should focus on academic needs and experiences. The guidance document could be used within Tech Transfer and Research and Knowledge Exchange (RKE) groups to support research groups, across career stages, as they embark upon research collaborations with industry partners.

Patient and Public Involvement Reflection

PPI had a meaningful influence on the study, contributing to both the design and interpretation of key components of the guidance. Our PPI members had direct experience with industry collaborations, which facilitated meaningful and engaged discussions. However, broader representation might have enriched the guidance further. Navigating discussions around industry involvement required careful facilitation to ensure contributors felt comfortable expressing concerns. Future research should consider how to support and diversify PPI contributors to ensure inclusive and informed dialog across stakeholder boundaries.

Conclusion

While industry partners identified several advantages of working with academics to develop and evaluate digital mental health interventions, they also reported significant barriers to collaboration. Many of these barriers centered around university processes, such as contracting and costings. It is important that universities address these structural and cultural barriers in order to create more effective and sustainable collaborations. The PIP guidance developed in this study offers a practical framework to support collaborations and improve mental health research capacity by streamlining institutional processes, aligning expectations, and improving collaboration models. While the guidance was developed in the context of digital mental health, it addresses cross-cutting issues that are relevant across sectors. As such, it provides a generalizable foundation for strengthening industry-academic collaboration and driving innovation in fields where interdisciplinary partnerships are key to addressing complex societal challenges.

Acknowledgments

This work was funded by the MRC-NIHR Trials Methodology Research Partnership (MR/S014357/1). This research was supported by the Office for Life Sciences and the National Institute for Health and Care Research (NIHR) Mental Health Translational Research Collaboration Mental Health Mission, hosted by the NIHR Oxford Health Biomedical Research Center. The research was hosted at the NIHR HealthTech Research Center for Mental Health (MindTech) at the University of Nottingham. Abstract

Background: Self-harm is a significant global concern with multiple negative outcomes. Self-harm research tools typically focus on single risk factors, meaning the temporal interplay between factors and their impact on self-harm is unknown. The Card Sort Task for Self-Harm (CaTS) addressed these deficits by using 117 cards to examine multiple self-harm factors. In-person research is time-consuming, costly, and limits participation opportunities. Developing an electronic version of CaTS (Card Sort Task for Self-harm—digital; CaTS-D) is necessary to address these issues, capture large datasets, and provide a stronger evidence base. Since CaTS' inception, understanding of self-harm has evolved, including increasing awareness that lesbian, gay, bisexual, transgender, queer, intersex, asexual, and other minoritized gender and sexual identities (LGBTQIA+) people are at high risk. Updating CaTS is essential to ensure its relevance to both LGBTQIA+ and cisgender-heterosexual self-harm.

Objective: We aimed to present results from two studies. Study 1 is a pilot study assessing the feasibility of CaTS-D. Study 2 used qualitative interviews to identify additions or amendments to CaTS to increase its relevance as understanding of self-harm evolves.

Methods: Study 1 recruited UK residents (N=13, aged 18 - 30 y) with lived self-harm experience. Feasibility and acceptability of CaTS-D were assessed using the Systems Usability Scale (SUS) and visual analog scale (VAS). Study 2 recruited UK residents (N=13; LGBTQIA+ n=9 and cisgender-heterosexual n=4; aged 21 - 29 y) with lived self-harm experience to one-on-one interviews.

Results: Study 1 found CaTS-D to be a feasible web application for use in self-harm research. VAS data showed no significant difference between pre- and poststudy mood (t_9=1.59; P=.15). In Study 2, thematic analysis resulted in 13 additional cards (eg, "Before 6 mo;" "I don't feel comfortable in my body;" "I was bullied on social media;" and "Self-harm gave me a feeling of control"). Cards were worded clearly, but minor amendments to wording on cards to increase LGBTQIA+inclusivity were identified (ie, changing "boyfriend/girlfriend" to "partner"). While participants felt selective additions were necessary, too many may overwhelm participants. Therefore, future additions should be carefully considered.

Conclusions: Pilot-testing shows CaTS-D is a usable, feasible web application to examine self-harm and capture large datasets. Importantly, completing CaTS-D does not negatively impact participants' mood. Updates and key additions were made to CaTS from consultation with people with lived self-harm experiences. These increase the relevance of CaTS and ensure LGBTQIA+ inclusivity.

Introduction

Background

Self-harm (here defined as any self-injury or poisoning regardless of intent) [1,2] is a global public health concern [3] and the result of complex, temporal interactions between various biological, social, and psychological factors [4]. Self-harm is a multifaceted [5] and prevalent [6] behavior linked to several maladaptive health, social, and well-being outcomes. For example, drug and alcohol misuse [7,8], repeated self-harm [8,9], and reduced education and employment outcomes [10]. Most concerningly, self-harm is also a key risk factor for future suicidal thoughts and behaviors [11] and the most significant

XSL•FO
RenderX

risk factor for suicide [12,13]. A recent large-scale study found suicide risk was 49 times greater in the year following self-harm [4]. Globally, suicide is a leading cause of death [14]. In 2019, approximately 703,000 people died by suicide [15]. Considering self-harm is a key antecedent for suicide, reducing self-harm is an important suicide prevention strategy and is included in the National Suicide Prevention Strategy for England and Wales [16,17]. People experience a multitude of risk (ie, hopelessness [11] and alcohol use [5]) and protective (ie, social and family support [18] and self-compassion [19]) factors for self-harm. However, historically, factors have been investigated in isolation [5,20]. This limits our understanding of the temporal dynamics between multiple self-harm factors and whether co-occurring factors increase or mitigate self-harm risk. Understanding complex temporal dynamics between risk and protective factors is recommended by researchers [20-22]. The Card Sort Task for Self-Harm (CaTS) was developed to address these issues.

The CaTS

CaTS examines multiple factors for self-harm using a set of cards with self-harm–related concepts. Participants use relevant cards to describe their self-harm pathway over time using 7 timepoint cards (6 months before, 1 month before, 1 week before, 1 day d before, 1 hour before, I self-harmed, and afterwards) and 106 cards with self-harm–related thoughts, behaviors, feelings, events, and self-harm supports and services. Concepts used in CaTS were developed from self-harm literature, theory, and models of self-harm, and with academics and clinicians in the field (see [5] for details on the development of CaTS). Example concepts include “I was drinking alcohol,” “I was angry,” “I felt better after self-harm,” “I was bullied,” “I talked to a friend which helped,” and “I trusted a caregiver.” Blank cards enable participants to enter personally relevant concepts not included. See Section S1 in Multimedia Appendix 1 for the complete list of CaTS cards. Concepts were placed into broad groups (ie, feelings and events) to reduce participants being overwhelmed by many cards rather than being representative of superordinate factors. Participants complete CaTS during in-person research [5,23-25] by placing cards relevant to their self-harm under relevant timepoints, usually for their most recent or first ever self-harm episode. Multiple card options enable CaTS to capture the complex pathway to self-harm and demonstrate the pathway is sequential in nature [5,25]. Previously, researchers have used CaTS to examine self-harm pathways in adolescents [5], young people [24], and children in public care [25], and to compare self-harm antecedents in young adults compared to older adults [26].

CaTS: Developing a Digital Research Tool

CaTS has some limitations. First, in-person research is time-consuming for both researchers and participants and limits recruitment opportunities. To address this, we developed a web application version of CaTS, called CaTS-Digital (CaTS-D). Digital tools provide a flexible, cost-effective option for researchers using technologies most individuals use daily [27]. They are also a useful, effective way to reach large and representative samples [28]. Indeed, approximately 95% of people report owning a smartphone [29,30] and 45% of young people report being online almost constantly [29]. Furthermore, many people are engaged and comfortable [31] using smartphone “apps,” suggesting research undertaken online is likely a favorable option. Digital tools also benefit researchers. For example, web applications can reduce response burden [32,33], which may result in more valid responses [28]. There is also evidence online research increases participant diversity [34]. Furthermore, online methods may reduce recruitment and research costs while increasing recruitment efficiency [28]. Therefore, CaTS-D may be an efficient, versatile, accessible self-harm research tool allowing researchers to capture large, diverse datasets. CaTS-D will also increase the efficiency of data management and analysis procedures.

Second, a digital prototype of CaTS was created following patient and public involvement that identified participants would favor a digital version [26]. Lockwood and colleagues [26] reported similar sequential results to in-person CaTS research suggesting CaTS-D is capable of capturing data comparable to the in-person version. Finally, the existing CaTS version only allows participants to use each card once. During previous in-person research (ie, [5]) participants were asked to place cards under the most pertinent timepoint. However, items may be relevant at multiple or all timepoints. Consequently, research using CaTS may not provide a complete picture of self-harm antecedents, or which factors occur more frequently than others. CaTS-D would address this deficit by allowing participants to select multiple time points for each card and better document their self-harm pathway. This would improve our understanding of self-harm and its antecedents and provide researchers with a stronger data set on which to base recommendations.

CaTS: Amendments, Updates, and Additions

Since the creation of CaTS in 2013, novel factors have emerged, which need including to ensure CaTS remains a relevant and appropriate research tool. For example, recent systematic [35] and narrative [36] reviews reported emerging evidence of both positive and negative effects of social media usage on self-harm. In addition, evidence indicates self-isolation, financial hardship, and loneliness resulting from the COVID-19 pandemic and associated restrictions may increase self-harm and suicidal thoughts and behaviors [37]. Consequently, cards allowing participants to document the impact of new factors emerging since 2013 may be important additions. Furthermore, some cards may need rewording or updating to incorporate changing social views and our understanding of self-harm. The National Institute for Health and Care Research in the United Kingdom emphasizes patient participation and involvement in all funded research. Also, the continued development of CaTS in collaboration with people with lived experience is recommended by other researchers using CaTS [26].

Adapting CaTS for High-Risk Groups—LGBTQIA+ People

There is increasing awareness that lesbian, gay, bisexual, transgender, queer, intersex, asexual, and other minoritized gender and sexual identities (LGBTQIA+ [38]) people are at increased risk compared to their cisgender (someone whose gender identity aligns with their birth-assigned gender and body [39]) and heterosexual [40,41] peers. Lifetime LGBTQIA+ self-harm prevalence estimates between 49.5% and 65.35%

XSL•FO
RenderX

have been reported [42,43]. High prevalence rates demonstrate the need for meaningful research tools capable of examining and identifying antecedents to LGBTQIA+ self-harm. However, many tools and measures used to examine LGBTQIA+ mental health are often cis- and heterocentered and may not capture LGBTQIA+ experiences adequately [44-46]. Other researchers have sought to adapt CaTS for other high-risk populations, including autistic people [47]. Co-producing self-harm tools and measures alongside people with lived experience is highly valuable and recommended by researchers in the field [45,46,48]. Considering the increased risk LGBTQIA+ people face [40,41], it is important to identify whether CaTS requires amendments or additions to ensure it contains meaningful, relevant factors for people who identify as LGBTQIA+.

Research Aims

Here, we present 2 studies conducted with people with lived experience. Study 1 aimed to pilot a web-app version of CaTS and assess its feasibility and usability. This is essential to establish before use in large-scale studies because poor feasibility and usability reduce engagement and may result in attrition [49]. We also present iterative prototype feedback that focuses on performance, design, and content (ie, whether items or cards needed adding or rewording) and findings from visual analog data examining participants' mood pre- and poststudy. The latter is important to ensure taking part in self-harm studies using CaTS-D does not adversely impact participants' mood. Study 2 presents findings from a qualitative interview study that captured amendments and additions that inform the development of the CaTS/CaTS-D. These are important to ensure CaTS remains a useful, meaningful research tool as our understanding of self-harm evolves.

Study 1—The CaTS-D: Pilot Study

CaTS-D was developed using react.js, a JavaScript library capable of developing modular user interfaces (ReactJS [50]). CaTS-D is accessed via a link or QR code, and it was primarily designed to optimize smartphone usage with a vertical layout allowing people to complete the task at their own pace and convenience. Performing CaTS-D involves participants working through cards individually. Each card has all timepoints underneath, and participants select all relevant timepoints for each card before moving to the next card (see Figure 1 for an example card presented in CaTS-D with selected timepoints). Participants select "not applicable" to cards not relevant to their most recent self-harm episode (see Figure 1). It is not possible to simultaneously select timepoints and "not applicable." Participants work through all cards in this manner until the task is complete. There is an opportunity at the end to manually add up to 4 cards not already included in the task. Here, we present findings from the pilot study that assess the usability and feasibility of the web application CaTS-D. There is also potential for amendments and updates from this pilot to improve user experience, increase task completion, and reduce attrition. To identify these amendments and updates, we captured iterative prototype feedback which focuses on performance, design, and content (ie, whether items or cards needed adding or rewording). Finally, we also present feasibility data and findings from visual analog data. This is important to ensure participating in self-harm studies using CaTS-D does not adversely impact participants' mood.

Figure 1. An example of a card presented in Card Sort Task for Self-Harm—Digital (CaTS-D) with several time points highlighted.

Aim

The pilot study aimed to establish the feasibility and usability of CaTS-D and assess the impact on participants' mood.

Methods

Participants

UK-based individuals with lived self-harm experience, internet access, and a smartphone, tablet, or desktop, and aged 18 years and older were invited to participate via email and social media advertisements through gatekeepers (mental health organizations). Participants were included on the basis of self-reported self-harm history.

Ethical Considerations

Participants read the study information and provided informed consent afterwards. Data were stored on a secure University of Nottingham database and will be kept for 5 years. All pilot data

XSL•FO
RenderX

is anonymous at the point of participation. Qualitative data was anonymized during thematic analysis and identifying information redacted. Each participant chose their own pseudonym. Participants received a £10 (US $13.45) Amazon voucher remuneration. This research adhered to and was approved by the University of Nottingham's School of Psychology Ethics Committee (S1543R).

Study Procedure

Participants followed the link provided by the research team, which took them to the web application, CaTS-D. Study information and instructions on how to complete CaTS-D were presented first. Participants provided informed consent by clicking a button at the bottom of the page. A unique identifier was provided at this stage, and participants were advised to email author KB with the identifier should they wish to withdraw data. Then, participants completed a brief well-being plan, which involved participants confirming they had details of a trusted person to hand should they need it, and to undertake a poststudy activity to improve mood. Details of support organizations were presented, and participants were advised these would be provided again afterwards.

Participants were asked for their demographic information (age range, sexuality, gender identity, sex assigned at birth, ethnicity, current employment or education status, household income, and education level). Data was collected between November 2023 and January 2024. All data, including consent, were captured during a single session per participant. In line with other self-harm studies (ie, [5,26]), participants completed CaTS-D while reflecting on their most recent self-harm episode. Participants selected all timepoints relevant to that card, or "not applicable." They worked through cards until the task was complete. To control for order effects, cards were randomly presented each time [51,52]. However, 7 cards relate to what occurred post self-harm; these cards were presented after all other cards. Response options for post self-harm cards were "yes," "no," and "not applicable." Only a single option could be selected. Participants were able to free-type up to 4 items missing from the task and select relevant timepoints, similar to blank cards included in the in-person variant of the task.

Afterwards, to assess feasibility, participants were asked questions based on the System Usability Scale (SUS; [27]). This scale evaluates overall usability and acceptability of technical products including software, hardware, and websites [53]. Questions focused on whether instructions were easy to follow, how participants found completing CaTS-D on their device, and whether CaTS-D was easy or difficult to complete (see Section S2 in Multimedia Appendix 1 for the SUS questions). We used a marginally revised SUS with some items reworded to increase relevance to CaTS-D (ie, changing "system" to "web-app"). An open-ended question requesting further feedback was included to elicit additional comments after each question, and again at the end. Questions in the SUS required dichotomous or Likert-scale responses. Questions 1 - 3 captured dichotomous (yes or no) responses, those selecting "no" could also free-type feedback. The remaining 12 items were scored on a 5-point Likert scale (ranging from 1 [strongly disagree] to 5 [strongly agree]). To monitor the emotional impact of using CaTS-D, participants rated their emotional state at the beginning and end of the study by completing a visual analog scale (VAS). This was presented as a scale ranging from 0 (illustrated with a sad face) to 10 (illustrated as a smiling face). Participants were prompted: "Please rate your current mood on the scale below." Pre- and poststudy VAS data were analyzed to identify whether participating in the study impacted mood. Participants were signposted to support organizations after the study and presented with cute animal pictures as part of debriefing. This presentation aligns with previous CaTS studies [26] and recommended good practice to mitigate mood when conducting sensitive research [54].

Results

Data Analysis

Data was downloaded as a .CSV file, transported into a Microsoft Excel spreadsheet, and analyzed using IBM SPSS (version 28.0). Descriptive statistics regarding participant characteristics were analyzed to characterize feasibility and engagement [55]. A general inductive approach was used to analyze qualitative responses for feedback on CaTS-D regarding whether concepts or cards were missing or needed updating [56].

Participant Characteristics

A total of 13 participants participated, and their ages ranged between 18 and 30 years. Demographic data is presented in Table 1. On average, participants spent a mean 16.32 (SD 12.12) minutes completing the task. This is reassuring considering the ideal length of time spent completing online studies is ~20 minutes [57].

The mean prestudy score on the emotional VAS was 7 (SD 1.25) and 5.89 (SD 0.52) afterwards. Therefore, scores persisted around the midrange of the scale (1-10) before and after completion. A paired-samples *t* test was conducted to compare pre- and poststudy VAS scores. This did not represent a significant difference (t_9=1.59; *P*=.15).

Employed full-time	4 (29)
Employed part-time	4 (31)
Unemployed	4 (31)
Prefer not to say	1 (8)
Household income	
£40,000-£49,000 (US $53,783-US $65,884)	2 (15)
£50,000-£59,000 (US $67,233-US $70,330)	1 (8)
£60,000-£69,000 (US $80,675 -US $92,776)	1 (8)
£70,000-£79,000 (US $94,120-US $106,222)	2 (15)
£100,000+ (US $134,464+)	1 (8)
Prefer not to say	5 (38)

[a]The options used to capture the demographic data in this study were in accord with demographic data captured by the Office for National Statistics or UK government studies [58].

[b]Demographic categories not selected by any participants are omitted.

XSL•FO
RenderX

Feasibility of CaTS-D

The maximum mean score for all SUS subscales was 5. Higher scores indicate greater perceived usability [53]; therefore, a mean score of 4 was selected as a test value. This is in line with other pilot studies which used the SUS to assess feasibility of self-harm and suicide interventions in smartphone applications [53]. Mean scores on the SUS subscale ranged from 3 to 5 (mean 4.65, SD 0.53). However, the mean response for Q10 ("I think that I would like to use this web-app frequently") was 3. This represented "neither agree nor disagree" that was an appropriate response considering the nature of the web application for single-use research purposes. Across all 15 SUS questions, there were some nonresponders. High scores on remaining questions are reassuring and indicate participants will not struggle to complete CaTS-D and should complete the task competently and efficiently. Considering the recorded mean was higher than the test score (4), statistical tests were not run.

Qualitative Feedback

Participants were given the opportunity to provide written feedback on all SUS questions. Overall, participant responses suggested pre-study instructions should be made clearer. Responses were provided for three questions ("Were instructions easy to follow?" "Are cards visually appealing?" "Did the instructions make completing the task easy?"). Feedback reported by participants included:

- "I wouldn't say they were difficult, but there were a few things that I missed originally, such as it being related to my most recent occasion of self-harm."
- "The timeline questions were a bit confusing, and I wasn't always sure how 'I self-harmed' matched up with the card. For some things it was just happening basically always."
- "I was not sure when I had to tick the 'I self-harmed' box"

We recommend researchers ensure instructions are clear when using CaTS-D in research, including which self-episode the research relates to, that participants can select multiple or all timepoints, and to explicitly state "I self-harmed" should be selected if factors are relevant during the moment of self-harm (a copy of the instructions we used is available upon request).

Discussion

Principal Findings

This pilot study found CaTS-D is a highly usable, feasible, and acceptable research tool and participation did not negatively impact participants' mood. The study aimed to assess the usability, feasibility, and acceptability of CaTS-D and capture iterative feedback of CaTS-D in order to identify amendments to increase the usability of this novel web application. Assessing usability, feasibility, and acceptability is an essential part of web-app development to ensure the web application is easy to use and complete in order to reduce attrition [49]. High scores on the SUS were endorsed by participants across all items. Responses to SUS questions indicate participants found CaTS-D consistent, easy to use, and easy to perform. Furthermore, participants felt confident using CaTS-D, did not feel CaTS-D was unnecessarily complex, and well-integrated. Regarding card design, feasibility data showed participants felt the font and card interface were easy to read and visually appealing. In addition, participants felt they would not need technical support or learn anything to use the web application. Considering the nature of online research, this is reassuring and indicates future participants will be able to complete CaTS-D remotely without difficulty. Finally, although VAS scores decreased slightly poststudy, statistically, participants' emotional state was not negatively affected by completing CaTS-D. However, our sample size may be too small to determine whether this reduction was statistically meaningful. A slight mood reduction may be due to the effects of thinking about self-harm experiences. Indeed, previous CaTS research noted mixed results with VAS reductions in mood shown for younger people but not for adults [26]. However, there is no evidence that partaking in self-harm research has significant negative impact on mood [59]. This is reassuring, but further studies with larger samples can confirm whether our sample was too small (low power) to detect an effect. Importantly, the positive mood induction at the end of the study ensures participants will not be negatively impacted by taking part in studies using CaTS-D.

The large number of nonresponders to the open-ended feasibility questions is disappointing. This may suggest participants were fatigued having responded to each card and completed the CaTS-D immediately before answering SUS questions. Indeed, response burden is associated with reduced attrition and unwillingness to engage in research [33]. Furthermore, some nonresponses may be due to the wording of particular questions. For example, Q6 whether "various functions of the web-app were well integrated." Possibly, participants were unsure how this concept related to CaTS-D or did not understand "integrated" in this context, so chose not to respond. Wording this question differently may have yielded more responses. In hindsight, it may also have been prudent to ensure participants could not continue without responding to feasibility questions. Though this may have meant participants felt forced to provide responses, this may result in attrition and fewer overall responses being provided. Despite this, however, feedback and responses provided were positive and indicate CaTS-D is easy to use, does not require additional learning or support to complete, and people feel comfortable completing CaTS-D. The pilot data presented here suggests CaTS-D is a promising, feasible, acceptable, and useful web application for use in self-harm and suicide-related research. It can be used to examine and identify key self-harm antecedents, which can be targeted during intervention, if present.

Qualitative feedback was brief and suggested instructions could be clearer. Based on this feedback, we make the following recommendations for researchers using CaTS in future research:

- Instructions should explicitly highlight which self-harm episode (ie, first ever, most recent) should be considered by participants taking part in the study
- Ensure instructions clearly explain "I self-harmed" is a timepoint that can be selected if cards are relevant to the point of self-harm
- To explicitly state all timepoints (including "I self-harmed") can be selected if necessary.

XSL•FO
RenderX

Following these recommendations will reduce participant confusion and ensure data captured in future studies directly relates to the research question.

Strengths and Limitations

Participant demographics included a range of employment statuses, education levels, and household incomes indicating the acceptability of CaTS-D in a wide population. Similarly, most participants (~70%) were White British. While this may seem an inflated figure, it is lower than recently reported population figures from the Office of National Statistics (81%; ONS [60]. Importantly, the sample included substantial representation from LGBTQIA+ communities (n=2, 15% nonbinary and n=5, 62% nonheterosexual) aligning with the higher prevalence of self-harm reported in these groups. Therefore, the pilot study sample is largely in line with, thus representative of, the UK population. However, we recommend further feasibility testing to ensure feasibility in other countries.

Conclusion

These findings indicate participants can complete CaTS-D easily and confidently. Using CaTS-D addresses some issues faced by researchers, such as gathering data from hard-to-reach populations [34]. Furthermore, the anonymity CaTS-D offers may be preferable, including people in hard-to-reach populations. Considering most people use smartphones and devices daily [29,31], tools developed for online mental health research are increasingly necessary and, in some instances, preferable to in-person research [53,61]. While many people quickly navigate new websites or web applications [62], accessibility and efficiency are essential [49]. Consequently, assessing the feasibility of newly developed web applications is an important, necessary step. CaTS-D is a novel, unique research tool allowing participants to document their bespoke self-harm pathway. Results from this pilot study establish CaTS-D as a feasible, usable research tool, suitable for capturing large-scale self-harm data.

Study 2—Co-Developing Updates to the CaTS With Young People With Lived Self-Harm Experience: Qualitative Interview Study

Since CaTS was developed in 2013, factors may have emerged which need including to increase the relevance and appropriateness of CaTS. In addition, cards may need rewording or updating to incorporate changing social views and our understanding of self-harm. Furthermore, considering LGBTQIA+ people are at increased risk of self-harm, it is important to know if and what needs adapting for people who identify as LGBTQIA+ to ensure CaTS is suitable to fully capture LGBTQIA+ self-harm experiences.

Study Aims

We asked cisgender-heterosexual and LGBTQIA+ people with a history of self-harm for their views on CaTS. These included the relevance of cards, the timeline, clarity, language, and wording on cards, and whether participants felt amendments or additions to CaTS were needed. We also asked whether LGBTQIA+-specific additions were needed to allow LGBTQIA+ people to best document their self-harm pathway using CaTS. This study will ensure CaTS is contemporary, sensitive, and appropriate for use in a diverse population, which is essential for CaTS to remain a useful, meaningful, and inclusive self-harm research tool.

Methods

Recruitment

Semistructured one-on-one interviews were conducted on Zoom with UK residents aged 18 years and older with self-reported self-harm and access to a tablet, smartphone, or desktop or laptop. Participants were recruited from the same organizations as study 1; therefore, some may have taken part in both studies. The anonymity of study 1 prevents us from determining whether any participants also took part in study 2. However, some interviews took place before recruitment for study 1 commenced.

Ethical Considerations

Ethical approval was received from the University of Nottingham's Ethics Committee (S1557). Participants were recruited via social media and via existing relationships with relevant organizations (ie, mental health charities; LGBTQIA+ organizations). Because we aimed to capture views from both LGBTQIA+ and general populations, advertising efforts targeted both groups. Participants expressed interest by contacting the lead researcher (KB) via email, who emailed them full study information, consent form, and a well-being plan. Participants were encouraged to ask questions before providing informed consent and subsequent interviews. The well-being plan ensured participants were supported before and after participation and detailed that safeguarding concerns would be disclosed to relevant parties should they arise. The plan provides information on support organizations and details what would occur should participants become distressed during and after the study. The well-being plan required participants to detail their poststudy activities and provide details of a trusted person, their general practitioner, and the address they will be at during the interview in the event they become distressed during the study and researchers needed to call an ambulance. A copy of the Wellbeing Plan is available in Section S13 in Multimedia Appendix 1. Once participants completed and returned consent forms and well-being plans, a mutually convenient meeting was organized using a Zoom or MS Teams link, and a PowerPoint document containing the original CaTS (see Section S1 in Multimedia Appendix 1) was emailed to participants to consider before the interview.

Procedure and Data Analysis

Interviews took place via between June 2023 and February 2024. Research shows that interviews that took place via Zoom elicit comparable participant-researcher rapport to in-person interviews, are a similar length, and are popular with participants [63]. The interview schedule explored participants' views of existing CaTS cards and concepts, the timeline, language, clarity, and wording on cards, and whether general population or LGBTQIA+-specific additions and amendments were necessary to ensure CaTS contains meaningful, relevant factors.

XSL•FO
RenderX

Before interviews, participants provided verbal confirmation they had read and understood study information and felt comfortable taking part. Participants were not primed by topics raised by previous participants to avoid influencing their responses, ensuring themes identified through subsequent thematic analysis reflected participants' independent perspectives. Interviews were undertaken by KB, lasted between 40 minutes and 1.5 hours, and were audio and video recorded. Interviews were manually transcribed verbatim and checked by a member of the research team. All transcripts were anonymized using pseudonyms chosen by each participant. Afterwards, participants were asked if their emotional state had changed during the study and additional debrief information, including signposting to support services and organizations, was emailed to participants. Interviews were followed by a pre-arranged call 24 hours post study to ensure participants' mood had not been negatively impacted by taking part. Participants received a £10 (US $13.45) Amazon voucher as remuneration for their time.

We used thematic analysis to identify themes in our qualitative dataset. This approach was ideal compared to other qualitative analysis methods because it is not underpinned by epistemological or theoretical frameworks [64]. The flexibility of thematic analysis allowed us to generate codes and identify key features within the data to inform amendments and additions to CaTS variants. We performed Thematic Analysis by completing its six phases: (1) familiarization with data via transcription, (2) systematically generating initial themes, (3) searching for themes, (4) reviewing themes, (5) defining and naming themes, and (6) producing the final report. Final transcripts were uploaded to NVivo (version 9; Lumivero) for initial coding by KB (phase 2). Initial coded themes were then used for overarching theme analysis. This was performed independently by KB and a member of the research team who resolved discrepancies in interpretations via discussion.

Results

Demographic information is presented in Table 2. Participants (N=13) aged between 21 and 29 years (mean 24.67, SD 4.95) from the United Kingdom were interviewed. A total of 9 participants were LGBTQIA+ (mean age 23.56, SD 3.24 y) and 4 were cisgender heterosexual participants (mean age 23.75, SD 3.59 y). Participant characteristics varied, ensuring wide representation in the LGBTQIA+ community. Data including potentially identifiable information (ie, location) was omitted from quoted extracts to ensure confidentiality.

Table . Demographic characteristics of participants (Interview study)[a].

Demographic characteristics[b]	Participants (N=13), n (%)
Sexual orientation	
Bisexual	6 (46)
Lesbian	1 (8)
Queer	1 (8)
Pansexual	1 (8)
Heterosexual	3 (23)
Gender identity	
Cisgender female	9 (69)
Cisgender male	2 (15)
Nonbinary	1 (8)
Questioning	1 (8)
Ethnicity	
Chinese	1 (8)
White British	10 (77)
Mixed (White and African)	1 (8)
Mixed (White and Asian)	1 (8)

[a]The options used to capture the demographic data in this study were in accord with demographic data captured by the Office for National Statistics/UK government studies [58].

[b]Demographic categories not selected by any participants are omitted.

Initial questions focused on the clarity and relevance of wording on cards. Here, data was descriptive and explicit and is presented as such. Thematic analysis identified themes resulting in the creation of 13 new cards and amendments to wording on specific cards. Additional suggestions included capturing neurodiversity data and emphasizing sexual violence trigger warnings. Participants provided themes for cards and most offered literal suggestions regarding how cards could be worded.

Language, Terminology, and Minor Updates

Update Terminology

Overall, participants felt the cards were clear and relevant to self-harm; however, some felt terminology should be updated.

XSL•FO
RenderX

This related specifically to cards, including "forum." Coral explains:

> *…there was like these two cards around….'I read about self-harm on the Internet' and 'I discussed self-harm in a forum'… I don't know if it's a little bit like old-school…maybe changing it to social media or something like that because…like although some people still use forums, I don't know if that's totally relevant or not.*

Others also felt "forum" should be replaced with "social media/the internet" to reflect changing internet habits (see SM3 for additional quotes). Consequently, cards containing "forum" will be updated to "social media/the internet" to reflect changing internet usage and associated terminology. In addition, several participants suggested updating cards using "girlfriend/boyfriend" to a gender-neutral term. Coral explains gender-neutral language is necessary to ensure inclusiveness:

> *…there was one here 'I had an argument with my boyfriend/girlfriend'. I think that should just be changed to 'partner', so it's a bit more inclusive…*

Others agreed the word "partner" would capture all romantic relationships, regardless of your sexuality or gender expression (see Section S4 in Multimedia Appendix 1 for further quotes). Changing cards worded "girlfriend/boyfriend" will ensure they are relevant to all romantic relationships, regardless of marital status, gender expression, or sexuality. Resultantly, these cards will be updated to reflect changing discourse around inclusivity.

Capture Neurodiversity Data

While neurodiversity was not the study focus, or specifically asked, several participants discussed the overlap between neurodiversity and LGBTQIA+ identities. Participants felt capturing neurodiversity alongside demographic data would be useful. For example, Bronwyn said:

> *There's obviously the big overlap with LGBTQIA and neurodiversity, and I'm not sure how much of neurodiversity is completely captured. Maybe it could be something that is talked about before the task…if you're gonna get some demographics beforehand, can they just type in or like click a button that says like, Yep, this neurodiversity…people tend to want to say 'by the way I have this sort of neurodiversity'. So, they want to kind of explain why they're saying things in a certain way*

Other participants highlighted the LGBTQIA+ and neurodiversity overlap, and how neurodiverse people like the option of explaining or discussing their neurodiversity (see Section S5 in Multimedia Appendix 1). Consequently, we recommend researchers capture neurodiversity alongside sociodemographic data to allow participants to describe this important aspect of their journey.

Highlight Sexual Violence Trigger Warnings

Some cards relate to sexual violence. The introductory information contains a trigger warning to alert participants to this. However, a participant, NE, felt this should be more significant:

> *…Luckily I don't have experience with that but I know people who do and I feel like if they were doing this card sort, that would have been very…triggering for them…But when I was doing the pilot study…it just feels like it comes out of nowhere, which can be quite triggering for some people… there was almost definitely was a sexual assault warning before the study. But I think emphasising that would be very good…*

While only a single participant highlighted this, ensuring trigger warnings are clear and explicit will ensure participants are forewarned some cards contain terms relating to violence and sexual violence. Evidence regarding the effectiveness of trigger warnings in reducing distress is mixed [65,66]. However, trigger warnings do not lead to task avoidance [67], and evidence suggests people expect and support trigger warning use in research to forewarn people of potentially traumatic content [65,66]. Consequently, we recommend researchers present content and trigger warnings in recruitment and consent literature regarding content relating to potentially traumatic events.

Timeline—Additional 'Before 6-Months' Timepoint

Overall, participants felt the existing timeline is appropriate to capture self-harm factors at specific times pre– and post–self-harm. However, 9 participants felt an additional timepoint to capture historic events would be beneficial to examine why self-harm began, or to document a particular historic event occurred which links to other factors. Below we present two 2 quotes but see Section S6 in Multimedia Appendix 1 for further quotes. Selma explains:

> *…some people will…develop, like, self-injurious patterns really early on. Like, I know it was the case for me…and that is relevant in how there's self-injury…I think, you know, maybe you could have, like, a card that says, more like 'historical', but maybe in, like, a different wording…*

Here, Selma discusses why historic factors are important to document when considering one's self-harm pathway:

> *…there's like 'I was abused'…ermm….so I think that's the case for a lot of people who self-harm…but a lot of the time is more historical…so people have that in their history. It might not be relevant, like directly relevant, to their most recent episode of self-harm, but it might contribute to why they started self-harming in the first place…*

Together, the quotes indicate participants feel capturing historic events with an additional "before 6-months" timepoint is important. Participants discussed the longitudinal nature of self-harm and the association between historic risk factors and subsequent self-harm and how an additional "before 6-months" timepoint would allow researchers to capture important data. Other reasons for including an earlier timepoint focused on significant childhood or historic events, particularly physical or sexual violence (see Section S6 in Multimedia Appendix 1 for further quotes). Participants felt documenting historic events occurring before 6 months, before a self-harm episode, will

XSL•FO
RenderX

provide deeper understanding. In particular, traumatic events that may result in self-harm and other related risk factors. Therefore, a card entitled "Before 6-months" will be added to ensure CaTS captures historic events which impact later self-harm and related factors is an important addition.

Additional Cards

Participants were asked whether cards or concepts were missing from CaTS. Thematic analysis identified themes which provided evidence for the creation of 12 new cards.

"I Did Not Feel Comfortable in My Body"

Participants recognized not feeling comfortable in their body as a risk factor. A total of 2 participants explicitly related this to gender dysphoria, but remaining participants discussed how general body image issues are a self-harm factor. The overarching theme encompassed not feeling comfortable in one's body, and participants felt CaTS should include a card relating to this. Here, James Hogg discusses how not feeling comfortable in one's body develops for different reasons:

> *…something to do with body image or feeling as if your body is not right…self-harm's very common with people with body dysmorphia, but also you know a lot of body dysmorphia comes with gender identity and stuff like that…being bullied can also cause you to have issues with your body as well, that you didn't have before…I think it's a very common thing that people who have self-harm experience that isn't currently covered and it also just by coincidence also links quite heavily to the LGBTQ-plus community.*

CH agrees a card incorporating body image issues would be useful for both LGBTQIA+ and non-LGBTQIA+ people:

> *…maybe there could be a card for like for dysphoria…like a 'I don't feel…that my body is correct' or like 'I, I hate my body' card or something, because I feel like that's general enough to apply to non-LGBT people, but then like I know body dysphoria is like a big thing for trans people.*

Similarly, NE agrees a card documenting body-image issues would apply to people in different communities for various reasons:

> *…there's no cards on like especially for transness. I am nonbinary, so…I feel like I can contribute a lot in this area, but there's no cards on…gender dysphoria, or just general body dysmorphia, which I think could contribute even for…non-LGBT people…*

Together these quotes (and others in Section S7 in Multimedia Appendix 1) indicate CaTS requires a card allowing participants to document body image issues as a self-harm risk factor. This aligns with emerging literature showing body image issues are associated with self-harm [68]. Body image issues are also associated with general psychopathology (eg, depression and anxiety [69]). Depression and anxiety are well-evidenced factors for self-harm [70] and already included in CaTS. Possibly, a temporal relationship between body-image issues and other factors exists which increases self-harm risk. Including a card relating to body image issues would ensure CaTS can examine this pathway. Many participants explicitly discuss gender dysphoria and body dysmorphia; however, participants using CaTS may not have received specific diagnoses, nor feel their experiences fit into diagnostic categories. Including a card that incorporates body discomfort more generally will appeal to more participants than cards applying to specific body image-related diagnoses. The term "I did not feel comfortable in my body" was selected because feeling comfortable in one's body is associated with body-image issues and is a phrase used in measures of body appreciation (eg, Body Appreciation Scale-II [71]). Furthermore, it is sufficiently broad to be relevant for various body-image issues.

"I Felt I Did Not Fit In"

Participants discussed feeling not fitting in with wider society, or sometimes their own community, and this relates to both LGBTQIA+ people and the general population. Here, NE describes conflict within the LGBTQIA+ community can make people feel they do not fit in with people they should fit in with:

> *…I would say there's quite a lot of infighting in the community which I think could severely isolate a person. I know there's a card on 'I felt isolated'…But maybe having like another card that's… something to do with I felt excluded from people who should…people I should be fitting in with or people I, I thought I could trust…*

Similarly, James Hogg discussed in-fighting within the LGBTQIA+ community can result in people feeling they do not fit in, and this may lead to self-harm:

> *…you've got the whole LGBTQ umbrella. But then within that each one of those letters in that acronym will have different issues related to their sexual identity or their gender identity. So, you know, there's infighting in the trans community, there's infighting between bisexual people and homosexual people, you know…there wasn't a question that related to the feeling of not fitting in…with queer people there's obviously the idea of not fitting in with the straight people…but then also within the community itself, as I said, there's infighting. There's rejection within the community because you're not properly trans, you're not properly gay, you're not properly whatever. So, I feel like…the feeling of not fitting in drives a lot of people to isolation and therefore self-harm.*

While NE and James Hogg discuss not fitting in from an LGBTQIA+ perspective, the concept may impact people from various sociodemographic backgrounds. Coral highlights this:

> *…I think there was another one…maybe like 'I felt like I didn't belong in my community'. I think that could be quite…a big one, especially if there's like a religious community or culture or something that I guess could be related.*

Here, Coral talks about how people from different social groups can feel they do not fit into their community, which could be a factor for self-harm. These quotes identify "not fitting in" as an important factor (see Section S8 in Multimedia Appendix 1 for further quotes). Not fitting in is strongly associated with

XSL•FO
RenderX

isolation [72], which is already captured within CaTS. However, not fitting in may precede isolation. Indeed, James Hogg states this at the end of his quote: "the feeling of not fitting in drives a lot of people to isolation and therefore self-harm." Adding a "not fitting in" card will allow participants to document this concept in their pathway and ensures CaTS can examine temporal relationships between not fitting in, isolation, and self-harm.

"I Found Support/a Community on Social Media" and "Social Media/Online Content Was Negatively Impacting My Mental Health"

Participants discussed the positive and negative impact of social media and online content on self-harm. First, Jo talks about the support people can find online:

> *…you've also got the flip side of people's self-harm, I think is particularly common at finding communities online, especially if you don't kind of feel accepted or have a place in the real world. I guess then, I think social media can actually be somewhat of a safe haven as well because you can present yourself differently or you can like share stuff easier with strangers online than you can face to face with people that you actually know. So, I think, yeah, obviously it can be toxic, and it can be a scary place. But I think for people who are struggling, it can also be quite a helpful place…it could be like…I reached out online which helped' or I yeah, 'I received peer support online and found a community online' or something like that because I think online support is missing from those [cards]…*

Here, Jo discusses how social media can provide solace, community, and a sense of belonging, especially if one lacks this in the "real world." She acknowledges social media can be toxic, but she clearly feels the positive effects of social media interaction should be documented within CaTS. Belle also highlights how online self-harm groups can provide a sense of community and belonging:

> *…people are doing this too like 'that's nice'. Like I'm not the only one doing it. And then you feel like you can compare and almost not do it with them in some way, even though it's your own pain, it's not the same…You're not experiencing the same thing, but you make it feel like it's an altogether group thing.*

Seeing self-harm content online may engender a sense of community and belonging. However, NE discusses how social media can negatively impact mental health:

> *…I feel like younger kids, like 13,14 social media is gonna be a huge impact on your mental health…If you're self-harming…that probably would be good to mention something about. I'm not sure what specific cards you would have…something mentioning about how…social media is impacting your mental health, or you know, like seeing if…other people are clearly doing much better in life…*

Here, NE discusses the impact that comparing yourself negatively with others on social media can have on mental health and self-harm, particularly in younger people. Others agree (see Section S9 in Multimedia Appendix 1 for further quotes), and some made suggestions on how a card could be worded. For example, Artemis suggested: "...just a generic 'I felt like social media was impacting my mental health'...it would mean different things to different people, but it would be kind of a useful catch all....."

CaTS was developed before the significant rise in social media and smartphone usage that occurred over the past decade [73], so the original version does not contain social media-related cards. The quotes presented here highlight the significant presence of social media in contemporary life and its potential impact on self-harm. The positive and negative impact social media has on self-harm has been documented by others (ie, [35,73]), and participants clearly feel cards allowing users to document social media experiences and its impact on self-harm are important additions.

"I Was Bullied on Social Media" and "I Was Discriminated Against on Social Media"

Alongside the potentially negative impact of social media on self-harm, participants talked specifically about being bullied or discriminated against online being a factor for self-harm. Artemis says:

> *…social media…it's more sort of a tool that kind of exaggerates things in your life rather than a standalone thing. So, you know, if you're talking to friends, it allows you to talk to them 24/7 rather than just when you're with them or if you're taking, you know, pictures, it allows you to send them to all your friends rather than…one by one. So, it…allows you to do things on…a bigger and quicker scale. So, it's sort of…initial things are kind of already encompassed by the cards…so maybe 'I was bullied' would include bullied over social media or bullied as a result of social media 'cause…it would be exacerbated by social media…*

Here, Artemis says social media is an extension of one's life and allows things to occur "on a bigger and quicker scale," rather than being a separate experience. They state bullying occurs online and on social media as well as in person, and CaTS needs cards which capture online experiences. CS agrees and feels CaTS should also include online discriminatory experiences:

> *…something…that's sort of social media. It could look around things like cyberbullying, or things like…sexual harassment on…Facebook or Instagram, or even like something like, I don't know…homophobic abuse on Twitter that someone may, might have, like, maybe responded to you on there…anything like that would be I think, quite relevant*

The narratives here underline bullying and discrimination that occurs in person and online. Clearly, participants feel CaTS should provide opportunities to document whether online bullying or discrimination precedes self-harm. Possibly, other phenomena may occur in dual settings. Future research should

XSL•FO
RenderX

explore whether other factors occur online and in-person, and whether additional cards should explicitly refer to factors occurring online.

"I Had an Upsetting Sexual Experience" and "I Was Sexually Abused or Assaulted"

Selma talked at length about the "I was raped" card, and how some people may be reticent to select that card, even though they had experienced rape, but may select a card describing unsettling sexual experiences. Selma also felt CaTS should include a card relating to being the victim of sexual assault:

> *…there's one card that says 'I was raped.' And I think a lot of people, even if it did happen to them, they're not going to pick it because just reconciling with that term takes a lot of, like, inner work…I think a lot of people, they would not, especially if they're…in the midst of their healing journey, they're not going to pick that card, even if it's relevant to them. I think there needs to be a bit like more nuanced like, like an 'upsetting, like sexual experience'… I don't think a lot of young women like, would outright say, 'oh, I was raped'… things are changing culturally, and people are using that term more freely, but there's still a lot of stigma…Whereas if you say, oh, you know, 'I had, like, a upsetting sexual experience', I'm not even saying sexually abused because even…implying abuse, I think for some people it's even too much…even though… sometimes clearcut rape or abuse does occur. But it takes the victim a long time to…reconciliate with the fact that it happened…they wouldn't pick that card even though it might have actually objectively happened, you know?*

Here, Selma talks at length about 2 things. First, she highlights that rape does not always occur, but unsettling sexual experiences may occur and be a significant factor. Second, Selma feels people may not reconcile their experience with the "I was raped" card. A card allowing people to document unsettling sexual experiences would address these issues and be used in lieu of the "rape" card if they feel unable to select that card or relate rape to their experience. Others agreed a card covering sexual abuse and assault is necessary to include (see Section S10 in Multimedia Appendix 1 for additional comments). The narrative presented shows CaTS should include cards relating to both sexual abuse and assault and unsettling sexual experiences. Furthermore, sexual assault in adults [74] and childhood sexual abuse [75] are known antecedents for self-harm. Therefore, additions to CaTS which explore their impact on self-harm in relation to other factors will provide valuable insight.

"I Was Bullied Because of My Sexuality or Gender Identity" and "I Was Discriminated Against Because of My Sexuality or Gender Identity"

LGBTQIA+ participants discussed being bullied and discriminated against and how, for LGBTQIA+people, this occurs for numerous reasons. CaTS currently includes cards documenting generic bullying and discrimination experiences. However, LGBTQIA+ participants felt discriminatory and bullying experiences specific to sexual and gender identity were important to include in CaTS. CS explains:

> *I think it would be good to have a bit more…LGBT specific…I'm maybe thinking something like…discrimination that someone might face. Or I don't know a card, for example saying, I don't know, 'I've been bullied or discriminated against because of my sexuality or identity' or whatever, so something may be more identity specific…bullying…so, it could be maybe a bit more, erm, specific [to their LGBTQ+identity]…*

Artemis agrees gender-specific factors are important and discusses how cards that explicitly specify LGBTQ+-specific experiences will encourage people to select cards if relevant:

> *…if your LGBTQ identity did tie into any kind of episodes of self-harm, so having that there might make you think, oh…was that part of the reason why I ended up self-harming, you know, because I thought it was just because I was feeling, you know, really sad that day. But looking back, the day before…someone had…pointed out something or someone was…being really prejudiced…but I think having said that [a card] explicitly mentions just an LGBTQ+ identity might be quite useful…you could have, you know, 'I felt discriminated against because of my…'sexual identity, gender identity, trans identity'…sort of almost, yeah, combine a few into the same card…*

Zoe also felt LGBTQ+-related specific discrimination or bullying cards may encourage people to select cards relevant to their self-harm:

> *…because there's so many ways of discriminating as well. It might be easier to pick it out if it's prompted, I guess [LGBTQ+ identity]. Because I feel like for me, when I think of discrimination that, like a few that come to mind. So yeah, I guess it could be interesting to explore the different types of discrimination…*

Here, Zoe states people may connect the existing "discrimination" card with other discriminatory experiences. Participants highlight how LGBTQIA+ people experience identity-related discrimination and bullying alongside other bullying and discrimination experiences (see Section S11 in Multimedia Appendix 1 for further comments). Therefore, adding LGBTQIA+-specific discrimination and bullying cards will allow participants to document both experiences. These will increase CaTS' inclusivity and relevance to LGBTQIA+ self-harm and are important considering LGBTQIA+ people are at increased self-harm risk [43] and tools used to examine self-harm are frequently insufficient to capture LGBTQIA+-specific experiences [44]. Furthermore, while LGBTQIA+ people experience greater levels of discrimination and bullying compared to their cis-hetero peers [76], cisgender women also experience elevated levels of gender-based discrimination [77,78]. Therefore, these cards may also be relevant to cis women.

XSL•FO
RenderX

"I Was Questioning My Sexuality or Gender Identity"

In addition, LGBTQIA+ participants felt people questioning their sexuality or gender identity needed the opportunity to document this if relevant to their self-harm. Artemis explains:

> *…maybe in events…erm…things to do with exploring your kind of identity. I was exploring my gender identity, my sexuality…being with someone or by, you know, just sort of thinking about it, kind of reflecting internally…something like having an identity crisis or 'I was questioning my sexuality and my gender identity', or yeah, I think there's, 'there's a lot of questioning' I think just in general and that might be a big factor…*

NE agrees questioning one's identity may be important for some to document:

> *"…I'm pretty sure there is a card about saying 'I didn't understand how I felt' or something like that…I, I think if you're having an LGBT-specific one either adding another one or just changing the wording of that where it's, I didn't understand like myself or my identity or I was struggling with my identity and how I felt or something like that…*

Artemis expands this by describing how exploring your identity can trigger feelings of uncertainty around societal acceptance and expectations of others:

> *…or…say you were sort of with someone and you thought, 'oh, I think maybe I'm attracted to them' or 'I'm not', you know, 'quite allowed to be'. 'I shouldn't be' and sort of…kind of event triggering something… like this…isn't what I should be doing. You know, 'my family wouldn't accept that', 'I can't be doing that'…But yeah, having that kind of, yeah, sort of exploring or thinking about or kind of reflecting on some aspect of your identity and not being happy with that might be quite triggering…*

The narrative here shows questioning one's gender identity or sexuality can lead to internal conflict or confusion, and people are concerned how others may react. People questioning their gender identity or sexuality may experience elevated rates of mental health difficulties and self-harm [79]. Therefore, a card has been added allowing people to document questioning one's sexuality or gender and self-harm (see Section S12 in Multimedia Appendix 1 for additional quotes).

"Self-Harm Gave Me a Feeling of Control"

The final theme identified was the sense of control self-harm can elicit. Participants talked of feeling powerless and how self-harm can help people regain some autonomy. Selma explains:

> *…I thought maybe it would be good to have something 'cause I know, again for a lot of women who self-harm, it's sort of a way to regain bodily autonomy, bodily ownership…erm, and I think it could be good to have a term that kind of captures that on the cards like 'I felt like, I …powerful'… I put 'ownership'… I can remember some feelings very clearly in this. Yes, this feeling of like ownership of power, of control.*

Zoe also talked about how external factors elicit a lack of control and how self-harm can help people regain control:

> *…I don't know if this was mentioned as well, but… one of them is like the lack of control…more as a general feeling of lack of control. Yeah, and how, when people's lives seem to not be in order. Umm, I guess self-harms one of the ways that they try to get control back…*

Similarly, Belle agrees self-harm can help people regain control:

> *…thoughts of like wanting to feel something, not necessarily like…yeah, just wanting to feel, not necessarily even like pain or like feeling upset…It's just feeling something…and wanting to take control, like a control thing…*

The narrative here indicates that people who self-harm may feel they lack control and autonomy. Participants feel self-harm can be used to regain some control, and this may relate to external or internal factors. This is in accord with findings from recent qualitative systematic reviews where participants described self-harm as a mechanism to regain control related to distal, proximal, and internal factors [80,81]. Indeed, regaining control may be an important factor for repeated self-harm. Considering this, a card entitled "Self-harm gave me a feeling of control" has been added to CaTS.

Discussion

Principal Findings

This qualitative study found that participants generally viewed CaTS as clear, relevant, and appropriately worded, while identifying key additions and amendments to improve inclusivity and relevance for both LGBTQIA+ and general populations. The aim of this qualitative interview study was to garner views of people in LGBTQIA+ and general populations about the content of CaTS, whether cards are worded appropriately, and whether important cards are missing that are relevant to both LGBTQIA+ people and people in the general population. This process identified key additions and 3 amendments to improve the relevance of CaTS to ensure it remains a meaningful, relevant self-harm research tool. Based on the research questions and grounded in the data, we clarified that participants felt cards were clearly and appropriately worded, and concepts on cards were largely relevant to self-harm. Resultantly, additions and future cards will be worded following a similar linguistic format. However, participants suggested changes to ensure CaTS uses contemporary and inclusive terminology: changing "forum" to "online/social media" and using the gender-neutral term "partner" where relevant. Furthermore, participants discussed the importance of capturing neurodiversity status. In accordance with extant literature [82,83], participants highlighted links between neurodiversity and LGBTQIA+ identity and expressed the need for neurodiverse people to document their neurodiversity. Capturing neurodiversity data alongside other sociodemographic data would identify neurodiverse-specific self-harm antecedents. Furthermore, researchers may identify links between neurodiversity and self-harm, and exploring this

XSL•FO
RenderX

pathway is recommended by experts (eg, [84]). We recommend researchers capture neurodiversity data using categories (eg, Autism, Autism Spectrum Disorder [ASD], Attention Deficit Hyperactivity Disorder [ADHD], dyslexia, dyspraxia, Asperger's, and others) in line with suggestions from service providers who support neurodivergent people (ie, Diversity Project and The Brain Charity). Finally, a participant discussed a clearer, concise trigger warning relating to sexual violence content. Because trigger warnings are commonplace, expected, and people support their use in research [65], we recommend researchers very explicitly state some cards relate to physical and sexual violence during recruitment and informed consent to avoid unnecessary surprise or discomfort.

New Cards

The heterogeneity of factorial themes developed from these data mirrors the heterogeneity, complexity, and variety of factors for self-harm experienced. However, thematic analysis identified themes that supported the development of 12 new cards and 1 timeline card. First, analysis showed participants felt CaTS should include a "before 6-months card." Participants felt this would allow people to document significant childhood or historic events important to their self-harm pathway. This inclusion will enable CaTS to examine historic factors and identify whether specific historic factors are temporally linked to subsequent factors and eventual self-harm. Because participants were aware that the study aimed to identify potentially new cards, most offered suggestions regarding how cards could be worded. While some LGBTQIA+-specific cards were developed from the data, overall, participants (including LGBTQIA+ participants) suggested themes and cards which could be applicable to people from various backgrounds.

The twelve cards created from themes identified within the data are:

1. "I don't feel comfortable in my body"
2. "I felt I did not fit in"
3. "I found support/a community online"
4. "Social media/online content was negatively impacting my mental health"
5. "I was bullied on social media"
6. "I was discriminated against on social media"
7. "I had an upsetting sexual experience"
8. "I was sexually abused/assaulted"
9. "I was bullied because of my sexuality or gender identity"
10. "I was discriminated against because of my sexuality or gender identity"
11. "I was questioning my sexuality or gender identity"
12. "Self-harm gave me a feeling of control"

Adding these cards ensures CaTS and CaTS-D contains factors relevant to self-harm and remains a useful, meaningful research tool. LGBTQIA+-specific additions are important to increase the inclusiveness of CaTS. This is particularly important considering self-harm prevalence in LGBTQIA+ people is elevated [42,43,85] and tools used to examine mental health in LGBTQIA+ people are often cis-hetero–centered [44,45]. The LGBTQIA+-specific cards added to CaTS will allow people to document whether factors specific to LGBTQIA+ people are key antecedents to self-harm in this high-risk group. These details are important to capture considering researchers largely focus on general risk and protective factors, meaning group-specific factors are poorly researched [86]. Therefore, the impact group-specific factors have on self-harm is not understood. Using CaTS with the additions developed here will address this deficit in understanding by identifying whether self-harm in LGBTQIA+ people is preceded by particular group-specific factors. Future research with LGBTQIA+ people may identify further additions and is recommended to increase the inclusivity and relevance of CaTS. The remaining additional cards may be relevant to people from various backgrounds and for different reasons. Furthermore, they are important additions reflecting changes in what can result in self-harm. For example, the rise in social media usage and the way we use and engage with others online has changed dramatically over the last decade. Without exception, participants in this study discussed the negative impact social media can have on self-harm. This impact is supported by other researchers in the field (ie, [87,88]) who report increases in self-harm risk correlate significantly with increased time spent on social media. However, participants also discussed the benefits of a community and sense of belonging that can be found online. A recent narrative review discussed benefits including being able to communicate authentically with peers online [36], meaning social media may provide solace to some. Findings regarding social media are polarized. However, adding social media-related cards allows participants to document these experiences and ensure CaTS includes cards relating to a concept, which has an evidence-based impact on self-harm behaviors. Their addition increases the relevance of CaTS, ensuring it remains a useful and meaningful research tool to examine self-harm in cis-heterosexual and LGBTQIA+ people and identify key antecedents which can be targeted during intervention. Future research may identify additional cards or support the development of a set of cards specific to a particular population. The study demonstrates the flexibility of CaTS and how amendments and additions can easily be made.

Strengths and Limitations

The primary strength of this study was the use of in-depth interviews that allowed the authors to explore factors for self-harm missing from CaTS, and amendments necessary to increase the relevance and meaningfulness of CaTS to ensure it remains a useful research tool. We were able to elicit in-depth motivations and experiences, which impact self-harm and may not have been relevant when CaTS was originally developed. Furthermore, we were able to elicit LGBTQIA+ experiences which will increase CaTS' inclusivity and relevance to LGBTQIA+ self-harm. Qualitative research aims to create descriptions and interpretations.

Our primary limitation pertains to our sample. Significant effort was placed into recruiting transgender and gender-diverse participants. Sadly, these focused recruitment drives were largely unsuccessful. It is possible transgender and gender-diverse people experience factors for self-harm which differ from the wider LGBTQIA+ community and were not identified by participants in this study. Future research should capture transgender and gender-diverse views of CaTS and other self-harm tools to ensure they contain meaningful items which

XSL•FO
RenderX

capture self-harm experiences of transgender and gender-diverse people. In addition, participants' ages ranged from 21 to 29 years. Younger adolescents, or older adults, may identify other self-harm factors or highlight amendments to CaTS, which increase its relevance and appropriateness to a wider age range. Indeed, previous CaTS research highlights differences between young (18 - 25 y) and older (26 - 57 y) adults' self-harm antecedents [26]. Similarly, most participants were White British. People from other racial backgrounds may experience factors specific to their racial or ethnic background that do not appear in the existing cards and task. Future research should focus on racial and ethnic groups to address this deficit. Furthermore, while some participants may have past or current clinical intervention or treatment, this sample was community-based. A clinical sample may identify additional factors relevant to clinical or in-patient self-harm experiences.

Conclusion

These 2 studies present updates and amendments to CaTS to ensure it remains a valuable self-harm research tool. First, findings from the pilot study found the newly developed web-app version, CaTS-D, is a feasible research tool. A small decrease in mood was observed poststudy; however, given the small sample size, the study was not powered to determine whether this change is statistically or clinically significant. Overall, participants' emotional state remained largely stable, suggesting CaTS-D can be used without substantial negative impact. Developing a feasible web-app version allows researchers to capture large datasets quickly and economically. Furthermore, it is likely preferable to participants used to interacting online, and who may find in-person research time-consuming and geographically limiting. We also identified important amendments and additions to CaTS using qualitative interviews that ensure CaTS captures relevant factors for self-harm. These include wording amendments and the addition of 13 cards, which reflect changes in our understanding of self-harm and changing experiences of people who self-harm. These evidence-based changes reflect emerging factors for self-harm that were not relevant when CaTS was originally developed and are important additions to ensure CaTS can meaningfully capture and examine self-harm antecedents in research. Future research should seek to identify whether additions or amendments specific to transgender, nonbinary, and different racial and ethnic groups could be added. In addition, adolescents and older people (>30 y) may elicit factors specific to their age group.

Finally, although VAS scores decreased slightly post-study, statistically, participants' emotional state was not negatively affected by completing CaTS-D. However, our sample size may be too small to determine whether this reduction was statistically meaningful. A slight mood reduction may be due to the effects of thinking about self-harm experiences. Indeed, previous CaTS research noted mixed results with VAS reductions in mood shown for younger people but not for adults [26]. However, there is no evidence that partaking in self-harm research has significant negative impact on mood [59]. This is reassuring, but further studies with larger samples can confirm whether our sample was too small (low power) to detect an effect. Importantly, VAS data indicated that participants' mood remained in the mid-range postparticipation, suggesting that CaTS-D participation did not result in substantial emotion reduction.

Abstract

Background: Large language models have shown promise in transforming how complex scientific data are analyzed and communicated, yet their application to scientific domains remains challenged by issues of factual accuracy and domain-specific precision. The Laureate Institute for Brain Research–Tulsa University (LIBR-TU) Research Agent (LITURAt) leverages a sophisticated agent-based architecture to mitigate these limitations, using external data retrieval and analysis tools to ensure reliable, context-aware outputs that make scientific information accessible to both experts and nonexperts.

Objective: The objective of this study was to develop and evaluate LITURAt to enable efficient analysis and contextualization of complex scientific datasets for diverse user expertise levels.

Methods: An agent-based system based on large language models was designed to analyze and contextualize complex scientific datasets using a "plan-and-solve" framework. The system dynamically retrieves local data and relevant PubMed literature, performs statistical analyses, and generates comprehensive, context-aware summaries to answer user queries with high accuracy and consistency.

Results: Our experiments demonstrated that LITURAt achieved an internal consistency rate of 94.8% and an external consistency rate of 91.9% across repeated and rephrased queries. Additionally, GPT-4 evaluations rated 80.3% (171/213) of the system's answers as accurate and comprehensive, with 23.5% (50/213) receiving the highest rating of 5 for completeness and precision.

Conclusions: These findings highlight the potential of LITURAt to significantly enhance the accessibility and accuracy of scientific data analysis, achieving high consistency and strong performance in complex query resolution. Despite existing limitations, such as model stability for highly variable queries, LITURAt demonstrates promise as a robust tool for democratizing data-driven insights across diverse scientific domains.

Introduction

Overview

The scientific process relies heavily on the community of scientists reliably and efficiently generating, collecting, organizing, and analyzing data based on reasonable hypotheses and quality datasets. This process is based on complex information that derives from every experiment and every observation. However, these raw data can be challenging to engage with, their valuable insights hidden in complexity and at times significant volume and multimodality of collected data. The information contained in these datasets cannot just be observed, it must be processed and analyzed. While trained analysts can access the underlying patterns given sufficient time, the wealth of knowledge contained within these data sets remains inaccessible to the average person. Thus, unlocking the full potential of scientific data requires analytical tools and techniques that can distill complex information into insights accessible to both experts and nonexperts alike.

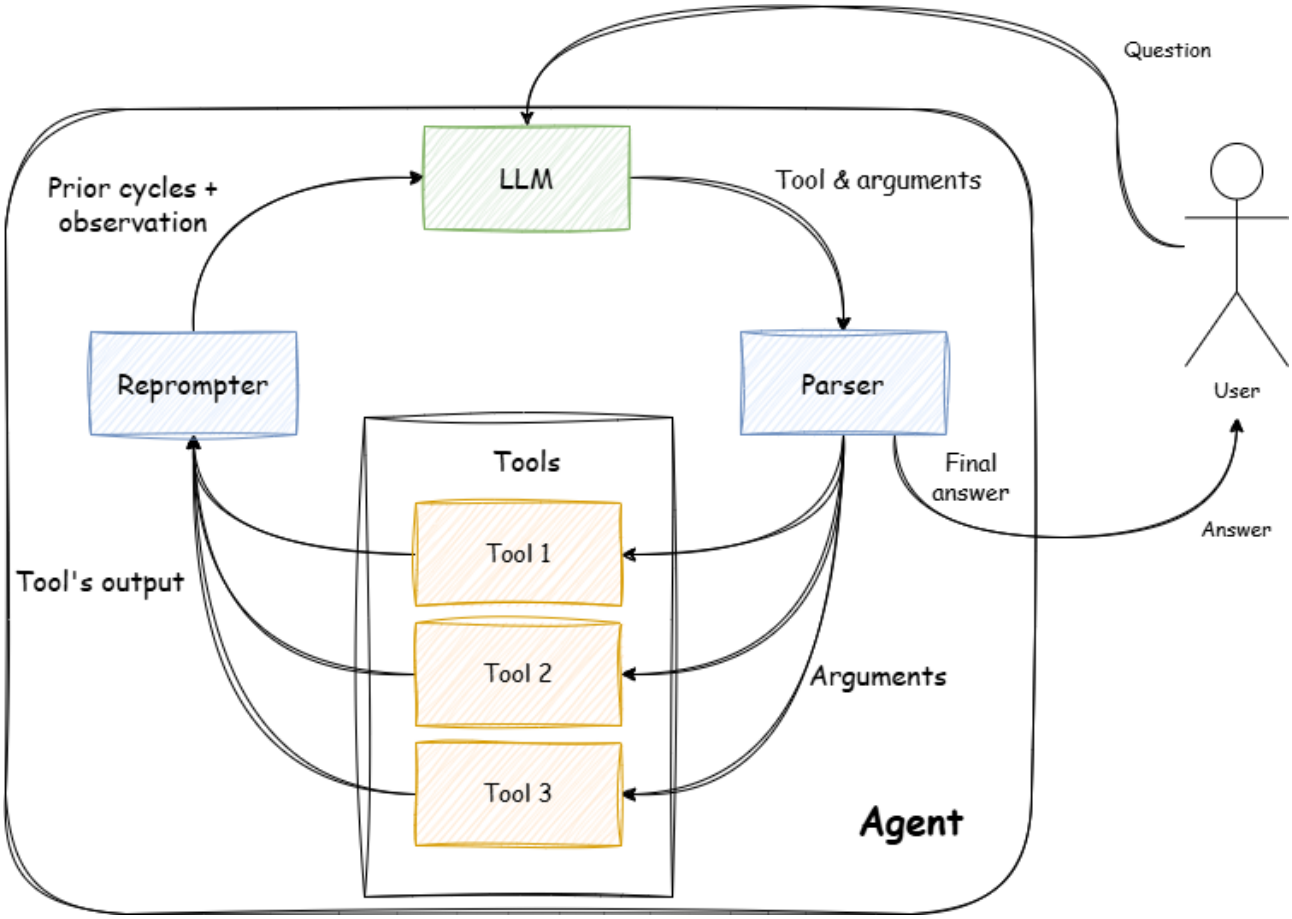
Large language models (LLMs) provide one possible solution to harnessing the valuable information hidden in large experimental data sets. These powerful artificial intelligence (AI) systems have demonstrated the ability to explain information. For example, GPT models have demonstrated remarkable abilities in explaining complex scientific concepts by generating coherent, human-readable summaries from vast data sets, making information more accessible to a broader audience. LLMs can tailor their explanations to various levels of expertise, providing concise summaries for the layperson as well as in-depth analyses for the scientist [1-3]. However, a

XSL•FO
RenderX

critical gap remains—how do we get the LLM to "know" the information we want it to report to the user?

We introduce the Laureate Institute for Brain Research–Tulsa University (LIBR-TU) Research Agent (LITURAt), a research assistant that provides easy access to and efficient analysis of data sets through a user-friendly interface. Leveraging LLMs, LITURAt enables users of any scientific background to explore hidden relationships within data sets. Recognizing that understanding relevant literature is time-consuming for scientists and challenging for nonexperts, our system searches PubMed for abstracts pertinent to the user's queries, enhancing the meaningfulness of the results. Consequently, the agent can answer specific questions and provide broader context from related research. Designed for both experts and novices, LITURAt allows scientists to delve into detailed analyses while offering laypersons clear and concise explanations, making complex scientific concepts more accessible.

Background



LLMs are AI models trained on massive amounts of text data. They have demonstrated remarkable abilities in various natural language processing tasks, including text generation, translation, summarization, and question-answering. However, their application in scientific domains presents challenges due to their potential for inaccuracies and the need for precise, domain-specific information. Even the most advanced LLMs are prone to recall information from their training data inaccurately. While LLMs demonstrate impressive capabilities in general language processing, their very training methodology presents a challenge for ensuring factual accuracy in specific domain scenarios. The vast amount of data used for training can lead to a phenomenon known as "catastrophic forgetting," [4,5] where the model prioritizes broader language patterns over the nuances of individual data points. This inherent limitation means we need a different approach other than simply training an LLM on a data set and expecting it to provide accurate responses to specific queries within that domain.

To combat this challenge, a recall system can be used to provide information to the LLM to help anchor its output to a correct context. However, for complex tasks requiring a multistep information retrieval process, where the answer to each query informs the next, a more sophisticated architecture is necessary. These systems are referred to as agents [6]. The architecture behind these agents typically shares 2 characteristics. First, they operate in a loop in which they "act" multiple times before returning an answer to a user. Second, they can use existing tools. These tools are subsystems that perform defined operations like a calculator or a search function. Tool use can be facilitated by many different implementations but almost all of them involve the agent generating a string in a specific format that the system can then parse as a command. Once the tool has finished running, the result produced is returned to the LLM and then the loop repeats.

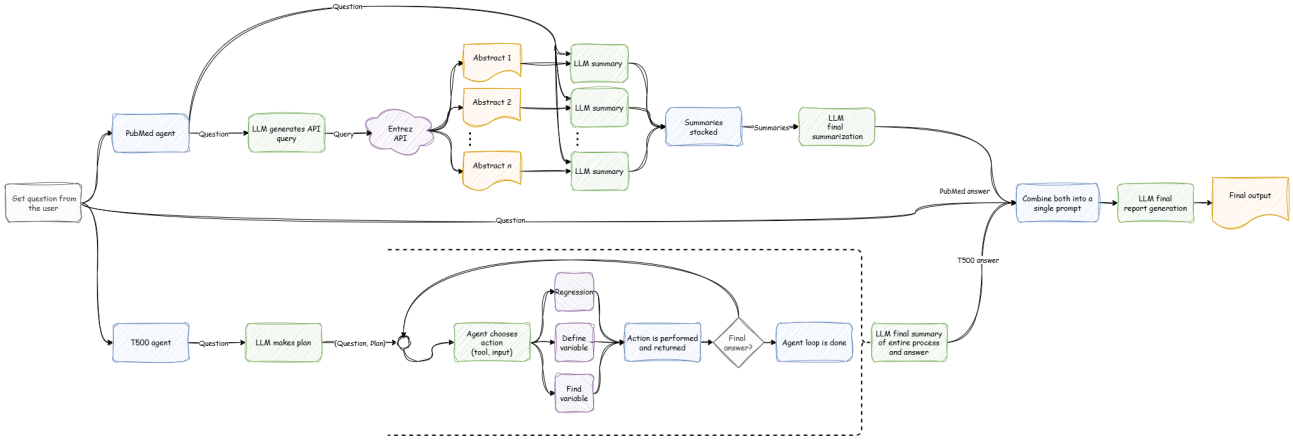
Figure 1 shows an example of a tool-using agent's core loop. When the user asks a question the LLM looks at the question and determines the first action that needs to be taken. The LLM generates a string that defines the next tool to be used and the arguments to be passed to it. The parser then reads the string and then calls the indicated tools with corresponding arguments. The selected tool runs with the specified arguments and returns some answers. The tool itself can be a piece of code, an application programming interface (API), or even another LLM-powered system [7]. The output of this tool is recorded, converted into a string, and added to the context window of the LLM as an observation by the reprompter. This reprompter is the mechanism responsible for the loop-like nature of the agent by running the LLM again with the newly added information. The loop repeats until the LLM decides it has enough to answer the question posed by the user. In that case, it generates a string that tells the parser to break out of the loop and present the user with the final answer.

XSL•FO
RenderX

Figure 1. Generalized agent loop example. LLM: large language model.

To facilitate the development of this agent architecture, our system uses the LangChain [8] library which includes all the building blocks required for the creation of such agents. LangChain has been used in many similar applications [9-13] as it provides a framework in which to quickly construct agents.

Most current systems focus on providing interactivity with text files [14]. However, a large amount of scientific data are stored in the form of tables. The most common way that LLMs can interact with a local data set is through some form of search. Traditional searches have a low chance of success when applied to scientific data sets because the information requested often does not already exist and needs to be calculated. When this is the case a simple text-based search would return no useful information. Because of the calculations needed many common retrieval strategies fail and cannot provide the information the user requested to the LLM. Since the LLM is not given any context with which to answer the question there is no guarantee that the answer is anything more than a hallucination of the LLM.



Methods

Overview

The goal of LITURAt is to answer questions about underlying relationships between the various entities in each data set and contextualize those answers using relevant literature. The user can pose questions such as “How strong is the connection between A and B?” or “Out of the set [A, B, and C] which is the best for predicting D?” Our system can then automatically perform the necessary analysis to answer this question while searching for relevant articles to provide the context to its answer. To accomplish this, the LITURAt uses a 2-pronged approach. One component looks at the local data while the other part summarizes the relevant retrieved literature. Figure 2 shows the overall architecture of LITURAt.

XSL•FO
RenderX

Figure 2. The architecture of LITURAt. API: application programming interface; LITURAt: Laureate Institute for Brain Research–Tulsa University Research Agent; LLM: large language model.

The first component is an LLM-powered agent-based system that uses local tabular data paired with a data dictionary to examine the relationships between underlying concepts. This allows the user to query about those concepts and the agent can answer questions about their relationships. The system uses an agent architecture like the one described above to allow for dynamic calculation of the requested information. The second component is an LLM-powered system designed to retrieve and summarize several published abstracts from PubMed. The summaries focus on information relevant to the user's question's context. The summarization happens along with the local retrieval system so that a user can see how local results fit into the current state of literature. Combining these systems gives the user the information extracted from the local data and informs them if this finding is consistent with other studies' information. This can help to expose potential patterns that reinforce one's own or others' findings or it can help detect the presence of other factors that might cause the 2 study's findings to differ.

For our implementation, we used Mixtral8 × 7b. While more powerful models exist, Mixtral8 × 7b has demonstrated the ability to be competitive with GPT-3.5 while being lightweight enough to run on midgrade commercial graphics processing units [15]. The combination of capability and lightweight performance makes Mixtral8 × 7b a practical choice for this task. While the initial goal was to develop a system that could answer questions of the format "What is the relationship between A and B," due to the flexibility that the LLM-powered system provides, we found that it can answer much more complex questions. It has shown promising abilities to compare variables and relationships allowing it to tackle more complex questions about predictive abilities like the one mentioned above that contrasts 3 relationships to determine the best predictor. As the number of cycles through the core agent loop increases, we notice a decrease in the stability of the agent which impacts reliability. However, this only reaches a problematic level when asking a question that requires the agent to process 5 or 6 variables.

Answering Questions From Local Dataset

Plan and Solve

Our agent uses a plan-and-solve approach. Its first step is to look at the question the user asked and the tools it has available. Before the agent begins its main loop, we have the LLM generate a plan to answer the question. The plan consists of which tools need to be used along with the order in which to use them. It also contains how the answer from one tool influences the arguments to other tools in future steps. This technique [16] helps guide the agent towards the solution while minimizing the chance of incorrect or unnecessary actions. It has been shown that adding a single planning step increases both the accuracy and efficiency of an agent by reducing the number of erroneous actions. This leads to agents taking a more direct path towards answering the question. We included the planning step to increase our system's reliability when answering more complex questions.

Main Loop

The main body of the agent uses a loop following the design shown in Figure 1. The LLM is prompted to select tools using a JSON-style string [17] which is parsed by the system into tools and arguments. These 2 fields are then used to specify the tool the LLM chose from the set of available options and the arguments are then passed to this tool. When the tool finishes executing and returns a value, the system formats the output into another JSON-style object which is then turned into a string and passed back to the agent. This loop continues until the agent generates a JSON designating "Final Answer" as the tool then the system exits the loop, and the argument is the message returned as the answer to the question. As will be discussed later, this final answer is not used directly by our system as it provides too little information.

Abstracting the Dataset Behind Tools

One of the main advantages of having the model interact with the data via tools is the layer of abstraction the arrangement provides. The agent has no direct interaction with the data and does not need to be trained on any data so if the data set is changed, such as being updated, the agent's ability to answer queries is unaffected. This also means that the system can be

XSL•FO
RenderX

used on a variety of data sets just by modifying the tools that access the data set.

Tools

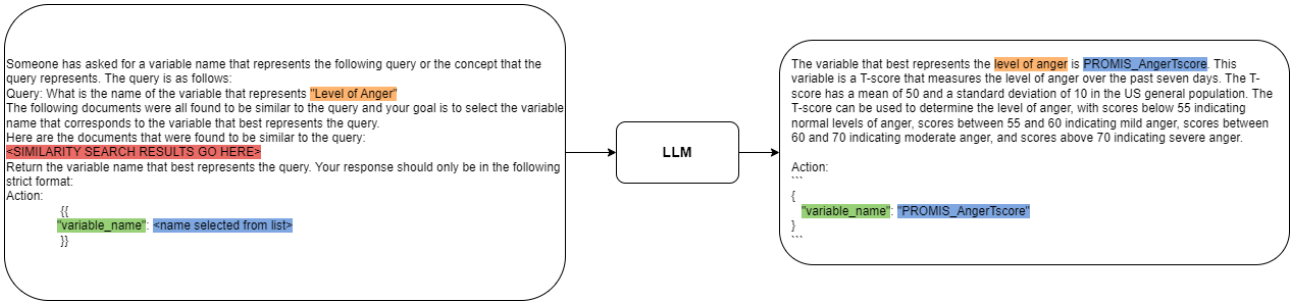
LITURAt uses 3 tools to answer the queries as follows.

Find Variable (Concept)

When this tool is passed a description of a concept as a query in the form of a string it searches the variable dictionary to find the variable in the data set that best represents the query.

Define Variable (Variable Name)

This tool simply retrieves the definition of the variable passed to it from the variable dictionary. This is used to give the agent more context leading to a more useful answer.



Linear Regression (Variable 1 and Variable 2)

Using the lm() function from the R language to create a linear regression model that uses variable 1, along with a set of manually-defined hardcoded controls, to predict variable 2. The summary() report contains the information to measure if there is a statistically significant relationship between the 2 variables.

Find Variable Tool

One of the main factors that allows LITURAt to perform operations on data stored in tables is the ability to find variables that represent concepts given a variable dictionary which is another table that contains all the variables and their descriptions. The system needs to translate the description of the concept given by the user into the matching variable in the dataset. The system uses a similarity search metric over the definitions in the variable dictionary and sends the top 5 variables retrieved to the LLM model as candidates. The LLM uses the description provided to pick the one that best represents the concept. This step proved useful since there is no guarantee that the variable with the highest score on the similarity metric used in the search is the best choice to represent the concept. The LLM is used for its ability to semantically discriminate and select the best option. This extra layer of abstraction, instead of returning the search results directly to the main loop, reduces clutter and helps prevent confusion by only adding one variable name to the context of the main loop. When all the candidates are presented to the main loop, the chance of the LLM using the wrong one later increases. Figure 3 shows an example of the tool.

Figure 3. Variable search tool example. LLM: large language model.

Linear Regression to Measure the Strength of Relationship

In LITURAt, linear regression is used to measure the strength of a relationship between 2 variables. We used R language's "lm" function to compare the 2 variables along with a standard set of covariates such as race/ethnicity, sex, employment, education level, income, and age. The result of the report was formatted with R's "summary" function which provides a string representation that can be used by the LLM to interpret the results. The LLM model we used, Mixtral8 × 7b, demonstrated proficiency in interpreting these summaries and was able to extract the required information.

Final Summary

When the loop returns a final answer, it frequently answers the initial query in the most basic form. Sometimes these answers can be as simple as "Yes, A is related to B." This concise format does not contain enough information to create a meaningful report. Our solution to this sparsity problem is to take the agent's entire loop history, the agent's output as well as observations, and feed this into the LLM with instructions to generate a summary. The LLM is instructed to describe all steps the agent took, and all the knowledge gathered such as variable names and takeaways from the linear regressions. This can be seen in Figure 2 by the bracket surrounding the agent's core loop. This final summary is an expanded version of the final answer, providing information such as the control variables used and the strength of the relationship between the concepts. We found that this gives a more comprehensive output leading to a better final report that allows the system to tailor the response to the user's needs.

Summarizing Relevant Literature

API Query Generation

To find papers relevant to the user's question we had to search the abstracts available in PubMed. This search can be performed through the Entrez API [18]. The first step is passing the question to the LLM so it can generate a query formatted for the API. Passing this query through the API and extracting the top results gives us PubMed abstracts that pertain to the user's question. The number of results retrieved can be adjusted and is a tradeoff between a more comprehensive search and the processing power required. In our experiments, we used the first 5 results returned by the API as relevant abstracts to the generated query.

Abstract Summary

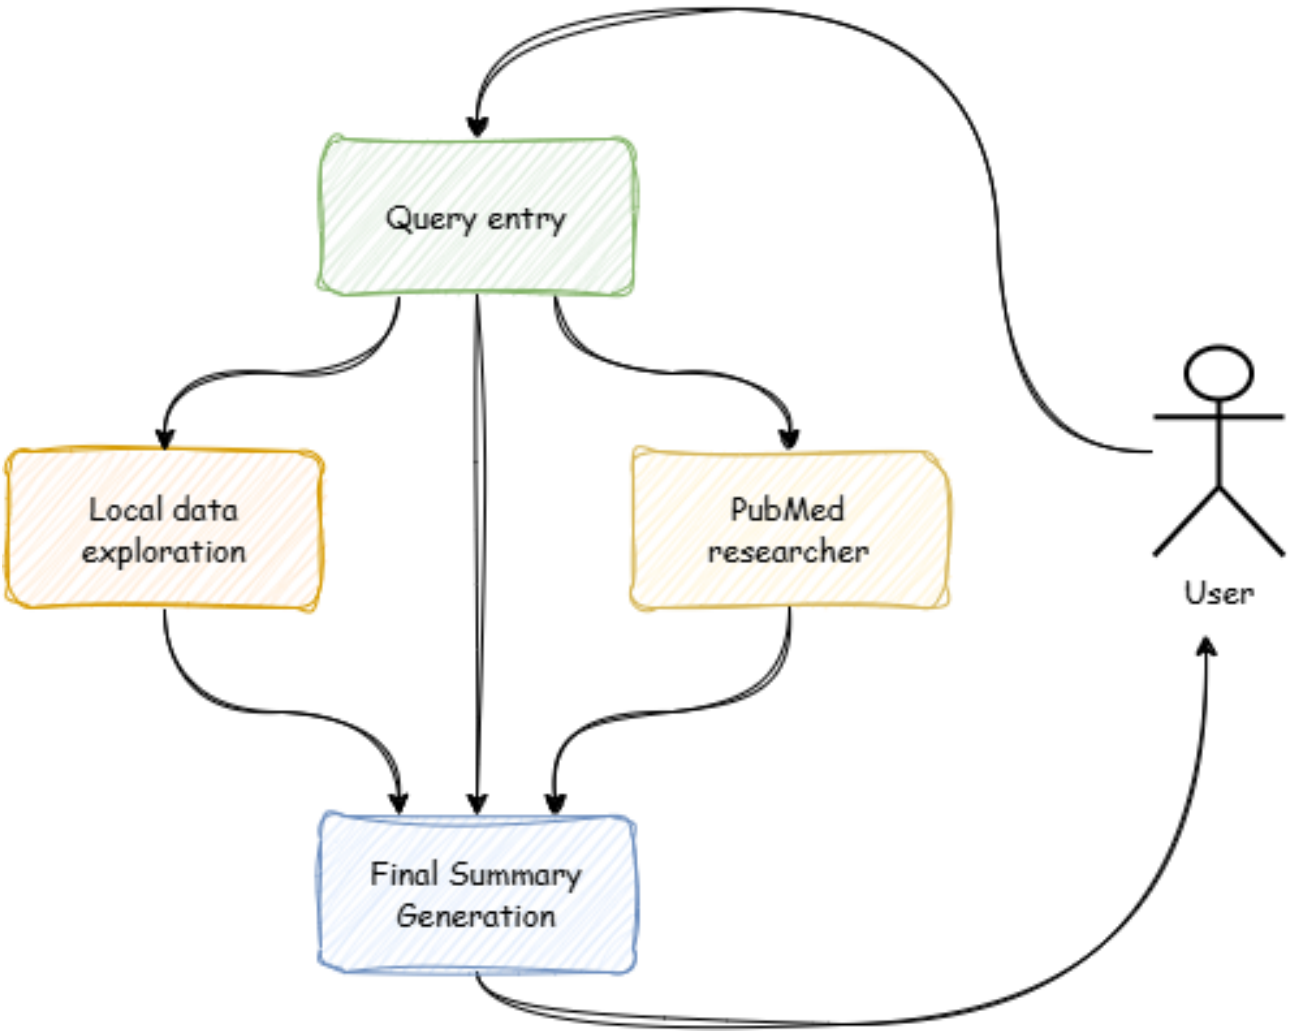
To help distill the relevant information and prevent the size of the context window from becoming unmanageable, each abstract

XSL•FO
RenderX

is passed through the LLM along with the initial question. The goal of this is to create a summary of the abstract within the context of the user's query. We found that this helps to remove any extraneous elements of the abstract and compress the information that we want to return to the user. The result of this is a much shorter and denser string of text that contains the details in the abstract that directly relate to the question. Since these summaries are produced independently, they can be generated in parallel. Parallelization allows for the process to be scaled up without directly impacting the running time given a sufficiently powerful system.

Summary of Compiled Summaries

After all the abstracts have gone through the initial summarization process, the summarized versions are compiled together and passed through another summarization process much like in the first step. This time, the summary is over the entire sample of the literature we collected. Because we passed the user's query to the LLM, the summary is focused on the relevant information. This 2-step summary process helps make the final summary useful when contrasting with the local results. It also helps filter extraneous information contained in papers that contain associated topics but do not provide a meaningful answer to the user's question.



Focus on Lightweight Retrieval

One of the biggest motivations for the design of our retrieval system is to develop a lightweight method of adding context to the examination of local data. The system does not provide a comprehensive survey of all literature pertinent to the question. However, it provides enough information so that a user can see if the relationship seen in the local dataset was repeated in the literature or if there is a discrepancy between the local observations and past reports.

Comparing and Final Report Generation

As seen in Figure 4, once both the local data exploration and the PubMed research are completed and their respective reports are generated, the final report is created. Both reports, along with the question, are passed to the LLM with a prompt to create a report stating the findings from both subprocesses and comparing them. The system generates a final report with a consistent predefined format as follows: (1) answer from local dataset, (2) answer from PubMed, (3) comparison of the 2 answers, (4) additional information, and (5) conclusion. An example can be seen in Multimedia Appendix 1.

Figure 4. High-level architecture.

XSL•FO
RenderX

This helps the model generate an accessible report in a consistent format. The goal is to convey the answers from both systems and discuss if the 2 support each other. This report is then given to the user as the answer to their question. If we wanted to use this system in the context of a chatbot, this report would be fed to the LLM inside the chatbot as context to aid in generating answers. The chatbot could then function as an interface to the human, providing an explanation at the desired level of detail. This process mirrors the way modern chatbots answer questions.

Experiments

Overview

To test the effectiveness of our agent we used as our local dataset the Tulsa 500 (T-500), which is a subset of the Tulsa 1000 (T-1000) dataset [19]. The T-1000 was a naturalistic study that recruited and longitudinally followed 1000 participants, including healthy controls and treatment-seeking individuals with mood, anxiety, substance use, and eating disorders. Participants completed interviews as well as behavioral, biomarker, and neuroimaging assessments over the course of 1 year. The study aimed to determine how disorders of affect, substance use, and eating behavior were organized across various levels of analysis, including genes, molecules, cells, neural circuits, physiology, behavior, and self-report, to predict long-term prognosis, symptom severity, and treatment outcomes. The T-500 is a subset consisting of half the participants of the T-1000. We used this smaller selection as a testbed for the system.

Consistency

The first aspect we investigated was whether our agent reliably produced consistent results. It is critical to establish this since any further statistical analysis assumes that the given sample is representative. We measured 2 types of consistency that together quantify whether the system's behavior is stable. First, we measured internal consistency, which we defined as the agent running with the same exact input multiple times and producing equivalent results each time. This measure captures the likelihood that the system will give different answers when asked the same question on separate occasions. The second type of consistency we compute is external consistency which measures the agent's tendency to generate equivalent results when the phrasing of the question varies. We measure this to understand the risk of the agent changing its answer in response to minor changes in how the question was asked.

Internal Consistency

For the first type, internal consistency, we ran the agent 10 times on the exact same query. The predictors and outcomes were all pairs from a set of 4 variables. The reports generated by the system were then compared pairwise by Mixtral8 × 7b tasked with classifying the 2 reports as consistent or inconsistent. For this test, consistency was defined as containing the same key information with the only differences being in the format in which that information was presented. To evaluate consistency, we used Cohen κ coefficient for agreement to calculate the degree to which our agent agreed with itself when given identical input.

External Consistency

To evaluate the external consistency of our agent, we created a set of queries to which the agent should respond with the same information. For example, "What is the relationship between someone's level of anger and their depression?" and "How does someone's level of anger affect their depression?" should both produce the same key facts and thus both queries were considered requests for equivalent information. When answering equivalent questions, the system should mention the same basic facts about the direction and significance of the relationship. To determine the external consistency, we collected results from 5 requests for equivalent information across all combinations of 4 variables passed to the model. As with internal consistency, an LLM performed pairwise comparisons, with the result being used to compute the Cohen κ coefficient for agreement. The value of κ was interpreted as the level of agreement between the model and itself when the same question was phrased in different ways.

LLM-as-Judge

After evaluating the consistency of our agent's output, we further evaluated the accuracy of the information produced by the agent. Any attempt to measure the accuracy of a literature review needs some reference with which to compare. Unfortunately, we could not find a proven baseline for literature review evaluation. Any system we created to help us with this test would be unproven and only lead to a comparison of 2 unknowns. Due to difficulties in establishing a ground truth for the literature review, our efforts focused on the local dataset exploration. To do this, we used GPT-4 as a judge. This practice has seen reliable results in multiple studies [20-22].

We tested the system with a batch of 192 questions, generated from 6 predictors and 7 outcomes, each phrased in multiple ways (Multimedia Appendix 2). All questions followed the basic format, "What is the relationship between A and B," expressed in 1 of 5 variations to ensure homogeneity for easier analysis. For each question, we provided GPT-4 with ground truth data, including the query, relevant variables, and linear regression results. GPT-4 was then given LITURAt's response from its local dataset module and asked to rate the accuracy of the agent's answer on a 0-to-5 scale based on predefined guidelines shown in Textbox 1.

Results

Consistency

Table 1 shows the results of our consistency experiments. Both tests gave results over 90% mark.

Table . Consistency results.

Experiment	Result
Internal	94.8%
External	91.9%

Accuracy

Table 2 shows the result of the accuracy tests. The result from the accuracy evaluation demonstrates the potential of this approach. GPT-4 rated 80.3% (171/213) as entirely correct with most of the remainder being classified as mostly correct. Whether GPT-4 rated a response as “comprehensive” or not seems to depend on the level of detail and the requested level of detail was not specified or given to GPT-4 during the test.

Table . GPT-4 grading results.

Rating	Count	Frequency
1	4	0.018779
2	15	0.070423
3	23	0.107981
4	121	0.568075
5	50	0.234742

Discussion

Principal Findings

This investigation aimed to create an AI agent to aid the scientific process by integrating previous results in the literature with novel results from a new dataset. The results presented here highlight the potential of using AI-driven agents like LITURAt to bridge the gap between raw data and actionable insights in scientific research. By combining an LLM-powered system with a multistep tool-based approach, we were able to demonstrate both the flexibility and accuracy of this system in answering complex research questions derived from local datasets. Moreover, the consistency results—over 90% in both internal and external contexts—indicate that LITURAt can reliably produce stable outputs when faced with identical or similarly phrased questions. These findings suggest that, with further refinement, such systems could significantly enhance the efficiency of data interpretation, making scientific knowledge more accessible and usable across varying levels of expertise.

The findings from our study align with the growing body of research demonstrating the utility of AI-driven systems in scientific data analysis, particularly in enhancing accessibility and efficiency. Recent advances in LLMs have shown impressive capabilities in natural language processing tasks, from text generation to domain-specific question answering. However, much of the previous work has focused on static text sources, leaving a significant gap in their ability to handle complex, multimodal datasets like those common in scientific research. Studies have pointed out the limitations of LLMs in managing raw data, noting their propensity for inaccuracies or “hallucinations” when lacking sufficient domain-specific context. By incorporating agent-based architectures and dynamic data retrieval processes, LITURAt addresses this gap, providing more reliable and tailored responses by drawing directly from live datasets and relevant scientific literature.

Moreover, the introduction of a tool-based approach, which abstracts dataset interactions through specialized modules, represents an advancement over traditional search and retrieval methods commonly used in scientific applications. The capacity

XSL•FO
RenderX

of LITURAt to use a "plan and solve" framework mirrors other innovations in AI research, such as the development of task-specific agents for complex problem-solving. This approach offers a more structured and interpretable framework, allowing LLMs to systematically approach multivariable questions in a way that traditional retrieval-based systems cannot. In doing so, our results contribute to a growing field that seeks to augment human-driven research with AI-powered tools capable of deep data analysis, reinforcing the idea that such hybrid systems will become crucial components of future scientific workflows. This integration of AI and human expertise holds significant promise for democratizing access to scientific knowledge, reducing barriers to data interpretation, and expanding the impact of research across disciplines. One of the most promising observations from this study was the way our system was able to scale up to more complex questions. The system could be asked for a simple relationship between A and B, but it could additionally answer a more complex related question such as determining if the relationship between A and B was stronger than the relationship between C and A. The ability to break larger tasks into smaller tasks and solve them step by step allows the system to tackle a wide variety of questions.

While the results of this study demonstrate the potential of LITURAt, several limitations must be acknowledged. First, the accuracy of the system heavily depends on the quality of the underlying dataset and variable dictionary, meaning that errors in data labeling or incomplete data could lead to misleading or incorrect results. Moreover, although the "plan and solve" approach improves performance in multivariable analyses, the system's stability decreases when handling more complex queries involving 5 or more variables, limiting its scalability for larger datasets or more intricate analyses. Another limitation is the reliance on pretrained language models, which, despite their capabilities, are still prone to inaccuracies, particularly in domain-specific contexts where factual precision is critical. Although LITURAt uses external literature to validate findings, the summarization of PubMed abstracts is itself subject to the limitations of LLMs, including potential biases or oversimplifications in how scientific information is interpreted and conveyed.

In addition, the system's performance was evaluated primarily using the T-500 dataset, a specific subset of the broader T-1000 dataset. As such, the generalizability of these findings to other types of datasets, particularly those with different structures or domains, remains uncertain. The reliance on Mixtral8 × 7b, a model chosen for its balance of computational efficiency and accuracy, also raises questions about whether more powerful models could yield better results, albeit at a higher computational cost. Last, while the consistency metrics are encouraging, the system's ability to handle nuanced or ambiguous questions still requires further testing and refinement. These limitations suggest that while LITURAt holds significant promise, further optimization and broader testing across diverse datasets and contexts are necessary to fully realize its potential.

Future Works

Several potential enhancements could improve system performance and reliability. First, integrating a rating mechanism for abstract summarization could prioritize more trustworthy sources based on criteria such as journal impact or author credentials. This would be particularly valuable in resolving disagreements between local results and published findings or inconsistencies across publications. In this study, linear regression was used to model relationships between variables. Future iterations could incorporate more sophisticated models to better capture complex relationships, enhancing analytical precision. Moreover, introducing an intermediate summarization step—where the LLM extracts only the most relevant information from statistical results—could reduce the buffer size in the main agent loop, improving stability for more complex tasks. The system architecture could also be scaled to incorporate multiple local datasets and literature repositories, providing more comprehensive and holistic results. Since the system's modular design allows parallel execution of subsystems, this enhancement would require minimal architectural modifications and would not significantly impact runtime on capable systems. To further optimize performance, a mixed-model approach could be used: advanced models for critical computations and simpler models for basic tasks such as summarization. This strategy would enable better parallelization, reduce computational effort, and accelerate response times, enhancing overall user experience.

Conclusion

In conclusion, this work has demonstrated the potential of a novel architecture that empowers both researchers and nonexperts to explore relationships within scientific datasets. LITURAt leverages the power of LLMs in combination with an agent-based system, allowing users of all backgrounds to interact with complex scientific data in a user-friendly manner. Our findings show that LITURAt not only exhibits strong consistency, ensuring reliable results, but also delivers accurate answers to a significant majority of user queries, further validating the viability of LLM-powered agents in extracting meaningful relationships from scientific datasets.

Moreover, the system shows promise in handling increasingly complex questions by automatically decomposing intricate queries into smaller, more manageable steps, broadening the scope of inquiries it can address. While challenges remain, particularly regarding model stability for more complex tasks and the limitations of the toolset, LITURAt represents a significant step forward in making complex scientific data accessible to a wider audience. These advancements pave the way for future systems that will further democratize access to scientific knowledge, enabling individuals from various fields and expertise levels to gain deeper insights from their data.

Abstract

Background: The use of natural language processing (NLP) in mental health research is increasing, with a wide range of applications and datasets being investigated.

Objective: This review aims to summarize the use of NLP in mental health research, with a special focus on the types of text datasets and the use of social determinants of health (SDOH) in NLP projects related to mental health.

Methods: The search was conducted in September 2024 using a broad search strategy in PubMed, Scopus, and CINAHL Complete. All citations were uploaded to Covidence (Veritas Health Innovation) software. The screening and extraction process took place in Covidence with the help of a custom large language model (LLM) module developed by our team. This LLM module was calibrated and tuned to automate many aspects of the review process.

Results: The screening process, assisted by the custom LLM, led to the inclusion of 1768 studies in the final review. Most of the reviewed studies (n=665, 42.8%) used clinical data as their primary text dataset, followed by social media datasets (n=523, 33.7%). The United States contributed the highest number of studies (n=568, 36.6%), with depression (n=438, 28.2%) and suicide (n=240, 15.5%) being the most frequently investigated mental health issues. Traditional demographic variables, such as age (n=877, 56.5%) and gender (n=760, 49%), were commonly extracted, while SDOH factors were less frequently reported, with urban or rural status being the most used (n=19, 1.2%). Over half of the citations (n=826, 53.2%) did not provide clear information on dataset accessibility, although a sizable number of studies (n=304, 19.6%) made their datasets publicly available.

Conclusions: This scoping review underscores the significant role of clinical notes and social media in NLP-based mental health research. Despite the clear relevance of SDOH to mental health, their underutilization presents a gap in current research. This review can be a starting point for researchers looking for an overview of mental health projects using text data. Shared datasets could be used to place more emphasis on SDOH in future studies.

Introduction

Natural language processing (NLP) has emerged as a valuable tool in mental health research, offering innovative ways to extract and analyze information from various sources. Studies have shown the feasibility of using NLP in extracting evidence of online gaming and internet use from electronic health records (EHRs) in adolescent mental health patients [1]. NLP applied to clinical notes has been found to more accurately identify mental illness and substance use among people living with HIV compared to structured EHR fields alone [2]. Furthermore, NLP in healthcare enables the transformation of complex narrative information into valuable products like clinical decision support and adverse event monitoring in real-time via EHRs [3,4].

Outside of EHRs, NLP techniques have been used to make inferences about individuals' mental states based on their social media posts [5]. Additionally, NLP, coupled with machine learning approaches, has shown promising performance in tasks such as text classification and sentiment mining in mental health contexts [6]. The application of NLP extends to identifying work-related stress among health professionals, highlighting its versatility in diverse health care settings [7].

In the context of mental health disorders like schizophrenia, schizoaffective disorder, and bipolar disorder, NLP applied to

XSL•FO
RenderX

EHRs offers opportunities to create large datasets for research purposes [8]. Furthermore, NLP has been used to increase prediction accuracy and reduce subgroup differences in personnel selection decisions, showcasing its value in improving decision-making processes [9].

At the same time, getting access to text datasets for NLP analysis is challenging for many researchers. Many of the datasets have strict privacy and personal data protection policies restricting access to the data for third-party researchers. This hinders research and introduces the problem of reproducibility since the results of the studies cannot be verified by unaffiliated investigators. One of the aims of this review is to compile a collection of datasets that are available to the mental health research community, which, in turn, may facilitate research in the field of mental health.

Another potential problem with research using NLP for mental health is insufficient consideration of social determinants of health (SDOH) information during the analysis. The association between social determinants and mental health outcomes is well-established, with factors such as poverty, inequality, stigma, discrimination, and social exclusion identified as significant contributors to mental health burdens [10,11]. NLP has become a valuable tool for extracting SDOH from sources like clinical notes, social media, and EHR in health care research [12-15]. Evaluating the use of SDOH in NLP projects for mental health is another goal behind this review.

To our knowledge, no previous study has examined the range of NLP datasets and the inclusion of SDOH data in research projects that use NLP for mental health. We have opted for a scoping review following the guidelines outlined by Arksey and O'Malley [16]. The goals of this scoping review are to review and summarize the literature on (1) the variety of mental health areas that leverage NLP, (2) information on the types of text datasets used in these projects and whether they are sharable, and (3) the extent to which SDOHs are used or investigated in these projects.

A novel aspect in this scoping review is the use of large language models (LLMs), a subfield of generative artificial intelligence (AI), to automatically parse a large volume of citations to find relevant studies and extract information under the minimal supervision of a human reviewer. A recent statement by the National Institute for Health and Care Excellence highlights the potential of AI in the systematic review process automation [17].

Methods

Study Design

This study was created and revised following the recommendation of PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) and updated JBI (formerly known as Joanna Briggs Institute) guidance for the conduct of scoping reviews [16,18-20]. The completed PRISMA-ScR checklist can be found in Multimedia Appendix 1.

Inclusion and Exclusion Criteria

All publications were considered if they did not meet one or more of the exclusion criteria. Citations were excluded if:

- They did not use any type of NLP, such as transformers, pattern-matching (eg, regular expressions), ChatGPT, GPT-3, Bidirectional encoder representations from transformers, Llama, Mistral, other LLMs, latent Dirichlet allocation and latent semantic analysis, deep learning or machine learning applied to text, and similar.
- They were not focused on one of the mental health areas, such as psychology, well-being, psychiatry, social work, substance abuse, marriage therapy, addiction therapy, suicide, grief, bereavement, trauma, stressful life events, or counseling.
- They were review papers (systematic, scoping, literature, narrative, and other type of reviews), conference papers, or book chapters.
- They were not related to human health or well-being.
- PDF file of the full-text publication could not be located automatically using Covidence (Veritas Health Innovation), EndNote (Clarivate), and Zotero (Corporation for Digital Scholarship).

Search Strategy

The initial search was conducted in September 2024 in PubMed, Scopus, and CINAHL Complete databases using title and abstract search filters. The search strategy (designed by DAS and JSO) was broad enough to capture different NLP and machine-learning methods related to mental health. Textbox 1 presents the search query for the databases.

Textbox 1. Search strategy for PubMed and Scopus.

Screening and Extraction Process: LLM Assistance

All citations were uploaded to Covidence, which was used to track the progress of the project in lieu of the protocol. The screening and extraction process took place in Covidence. The specific method we used to conduct this review was automating the process of screening and extraction with the help of the LLM module for Covidence that we developed. The process of using LLM for screening and extraction is depicted in Figure 1.

Figure 1. LLM add-on assistant in Covidence screening. LLM assists in the abstract screening, full-text screening, extraction, and document drafting phases. Both human and LLM screen and/or extract data using a subset of abstracts/full texts, human compares their results and reaches a consensus ("LLM consensus" in the figure), and the benchmarks of both—human and the LLM—against this consensus are recorded. LLM: large language model.

Our LLM module works by interacting with Covidence using R scripts with the Selenium automation package [21]. Our scripts, which can run both locally or on a server, pass content between Covidence and an Azure OpenAI LLM (Microsoft Corporation) using the application programming interface wrapped in the Python "openai" library [22]. The models used in this study were GPT-4o and GPT-4o-mini. Once the model generates the response, our add-on module automates actions in Covidence, such as clicking the Include/Exclude buttons. Our automation scripts require a PDF file of the full text to be uploaded into Covidence for full-text screening and extraction. The LLM module supports non-English languages natively. Our software code used in this module is still under development and has not yet been made public; however, the LLM prompts for each phase of the review are provided in Multimedia Appendix 2. A similar approach was described in our recent paper on the utility of LLMs in literature reviews [23].

The resulting process can be described as follows. Each of the three main stages of review in Covidence (abstract screening, full-text screening, and extraction) included (1) a calibration phase, where a human reviewer (DAS) experienced in conducting scoping and systematic reviews screened a small sample of abstracts or full-text studies to get a deeper understanding of inclusion criteria and extraction categories; (2) we then created a prompt for the LLM and tested the LLM performance on another sample of abstracts or full texts; and (3) three repeated requests to the LLM with the same prompt were automated using software scripts, and the majority vote principle was used to determine the LLM vote (eg, LLM votes for an abstract: "include," "exclude," "include" means LLM final vote is "include"). Out of these three requests, two were made using GPT-4o-mini and one using more powerful GPT-4o for screening; all three requests used GPT-4o-mini for extraction to cut application programming interface costs.

During the benchmark, a human reviewer (DAS) first compared his votes against the LLM votes to produce a new reference set of labels (called "human-LLM consensus"). This step is required because LLM can detect cases missed by a human. Then, both the initial human reviewer's (DAS) and LLM votes were measured against the human-LLM consensus labels. Extraction precision was measured using a simplified benchmark where the LLM results on 30 publications were checked by a human reviewer (DAS) for precision only. The benchmarks are provided in Multimedia Appendix 3.

Data Extraction Categories

The data charting form for extraction was designed by human experts (DAS and JSO) and adopted into the LLM prompt to collect the following primary information:

- Author, year, title
- Country or US state (if it is in the United States) where the study was conducted or first author's affiliation location
- NLP method that was used (generally described in the Methods section), for example, recurrent neural network,

XSL•FO
RenderX

convolutional neural network (CNN), random forest, deep learning, pattern-matching, ChatGPT, and GPT-4
- What mental health problem or problems were investigated in the paper?
- What is the mental health area or specialty that best represents this paper (psychology, well-being, psychiatry, social work, substance abuse, marriage therapy, addiction therapy, suicide, grief, bereavement, trauma, stressful life events, counseling, other)?
- Variables used in the study related to demographics, for example, age, race, ethnicity, gender, sex at birth, marital status, relationship status, and sexual orientation
- Variables used in the study related to SDOH, such as none mentioned, urban or rural, transportation availability, access to health care, incarceration, income, poverty, health insurance, language knowledge, living arrangement, children or childless, family, adverse childhood experiences, housing, education, religion, stress, traumatic events, and stressful life events
- Name of the text dataset that was used in the study
- What is the type of this text dataset (eg, clinical notes, therapy session notes, social media platforms, web forum, other)?
- What information or variables were extracted from this text dataset?
- Is it mentioned in the paper if other researchers can get access to this text dataset?
- If it is mentioned in the paper that it is possible to get access to this text dataset, what kind of access is it (eg, public, public with restrictions, private, not given, not mentioned)? If the dataset can be found on the web or in well-known competition platforms like Kaggle, it is considered public
- If it is mentioned in the paper that access to this text dataset is public or public with restrictions, what is required to get access (can be training, signing a use agreement, emailing the author, or similar)?
- A URL to the text dataset, if provided. The returned URL was validated using an R script to test if an "OK" reply is returned by the server.

Extracted results were synthesized using a table with a complete list of all citations, using maps for location information and column plots displaying frequency statistics for other extracted variables.

Data Cleaning and Paper Drafting

ChatGPT with the GPT-4o model was used to clean the extraction data, specifically, format the case, remove duplicates, and sort entries into higher-level groups. Scite.ai (Research Solutions) was used to draft parts of the *Introduction* and *Discussion* sections, while ChatGPT was used to draft the abstract and *Results* section of this paper by generating text and R code snippets. All output generated by the LLMs was verified, reviewed, and edited by the authors. Due to the significant number of reviewed citations, publication information, such as authors, title, and DOI, is provided in Multimedia Appendix 4.

Results

During the abstract and title screening phase, 8197 studies were excluded based on the exclusion criteria, leaving 3681 studies for retrieval. Out of these, 1649 studies could not have their full-text PDFs retrieved using automated tools such as Covidence or EndNote. Consequently, 2032 studies were assessed for eligibility. Of these, 264 studies were excluded for the following reasons: 217 studies were not focused on one of the mental health areas, 39 studies did not use any NLP methods, 1 study was too brief and lacked sufficient information, and 2 studies were review papers (systematic, scoping, literature, narrative, or other types of reviews), and 5 additional duplicates were identified during full-text screening. The final review included 1768 studies. The flow diagram of the scoping review process is shown in Figure 2.

XSL•FO
RenderX

Figure 2. Shows the flow diagram of the scoping review process. Initially, 12,901 studies were identified from various databases and registers: 6791 from Scopus, 5500 from PubMed, and 610 from CINAHL Complete. After the removal of 1023 duplicates by Covidence, 11,878 studies were retained for screening.

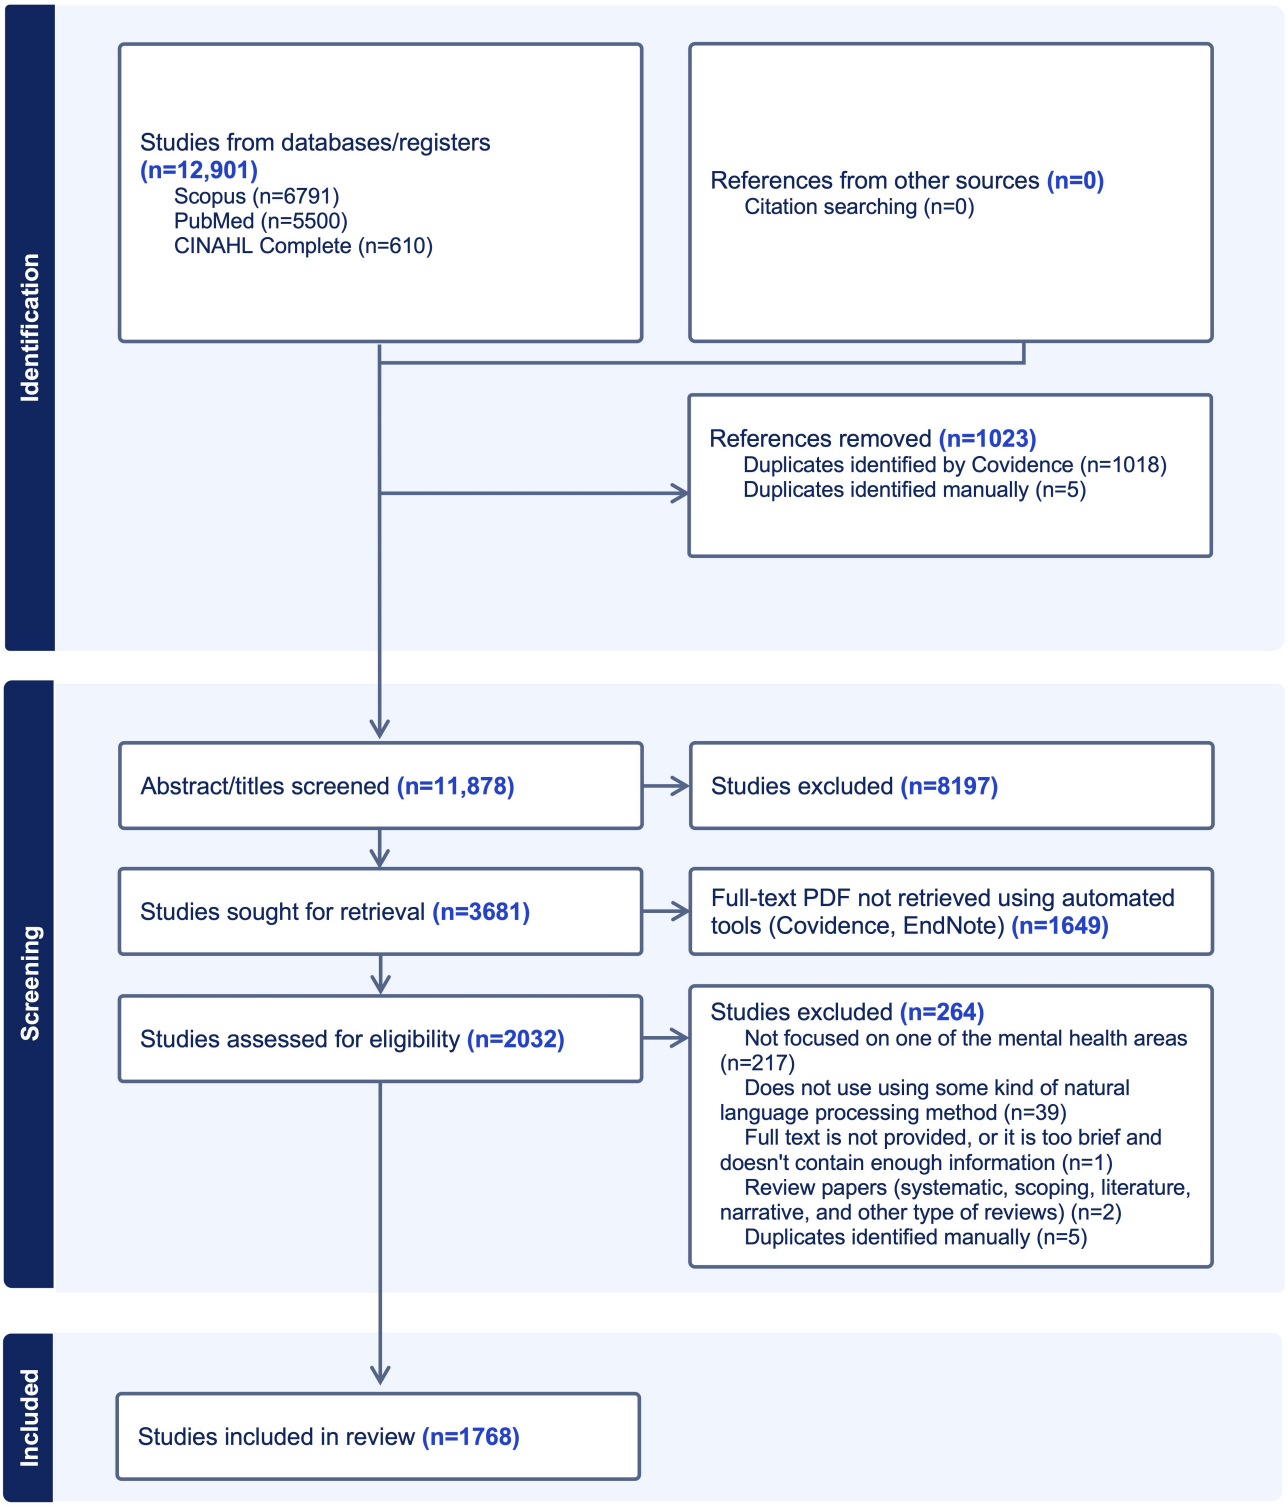

Figure 3 illustrates the geographic distribution of 1768 studies reviewed in this analysis. Most studies originated from the United States, with 624 (35.3%) studies. China contributed 197 (11.1%) studies, followed by the United Kingdom (n=167, 9.4%) and India (n=120, 6.8%).

Canada contributed 51 (2.9%) studies. Other notable contributors include Japan with 49 (2.8%) studies, Spain with 39 (2.2%) studies, Australia with 38 (2.1%) studies, South Korea (n=27, 1.5%), Germany (n=26, 1.5%), the Netherlands (n=25, 1.4%), Saudi Arabia (n=24, 1.4%), Italy (n=22, 1.2%), and France (n=21, 1.2%), and several other countries each contributing between 1 and 16 studies.

Within the United States, Massachusetts led the contributions with 88 (14.1%) studies, followed by California with 66 (10.6%) studies. New York contributed 55 (8.8%) studies, while Pennsylvania provided 43 (6.9%) studies. Ohio and Illinois each

XSL•FO
RenderX

contributed 21 (3.4%) studies. Other states, such as Utah, Washington, and Texas, contributed 20 (3.2%), 19 (3%), and 18 (2.9%) studies, respectively. Michigan and Florida each added 16 (2.6%) studies, while Maryland, Georgia, and Indiana each contributed 15 (2.4%) studies. Tennessee, Minnesota, and Connecticut each contributed 14 (2.2%) studies, followed by New Jersey, Oregon, and South Carolina with 13 (2.1%) studies each. Other states contributed fewer than 10 studies.

Figure 3. (A) Number of publications by country of origin. (B) Number of publications by state in the United States. Darker shades represent locations with more publications. Grey color means the absence of publications from a given location.

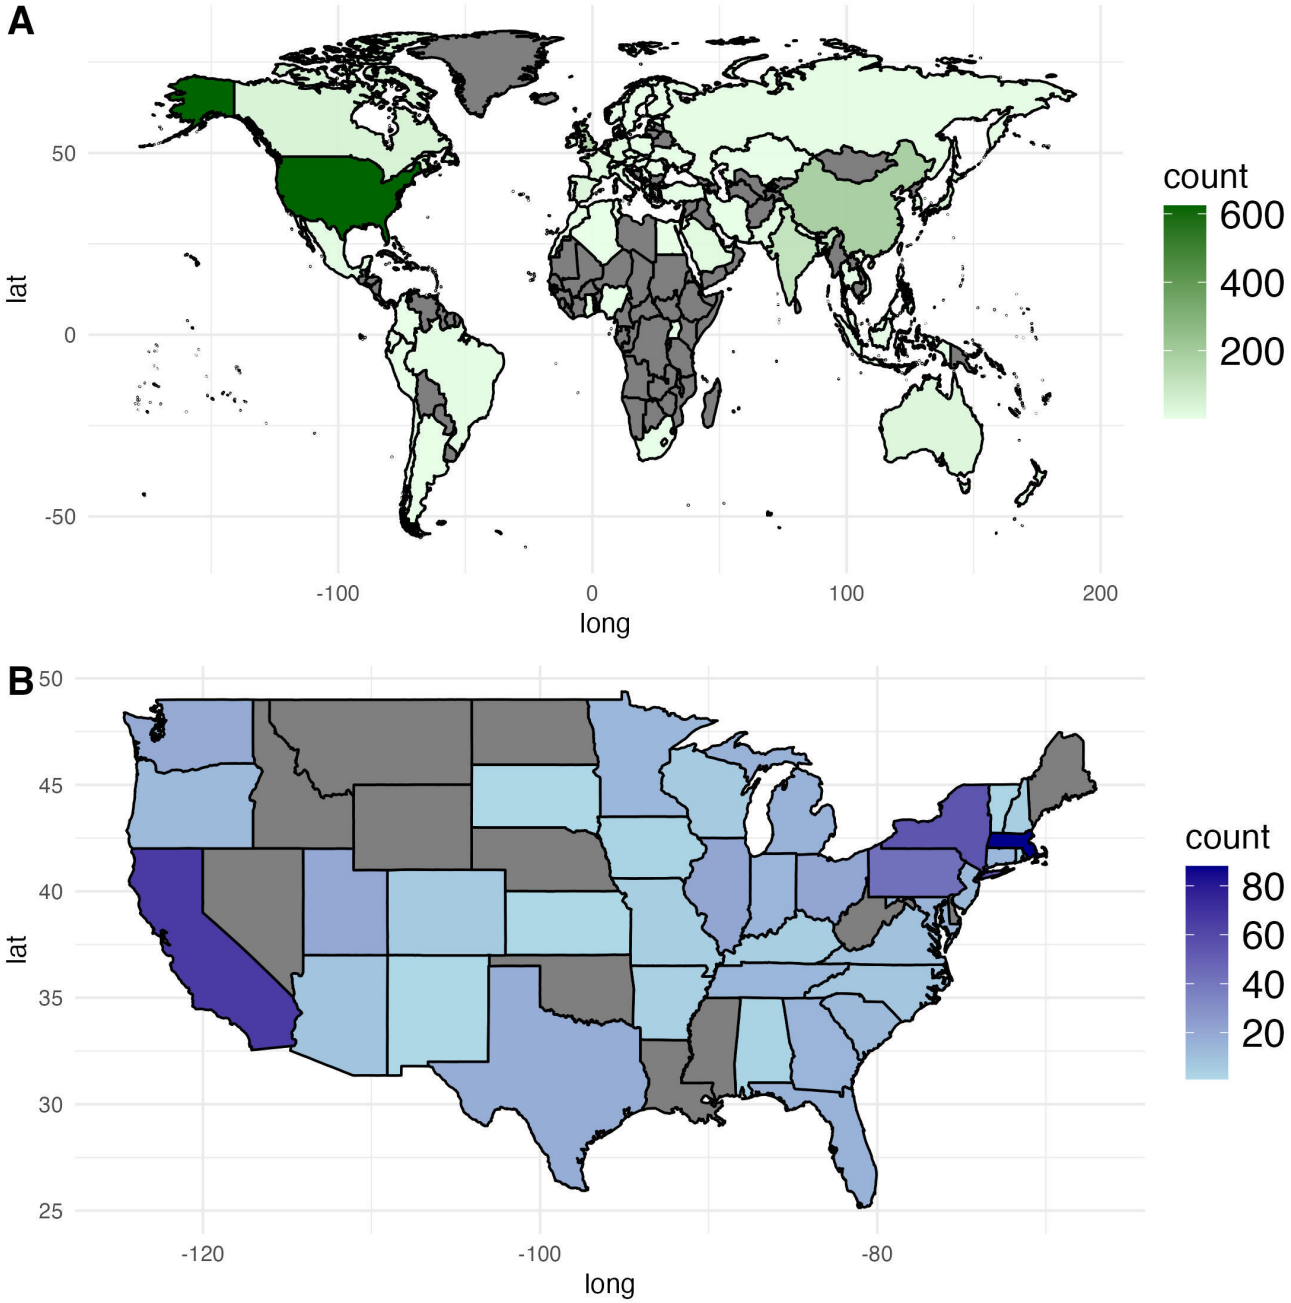

Figure 4A illustrates the various mental health topics covered in the reviewed papers. The most frequently discussed topic is depression, which is covered in 518 (29.3%) papers. This is followed by suicide, featured in 273 (15.4%) papers, and anxiety, discussed in 202 (11.4%) papers. Substance use disorder is also a significant topic, appearing in 166 (9.4%) papers, while mental health (unspecified) is mentioned in 120 (6.8%) papers.

Other notable topics include stress (n=62, 3.5%), dementia (n=59, 3.3%), posttraumatic stress disorder (n=53, 3%), and schizophrenia (n=53, 3%). Bipolar disorder appears in 43 (2.4%) papers, and domestic violence is discussed in 29 (1.6%) papers. Eating disorders are mentioned in 26 (1.5%) papers, while cyberbullying and cancer-related topics are covered in 23 (1.3%) and 22 (1.2%) papers, respectively. Self-harm is discussed in 21 (1.2%) papers, and loneliness is covered in 19 (1.1%) papers.

Additionally, other mental health issues such as attention-deficit/hyperactivity disorder (n=18, 1%), psychosis (n=18, 1%), autism spectrum disorder (n=17, 1%), and diabetes-related mental health issues (n=13, 0.7%) are also represented. Topics such as pain (n=12, 0.7%) and fear (n=11, 0.6%) are covered, along with personality traits (n=11, 0.6%)

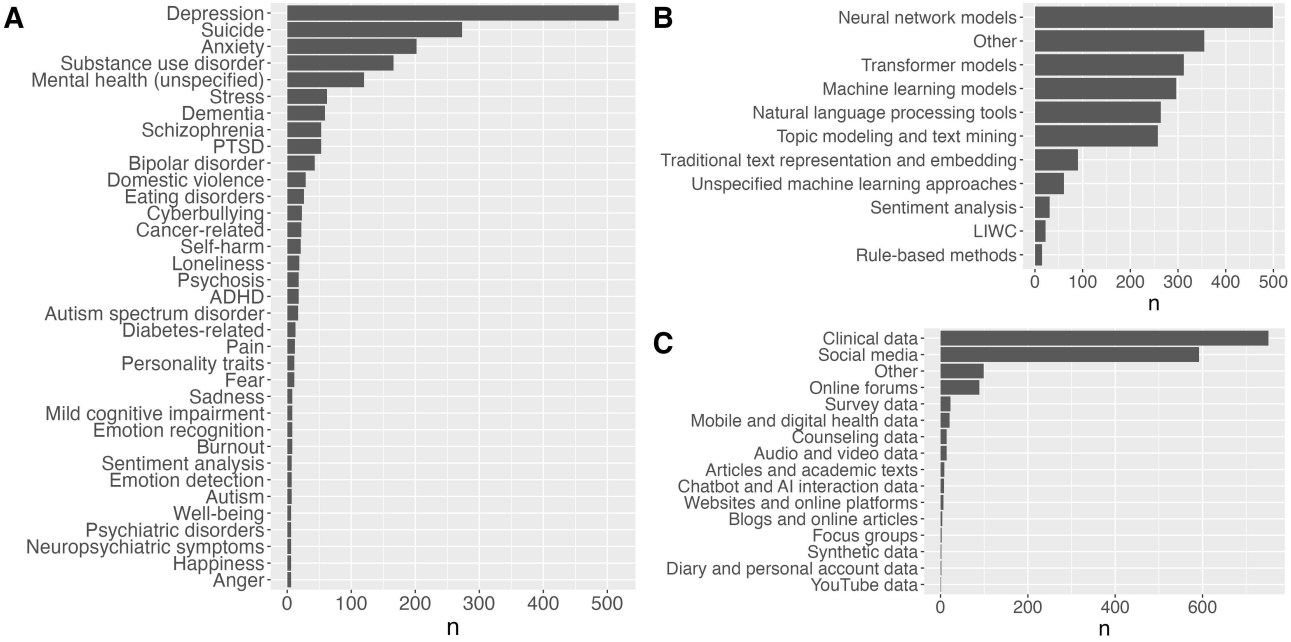
XSL•FO
RenderX

and burnout (n=8, 0.5%). A variety of other mental health topics appear in 1 - 7 papers.

Figure 4B illustrates the various NLP methodologies and tools discussed in the papers. The most frequently mentioned are neural network models (n=499, 28.2%), which include examples such as CNN, long short-term memory (LSTM), Bidirectional LSTM-CNN (BI-LSTM-CNN), gated recurrent unit, and recurrent neural network. Other machine learning models are discussed in 289 (16.3%) papers, highlighting the use of random forest, support vector machine, regression models, and gradient boosting trees.

Transformer models appear in 312 (17.6%) papers, examples include Bidirectional encoder representations from transformers, GPT-3, LLAMA-2, and Roberta. NLP tools are featured in 264 (14.9%) papers, which use tools such as Spacy NLP Library, Stanford CoreNLP, and GATE for processing and analyzing text data. Topic modeling and text mining are discussed in 258 (14.6%) papers, using techniques such as latent Dirichlet allocation, structural topic modeling, and biterm topic modeling for extracting themes and patterns from text data.

Traditional text representation and embedding methods are mentioned in 90 (5.1%) papers, including methods such as term frequency-inverse document frequency, Word2Vec, and N-gram representation. Unspecified machine learning approaches appear in 61 (3.4%) papers, while sentiment analysis is discussed in 31 (1.8%) papers. Finally, linguistic inquiry and word count (LIWC) is mentioned in 22 (1.2%) papers, showcasing tools such as LIWC15 Text Analysis and LIWC Dictionaries. Rule-based methods are included in 15 (0.8%) papers.



Sentiment analysis is discussed in 30 (1.9%) papers, with approaches such as Valence Aware Dictionary and sEntiment Reasoner, aspect-based sentiment analysis, and text sentiment analysis. Rule-based methods are featured in 15 (1%) papers, using approaches such as pattern-matching and lexicon-based NLP to perform specific text-processing tasks based on predefined rules. Finally, Bayesian models are mentioned in 3 (0.2%) papers, where techniques, for example, Bayesian networks and Bayesian logistic regression, are applied, indicating a more niche focus on this approach within the reviewed literature. The other category, covered in 355 (20.1%) papers, represents a wide range of techniques beyond the most common methods, including various specialized or less frequently used approaches.

Figure 4C presents an overview of the types of datasets used in the reviewed studies. The most commonly used dataset type is clinical data, which appears in 751 (42.4%) papers, followed by social media datasets with 592 (33.4%) papers. Web forums have some representation as well, with 89 (5%) papers, and the other category comprises 99 (5.6%) papers. Survey data is also notable, appearing in 23 (1.3%) papers, while mobile and digital health data is used in 21 (1.2%) papers.

Less frequently used datasets include counseling data (n=14, 0.8%), audio and video data (n=14, 0.8%), and chatbot and AI interaction data (n=8, 0.5%). The studies and academic texts category is represented in 9 (0.5%) papers, while websites and web platforms account for 7 (0.4%) papers. Blogs and web studies have 4 (0.2%) papers.

Other datasets, such as diary and personal account data and synthetic data, each appear in 2 (0.1%) papers, along with focus groups, which are represented in 3 (0.2%) papers. Finally, YouTube data is noted in 1 (<0.1%) paper, indicating niche areas of study or emerging methodologies within the broader field.

Figure 4. (A) Mental health outcomes studied in reviewed publications (mentioned in ≥5 citations). (B) NLP methods or tools used (mentioned in ≥5 citations). (C) Types of datasets used for analysis. The x-axis represents the number of publications featuring a given outcome (A), method (B), or dataset type (C). ADHD: attention-deficit/hyperactivity disorder; AI: artificial intelligence; LIWC: linguistic inquiry and word count; NLP: natural language processing; PTSD: posttraumatic stress disorder.

RenderX

Figure 5A presents a detailed overview of the demographic variables frequently used in the reviewed studies. Age is the most commonly extracted variable, appearing in 993 (56.2%) studies. Following closely is gender, featured in 863 (48.8%) studies. Other significant demographic variables include race (n=171, 9.7%) and ethnicity (n=161, 9.1%). Sex is documented in 114 (6.4%) studies, while marital status appears in 101 (5.7%) studies.

Less frequently reported variables include education (n=48, 2.7%), race or ethnicity (n=46, 2.6%), and insurance (n=26, 1.5%). Income is mentioned in 19 (1.1%) studies, with employment in 15 (0.8%) studies, relationship status in 13 (0.7%) studies, and occupation in 8 (0.5%) studies. More specialized demographic insights are provided by variables, for example, nationality (n=6, 0.3%), religion (n=4, 0.2%), and region (n=3, 0.2%). Additionally, niche variables such as aboriginal status, career, and socioeconomic status are noted, each appearing in 2 (0.1%) studies.

Figure 5B offers an overview of the SDOH variables used in the reviewed studies. The urban or rural status is the most frequently reported variable, appearing in 20 (1.2%) studies. Following closely is the deprivation index, included in 17 (1.1%) studies. Income is mentioned in 11 (0.7%) studies, underscoring its significance in assessing economic conditions.

It is important to highlight that demographic variables had a notable number of false positives during extraction, with a precision rate of 0.66, suggesting that the actual counts for gender and age may be significantly lower.

The relevance of access to health care and insurance is reflected in their occurrence in 9 (0.5%) and 8 (0.5%) studies, respectively. Education and socioeconomic status are recorded in 6 (0.4%) studies each, while housing is featured in 5 (0.3%) studies.

Less frequently reported variables include poverty and substance use, each appearing in 4 (0.3%) studies, as well as employment status and prior illness, each in 3 (0.2%) studies. Additional variables such as unemployment (n=2, 0.1%) and various specific factors—for example, domestic violence, drug involvement, and others—are noted in just 1 (0.06%) study each.

XSL•FO
RenderX

Figure 5. (A) Demographic variables used in the studies (with ≥3 mentions). (B) Social determinants used in the studies (≥2 mentions). The x-axis represents the number of publications featuring a given social determinant (A) or demographic variable (B). SDOH: social determinants of health.

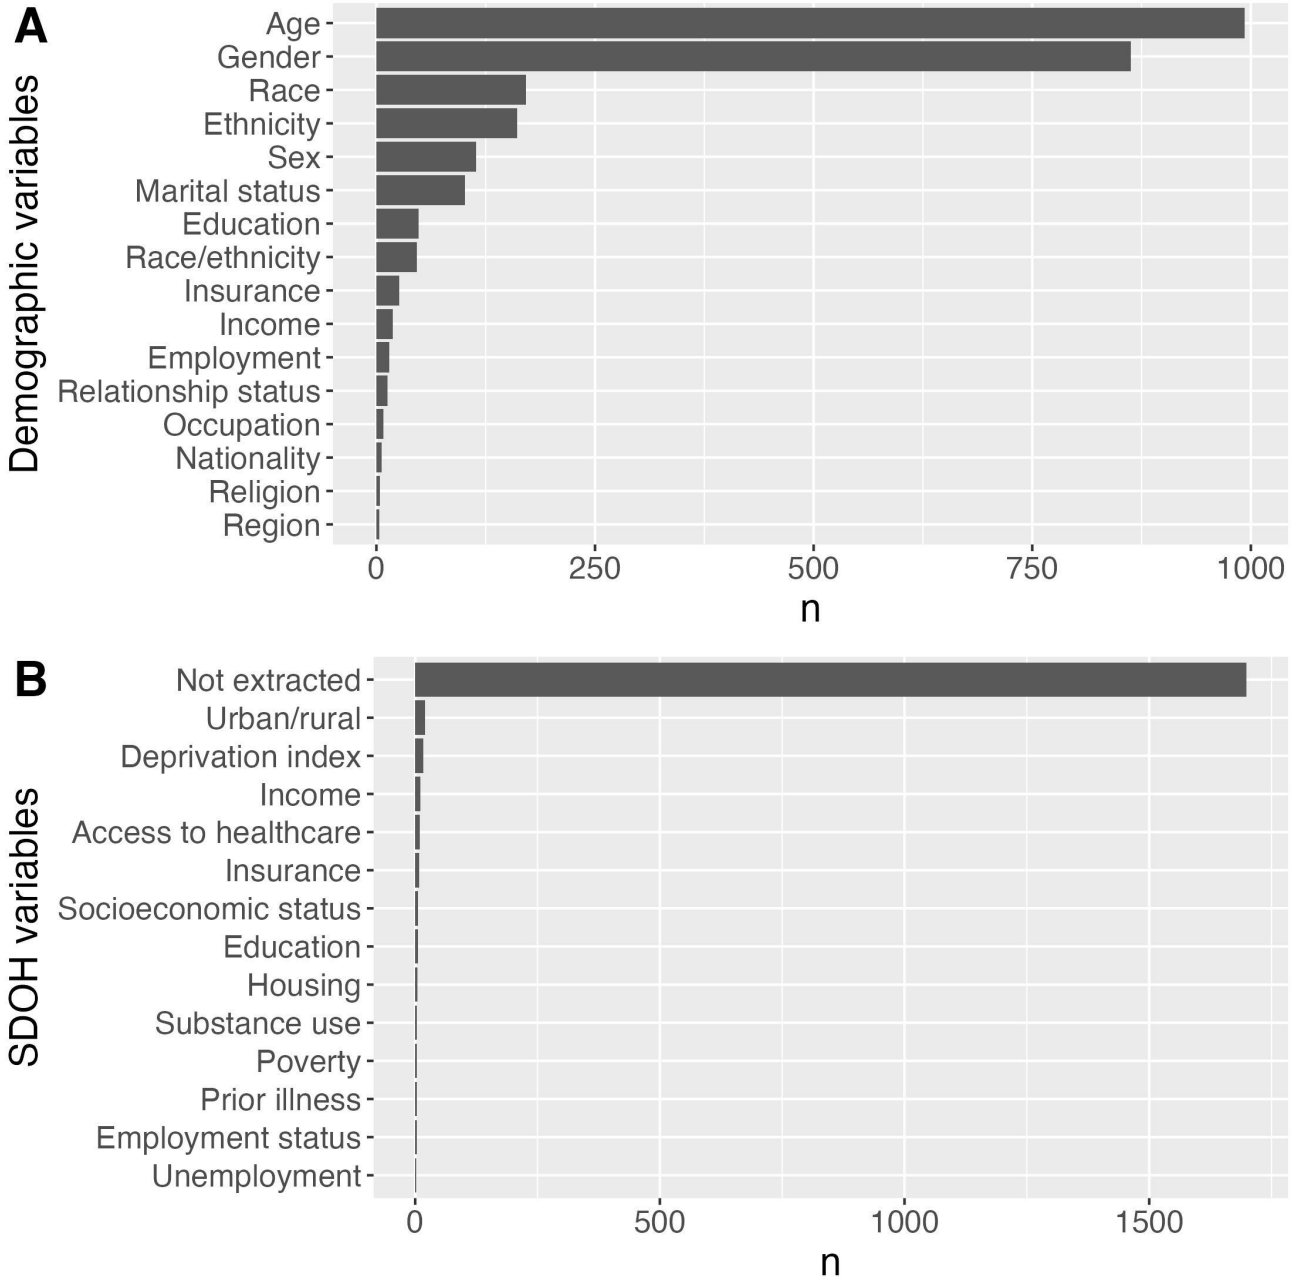

Table 1 shows the most frequently extracted information from the text datasets. The scope of extracted data includes information related to sentiments and emotions, health conditions, health symptoms, personality traits, violence and bullying, suicide indicators, user engagement (likes, shares), survey data, and language features, to name a few.

A significant majority of studies (n=911, 51.5%), did not clarify whether their datasets were accessible, while 857 (48.5%) studies included access information for their datasets. Regarding the specific levels of access, the vast majority of studies fell into the "unclear" category, with 1128 (63.7%) studies failing to provide explicit information about dataset accessibility. In contrast, 362 (20.5%) studies indicated that their datasets were publicly accessible, while 263 (14.9%) studies allowed public access with certain restrictions, thus enabling data use under specific conditions. Only a minimal number of studies categorized their datasets as private, with just 9 (0.5%) studies restricting access to particular individuals or groups. Additionally, 4 (0.2%) studies did not provide any information regarding their dataset access levels.

Additional information on the text datasets, access levels, links, and other extracted information can be found in Multimedia Appendix 4.

Discussion

Principal Findings

Our LLM-assisted scoping review revealed a wide range of projects related to mental health topics that use NLP. The United States was the dominant source of publications, with more than a third of all publications, but China, the United Kingdom, and India follow closely behind, reflecting the worldwide interest in the application of NLP to mental health problems. The United States has a significant concentration of funding and resources dedicated to mental health research, which is not as prevalent in low- and middle-income countries with financial constraints and inequities in health care resources [24,25]. The disproportionate share of high-income countries in our review is noted by other authors as “the 90:10 research gap,” where 90% of mental health research focuses on the 10% of the global population residing in high-income countries, including the United States [26].

XSL•FO
RenderX

Depression emerged as the top mental health problem investigated, reflecting the current trends: a study by Wang et al [27] using Google Trends data in the United States reported a 61% increase in depression prevalence from 2008 to 2018. Another study by Jonson et al [28] in Sweden observed a decline in depression prevalence among 85-year-olds, potentially influenced by rising trends in younger age groups. The topic of suicide was especially well represented in our sample, highlighting the fact that suicide mortality remains a significant global public health concern. This finding is echoed by studies indicating that suicide continues to be a notable contributor to mortality worldwide [29].

Artificial neural networks appear to dominate the landscape of tools used in NLP research, with transformer models catching up in the race. Artificial neural networks represent a large and versatile category of machine learning algorithms that typically require a significant amount of training data, whether supervised or unsupervised [30]. The self-organizing, self-learning, and parallel distributed information processing capabilities of neural networks have made them invaluable in pattern recognition, signal processing, and optimization problems [31]. Moreover, artificial neural networks are recognized for their versatility in solving nonlinear problems with multiple independent variables [32], including NLP tasks.

Clinical data and social media dominate the types of datasets that were used in the reviewed papers, showing two major avenues of NLP mental health research, one with medical records data and the other with using public social media platforms.

As for SDOH and demographic variables, there is considerable overlap between the two in the extracted data. Previous work suggests that demographic variables should be part of SDOH; for example, the commonly used variable marital status reflects the social connections, stage of life, and other important social implications for individuals' health [33]. The same can be said about age, the most frequently reported demographic variable. Research has shown that disparities in mental health outcomes persist across different age groups and are often linked to social stress, discrimination, and stigma [34]. These disparities can be exacerbated by obstacles to health care access based on factors such as ethnicity, sex, and occupation [35].

A narrative review by Shokouh et al [36] explores the idea that demographic variables could be considered an essential part of SDOH. A similar solution is to think of them as combined "sociodemographic factors" [37], where both demographic and social factors play an equally important role.

This review suggests that social and demographic factors, besides gender and age, were rarely used in the studies, highlighting a significant gap that should be addressed in future work. In addition, a manual review of LLM outputs (see Multimedia Appendix 3 for benchmark) revealed that the demographic variables category had a high rate of false positivity, which suggests that gender and age were actually used even less frequently than our numbers indicate. Most commonly, they were reported in the introduction sections as important factors and ignored in the actual analysis.

The paucity of mental health NLP studies that consider SDOH is concerning, especially considering that these factors, including stress, marital status, race, gender-based discrimination, and many others, have been shown to impact mental health outcomes [38]. One of the challenges for mental health researchers is a lack of versatile NLP tools that would allow the extraction of attributes related to SDOH and demographics. For example, while NLP models for extraction of marital status and gender exist [39,40], few models can extract a big range of SDOH at once [41], making a subgroup analysis limited to select demographic attributes (eg, age and gender). Another solution could be to extract this information from structured data. However, this is often not feasible; for example, social media metadata rarely contain information about age, region, and other sociodemographic attributes, while EHRs that contain clinical notes do not routinely collect social information [41].

Our review method proved to be sensitive at detecting relevant citations and fetched our previous work on suicide, self-harm, opioid addiction, and other topics [42-50]. LLM performance in this review surpassed the performance of a single human reviewer during the screening phase, as evident from the screening benchmarks. Reviews conducted by more than one individual human could reduce selection bias but would require significant additional research effort. Based on the estimation methodology provided by Haddaway and Westgate [51], we estimate this effort to be approximately 3500 person-hours (ie, close to a year of work for two reviewers) to conduct a review of such scope. In addition, the LLM method allowed for the inclusion of non-English papers, as LLMs are multilingual, potentially reducing the language bias; however, the performance of OpenAI GPT can vary depending on the language and the task [52], and we did not benchmark the LLM performance in other languages.

Future work could be facilitated by this review, which revealed a considerable number of shared research datasets, including URLs for some. In fact, over 600 publications disclosed the datasets they used and the level of access as public or semipublic. Disclosure of dataset use is important in research because it increases reproducibility and facilitates collaborative secondary research using existing data. A recent publication has reported that over half of the studies in psychology could not be replicated [53], which is why it is crucial to be transparent about the datasets used and the NLP methods used. Moreover, making both the code and data available to the scientific community whenever possible or providing information on why access to data is restricted is also valuable. A dataset prepared for a specific study can be used in secondary research different from the original work and may help prevent redundant data collection. A 2024 crowdsourcing challenge on HeroX was specifically aimed to "demonstrate the power of data reuse in advancing human health by proposing an impactful secondary data analysis research project" and promoted the reuse of data that has already been published.

Finding data for research is always challenging. We hope that this review can serve as a stepping stone in mental health research that leverages NLP.

XSL•FO
RenderX

Limitations

We used LLMs, with prompts engineered using a small subset of studies, as assistants in this review project. Some extraction categories, such as demographic variables, had relatively lower accuracy, so the results of this extraction category should be taken with caution. Nevertheless, in this review, LLMs achieved remarkable results in other categories, making it possible to delegate time-consuming aspects of a literature review to the LLM, allowing researchers to spend more time on the supervision, benchmarking, and synthesis of the findings.

This study used a single human reviewer assisted by LLMs. Studies generally recommend a single-reviewer approach in some cases, such as rapid reviews [54]; however, we believe that the LLM approach could automate many of the mundane aspects of literature reviews, allowing human authors to redirect their effort toward the supervision and synthesis of the results.

Our method relies on the availability of PDFs for publications. A considerable number of papers did not have accessible PDF versions using the citation manager tools, for example, EndNote and Zotero. Thus, we had to exclude these papers from our analysis. However, we believe that the number of full-text citations that we obtained was large enough to get a statistical representation of the extracted categories and to support our observed findings discussed above.

Conclusions

This review highlights the range of projects using NLP for mental health areas, with depression and suicide being the most frequent topics under study. Social determinants were only used in a handful of papers, with traditional demographic variables, such as age and gender, being more frequent. The extracted information could be leveraged by other researchers pursuing text datasets for mental health research projects in specific areas.

Abstract

Background: Anxiety and depression are serious mental health conditions affecting millions of people worldwide; however, they are often underdiagnosed due to limited health care resources. Mobile games, with their widespread popularity and availability, offer a unique opportunity to use user-game interaction data for mental health screening.

Objective: This study aimed to explore whether swipe gesture interactions from mobile games can serve as indicators of anxiety and depression symptoms.

Methods: A total of 82 participants played 3 casual mobile games (puzzle, infinite runner, and object slicing games) for 15 minutes each and completed validated measures of anxiety (Generalized Anxiety Disorder-7; GAD-7) and depression (Patient Health Questionnaire-8; PHQ-8). Data were logged for each swipe event, and metrics were computed using statistical measures, yielding roughly 150 metrics per game. Spearman rank correlations were calculated between each metric and GAD-7 and PHQ-8 scores.

Results: Multiple swipe gesture metrics showed significant associations with both anxiety and depression scores. For the puzzle game, mean swipe speed correlated with PHQ-8 (ρ=−0.405; P<.001) and GAD-7 (ρ=−0.400; P<.001) scores. For the infinite runner game, mean variance in swipe end pressure showed moderate to strong negative correlation with PHQ-8 (ρ=−0.405; P<.001) and GAD-7 (ρ=−0.309; P=.007) scores. In the object slicing game, minimum swipe start position along the y-axis correlated positively with PHQ-8 (ρ=0.368; P<.001) and GAD-7 (ρ=0.370; P<.001) scores.

Conclusions: The findings from this exploratory study provide preliminary evidence supporting the feasibility of using swipe gesture interactions in mobile games as novel, engaging, and nonintrusive indicators of anxiety and depression.

mobile games; swipe gesture; anxiety; depression; mental health; game data; screening

Introduction

Background

Could a simple swipe interaction during mobile gameplay reveal hidden insights into our mental well-being? In this digital age, mobile phones have become ubiquitous and have engaged billions of people worldwide in mobile gaming activities. These activities generate vast amounts of data on user-game interactions that may offer insights into our underlying mental health. If these data can be harnessed purposefully, mobile games could serve as a widely accessible tool for screening symptoms of mental health disorders such as anxiety and depression. Symptoms of anxiety and depression are a global concern, affecting millions of individuals worldwide [1,2]. However, these conditions often go undiagnosed or untreated due to factors that include resource shortages, lack of trained professionals, societal stigma, and restricted access [3-6]. In response to these challenges, emerging research has begun to

XSL•FO
RenderX

increasingly pivot toward leveraging digital platforms such as mobile devices for screening the symptoms of anxiety and depression.

Previous research has examined the relationship between symptoms of mental health disorders and mobile device interactions. Particularly, data derived from smartphone use patterns including touch behavior, keyboard dynamics, and app use can be associated with symptoms of mental health disorders [7-11]. Early studies reported promising associations between typing speed, accuracy, and mood disturbances [12-16]. However, recent literature involving larger sample sizes has yielded mixed results [17]; for example, Ning et al [18] found that keyboard dynamics coupled with accelerometer data from smartphone typing interactions correlated primarily with cognitive performance rather than mood directly. Similarly, Braund et al [17] reported that adolescents with higher anxiety or depression symptoms tended to type slightly faster on smartphones, although this showed weak correlations in a large-scale study. However, Knol et al [19] demonstrated substantial relationships between typing patterns and affective symptoms (eg, anhedonia) in a clinical sample experiencing suicidal ideation. These mixed outcomes highlight the necessity of exploring additional, potentially complementary digital biomarkers.

Particularly, swipe gesture interactions during mobile gameplay present a promising alternative. Mobile games are highly engaging; fun to play; and, by their design, inherently test a variety of cognitive and psychomotor processes such as reaction times or reflexes, sustained attention and focus, hand motor coordination, and quick decision-making through precise touch gesture interactions, all of which can be influenced by anxiety and depression [20]. Given that impairments in these cognitive and psychomotor processes are often associated with symptoms of anxiety and depression [21,22], it seems reasonable to hypothesize that they can be captured through mobile game interactions. However, research on gesture patterns from mobile games and their relationship with symptoms of anxiety and depression remains largely unexplored [23], leaving several important questions unanswered. For instance, which category of mobile games can be effectively used or what game mechanics should be included to elicit game interactions pertinent to symptoms of anxiety and depression? Which gesture or swipe pattern metrics should be tracked? What is the minimum duration of data collection required? These unanswered questions regarding crucial design decisions highlight the need for an exploratory study to establish the foundation for this emerging topic and were the primary motivation behind this work.

To address these questions, we conducted an exploratory study with 82 participants using 3 casual mobile games (CMGs)—a puzzle game, an infinite runner game, and an object slicing game. These games were selected for their simplicity, while also being distinct enough in their design and swipe interactivity to allow for the examination of a range of cognitive and behavioral responses. This simplicity ensures that the games are accessible to a broad audience while potentially minimizing the effect of confounds such as previous gaming experience or gaming skill. As there is no consensus regarding specific swipe or gesture metrics, we adopted a broad approach by collecting a wide range of swipe gesture attributes including swipe speed, swipe positions, pressure applied during the swipe, and more.

The primary aim of this exploratory study was to determine whether subtle swipe gesture interactions during mobile gameplay can serve as behavioral biomarkers of anxiety and depression symptoms. Specifically, we examined correlations between standardized mental health questionnaires such as Generalized Anxiety Disorder-7 (GAD-7) and Patient Health Questionnaire-8 (PHQ-8) and a broad range of swipe metrics. Our findings revealed significant associations between several swipe data metrics and symptoms of anxiety and depression. Key metrics such as swipe speed, swipe pressure variability, and swipe starting positions were significantly correlated with both anxiety and depression scores across the 3 games. These results suggest that subtle patterns in swipe gesture interactions during mobile gameplay can possibly provide meaningful insights into an individual's mental health. The findings from this study establish a foundational groundwork that speaks to the potential of mobile games as a novel, scalable, accessible, and highly engaging tool to support and enhance traditional methods of screening anxiety and depression.

Related Works

This research topic is still an emerging field, with fewer than 5% of the studies that have looked at gaming technologies as potential tools for mental health focused on their value in detecting symptoms of anxiety and depression [23,24]. Digital technologies have emerged as promising tools for mental health screening over the past decade [25]. These methods seek to exploit the potential of automatically generated and aggregated data from smartphones, wearables, and other sensory devices to measure digital behavioral markers of mental health conditions [26-30]. Despite these advances in leveraging general digital and smartphone behaviors as digital biomarkers or interventions for mental health, the potential of mobile games remains largely unexplored. Given that this research field is still in its infancy, we first present an overview of the broader literature on mobile games and mobile touch interactions in relation to symptoms of mental health disorders.

Due to the huge popularity of mobile games along with their effects on cognitive functioning and well-being, research on their potential to track symptoms of mental health disorders has attracted growing interest. For example, researchers used a mobile game called Sea Hero Quest [31] to track and assess symptoms of dementia by collecting spatial navigation data from over 4.3 million players. This project remains one of the largest studies on spatial navigation deficits and provided compelling evidence that proved that this cognitive ability begins to decline from the age of 19 years with significant differences between men and women.

Building on the premise of mobile gameplay, Anzulewicz et al [13] demonstrated the potential of using 2 tablet games to detect motor abnormalities in children with autism spectrum disorder (ASD). They analyzed gesture patterns using machine learning and were able to differentiate between children with ASD and typically developing children with 93% accuracy. Motor patterns such as movement kinematics and gesture force were found to

XSL•FO
RenderX

be core features of ASD that could be identified using mobile gameplay. The principles behind this study of analyzing gesture patterns can thus be extended in the context of anxiety and depression where motor and other cognitive impairments are also common. For instance, individuals with anxiety often exhibit psychomotor agitation, while those with depression experience psychomotor retardation.

An interesting study by Dechant et al [32] explored the use of games for assessing social anxiety. The gaming task involved participants moving toward a target location and answering an attention test in the presence of nonplayable characters. The key findings revealed that players with higher social anxiety scores tended to stay further away from nonplayable characters and exhibited larger errors in their estimates of the target location similar to avoidance behaviors shown in the real world. Although this study used video games, these results demonstrated that characteristic behaviors associated with social anxiety could also be manifested and tracked in gaming environments.

Recent research has increasingly recognized the potential of mobile games in identifying cognitive difficulties [33-38]. For instance, Intarasirisawat et al [39] conducted a study to explore if the touch and motion features extracted from popular off-the-shelf mobile games such as Candy Crush, Tetris, and Fruit Ninja can be useful for cognitive assessment. They reported several features that were significantly associated with cognitive scores. For instance, an increase in swipe speed was associated with a decrease in performance on cognitive capacity for visual search, mental search, and response inhibition. Other metrics such as swipe length, maximum score, and accelerometer data were also found to be associated with poorer cognitive test scores.

Similar research by Gao et al [40] explored whether touch interactions such as swipe speed and swipe pressure collected from the mobile game Fruit Ninja could indicate the player's emotional states. They investigated whether variations in touch dynamics were associated with different emotional states during gameplay. They observed that certain touch features such as the pressure metrics could discriminate frustration from excitement, relaxation, and boredom. For instance, they reported that higher pressure often correlated with frustration, and lower pressure was associated with relaxation. Despite the relatively preliminary nature of this research area, these studies collectively demonstrate the potential application of mobile games as a promising platform to analyze touch gesture patterns that could indicate the presence of symptoms of underlying mental health conditions.

Methods

We conducted an exploratory study in which participants were asked to complete validated measures of anxiety and depression and play 3 CMGs. We aimed to investigate whether there are significant associations between swipe gesture metrics and symptoms of anxiety and depression.

Recruitment

A total of 82 participants between the ages of 18 to 40 years were recruited from the general population through social media platforms (eg, Facebook and LinkedIn), email invitations, and flyer distributions in the university. Participants were required to be aged at least 18 years with a basic understanding of the English language to complete the required questionnaires. Participants with severe physical or cognitive impairments that limited their ability to interact and play mobile games were excluded from the study.

Measures

In this study, we used several standardized measures to assess symptoms of anxiety and depression among the participants.

The PHQ-8 and GAD-7 Questionnaires

The GAD-7 [41] and PHQ-8 [42] questionnaire were used to measure symptoms of anxiety and depression, respectively. The GAD-7 is a 7-item self-report questionnaire that evaluates the presence and frequency of general anxiety symptoms experienced over the past 2 weeks on a scale range from 0 (not at all) to 3 (nearly every day). The total scores range from 0 to 21, with higher scores indicating greater severity of anxiety symptoms. The GAD-7 is a widely used and validated self-report measure, with high internal consistency (Cronbach α=0.92) and good test-retest reliability [41]. Similarly, PHQ-8 is an 8-item self-report questionnaire that assesses the frequency of common depression experienced over the past 2 weeks on a scale range from 0 to 3, with higher scores indicating more severe depressive symptoms. PHQ-8 is a variant of the PHQ-9 measure, which excludes the ninth item related to suicidal thoughts, making it more suitable for use among the general population. PHQ-8 is well established as a valid diagnostic tool for assessing depression with excellent internal consistency (Cronbach α=0.89) [41].

In our sample, the mean anxiety score was 9.09 (SD 5.26) while the mean depression score was 8.24 (SD 4.95) as indexed by GAD-7 and PHQ-8 questionnaires, respectively. Table 1 summarizes the clinical severity categories.

Mild	25 (30)
Moderate	23 (28)
Severe	9 (11)

[a]GAD-7: Generalized Anxiety Disorder-7.

[b]PHQ-8: Patient Health Questionnaire-8.

Demographics and Gaming Behavior Questionnaire

Participants were asked to provide basic demographic information including age, gender, and gaming habits. Gaming habits were quantified using questions about gameplay frequency (daily, regular, or occasional gamer); average time spent playing games in one session (short, moderate, or long sessions); and self-identified gamer identity (nongamer, casual gamer, or gamer). Table 2 provides an overview of the demographic and gaming behavior characteristics of participants.

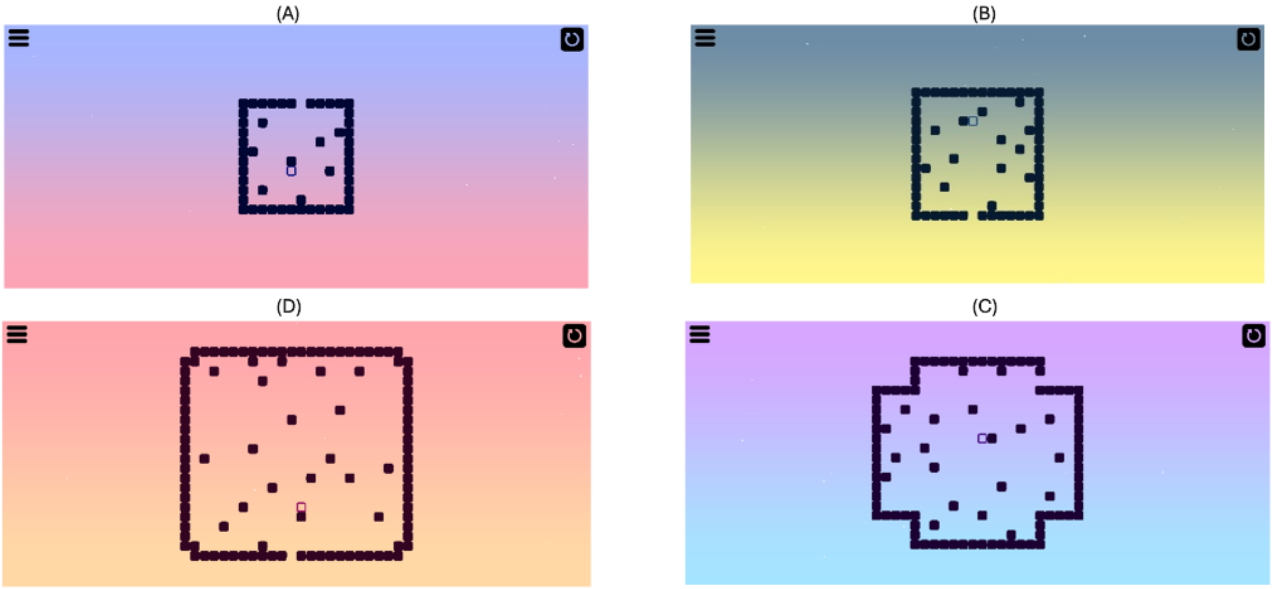
Game Design

Overview

Due to the diversity of mobile games in terms of genres and mechanics, it is essential to understand which types of game elements hold the most potential to allow for swipe gesture interactions that could indicate symptoms of anxiety and depression. At the same time, it is crucial that these game elements or mechanics are simple enough to reduce the effects of potential confounds such as previous gaming experience or gaming skill. This would minimize the risk of skewing results due to an individual's familiarity with gaming rather than due to symptoms of anxiety or depression.

Therefore, for this study, we decided to use 3 CMGs: a puzzle game, an infinite runner game, and an object slicing game. CMGs refer to games that are easy to learn and play with simple mechanics involving short gameplay sessions. Some examples of CMG include popular games such as Candy Crush, Subway Surfers, Fruit Ninja, and Angry Birds. These games also have the advantage of being played by a wide range of demographics, which makes it easier to gather data from diverse populations, including people from different ethnicities, age groups, and genders. In contrast, games such as Space Invaders that rely on multibutton taps and often 2-handed controls cannot provide continuous swipe data. Therefore, highly complex games were avoided to minimize confounds from previous gaming skill and to isolate pure swipe behavior. Furthermore, the positive reception and potential benefits of casual games in mental health contexts, as reported by Pine et al [43], suggest that CMGs could potentially enhance user experience and compliance.

To optimize the benefits of games, it is also critical that the games are well-refined and engaging enough to keep players immersed and motivated throughout the gaming sessions. We used the Unity3D game engine to develop our own versions of the 3 games based on the commercially available off-the-shelf mobile games using the available assets from the Unity3D asset store [44-46]. These games were embedded with our custom data collection pipeline that allowed for tracking several metrics related to the swipe behavior patterns as well as the device motion data recorded from the accelerometer and the gyroscope sensors. All games were play-tested before the actual experiment session to identify and resolve bugs within the gameplay and data collection systems.



Puzzle Game

Figure 1 depicts the design of the puzzle game. In this game, the objective is to help the player (transparent square block) escape the maze of square blocks from the designated way out (blank space in the outer blocks). The interactions are extremely simple with only swipes in 4 directions (up, down, left, and right), moving the player in the corresponding swipe direction. The player continuously moves in the given direction until it hits another block or any of the outer blocks. The player's direction cannot be changed while in motion.

A retry button (top right corner button in all images from Figure 1) was provisioned to reset the level if users were stuck completing a level, which simply put the player back to the original starting position when the current level was loaded. There was no time limit or retry limit for each individual level, except for the total time limit of 15 minutes for the current game session duration. The puzzle game was played in a landscape orientation of the smartphone. We chose a puzzle game genre because it places demands on various cognitive abilities such as visuospatial processing, working memory, and information processing speed [47-49]. Completing levels demands attentional focus and strategic planning and, at the same time, failure to complete could trigger frustration or irritation. We believe that symptoms such as frustration, visuospatial capabilities, ability to maintain focus, or irritability and hesitation could be manifested within such a type of gameplay. The design also incorporates levels with increasing difficulty as the game progresses, as research has shown this type of design keeps the players motivated and engaged with the gameplay for a longer duration [49].

XSL•FO
RenderX

Figure 1. Four screenshots from the puzzle game depicting various 2D levels, with increasing difficulty clockwise from top left. Bottom left shows level 17, the average level reached by participants.

Infinite Runner Game

Figure 2 shows the design of the infinite runner game. The gameplay is a clone of the popular infinite runner game called Subway Surfers. In this game, the task is to navigate the player character (orange cat) that automatically moves forward through an endless environment filled with obstacles, collectibles, and power-ups. The users control the player character using only swipes in 4 directions that correspond to different player actions. The "up" direction swipe causes the player to jump over obstacles, while the "down" direction swipe slides the player below the incoming obstacles. The left and right swipes move the player in the left or right direction, respectively. The speed of the player moving forward gradually increases as the game progresses, with collectibles and power-ups assisting the player to boost their score and overcome obstacles. The player receives 3 lives (depicted as 3 hearts at the top middle portion of the screen in Figure 2) in each round before eventually reaching the game over status. Every participant is allowed to play as many rounds as they can complete within a total duration of 15 minutes. The infinite runner game was played in a portrait orientation on the smartphone.

This specific design was chosen because the gameplay demands sustained attention, quick reflexes, and precise hand motor coordination to make the appropriate swipes for dodging the incoming obstacles. In addition, players need to successfully obtain collectibles (fishbones), premium valuables (gold bars), and power-ups to boost their score, challenging their working memory capacity by requiring them to keep track of several things at once. Moreover, infinite runner games have been previously shown to be effective in tracking symptoms of mental health disorders [33,50,51].

RenderX

Figure 2. A screenshot of the 3D infinite runner game depicting the player character (orange cat) with collectibles (fishbones) and obstacles. The top right corner displays total items collected and the top left corner displays the total score and distance covered.

Object Slicing Game

Figure 3 shows the design of the object slicing game. The game was developed as a clone of the popular Fruit Ninja game with a few modifications. The game requires the user to swipe the device screen to slice the objects that appear. The goal is to slice as many objects as possible within a time limit of 90 seconds for each round. If the users miss 3 objects (depicted as 3 crosses at the top middle portion of the screen in both images in Figure 3) or if a bomb is sliced (right image in Figure 3), it results in a game over status. Every participant gets to play as many rounds as they can complete within a total duration of 15 minutes. This game was played in a landscape orientation on the smartphone.

This game was chosen as it involves participants to carefully execute swiping gestures to ensure only objects are sliced while avoiding the bombs thrown in the mix, which requires precise gestures and hand-eye-coordinated movements. Unlike the previous two games, this game does not involve swipe gestures in any particular direction but rather requires users to make longer and continuous swipes. These types of interactions have been previously shown to be sensitive to cognitive difficulties and frustration [39,40]. We believe the addition of time pressure and game over threat from missing objects will increase its sensitivity to symptoms related to flight-or-fight responses, frustration, fatigue, and motor abnormalities within the swipe gesture patterns of the participants.

Figure 3. Two screenshots from the object slicing game with the left image depicting slicing of objects while the right image shows 2 bombs that should be avoided. The screenshots also display several user interface elements such as the 3 crosses in the top middle portion of the screen.

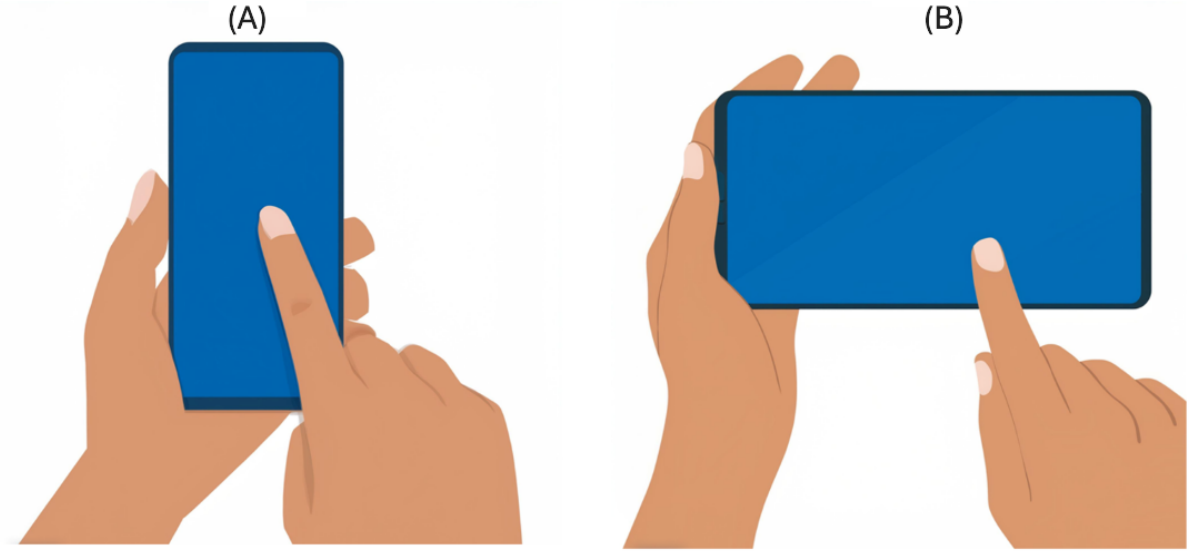
Ethical Considerations

This study was approved by the University of Queensland Human Research Ethics Committee A (2023/HE000853). Participants were first given a brief introduction to the experiment and asked to provide written informed consent before commencing the study. Adherence to ethical guidelines, participant privacy, safety and data integrity were prioritized at every stage of the study. Participants were reminded that their participation was voluntary, and they were free to withdraw from the study at any time. All collected data were encrypted, anonymized and deidentified before conducting any analyses. Compensation for participation was offered in the form of either course credits or an AUD $10 (US $6.50) gift card voucher.

Procedure



Overview

After providing consent, participants were asked to provide brief demographic information and respond to gaming behavior questions that asked about their gaming habits, such as their gaming frequency and the average time they spent playing games. On completion, participants were provided an Android Google Pixel 6a smartphone (without a screen protector), which was preloaded with the 3 games designed for the study. Participants were given detailed instructions on the protocol that they needed to follow while playing the games. The participants were advised to play the games while seated on a chair, holding the device in one hand while playing the game with the other hand, as illustrated in Figure 4. They were asked not to place the hand or rest the hand on the table during the gameplay. Furthermore, they were instructed to only use a single touch (ie, only 1 finger was allowed to touch the screen at a time) while playing the games. Finally, participants were encouraged to play the games as they normally would while abiding by the protocol.

The rationale for asking participants to strictly follow the protocol was to ensure consistency and reduce the influence of extraneous factors such as variations in hand size and finger length that can influence the collected data and potentially lead to false associations. For instance, differences in the hand and finger measurements can affect how participants interact with the smartphone, thereby influencing swipe metrics such as swipe speed or touch radius. By adhering to a standardized protocol, these variations were controlled, helping to ensure that any individual variance observed in the collected swipe gesture metrics is more likely to reflect differences in underlying psychomotor and cognitive processes rather than anatomical differences. Therefore, this standardized protocol helps minimize potential confounds, allows for replicability, and enhances the validity of the study's findings.

Thereafter, participants were asked to complete a tutorial session of approximately 10 minutes, in which they played games like the ones used in the study. The purpose of this tutorial session was to allow the participants to become comfortable with the size and shape of the smartphone while familiarizing themselves with the protocol and the gameplay. The tutorial session also aimed to reduce any potential biases related to previous gaming experience or varying skill levels among the participants before the actual data collection. Upon completion of the tutorial session, participants were randomly allotted to 1 of 2 groups. Participants in group 1 played the mobile games first and then completed the anxiety and depression questionnaires, while the participants in group 2 completed the questionnaires first and then played the games. In addition, the order of the games and the questionnaires was randomized within each group. This randomization and counterbalancing were implemented to reduce any potential biases that could arise from the sequence of activities. Participants played each game for 15 minutes, with the entire experimental session lasting around 120 minutes. An instructor was present during the gameplay session to ensure participants adhered to the gameplay protocol and to monitor for any signs of disengagement or noncompliance, but all participants completed the mental health questionnaires privately.

Figure 4. Protocol to hold the phone in one hand and play the game with the other using single finger touch in two different phone orientations.

RenderX

Data Collection

The swipe gesture data collection occurred in real time during the gameplay session. Because of limited knowledge with respect to which metrics to track, we used a broad data collection approach, designed to capture a wide range of data metrics in real time. As overcollection of data could result in lags or framerate drops (ie, temporary reductions in the game's rendering rate causing choppy visuals, game stutter, and input lag) that are known to negatively impact user engagement and experience, we used event-based data collection. Because the main interactions with mobile games were using swipe gestures, we opted to log data entries whenever a swipe event occurred within the game along with a timestamp. This resulted in a large volume of datasets, rich with patterns of swipe gesture behaviors. For example, the entire raw dataset included >60,000 entries only for the puzzle game. Table 3 lists the swipe gesture metrics that were collected during the gameplay. The collected data were stored on the device locally as JSON (JavaScript Object Notation) files before it was transferred to the server. A unique user ID was assigned to each log file as well as the questionnaires to link them. A visual depiction of the swipes from each of the 3 games is provided in Multimedia Appendix 1.

The primary categories of data metrics included swipe behavior metrics (swipe speed, swipe direction, swipe duration, swipe pressure, etc). The swipe positions were stored separately for individual X and Y components, resulting in additional metrics corresponding to the x-axis (swipe_posX) and y-axis (swipe_posY). Due to hardware limitations that currently restrict direct measurement of touch screen pressure, the swipe pressure was quantified using the size of each participants' fingertip contact area with the screen as a proxy for the pressure. This approach is a common practice in research involving touch-based interactions and has been validated in previous research as a reliable approximation [40,51]. In addition to the swipe gesture metrics, the device sensor metrics were also recorded from the accelerometer and gyroscope sensors, independently of the swipe events.

Table 3. Swipe gesture metrics collected from all 3 games.

Metric	Description
swipe_ID	The swipe event identifier
swipe_event_time	Time in seconds from the game launch when this swipe event occurred
swipe_start_time	Time in seconds from the game level when this swipe started
swipe_end_time	Time in seconds from the game level when this swipe ended
swipe_start_pos	The x-axis and y-axis coordinate positions of the screen touch when swipe started
swipe_end_pos	The x-axis and y-axis coordinate positions of the screen touch when swipe ended
swipe_pos	A list of all x-axis and y-axis coordinate positions for the current swipe
swipe_start_press[a]	The pressure applied to the screen when swipe was started
swipe_end_press	The pressure applied to the screen when swipe was ended
swipe_start_press_variance	The variance in the pressure when the swipe was started
swipe_end_press_variance	The variance in the pressure when the swipe was ended
swipe_press	The average pressure applied for the duration of the current swipe
swipe_press_variance	The overall variance in the pressure for the duration of the current swipe
swipe_speed	The speed of the current swipe
swipe_duration	The total time in seconds it took to complete the current swipe
swipe_distance	The total distance of the screen covered during the current swipe
swipe_direction[b]	The direction in which the current swipe was performed
time_between_swipes	The time in seconds that elapsed since the previous swipe

[a]press: touch pressure.

[b]Swipe direction was calculated only for puzzle and infinite runner games.

Data Analysis and Preprocessing

Before the analysis, data preprocessing steps were carefully planned and implemented to ensure that the data were clean, of high quality, and suitable for subsequent analyses because of the large amounts of data collected. Performing analyses on poor-quality data can compromise the validity of the results.

Data Cleaning

Initially, the data were cleaned by removing unwanted attributes or incorrectly logged entries that were collected. Incorrect swipe entries such as swipe entries logged from the main menu interactions before and after the gameplay were removed. This ensured that only the gameplay interactions were included in the final analysis rather than menu navigation metrics. A visual inspection of the data revealed a few unusual swipe entries such

XSL•FO
RenderX

as taps on the screen or false touches at the screen edges, possibly due to unwarranted screen contact with participants' palms. These entries were removed by establishing a minimum threshold distance to differentiate between intentional swipes and unintended interactions. Following the initial data cleaning, outlier detection methods were used to detect and remove outliers from the dataset. This is an important step in the preprocessing phase as outliers can significantly impact the subsequent analyses. The IQR method was used to detect and remove outliers. The IQR method was chosen due to its robustness to various data types, including null entries and zero values, ensuring that the outliers are correctly identified and resolved.

Data Aggregation

Because we opted for event-based data collection, our dataset resembles trace data with each individual entry having no meaningful interpretation. For example, a single entry of the recorded swipe metrics such as the swipe position x and y coordinates provides no information about the underlying psychomotor or cognitive processes. However, aggregated data for each user with appropriately engineered features allow us to draw valuable insights. This is because, by aggregating data with engineered features, we transformed the raw event-based data into more interpretable metrics that could potentially indicate symptoms of anxiety and depression.

Therefore, we first aggregated the data for each user across the entire game session separately for all 3 games. This process included summarizing the raw data into more comprehensive statistical metrics to capture the broader forms of gesture patterns. For each game, we extracted several swipe gesture properties (eg, swipe speed, swipe duration, swipe pressure, and swipe start and end positions on x- and y-axes separately). We then aggregated each metric across the 15-minute session using 8 statistical functions (mean, median, maximum, minimum, SD, range, first, and last) wherever appropriate for each relevant metric. This yielded approximately 150 metrics for each game. Some of these higher-order metrics can be challenging to interpret. For instance, "swipe_press_variance_std" represents the SD of the variance in touch pressure values across all swipes performed during the entire game session. It quantifies the inconsistency in how variable the user's touch pressure is across swipes. Higher values indicate that some swipes are performed with highly fluctuating pressure while others are more stable, suggesting erratic or dysregulated motor control. To ensure transparency and facilitate understanding, a complete list of all the metrics generated along with their plain language definitions has been provided in Multimedia Appendix 2.

Data Analysis

Due to the large number of metrics, it was crucial to account for multicollinearity by identifying pairs of metrics that were highly correlated ($r \geq 0.90$). Features that met this threshold were consequently reduced to a single metric. From each pair or group of collinear features, a single representative feature was retained. The choice of retained features prioritized interpretability and relevance, such as preferring SD for assessing variability, rather than combining features mathematically. For instance, "swipe_distance" was excluded in favor of "swipe_speed," which incorporates both time and distance components and has greater clinical relevance by more directly reflecting psychomotor functioning. This approach ensured the final set of metrics remained informative while reducing redundancy and preserving computational efficiency.

Spearman rank correlation was used to investigate the relationship between the mobile game swipe metrics and symptoms of anxiety and depression as indexed through the standardized measures. Spearman rank correlation was chosen because it is a nonparametric test that does not make assumptions about normality and linearity in the data. For instance, Spearman rank correlation is robust to nonlinear relationships in a dataset because it focuses on the monotonic relationship between variables, meaning it only looks for a consistent trend of increase or decrease between the variables, regardless of whether that trend follows a straight line (linear relationship) or a curved path (nonlinear relationship). As the primary objective was to identify metrics that show potential associations with anxiety and depression scores to inform future confirmatory analyses, we did not apply a correction for multiple comparisons. Therefore, the reported *P* values are uncorrected, and the results should be interpreted as preliminary.

All analyses were conducted using Python programming language (version 3.10.11) and the relevant statistical packages. The primary packages used included *Pandas* (version 2.2.2), *NumPy* (version 2.0.0), *SciPy* (version 1.14.1), *Pingouin* (version 0.5.4), *Matplotlib* (version 3.9.2), and *Seaborn* (version 0.13.2) for visualization and *iTables* (version 2.1.4) for interactive table views in Visual Studio Code.

Due to device labeling errors, the unique "user_ID" assigned to the last 4 participants could not be matched between gameplay logs and questionnaire responses. The corresponding entries for these users were removed, resulting in data from 78 participants contributing to the final analysis.

Results

Overview

Spearman rank correlation coefficients were computed to examine the relationship between mobile game swipe metrics with anxiety and depression scores as measured by GAD-7 and PHQ-8, respectively. The results revealed significant correlations, which are summarized in following sections. Due to the large number of data metrics from all the games, only statistically significant results ($P<.05$) are presented.

Correlation Analysis

Puzzle Game Analysis

As shown in Table 4, several puzzle game swipe metrics were significantly associated with PHQ-8 and GAD-7 scores. The variance in the swipe end pressure showed some of the strongest correlations with the PHQ-8 score, with the mean variance ($\rho=-0.425$; $P<.001$) and the SD of the variance in swipe end pressure ($\rho=-0.403$; $P<.001$) both moderately to strongly related to depression. Similarly, the average variance in the overall swipe pressure during the entire session was moderately

XSL•FO
RenderX

associated with PHQ-8 scores (ρ=−0.326; *P*=.004). Notably, the average swipe speed was also moderately to strongly correlated with PHQ-8 scores (ρ=−0.405; *P*<.001).

In relation to GAD-7 scores, the SD of the swipe end pressure (ρ=−0.334; *P*=.003) and the mean variance of the swipe end pressure (ρ=−0.317; *P*=.006), both showed moderate negative correlations. Furthermore, the average swipe speed was moderately to largely negatively correlated with GAD-7 scores (ρ=−0.400; *P*<.001). The average swipe duration was also positively correlated with GAD-7 scores, consistent with our finding that slower swipe speeds (meaning longer swipe durations) are associated with high anxiety and depression scores.

Infinite Runner Game Analysis

Table 5 reports significant Spearman rank correlations between the infinite runner game swipe metrics and anxiety and depression scores. Negative correlations emerged between several swipe pressure metrics, with the strongest of these between the average variance in swipe end pressure and PHQ-8 scores (ρ=−0.405; *P*<.001) as well as with GAD-7 scores (ρ=−0.309; *P*=.007). Similar to the puzzle game, the mean swipe speed was significantly negatively associated with both PHQ-8 (ρ=0.331; *P*=.003) and GAD-7 (ρ=−0.272; *P*=.02) scores. Interestingly, the SD of the y-coordinate position when starting the swipes was significantly negatively associated with both PHQ-8 (ρ=−0.244; *P*=.03) and GAD-7 (ρ=−0.271; *P*=.02) scores. In addition, the total number of swipes was negatively associated with anxiety (ρ=−0.266; *P*=.02).

Notably, for the infinite runner game, substantial associations were evident between several accelerometer metrics and mental health indices. For instance, there was a moderate to strong positive relationship between the minimum value of accelerometer data along the x-axis (acl_X_min) and depression (ρ=0.410; *P*<.001) and anxiety (ρ=0.338; *P*=.003) scores. A significant negative relationship also emerged between the SD of accelerometer data along the x-, y-, and z- axes (acl_X_std, acl_Y_std, acl_Z_std) and depression (ρ=−0.314; *P*=.006; ρ=−0.309; *P*=.007; and ρ=−0.249; *P*=.03, respectively). A significant positive relationship was evident for anxiety scores, particularly strongly for minimum value along the y-axis (acl_Y_min) and GAD-7 scores (ρ=0.349; *P*=.002).

Object Slicing Game Analysis

Several metrics exhibited significant correlations with PHQ-8 and GAD-7 scores, as shown in Table 6. Notably, the minimum y-coordinate position when starting the swipes (swipe_start_posY_min) was significantly positively correlated with depression (ρ=0.368; *P*<.001) and anxiety (ρ=0.370; *P*<.001) scores. In addition, the minimum average swipe pressure also demonstrated a moderate positive correlation with depression (ρ=0.388; *P*<.001) and a moderate to strong positive correlation with anxiety (ρ=0.430; *P*<.001). Furthermore, accelerometer measurements were negatively associated with acl_Z_max, having the strongest negative association with both depression (ρ=−0.402; *P*<.001) and anxiety (ρ=−0.324; *P*=.004) scores.

Discussion

Principal Findings

Overview

In this exploratory study, we investigated the relationship between swipe gesture interactions and symptoms of anxiety and depression across 3 distinct mobile games. This study presents novel evidence and is among the first to examine how specific swipe gesture interactions from mobile games can act as potential indicators of anxiety and depression symptoms. Our findings revealed that swipe metrics such as swipe speed and swipe pressure were significantly associated with symptoms of anxiety and depression, as measured by the GAD-7 and PHQ-8 measures, respectively.

Psychological Interpretation

Anxiety and depressive disorders are linked to abnormalities in core cognitive and psychomotor processes. It is well known that these conditions are often associated with impairments in attention, decision-making, working memory, speed of information processing, and motor coordination. A central tenet of the attention control theory [52] is that anxiety can disrupt attentional control mechanisms, such as the ability to shift attention, inhibit irrelevant information, and maintain attentional focus that can subsequently negatively impact goal-oriented motor processing and working memory capacity. In the context of our findings, slower swipe speed observed among participants with higher anxiety scores may reflect difficulties with attentional control, as they may process and respond to in-game stimuli less efficiently. Furthermore, psychomotor slowing, known to be associated with depressive disorders, may contribute to the slower interactions within the games, as this involves a general slowing of both physical movements and cognitive processing and could therefore easily manifest as slower user-game interactions in the form of slower swipe speed.

Increased pressure during the swipes could be interpreted as an indicator of frustration or heightened muscle tension, both of which are physiological symptoms associated with anxiety disorders. The relationships between swipe pressure and mental health indices identified in this study elaborate on previous research on handwriting analysis, where heightened pen pressure during handwriting tasks was linked with anxiety and depression [53,54]. The novel findings from this study linking swipe pressure to symptoms of anxiety and depression opens up new avenues and suggests that the association between elevated pressure and mental health can be extended to subtle swipe gestures performed during mobile gaming. In addition, the device motion metrics recorded through an accelerometer were also significantly associated with anxiety and depression during the object slicing and infinite runner games. Therefore, the device's motion could indicate symptoms such as lack of energy, fatigue, or heightened muscle tension commonly reported in individuals with anxiety and depression.

It is well-documented that attentional biases are a pervasive feature of anxiety disorders, with anxious individuals more likely to allocate disproportionate attention to perceived threats or particular stimuli [55]. In this study, an intriguing finding was in regard to the starting positions of the swipe gestures along the x- and y- axes, which were consistent and higher for those with elevated anxiety levels in the infinite runner and object slicing game but not in the puzzle game. For these two games, players need to avoid hitting the obstacles or avoid missing the objects resulting in a game over status. In contrast, the puzzle game lacked the same immediate threat of failure or time pressure to complete individual levels, offering the players enough time to plan their moves without the risk of an immediate game over status. It seems plausible that these differences in game mechanics, such as time pressure or immediate game over status, heighten the perceived threat of failure, eliciting an attentional bias that can lead to increased attentional fixation on specific locations of the screen leading to higher swipe positions observed during these games. However, given the exploratory nature of this study, further research is needed to validate these new findings.

Collectively, this study makes several notable contributions, with the identification of these novel metrics representing a substantial advancement in understanding how simple swipe gesture interactions during mobile gameplay can reflect underlying cognitive and behavioral responses associated with anxiety and depression.

Game Design Implications

If the long-term vision is to use mobile games as potential screening tools for anxiety and depressive disorders, it is crucial to understand what type of games are optimally effective or which game mechanics most consistently elicit behavioral responses indicative of symptoms of anxiety and depression. This was the reason we experimented with 3 games that differed substantively in their design and gameplay mechanics to identify whether one game genre or gameplay design is more effective than the other.

It is important to consider that mobile gameplay can introduce several confounding variables in the form of familiarity with mobile games, previous gaming skill and experience, or even age and gender. For instance, such mobile game genres as role-playing games or action and adventure games may not be ideal, as these often require complex controls, potentially skewing the data. In contrast, CMGs, such as the ones used in this study, rely on simple mechanics that are less likely to be influenced by gaming skills. However, there may be a case that more experienced mobile game players may have developed specific strategies that might make it harder to detect subtle anxiety and depression related behaviors. Therefore, an important next step in this literature is to investigate whether the observed metrics and their relationship with anxiety and depression are moderated by previous gaming experience and familiarity with the game.

The core element to consider in the design of mobile games is swipe gestures, as that is the most basic interaction. Our results indicated that various swipe gesture metrics, particularly swipe speed, swipe pressure, and swipe positions, were significantly

XSL•FO
RenderX

related to anxiety and depression scores across all 3 games and may be independent from the game type and game mechanics. If this is the case, then many other types of touch interactions such as tapping and dragging should theoretically also be sensitive to these impairments. Furthermore, game interactions that involve pressure variability to dodge the obstacles or to jump higher or lower depending on the touch pressure, or those mechanics that require users to swipe faster or slower in response to in-game stimuli could provide additional insights into whether individuals tend to exhibit anxious or depressive tendencies as reflected in these interactions. Further research is the next important step to directly test these possibilities.

Ethical Challenges and Concerns

Despite the promising findings from this study on the potential of swipe gestures from mobile games as indicators of anxiety and depression, several important ethical considerations need to be acknowledged. As mentioned previously, data collection from mobile devices has been a part of growing debate regarding its privacy concerns [56-58]. Although mobile games pose fewer privacy concerns compared to other approaches, it is crucial that no personal or sensitive information is collected and that the collected data are anonymized. A further key ethical challenge lies in ensuring that any communication of mental health information generated from the mobile gameplay is done so in a manner that does not elicit distress. Any insights or potential indications should be communicated carefully, providing users with appropriate guidance and resources to seek professional help. The feedback from the mobile games should be clearly framed as nondiagnostic and encourage users to consult a trained mental health professional for a comprehensive assessment.

While CMGs offer a nonintrusive, engaging approach using only virtual data generated within gaming worlds, they also have the potential to be misused. For instance, commercial companies might use these data to target susceptible individuals with manipulative strategies, such as in-game purchases to players exhibiting impulsivity disorders like obsessive compulsive disorders, because they are likely to buy more. As mentioned earlier, game analytics has been predominantly used for monetization benefits. Therefore, companies could dynamically adjust game mechanics to exploit the end users' mental health vulnerabilities, encouraging addictive gameplay behaviors or excessive spending.

Therefore, ethical safeguards surrounding the potential use of CMGs to track mental health symptoms must be enforced to address these ethical concerns. It is important to underscore that swipe gesture interactions or any other data provided by mobile games in general seem to offer the greatest promise with several advantages, including easy accessibility, scalability, and a noninvasive and highly engaging screening tool, but are not a replacement for traditional clinical assessment.

Limitations and Future Work

This study provides valuable insights into the relationship between swipe gesture interactions from mobile games and symptoms of anxiety and depression, but several limitations of this study also need to be acknowledged. First, the sample size of 82 participants, while adequate for exploratory analysis and preliminary findings, may limit the generalizability of the results to the broader population. Our sample consisted predominantly of young adults, with 95% (n=78) of participants aged between 18 and 30 years, while only 5% (n=4) were aged between 31 and 40 years, as shown in Table 2. Consequently, the findings may not generalize to older adults. Future studies should aim to recruit larger and more diverse samples from different demographic characteristics and varied gaming behavior groups to cross-validate the findings.

Second, the presence of an instructor with the participants when they played the games introduces the possibility of a potential observer effect. Finally, in this study, we did not test whether there were potential demographic and gaming behavior differences that might influence the swipe gesture patterns, and future work should explore how demographic factors, such as age and gender as well as gaming habits, influence these interactions.

In addition, the study was conducted in a controlled environment where participants followed a strict protocol of holding the device in one hand and playing the game with the other hand using only a single finger touch. While this approach helped to minimize the effect of confounding variables, it may not reflect participants' natural behavior when playing mobile games. Therefore, future studies are needed to assess these interactions in a natural setting where participants can play mobile games without any protocol.

Another limitation is that no correction for multiple comparisons was applied to the correlation analysis. This was because of the preliminary nature of this study, which was designed simply to identify potentially relevant behavioral metrics for future investigation. However, future confirmatory studies based on these findings, especially those with prespecified hypotheses and smaller feature sets, constitute the next important contribution to the literature in this field of study.

Future research could also expand the findings from this study to include gameplay performance metrics such as maximum score, total levels cleared, time taken to clear levels, total obstacles hit, or maximum distance run. Combining gameplay performance metrics with swipe gesture metrics could provide a more comprehensive understanding of how anxiety and depression symptoms manifest within the mobile gaming contexts. We used event-based data collection where swipe metrics were recorded for each swipe event during the gameplay. While this approach helped prevent any framerate drops and overcollection of data, it may overlook granular swipe gesture patterns. Therefore, future work should consider sampling data more frequently based on smaller time intervals to capture more detailed and fine-grained insights into swipe and gameplay behaviors. Finally, the findings from this study also set a precedent for future work involving machine learning algorithms to develop predictive models using mobile gameplay data that could potentially predict anxiety and depression scores.

Conclusions

This study reports novel data that speak to the potential value of swipe gesture interactions from mobile games as indicators

XSL•FO
RenderX

of symptoms of anxiety and depression. To the best of our knowledge, this is the first study to explore the relationship between swipe gesture metrics and validated measures of anxiety and depression. Across 3 distinct mobile games (a puzzle game, an infinite runner game, and an object slicing game), the results revealed significant associations between swipe gesture metrics that included swipe speed, swipe pressure variability, and swipe starting positions with both anxiety and depression. These new insights can be supported by the broader mental health literature that shows both depression and anxiety are associated with abnormalities in core psychomotor and cognitive processes as well as attentional biases. In conclusion, this study makes a significant contribution by presenting important foundational evidence on the potential of swipe gesture interactions from mobile games as a novel method for screening symptoms of anxiety and depression.

Abstract

Background: Mental health researchers are increasingly using large language models (LLMs) to improve efficiency, yet these tools can generate fabricated but plausible-sounding content (*hallucinations*). A notable form of hallucination involves fabricated bibliographic citations that cannot be traced to real publications. Although previous studies have explored citation fabrication across disciplines, it remains unclear whether citation accuracy in LLM output systematically varies across topics within the same field that differ in public visibility, scientific maturity, and specialization.

Objective: This study aims to examine the frequency and nature of citation fabrication and bibliographic errors in GPT-4o (Omni) outputs when generating literature reviews on mental health topics that varied in public familiarity and scientific maturity. We also tested whether prompt specificity (general vs specialized) influenced fabrication or accuracy rates.

Methods: In June 2025, GPT-4o was prompted to generate 6 literature reviews (~2000 words; ≥20 citations) on 3 disorders representing different levels of public awareness and research coverage: major depressive disorder (high), binge eating disorder (moderate), and body dysmorphic disorder (low). Each disorder was reviewed at 2 levels of specificity: a general overview (symptoms, impacts, and treatments) and a specialized review (evidence for digital interventions). All citations were extracted (N=176) and systematically verified using Google Scholar, Scopus, PubMed, WorldCat, and publisher databases. Citations were classified as fabricated (no identifiable source), real with errors, or fully accurate. Fabrication and accuracy rates were compared by disorder and review type by using chi-square tests.

Results: Across the 6 reviews, GPT-4o generated 176 citations; 35 (19.9%) were fabricated. Among the 141 real citations, 64 (45.4%) contained errors, most frequently incorrect or invalid digital object identifiers. Fabrication rates differed significantly by disorder (χ^2_2=13.7; *P*=.001), with higher rates for binge eating disorder (17/60, 28%) and body dysmorphic disorder (14/48, 29%) than for major depressive disorder (4/68, 6%). While fabrication did not differ overall by review type, stratified analyses showed higher fabrication for specialized versus general reviews of binge eating disorder (11/24, 46% vs 6/36, 17%; *P*=.01). Accuracy rates also varied by disorder (χ^2_2=11.6; *P*=.003), being lowest for body dysmorphic disorder (20/34, 59%) and highest for major depressive disorder (41/64, 64%). Accuracy rates differed by review type within some disorders, including higher accuracy for general reviews of major depressive disorder (26/34, 77% vs 15/30, 50%; *P*=.03).

Conclusions: Citation fabrication and bibliographic errors remain common in GPT-4o outputs, with nearly two-thirds of citations being fabricated or inaccurate. Reliability systematically varied by disorder familiarity and prompt specificity, with greater risks in less visible or specialized mental health topics. These findings highlight the need for careful prompt design, rigorous human verification of all model-generated references, and stronger journal and institutional safeguards to protect research integrity as LLMs are integrated into academic practice.

KEYWORDS

large language models; artificial intelligence; AI; mental health; psychiatry; citations; academic research

Introduction

Researchers today face growing pressure to maintain high levels of productivity to remain competitive for funding, tenure-track positions, academic promotions, and international recognition in their fields [1]. This intensifying demand for outputs—which typically spans research, teaching, supervision, and service—has led to a need for innovative solutions that can streamline administrative and research-related workflows. As the academic workload becomes increasingly complex and resource constrained, tools that can support efficiency without compromising quality are gaining significant attention.

Large language models (LLMs) are a class of tools gaining traction in academic settings to support researchers. LLMs are advanced artificial intelligence systems trained on vast amounts of textual data to generate coherent and contextually relevant natural language responses [2]. Among the many LLMs available, ChatGPT (OpenAI) has emerged as the most widely used, both in the general population [3] and among researchers [4,5]. A recent study showed that nearly 70% of mental health scientists reported using ChatGPT to assist with research-related tasks, including writing and drafting, coding, and administrative support [4]. However, while most LLM adopters reported that these tools enhanced research efficiency and improved the quality of their work, many also expressed concerns about inaccuracies, misleading content, and biases in the responses generated by these models [4]. These concerns are not unfounded, as one of the most well-documented limitations of LLMs is their tendency to "hallucinate," which occurs when the model generates false, fabricated, or unverifiable information that appears coherent and credible [6].

One type of hallucination generated by LLMs that has received increasing attention among researchers is fabricated bibliographic citations that cannot be traced to existing scholarly publications. This is a critical issue reported in LLM output because citations serve as the foundation of scholarly communication—they guide readers to source evidence; build cumulative knowledge; and inform research, policy, and clinical practice. Fabricated references can mislead readers, distort scientific understanding, and compromise the integrity of academic work.

Recent work has sought to quantify the extent of these hallucinations, typically by analyzing the citations produced when LLMs are prompted to generate academic literature reviews on specific topics. Walters and Wilder [7] prompted GPT-3.5 and GPT-4 to generate short literature reviews on 42 multidisciplinary topics and found that 55% and 18% of the citations, respectively, were fabricated, and 43% (GPT-3.5) and 24% (GPT-4) of the real citations contained substantive errors. Mugaanyi et al [8] compared citation fabrication rates in GPT-3.5–generated literature reviews across disciplines by analyzing 5 reviews each in the natural sciences and humanities. They found that while there were no differences in fabricated citation rates between the 2 disciplines (27.3% vs 23.4%), the rate of digital object identifier (DOI) hallucinations among the generated citations was higher for humanities (89.4%) than for natural sciences (61.8%) [8]. In another study, McGowan et al [9] used Google's Bard (now Gemini) to assess citation accuracy when prompted to generate references for research topics that were broad (ie, evidence for hallucinations in schizophrenia) versus specific (ie, research using natural language processing to assess suicidal behavior) in nature. When prompted on the broader topic, none of the 10 citations generated by Bard were accurate, with several linking to entirely unrelated papers. In contrast, when prompted on the specific topic, all 5 citations contained misattributed authorship but linked to real papers with matching titles [9]. These findings collectively demonstrate that both the disciplinary domain and the specificity of the prompt can influence the likelihood and nature of citation hallucinations, highlighting the need for systematic evaluations of LLM citation reliability across varied research contexts.

In this study, we provide a more nuanced examination of citation fabrication in the most recent version of GPT (GPT-4o; Omni) outputs by systematically varying the level of public awareness and depth of existing scientific literature on the topic within the domain of mental health. In particular, we prompted GPT-4o to generate academic literature reviews for 3 distinct mental disorders that differ in public visibility and research maturity. We selected major depressive disorder, binge eating disorder, and body dysmorphic disorder because they reflect varying levels of clinical familiarity and scientific development within the mental health field. Major depressive disorder is widely studied and publicly recognized, with a substantial volume of research and clinical trial activity. Binge eating disorder occupies an intermediate position in terms of research output and public awareness, whereas body dysmorphic disorder remains comparatively understudied and less widely known [10]. These classifications are supported by differences in publication volume, clinical trial prevalence, and general population familiarity across the 3 disorders. We also varied the level of prompt specificity, asking GPT-4o to generate either a general overview of each disorder (including its symptoms, societal impacts, and treatment approaches) or a specialized review focused on the narrower topic (the evidence base for digitally delivered interventions).

Given that LLMs are trained on large-scale text corpora comprising publicly available and licensed content [2], it is plausible that topics with lower online visibility, limited research coverage, or highly specialized scope are more prone to citation-related hallucinations. This may be because such topics are underrepresented in the training data and often lack readily accessible, high-quality academic content in the public domain, thereby reducing the model's ability to retrieve accurate and verifiable sources. The novelty of this study is that it goes beyond previous cross-disciplinary examinations of citation

XSL•FO
RenderX

hallucinations to provide the first within-domain test of how topic familiarity and prompt specificity shape LLM reliability. By manipulating both the disorder under review and the granularity of the task, we were able to generate new insights into when and why citation hallucinations are more likely to occur in scientific contexts. Therefore, we aimed to examine whether citation fabrication and bibliographic accuracy in GPT-4o outputs systematically vary by disorder type and review specificity.

Methods

Design

We used GPT-4o to generate brief literature reviews on 6 different topics and then aggregated data on the citations generated in the papers. We then searched online databases and websites to examine the frequency of (1) fabricated citations, (2) errors in the citations of nonfabricated sources, and (3) completely accurate citations among the nonfabricated sources. Multimedia Appendix 1 presents the prompts given for the 6 review topics, the text generated by GPT-4o, and the full citations provided in the output.

Review Topics and Prompts

GPT-4o was tasked (June 2025) with generating a short literature review on 6 distinct topics. For each prompt, a new session was initiated, and chat history was cleared to eliminate any influence from previous interactions. The topics spanned 3 different mental disorders that varied in public knowledge, volume of scientific research, and the level of specificity of the research questions provided to GPT-4o. For the general overview, GPT-4o was asked to write about the causes, societal and economic impacts, and available treatment approaches for 1 of the 3 disorders (major depressive disorder vs binge eating disorder vs body dysmorphic disorder). For the specialized reviews, GPT-4o was asked to synthesize the evidence base for digital interventions and discuss the factors that may influence their effectiveness. We selected digital interventions as the specialized topic because all 3 disorders have a growing yet uneven body of research in this area, making it a suitable test case for examining GPT-4o's ability to retrieve and summarize nuanced evidence across conditions that differ in research maturity. For example, more than 100 clinical trials have evaluated digital interventions for depression [11] compared to approximately a dozen for binge eating disorder [12] and an even smaller number for body dysmorphic disorder [13].

Prompt development was guided by 2 principles: replicability and ecological validity. First, we closely mirrored the style of prompts used in previous studies of LLM-generated literature reviews in other disciplines [7]. Second, we sought to design prompts that reflected how researchers might realistically request literature reviews from an LLM in practice. Draft prompts were discussed extensively among all authors and revised to ensure consistency, neutrality of tone, and appropriateness for the study aims. Importantly, we did not test these prompts within GPT-4o during development to avoid introducing previous knowledge or contamination from earlier runs. While advanced prompt engineering strategies (eg, chain of thought, few-shot examples, and retrieval-augmented prompts) were considered, these were not implemented, as our study sought to assess citation reliability under straightforward prompting conditions that approximate typical researcher use.

We asked GPT-4o to simulate an academic researcher and write a literature review of approximately 2000 words, using at least 20 citations from peer-reviewed academic sources, preferably within the last 10 years. Two major prompts were used, 1 generic and 1 specialized, and were held constant across reviews, with only the target disorder substituted in the text. Prompts, outputs, and citations generated by GPT-4o are presented in Multimedia Appendix 1.

Data Collection and Analysis

For the 6 literature reviews generated by GPT-4o, we recorded the number of words generated, number of citations provided, frequency of sources provided (eg, journal articles and books), and the full bibliographic information. For each citation, we first searched Google Scholar to see whether it was real or fabricated. If no matching source was found, we then searched using the full author list to identify any resembling publications. If this was also unsuccessful, we searched using the full title of the citation. If the citation still could not be verified, we repeated the process across other databases, including Google, Scopus, PubMed, and WorldCat. As a final step in verifying potentially fabricated works, we manually reviewed the relevant journal volume and issue and used the publisher's website search function to confirm that the cited work did not exist.

We considered a citation to be genuine (not fabricated) if we could identify a real publication that closely matched both the title and the authors. In other words, inaccuracies in the citation were permitted if the cited work could be reliably traced to an actual source. For example, a GPT-4o citation that listed the correct authors and title but included an incorrect volume number, page range, or DOI was still considered a real (nonfabricated) source. For these nonfabricated sources, we then compared the GPT-4o citation to the actual citation and recorded whether there were any discrepancies and errors in the author list, year, title, journal, volume, issue, page range, and DOI. This did not include formatting errors (eg, italicized journal names). We then recorded the number of GPT-4o real (nonfabricated) citations that contained no errors in any of the bibliographic details.

Fabrication and accuracy rates were calculated as proportions and expressed as percentages. These rates were presented descriptively overall and separately by target disorder (major depressive disorder vs binge eating disorder vs body dysmorphic disorder) and review type (general vs specialized).

To examine whether fabrication and accuracy rates varied by disorder and review type, we conducted a series of chi-square tests. Specifically, we tested for main effects by evaluating the association between review type and fabrication and accuracy rates and between disorder and fabrication and accuracy rates across all reviews.

Although interaction effects were not formally modeled because of low expected cell counts in some conditions, we conducted stratified chi-square tests to explore potential group differences within each level of the independent variables, that is, we

XSL•FO
RenderX

examined whether review type (general vs specialized) was associated with fabrication or accuracy rates within each of the 3 diagnostic subgroups and whether diagnostic subgroup was associated with fabrication or accuracy rates within each review type.

All chi-square tests were 2 tailed, and pairwise comparisons were conducted where omnibus tests were significant. Significance was set at $P<.05$.

Ethical Considerations

This study was exempt from ethical review as no human participants were involved.

Results

Overview

The number of words generated by GPT-4o across the 6 literature reviews ranged from 1096 (specialized review for binge eating disorder) to 1326 (general review for binge eating disorder). The total number of references provided by GPT-4o was 176, which ranged from 17 (specialized review for body dysmorphic disorder) to 36 (generic review for binge eating disorder) across the 6 conditions (Table 1). Most citations provided by GPT-4o were journal articles, with books and book chapters comprising the rest. Multimedia Appendix 2 provides the citations provided by GPT-4o, along with the correct citation identified by the author team.

Table 1. Prevalence of fabricated and accurate citations generated by ChatGPT-4o overall and by literature review and diagnostic subtype.

Variable	Major depressive disorder, n/N (%)		Binge eating disorder, n/N (%)		Body dysmorphic disorder, n/N (%)		Combined references, n/N (%)		
	General (n=35 references; 1302 words)	Specialized (n=33 references; 1146 words)	General (n=36 references; 1326 words)	Specialized (n=24 references; 1096 words)	General (n=31 references; 1225 words)	Specialized (17 references; 1239 words)	General (n=102)	Specialized (n=74)	Total (N=176)
Fabricated references	1/35 (2.9)	3/33 (9.1)	6/36 (16.7)	11/24 (45.8)	10/31 (32.3)	4/17 (23.5)	17/102 (16.7)	18/74 (24.3)	35/176 (19.9)

Journal article	34/35 (97.1)	33/33 (100)	33/ 36 (91.7)	23/24 (95.8)	27/31 (87.1)	15/17 (88.2)	94/102 (92.2)	71/74 (95.6)	165/176 (93.8)

[a]Percentage derived for accurate references does not factor in hallucinated references in the denominator. Denominator varies based on whether information was provided in the citation generated by ChatGPT (eg, missing volume number for one citation was not included in the denominator for accuracy rate for overall volume numbers).

[b]Error type was only relevant for actual references. Sources that did not include specific information to form an American Psychological Association reference (eg, volume, issue, journal, and page number for books) were counted as missing and did not contribute to the denominator.

[c]DOI: digital object identifier.

Fabrication Rates

Of the 176 citations provided by GPT-4o, 35 (19.9%) were fabricated. When GPT-4o provided a DOI for a fabricated citation, 64% (21/33) of the DOIs were valid but linked to irrelevant and unrelated journal articles, whereas 36% (12/33) were completely invalid or nonfunctional.

XSL•FO
RenderX

The number of fabricated sources overall did not significantly differ between general (17/102, 16.7%) and specialized (18/74, 24%) literature reviews (χ^2_1=1.6; *P*=.21). However, when conducting stratified analyses by diagnostic subgroup, a significant association between literature review type and fabrication rate emerged only for binge eating disorder: fabrication rate was significantly higher for specialized (11/24, 46%) compared to generic (6/36, 17%) reviews on binge eating disorder produced by GPT-4o (*P*=.01).

When comparing the number of fabricated sources overall between the 3 diagnostic subtypes, a significant overall difference was observed (major depressive disorder: 4/68, 6%; binge eating disorder: 17/60, 28%; body dysmorphic disorder: 14/48, 29%; χ^2_2 =13.7; *P*=.001). Pairwise comparisons show that the fabrication rate was significantly higher for binge eating disorder compared to major depressive disorder (*P*=.001) and for body dysmorphic disorder compared to major depressive disorder (*P*=.001), but no difference emerged when comparing binge eating disorder to body dysmorphic disorder (*P*=.92). When conducting stratified analyses by review type, significant differences in fabrication rates were found between the 3 diagnostic subtypes for both general (*P*=.006) and specialized (*P*=.006) reviews. Within generic reviews, fabrication rates were significantly lower for major depressive disorder than for body dysmorphic disorder (*P*=.001). Within specialized reviews, fabrication rates were significantly higher for binge eating disorder than for major depressive disorder (*P*<.001).

Accuracy Rates

Only 77 (54.6%) of the 141 real (nonfabricated) citations provided by GPT-4o were accurate and contained no errors. The number of accurate citations overall did not significantly differ between general (47/85, 55%) and specialized (30/56, 54%) literature reviews (χ^2_1 =0.4; *P*=.84). However, when conducting stratified analyses by diagnostic subtype, differences in accuracy rates between review types did emerge. Within major depressive disorder, accuracy was significantly higher for generic (26/34, 77%) compared to specialized (15/30, 50%) reviews (*P*=.03), whereas within body dysmorphic disorder, accuracy was significantly higher for specialized (7/13, 54%) compared to generic (3/21, 14%) reviews (*P*=.01).

When comparing accuracy rates overall between the 3 diagnostic subtypes, a significant overall difference was observed (major depressive disorder: 41/64, 64%; binge eating disorder: 26/43, 60%; body dysmorphic disorder: 10/34, 29%; χ^2_2 =11.6; *P*=.003). Pairwise comparisons show rates of accurate citations were significantly higher for major depressive disorder compared to body dysmorphic disorder (*P*=.001) and for binge eating disorder compared to body dysmorphic disorder (*P*=.007) but not when comparing major depressive disorder to binge eating disorder (*P*=.71). When conducting stratified analyses by review type, significant overall differences in accuracy rates between diagnostic subtypes emerged only for generic reviews (*P*<.001). Specifically, accuracy rates within generic reviews were significantly lower for body dysmorphic disorder compared to both major depressive disorder (*P*<.001) and binge eating disorder (*P*=.001).

Citation Errors

Table 1 also provides the percentage of specific errors observed across real (nonfabricated) citations overall and by condition. Combined, the highest error rate was observed for DOIs for journal articles (51/141, 36.2%), and the lowest error rate was observed for the author list (21/141, 14.9%). Similar trends were observed when inspecting error rates across the 6 study conditions (Table 1).

Discussion

Principal Findings

This study examined whether citation fabrication and bibliographic accuracy in GPT-4o output systematically vary across topic areas of different public visibility, scientific development, and specialization. We prompted GPT-4o to generate literature reviews on 3 psychiatric conditions (ie, major depressive disorder, binge eating disorder, and body dysmorphic disorder) that vary in public knowledge and research maturity. The literature reviews generated by GPT-4o also varied in scope, comprising both general overviews of each disorder (including symptoms, impacts, and treatment approaches) and highly specific reviews focused on the efficacy and moderators of digitally delivered interventions for these disorders. Given that LLMs are trained on large-scale text corpora comprising publicly available content [2], we expected that literature reviews focused on more widely recognized disorders (ie, major depressive disorder) and those addressing general topics would yield lower rates of citation fabrication and bibliographic errors compared to reviews on less familiar disorders or more specialized subfields.

Our expectations were mostly supported. Overall, GPT-4o generated 176 citations from 6 literature reviews. A total of 35 (19.9%) citations were fabricated, and among the 141 nonfabricated citations, 77 (54.6%) contained bibliographic errors, with incorrect DOIs being the most prevalent error type. Fabrication and accuracy rates varied by disorder, with the lowest fabrication rates observed in reviews on major depressive disorder and the lowest citation accuracy rates found in reviews on body dysmorphic disorder. While citation fabrication and accuracy rates did not differ *overall* by review type, stratified analyses revealed important within-disorder differences. First, fabrication rates were higher in specialized than general reviews within binge eating disorder. Second, citation accuracy was higher for general than specialized reviews within major depressive disorder. Third, accuracy was unexpectedly higher in specialized than general reviews within body dysmorphic disorder. Collectively, these findings demonstrate that both the subject area and prompt granularity can influence the likelihood and nature of citation hallucinations and the accuracy generated by LLMs.

Comparisons With Prior Work

The findings of this study align with previous research across various disciplines showing that citation fabrication and bibliographic inaccuracies are common in LLM-generated outputs [7-9,14]. However, this study extends this work in several important ways. First, while previous research has

XSL•FO
RenderX

compared model outputs across distinct disciplines [7,8], which has made it difficult to draw conclusions about relative performance across topics of differing complexity within the same field, we examined how citation reliability varies within the same domain by systematically manipulating public familiarity, scientific visibility, and prompt granularity. This approach enabled a more fine-grained analysis of how topic characteristics influence LLM performance, revealing meaningful variation even within a single area of research. Second, while most earlier studies evaluated older versions of GPT [8,15,16], our use of GPT-4o allowed us to assess whether citation reliability has improved in newer iterations. Despite expectations of enhanced accuracy, we found no clear evidence of reduced hallucination rates, although cross-study comparisons are inherently limited due to variation in topic selection, task framing, and evaluation methods.

A key novelty of this work in comparison to previous literature lies in its design. Rather than contrasting different disciplines or older model versions, we systematically manipulated topic familiarity and review specificity within the same research field. This approach revealed important topic-level differences in citation reliability that would have been obscured in cross-disciplinary comparisons. Thus, this study not only extends existing evidence on LLM hallucinations but also introduces a new framework for evaluating how characteristics of the research question itself influence model performance.

Limitations

This study has several limitations that should be acknowledged. First, although a key strength of this study was the manipulation of topic complexity and public familiarity within a single domain, the findings may not generalize to other psychiatric disorders or specialized subfields not examined here. Future research should assess whether similar patterns of citation fabrication and bibliographic errors are observed across a broader range of mental health topics and other academic disciplines.

Second, our findings are specific to GPT-4o and may not generalize to outputs generated by other LLMs. We selected GPT-4o because it is the most recent and widely adopted LLM among academic researchers [4], making our results relevant to a significant proportion of users. Nevertheless, further studies should investigate whether different LLMs exhibit comparable patterns or whether model-specific factors influence citation reliability.

Third, we did not use prompt engineering strategies; instead, we used standardized but straightforward prompts to reflect typical researcher use. It is possible that performance could be improved through techniques such as citation verification prompts or structured reference formatting. Future studies should directly test whether such prompt engineering methods reduce hallucination and error rates.

Fourth, we analyzed a single output per prompt and did not assess intraprompt variability across multiple generations. As LLMs such as GPT-4o produce outputs stochastically, it is possible that replication of the same prompt would produce different citation fabrication or accuracy rates. Future work should examine multiple generations per prompt to assess the consistency and reproducibility of results.

Broader Implications

This research has broader implications for the conduct of scientific research. First, researchers and students should be aware of the risks associated with relying on LLMs for literature generation and ensure that all outputs are subjected to careful human oversight. This includes systematically checking, validating, and verifying the accuracy and authenticity of any citations or claims produced by models. Without such oversight, the field risks the proliferation of fabricated or inaccurate references, which can erode scientific integrity and mislead readers, reviewers, and the public.

Second, journal editors and publishers have a critical role to play in maintaining scholarly standards by ensuring that LLM-generated citations do not make their way into published outputs unchecked. One practical strategy is to use plagiarism detection software that flags whether citations appear in known published sources. If a citation is identified by such software as plagiarized or matching existing content, this can serve as a positive indicator that the reference is real. Conversely, if a citation does not trigger any match, it may signal that the source does not exist and was potentially hallucinated by the LLM, warranting closer inspection and manual verification.

Third, academic institutions and research organizations should develop clear policies and training guidelines around the responsible use of LLMs in scientific writing. As these tools become more deeply integrated into research workflows [5], it is essential to equip users with the knowledge and skills to critically assess model-generated outputs. This includes instruction on how to identify hallucinated citations, validate bibliographic content, and appropriately disclose the use of generative artificial intelligence in scholarly outputs.

Conclusions

In conclusion, this research offers novel insights into how the characteristics of a topic influence the reliability of citations produced by LLMs. While we found that citation fabrication and error rates are common overall, these inaccuracies were less frequent when prompts addressed topics with greater public awareness, an established evidence base, and a broad scientific consensus. This suggests that the reliability of LLM-generated citations is not fixed but contingent on the informational terrain they are asked to navigate. Importantly, these findings have broader implications for the integration of LLMs into scholarly workflows. They indicate that improving citation accuracy is not solely a technical challenge but also a matter of strategic prompt design and topic selection. Researchers can leverage this insight using LLMs preferentially for well-established domains while exercising caution and implementing verification protocols when working in specialized areas where training data may be sparse or inconsistent. More broadly, our results highlight the need for institutional guidance and training that explicitly addresses the contextual factors influencing LLM reliability rather than treating citation errors as random or inevitable. By embedding such practices, the academic

XSL•FO
RenderX

community can harness LLMs' efficiencies while safeguarding the integrity of scholarly work.

Abstract

Background: The early detection of mild cognitive impairment is crucial for providing treatment before further decline. Cognitive challenge tests such as the Loewenstein-Acevedo Scales for Semantic Interference and Learning (LASSI-L) can identify individuals at highest risk for cognitive deterioration. Performance on elements of the LASSI-L, particularly proactive interference, correlate with the presence of critical Alzheimer disease biomarkers. However, in-person paper tests require skilled testers and are not practical in many community settings or for large-scale screening in prevention.

Objective: This study reports on the development and initial validation of a self-administered computerized version of the Loewenstein-Acevedo Scales for Semantic Interference (LASSI), the digital LASSI (LASSI-D). A self-administered digital version, with an artificial intelligence–generated avatar assistant, was the migrated assessment.

Methods: Cloud-based software was developed, using voice recognition technology, for English and Spanish versions of the LASSI-D. Participants were assessed with either the LASSI-L or LASSI-D first, in a sequential assessment study. Participants with amnestic mild cognitive impairment (aMCI; n=54) or normal cognition (NC; n=58) were also tested with traditional measures such as the Alzheimer Disease Assessment Scale-Cognition. We examined group differences in performance across the legacy and digital versions of the LASSI, as well as correlations between LASSI performance and other measures across the versions.

Results: Differences on recall and intrusion variables between aMCI and NC samples on both versions were all statistically significant (all $P<.001$), with at least medium effect sizes ($d>0.68$). There were no statistically significant performance differences in these variables between legacy and digital administration in either sample (all $P<.13$). There were no language differences in any variables ($P>.10$), and correlations between LASSI variables and other cognitive variables were statistically significant (all $P<.01$). The most predictive legacy variables, proactive interference and failure to recover from proactive interference, were identical across legacy and migrated versions within groups and were identical to results of previous studies with the legacy LASSI-L. Classification accuracy was 88% for NC and 78% for aMCI participants.

Conclusions: The results for the digital migration of the LASSI-D were highly convergent with the legacy LASSI-L. Across all indices of similarity, including sensitivity, criterion validity, classification accuracy, and performance, the versions converged across languages. Future studies will present additional validation data, including correlations with blood-based Alzheimer disease biomarkers and alternative forms. The current data provide convincing evidence of the use of a fully self-administered digitally migrated cognitive challenge test.

Introduction

Diagnosis of common cognitive neurodegenerative illnesses such as Alzheimer disease (AD) and Alzheimer disease–related disorders (ADRD) has typically relied on clinical impressions and traditional cognitive assessments. Given the rising prevalence of these diseases, and the continuing development of disease modifying therapies, it is important to detect the earliest cognitive manifestations of disease before multisystem damage has occurred. Traditional neuropsychological measures, such as those involving memory, are based on paradigms over 5 decades old and may not be sensitive to the earliest cognitive changes that accompany AD/ADRD [1-3]. Early detection of cognitive deficits in AD/ADRD provides the best opportunities for interventions, as current and emerging therapies are likely to be considerably more efficacious before the onset of multisystem pathology. Thus, a recent focus has been on the development of "cognitive stress" [4,5] or "cognitive challenge" tests that tax compensatory mechanisms that may reveal the earliest clinical changes associated with AD/ADRD.

One such measure is the extensively studied Loewenstein-Acevedo Scales of Semantic Interference and Learning (LASSI-L) [6]. This paradigm taps vulnerability to proactive semantic interference, which is known to increase in older individuals [7]. The first task in the LASSI-L is for participants to learn a list of 15 words belonging to 3 semantic categories, (list A). A competing semantically similar set of targets (list B) is then presented. As a result, proactive semantic interference (PSI) can be measured, which is a type of interference that occurs when previously learned information interferes with the ability to learn and remember new, semantically related, information. These effects are indexed by reduced learning of the words in list B and possible intrusions of list A words into the recall of list B. A unique feature of the LASSI-L is a second presentation of the second target list that taps failure to recover from proactive semantic interference (frPSI) [8], indexed by continued learning deficits after a second presentation of the B targets and continued increases in the relative number of intrusions from list A.

The LASSI-L frPSI measure has been found to be highly related to total and regional amyloid load in apparently neuropsychologically normal community-dwelling elders [9,10]; to differentiate between aMCI patients with suspected AD from cognitively unimpaired elderly controls (cognitively normal) [6,11,12]; and has been associated with volumetric loss in AD-prone areas among elders with aMCI [13,14]. In contrast, other LASSI-L indices and standard memory tests were not related to volumetric findings and progression to mild cognitive impairment (MCI) [15,16]. Particularly relevant to AD/ADRD, are findings that semantic intrusion errors on the PSI and frPSI indices of the LASSI-L are greater in persons with aMCI who are amyloid positive on positron emission tomography compared with individuals with aMCI due to other neurological or neuropsychiatric conditions, who are amyloid negative [17,18]. This indicates a remarkable ability of the LASSI-L to differentiate those with AD pathology from those without. The LASSI-L has also differentiated between persons who are amyloid positive versus amyloid negative on the basis of other AD biomarkers such as plasma p-tau 181 [19] as well as plasma AB42/AB40 ratios using mass spectrometry.

A critical pragmatic factor associated with the LASSI-L is its cross-cultural sensitivity. Spanish and English versions of the test are equivalently valid [20-22] and have shown both multilingual and cross-cultural validity. For example, in a study in Madrid, Spain, performance on the LASSI-L was associated with regional cerebral metabolic deficits associated with AD on positron emission tomography [23]. Furthermore, the LASSI-L has shown specificity to aMCI in African American populations [24], suggesting that it has wide ranging cross-cultural applicability. In the Rosselli et al [22] study, it was found that bilingual Spanish-English speakers outperformed monolingual Spanish speakers, suggesting that testing language is an important consideration when persons are bilingual.

Although the LASSI-L is both relatively brief and administered with high reliability by examiners, its deployments for large-scale screening, such as for clinical trials, particularly those focused on prevention, may be limited by inadequate professional resources to administer the test. The initial research-focused computerized version of the LASSI-L, the Loewenstein-Acevedo Scales for Semantic Interference and Learning, Brief Computerized Version is both abbreviated and computerized, eliminating delayed recall conditions and enhancing validity of test administration. The initial studies of this assessment found that it had excellent convergence with the LASSI-L and sensitivity to aMCI and pre-MCI [25,26], as well as sensitivity to AD biomarkers during prodromal stages of the disease [27]. However, the Loewenstein-Acevedo Scales for Semantic Interference and Learning, Brief Computerized Version still requires a trained psychometrist to supervise the assessment, and manual scoring to ensure that the data captured by computer match the data captured by the human.

In this paper, we report on the further digital migration of the LASSI-L through development of a fully self-administered, computerized version of the Loewenstein-Acevedo Scales for Semantic Interference (LASSI), the LASSI-D. Using cloud-based administration and an AI-generated humanoid avatar testing assistant, the LASSI-D was examined for its convergent and discriminative validity in a structured digital migration study. The migration of the task from in person and paper to computerized self-administration is a critical first step in demonstrating convergent validity of the paper-and-pencil LASSI-L with the computerized LASSI-D. As part of the development process, we developed an identical digital version of the LASSI-L, with identical stimuli (designated LASSI-D, form A). An exploratory additional feature of the development process was to create 2 alternative forms by using the same stimuli, but reorganizing their order of appearance across target lists.

We administered the LASSI-L or the LASSI-D first in a sequential design, to community-dwelling individuals, who first received an in-person cognitive assessment for categorization of their cognitive status. In addition, at the LASSI assessment for both cohorts, we administered several standard cognitive measures used for staging AD/ADRD, including immediate and delayed paragraph recall [28], the Hopkins Verbal Learning

XSL•FO
RenderX

Test-revised [29], and Alzheimer Disease Assessment Scale-Cognition (ADAS-Cog) [30].

Our overall study goals were to examine convergence of the LASSI-D form A with standard administration, and the LASSI-L, in terms of performance. Further we assessed validity in terms of the convergence of the Spanish and English versions of each test, and to explore the correlations of the LASSI-L and the LASSI-D with more traditional assessments of cognition related to aMCI.

Methods

Overall Study Design

This was the first part of a longitudinal observational study conducted at 7 community centers or locations in South Florida and 4 in New York City. Following screening and orientation to the study, participants received an in-person assessment to characterize their cognitive status. Participants who met inclusion criteria and adequately completed the initial assessment progressed to later parts of the study.

Participants

The sample included English- or Spanish-speaking adults aged 59 years or older who lived in the community, had at least 20/60 vision, were able to read a computer screen, and had adequate hearing for an auditory-based assessment. Men and women were recruited, without restrictions on racial or ethnic status. MCI status was ascertained with a neuropsychological assessment using the Jak-Bondi criteria [31].

Exclusion criteria included a Montreal Cognitive Assessment (MoCA) [32] score of <19 or a reading score, in their dominant language, at less than a 6th grade level. Other exclusions included the inability to undergo assessments in either English or Spanish, having been tested with the LASSI-L in the past 12 months, a diagnosis of a serious psychiatric condition apart from clinical depression, a previous medical history of brain disorder such as stroke, seizures, tumor, or significant traumatic brain injury with extended loss of consciousness.

Reading Performance

The literacy level of English speakers was examined with the Wide Range Achievement Test [33], third edition. Spanish speakers were assessed with the Batería III Woodcock-Munoz Identificacion de letras y palabras subtest [34].

Cognitive Assessments

Cognitive assessments were used to collect data for the performance-based MCI criteria. The LASSI measures were not used in diagnostic determination. All assessments were performed in each participants' preferred language (English or Spanish). Montreal Cognitive Assessment (MoCA [32]) examines cognitive performance with scores ranging from 0 - 30. Assessments were performed by certified bilingual raters. Using Wechsler Memory Scale- revised, Logical Memory I and II (Anna Thompson Story) [28], participants were asked to read a story and then asked for immediate recall, followed by a 20-minute delayed recall filled with other nonverbal assessments. Hopkins Verbal Learning Test-Revised [29] was administered before assessment with the Brief Assessment of Cognition (BAC), substituting this shorter 12-item, 3 trial verbal learning assessment for the much harder 15-item 5-trial BAC word list test. We also examined delayed recall to contribute to the MCI classification.

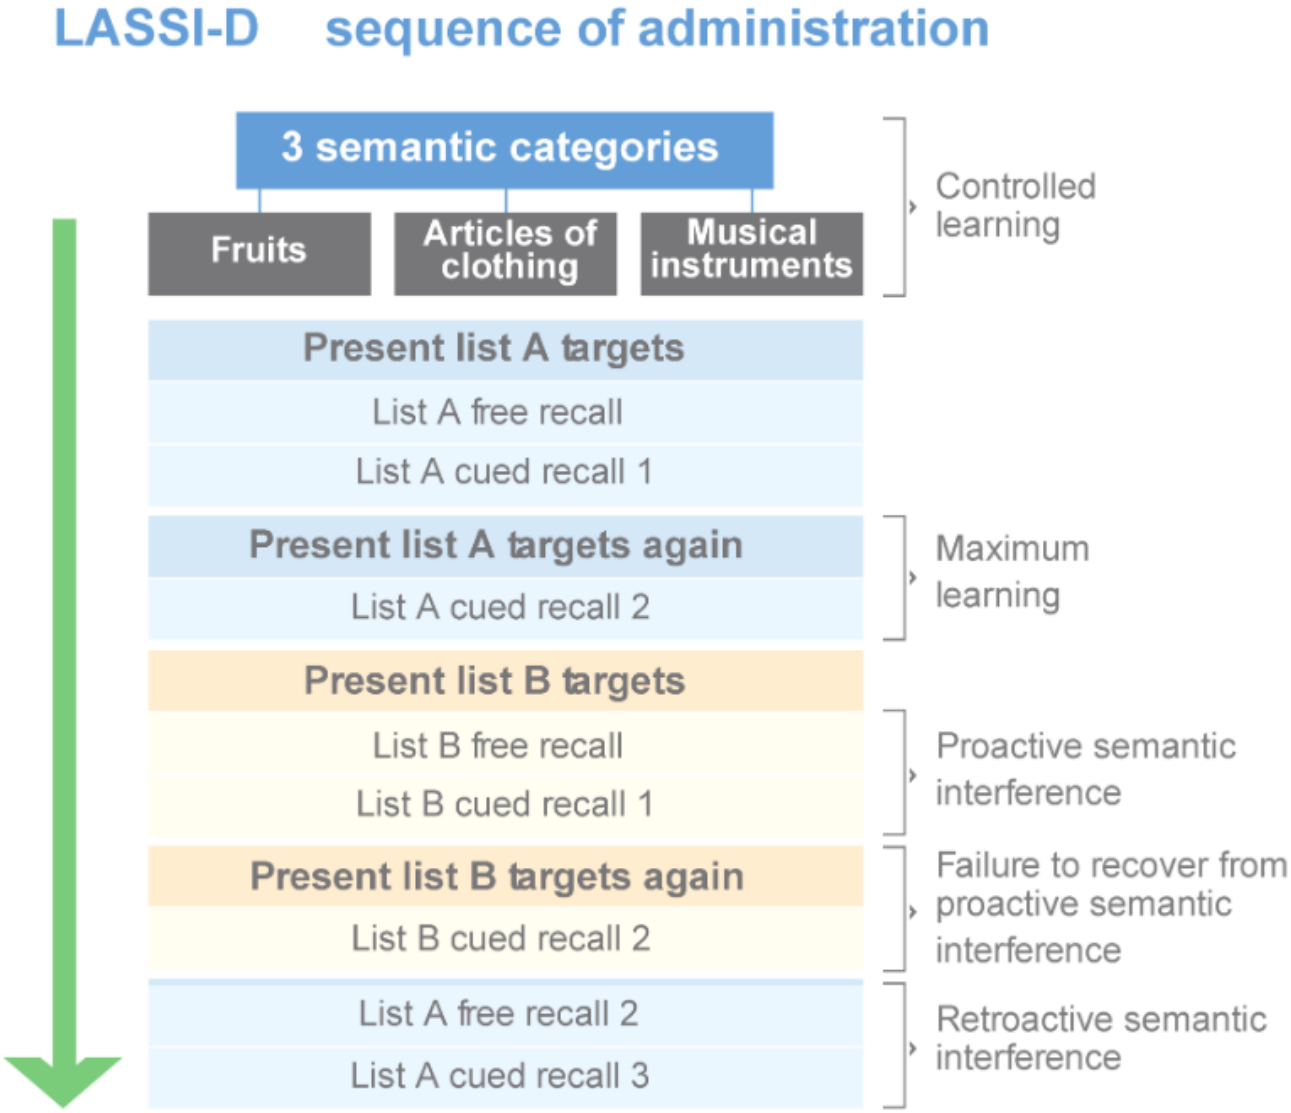
Wechsler Memory Scale- revised, Logical Memory I and II (Anna Thompson story) [28]. Participants were asked to read a story and then asked for immediate recall, followed by a 20 -minute delayed recall filled with other non-verbal assessments.

The BAC app version [35] measures domains of cognition known to be related to everyday functioning. The BAC app delivers the same assessments with cloud-connected tablet delivery for ease of administration and standardization. The BAC-app has been widely used in studies of MCI. The cognitive domains assessed include: Digit Sequencing, Token Motor; Verbal Fluency; Symbol Coding; Tower of London. Participants with MoCA scores less than 19 were not tested further and testing also stopped if participants did not have the required literacy level.

Warm-Up Testing Before LASSI Assessments

Two short tests, Trail-Making Test part A and Animal Naming Fluency were administered immediately before the LASSI-L and the LASSI-D. This assessment was designed to ensure that the participants were ready to be assessed with the somewhat longer LASSI procedure and to provide additional information about the similarities of the participant samples. Performance on these tests were not used for participant selection.

The LASSI



Participants were examined with 2 variants of the LASSI: the legacy technician delivered paper version: the LASSI-L and the LASSI-D, which has identical stimuli to the LASSI-L. The LASSI uses controlled learning and cued recall to maximize encoding of a list of to-be-remembered target words representing three semantic categories. The examinee learns a list of 15 common words comprised of musical instruments, fruits, or articles of clothing (5 words per semantic category) which they are asked to recall immediately after exposure. Critically, exposure to stimuli occurs with the participant being shown each of the words, one at a time, and being asked to read the word aloud, thus ensuring encoding of every stimulus. Words that were read incorrectly are immediately cued in the following way: "The word is XYZ. Please say XYZ."

After the free recall trial, the examinee is presented with each category cue (eg, clothing) and asked to recall the words from that category, yielding a cued recall score (cued A1). The examinee is then exposed to the same target stimuli for a second learning trial with subsequent cued recall, with a goal of strengthening the acquisition and recall of the list A targets, providing maximum encoding of the to-be-remembered information (cued A2). As the LASSI-L targets identification of semantic intrusions in individuals without major memory challenges, previous studies of the LASSI-L have excluded participants who were unable to learn at least 11 of the 15 list A stimulus words [18-20].

XSL•FO
RenderX

Following the second presentation of list A, the participant is presented a semantically related list (list B) which consists of 15 words which are different from list A, with 5 from each of the same categories and again asked to read them aloud. Following the list B presentation, the examiner asks the participant for free recall of the list B words (B1 free recall); reduced learning compared with list A defines immediate proactive semantic interference (PSI). Then, the participants are cued to recall the list B words. Next, the participants read the list B words again, followed by a second cued recall trial (cued recall B2). Recall performance on this second learning trial measures whether the examinee's manifests failure to recover from PSI (frPSI). Refer to Figure 1 for the sequence of assessments contained in the LASSI.

Figure 1. Assessment flow within Loewenstein-Acevedo Scales for Semantic Interference Assessments. LASSI-D: digital Loewenstein-Acevedo Scales for Semantic Interference.

An additional critical set of outcomes are intrusion scores. During both free and cued recall conditions for list B any recalled words that are not from the are recorded. This dependent variable is calculated into an index, dividing the number of intrusion errors by the total words recalled, including words correctly recalled and intrusions, yielding "percentage of intrusion errors" (PIE) This index captures the proportion of all recalled information that constitutes intrusions. PIE has been shown to be the most sensitive predictor of risk for subsequent cognitive decline [16,36]. The LASSI-L has been translated into multiple languages, including Spanish. We used the English and Spanish versions in this study.

Digital Migration of the LASSI-L

The digital assessments with the LASSI-D were computerized, cloud-based, and completely self-administered. To ensure that the LASSI-D is a valid equivalent of the LASSI-L, several important steps were undertaken in the migration. The first was piloting and refining the (Google) voice recognition software through pilot testing to ensure accurate of identification of words read and recalled by participants (taking into consideration different English and Spanish accents, physical environments, etc). Second was the development of a realistic AI generated humanoid avatar. The avatar vocalizes the instructions and feedback during assessment that are read by the human tester during LASSI-L assessments. Third was the development of a digitally administered pretesting orientation and preparation

XSL•FO
RenderX

session to ensure attentiveness and understanding on the part of the participant. This orientation serves to ready the user to properly interface with the LASSI-D application, while testing the functionality of the user's internet connection, the microphone, and speakers. In the orientation, the participant is asked to name some simple shapes that appear on the device's screen, continuing until correct responses are detected by the software. Thus, the resulting software program interactively provides instructions and feedback to participants, presenting all stimuli and identifying and collating the words spoken by the examinee.

Procedure

Participants were screened for cognitive functioning as described above. Participants were designated as having normal cognition (NC) or 1 of 3 different MCI subtypes: aMCI (impairments on 2 or more memory tests but no other cognitive domains); multidomain mild cognitive impairment (2 or more impairments on both memory and other cognitive domains); nonamnestic mild cognitive impairment (NAMCI; impairments on 2 nonmemory cognitive domains, but no more than 1 memory domain). Normative standards for the screening tests were used to evaluate performance, with impairment defined as SD 1 below normative values on each test. The LASSI data for participants with NAMCI were collected, but their data was not examined because the LASSI-L is focused on aMCI. We did not inform the research participants whose data were being excluded because they may have known other participants and discussed the research procedures with them. NC participants were required to have a MoCA score of 26 or more, which was downwardly adjusted due to low levels of education/literacy present in the samples at our community centers.

A fully bilingual testing assistant was present during all assessment sessions and administered all the paper-and-pencil screening tests as well as the LASSI-L. At the end of the first assessment with the LASSI, participants also were administered the ADAS-Cog. Testing order of the LASSI variants was sequentially based, presented in Figure S1 in Multimedia Appendix 1, and is separated by 2 weeks. We started with the LASSI-L and tested until we had at least 50 confirmed eligible participants (MoCA >19, list A2 recognition >10, does not meet criteria for NAMCI). Next, we administered the LASSI-D-form A, until we were certain we had 50 eligible participants. Because of delays in confirmation of MCI status, more than 50 cases were in each of the final samples. We did not attempt to balance the samples for potential factors (language, aMCI vs NC, sex). Baseline performance on forms B and C and weeks 2, 4, and 6 reassessments with the alternative forms of the LASSI-D will be presented in a comprehensive paper on alternative forms and test-retest effects when the study is completed.

Data Analyses

The goal of the analyses was to examine the similarity of the LASSI-L and LASSI-D, form A (identical stimuli to LASSI-L). Analyses were performed on the 6 critical variables, cued recall of list B trial 1 (B1), cued recall 2 of list B (B2), intrusions on list B trials 1 (B1) and 2 (B2), and percentage of intrusion errors (PIE) for list B trials 1 and 2 (PIE1 and PIE2) for participants who achieved a qualifying cued A2 score. We used *t* tests to compare performance of NC and aMCI participants on all 6 variables in each of the 2 forms (LASSI-L vs LASSI-D form A). We then compared the difference between aMCI and NC for each of the 6 variables within each version. Then we examined the correlations of the 6 variables with other indicators of cognitive impairment (ADAS-Cog and MoCA) separately for the LASSI-L and LASSI-D. To confirm that the samples were comparable in their overall cognitive performance, the NC and aMCI within the were compared for similarity of performance on the MoCA, the TMT-A, and animal naming. Final analyses included examination of classification accuracy, using forward entry stepwise discriminant function analyses to examine the ability of the 6 LASSI variables in each version to classify participants as aMCI versus NC. We then added ADAS-Cog scores to the classification model to see if classification was improved by a standard cognitive assessment targeting AD/ADRD. We used receiver-operating characteristic curve analyses to examine correct classification of aMCI and NC, collapsing across the 2 versions of the LASSI.

Ethical Considerations

The Western Coppernicus Group Institutional Review Board approved the study (approval number 2022 - 1540) and all participants provided signed informed consent. All data were fully anonymized for storage and analysis. Participants received $40.00 in compensation for each assessment session.

Results

Participant Characteristics

There were 9 NAMCI participants scheduled for initial testing with the LASSI-L and 4 NAMCI participants scheduled for initial assessment with the LASSI-D. There were also 30 participants who did not meet the list A learning criteria. When the MoCA scores of the 30 participants who did not meet the minimum LASSI learning score were compared with those who did, those who failed to qualify had significantly lower MoCA scores (mean 21.03, SD 2.8), compared with those who qualified (mean 24.21, SD 2.8; t_{140}=5.45; P<.001).

Table 1 presents information on the eligible participants, characterized by which version of the LASSI they received at their assessment. There were no significant differences in age, education, and MoCA scores across the participant samples. There were slightly more Spanish speakers in the LASSI-D cohort, but there were no differences in any of the 6 critical LASSI variables, age, or MoCA scores across the Spanish and non-Spanish speakers (all t_{111}<1.64; all P>.10).

Table 2 presents the results of the comparison of performance across the 2 forms of the LASSI.

PIE list B trial 2	0.14 (0.11)	0.25 (0.15)	0.13 (0.14)	0.25 (0.17)

[a]NC: normal condition.

[b]aMCI: amnestic mild cognitive impairment.

[c]PIE: percentage of intrusion errors in relation to total correct responses on the trial.

Performance Differences Across Test Forms

The largest difference between the LASSI-L and LASSI-D on any variable was cued recall B1 for the MCI group, with an effect size of d=0.3 (t_{56}=1.13; P=.13), with better performance on the LASSI-L. All of the other 5 *t* tests were also nonsignificant (P>.05). Scores on the 2 critical variables of percentage intrusion errors were essentially identical across both versions of the LASSI for both participant groups (P>.71).

Table 3 presents the results of comparisons of form differences across NC and MCI participants for all the critical variables as well as diagnostic differences for each of these variables.

XSL•FO
RenderX

Table . Effect sizes for form differences and diagnostic status differences. Effects sizes are presented as Cohen *d*.

LASSI[a] variables	Form differences		Diagnosis differences	
	NC[b] (n=58), Cohen *d*	MCI[c] (n=54), Cohen *d*	NC (n=54), Cohen *d*	MCI (n=58), Cohen *d*
Cued recall list B trial 1	0.29	0.3	0.97	0.91
Cued recall list B trial 2	0.06	0.05	1	1.01
Intrusions cued recall list B trial 1	0.25	0.25	0.97	0.91
Intrusions cued recall list B trial 2	0.25	0.04	0.7	0.68

PIE list B trial 2	0.1	0.02	0.83	0.81

[a]LASSI: Loewenstein-Acevedo Scales for Semantic Interference

[b]NC: normal condition.

[c]MCI: mild cognitive impairment.

[d]PIE: percentage of intrusion errors in relation to total correct responses on the trial.

Performance of the aMCI participants was worse than the NC participants on all LASSI variables with the 2 forms combined. The smallest difference between aMCI and NC participants across the forms was for intrusions on cued recall B2, which had an effect size of d=0.68 (t_{56}=2.3; P=.03). All other tests had larger effect sizes, higher t statistics, and lower P values.

As can be seen in Table 4, every LASSI-L and LASSI-D variable was significantly correlated with MoCA and ADAS-Cog scores in the combined sample. Correlations were smaller for the intrusion variables than for the learning variables comprised of correct responses.

Table . Pearson correlations with other cognitive indicators collapsed across diagnosis and separated by which test was administered first.

LASSI[a] Variables	MoCA[b]		ADAS-Cog[c]	
	LASSI-L[d] (n=54), Pearson *r*	LASSI-D[e] (n=58), Pearson *r*	LASSI-L (n=54), Pearson *r*	LASSI-D (n=58), Pearson *r*
Cued recall list B trial 1	0.62[f]	0.53[f]	−0.62[f]	−0.54[f]
Cued recall list B trial 2	0.61[f]	0.54[f]	−0.63[f]	−0.53[f]
Intrusions cued recall list B trial 1	−0.29[g]	−0.30[g]	0.38[g]	0.26[g]
Intrusions cued recall list B trial 2	−0.29[g]	−0.31[g]	0.30[g]	0.24[g]
PIE[h] list B trial 1	−0.43[f]	−0.34[g]	0.47[f]	0.38[g]
PIE list B trial 2	−0.33[g]	−0.41[f]	0.42[f]	0.31[g]

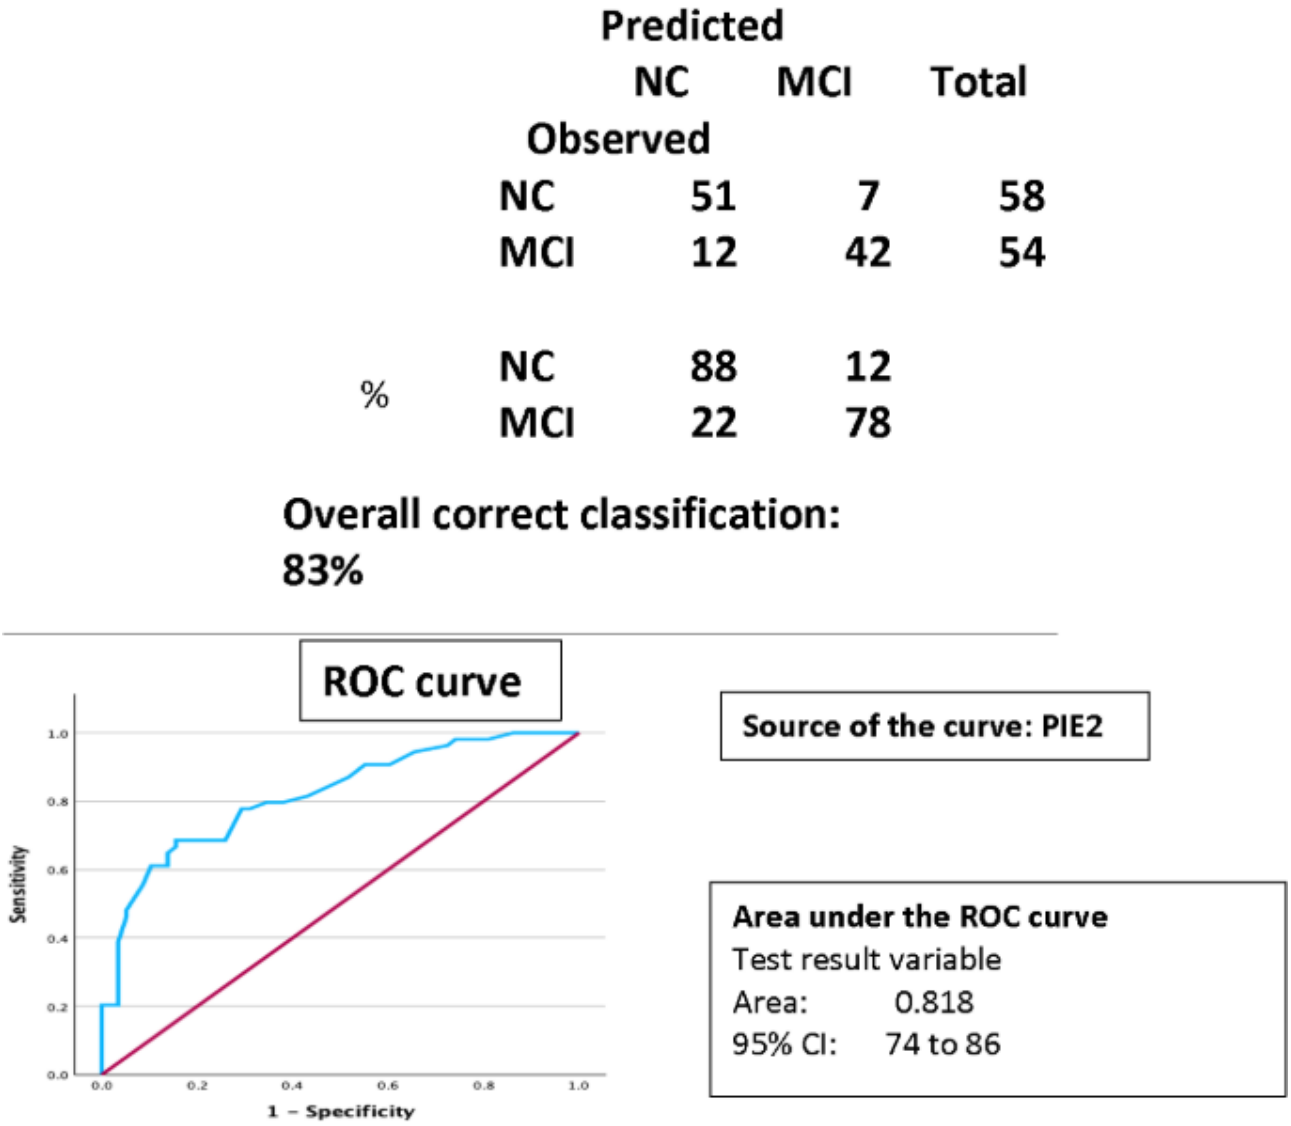
[e]LASSI-D: digital Loewenstein-Acevedo Scales for Semantic Interference.

[f]P<.001.

[g]P<.01.

[h]PIE: percentage of intrusion errors in relation to total correct responses on the trial.

We performed comparative analyses of the 2 samples across the cognitive variables administered at each assessment and at baseline and present them in Table S1 in Multimedia Appendix 2. As can be seen in that table, there were no significant differences in any of the variables across the 2 samples of participants.



Finally, Figure 2 presents the results of discriminant analyses using the PIE intrusion variables to classify cases into aMCI versus NC status. The PIE2 intrusion variable was the only one to enter the analysis (Wilks Lambda=7.03; χ^2_1=38.6; Pillas approx. $F_{1,110}$=46.49; P<.001). Correct classification of the cases was 88% (51/58) for NC (7/58, 12% false positive) and 78% (42/54) for MCI (12/54, 22% false negative) for total

XSL•FO
RenderX

correct classification of cases of 83% (93/112). Adding the ADAS-Cog as an additional predictor did not change the results, as it did not enter the equation ($F_{1,110}$ =3.85; P=.06). The area under the receiver operating characteristic curve (AUC) statistics are also presented in Figure 2. Importantly, the AUC statistic overall was 0.82, consistent with the overall correct classification rate.

When the samples were split into subgroups based on LASSI-L or LASSI-D first and the analyses rerun, only PIE2 intrusion errors again entered the analysis at P<.001 in both subgroups. Classification accuracy was 77% (23/30) for NC and 66% (16/24) for aMCI in the LASSI-L first group and 82%(23/28) for NC and 77% (23/30) for aMCI. Despite the smaller size of these samples, the data suggest quite similar classification accuracy for each version of the LASSI.

Figure 2. Classification accuracy for amnestic mild cognitive impairment versus normal control status including area under the curve. MCI: mild cognitive impairment; NC: normal condition; PIE: percentage of intrusion errors in relation to total correct responses on the trial; ROC: receiver operating characteristic.

Discussion

This study examined convergence between a legacy paper-and-pencil assessment sensitive to the earliest stages of aMCI and decline over time and a digital remotely deliverable version of the assessment. Our goal was to determine if the scores obtained across legacy and migrated measures suggest that they are essentially equivalent alternative forms of the same test. The results suggested a high level of similarity of performance on the legacy and migrated versions of the LASSI across all critical variables. There were no significant differences between paper and digital forms for any variable within cognitive status subgroups. Furthermore, all variables manifested a moderate to large effect size for the performance differences between the aMCI and NC participants.

The variables that optimally classified the groups, were the same as in the previous studies of the LASSI-L, the percentage of intrusion errors on the second recall trial of list B. Interestingly, adding the gold standard ADAS-Cog to the models did not improve classification accuracy based on the PIE2 intrusion variable. The remarkable similarity of the PIE1 and PIE2 intrusion scores across legacy and migrated versions of the LASSI in this study compared with previous studies merits comment. In the Crocco et al [16] study, longitudinally stable

XSL•FO
RenderX

cognitively normal participants received PIE1 scores of 0.22 and PIE2 scores of 0.11 when tested with the paper-and-pencil LASSI-L and participants who later declined into aMCI received baseline PIE1 scores of 0.38 and PIE2 scores of 0.22. These scores are essentially identical to LASSI-L scores in the current study for cognitively normal participants (PIE1=0.22 and PIE2=0.11) and for aMCI participants (PIE1=0.38 and PIE2=0.25). The LASSI-D scores are also equivalent to the current and previous LASSI-L scores (NC: PIE1=0.22, PIE =0.13; aMCI PIE1=0.37; PIE2=0.25), suggesting similarity to previous and current results.

Classification accuracy into aMCI and NC groups with discriminant analysis based on LASSI criteria alone was similar, although somewhat reduced compared with previous studies. For instance, in the Crocco et al [16] study, sensitivity was 89% for NC and specificity was 86%, while in the current study detection accuracy for NC was essentially identical at 88% (51/58) and lower for identification of aMCI at 78% (42/54). This difference likely lies in the definition of aMCI. In previous studies, such as Crocco et al, ascertainment of cognitive status included the full recommended strategy of the National Alzheimer's Coordinating Center dataset [37], which includes assessment of subjective cognitive decline, a neurological assessment, and a reliable collateral informant resulting in a Clinical Dementia Rating score [38], as well as a neuropsychological assessment. Although our study identified NC with essentially identical accuracy compared with previous studies, some individuals with aMCI were not identified, likely due to differences in ascertainment criteria.

Our study was performed at nonclinical community centers. In this regard, it is an ecologically valid examination of the LASSI-D as the administration protocol is like the assessments available in these centers, where there are no professional assessors. In fact, the rate of false positive diagnosis of NC as aMCI is the same as in an ADRC-quality sample. When balancing the risk of false negative assessments versus likely impossibility of ADRC-quality assessments in community centers, a reduced detection accuracy of 10% appears to be a costeffective trade-off.

We are currently evaluating alternative forms of the LASSI-D, for repeated administration. Such repeated assessments will be required to screen and monitor cognitive change as the field moves forward with developing therapeutics for AD/ADRD. We are also collecting blood biomarkers (p-tau 217) on participants to examine convergence of the LASSI-D results with state-of-the-art AD biomarkers. Spanish and English versions of the LASSI generated similar scores, although analyses of task × MCI status will need to be repeated across the other forms. In summary, these data suggest that scores obtained from professional tester administered, manually scored LASSI-L assessments to the self-administered LASSI-D have excellent convergence and discriminant validity.

Conflicts of Interest

RCC abd DL, co-developers of the LASSI-L, along with the University of Miami retain the rights to the intellectual property utilized in the study and may financially benefit from its commercialization. Both RCC and DL have also served as paid consultants for iFunction in the development of the new digitized version, the LASSI-D. SC holds the position of Co-Scientific Officer at iFunction, while PH, ARM, and PK are employees of the company.

Abstract

Background: Dementia is a syndrome that compromises neurocognitive functions of the individual and that is affecting 55 million individuals globally, as well as global health care systems, national economic systems, and family members.

Objective: This study aimed to determine the status quo of scientific production on use of digital health technologies (DHTs) to support (older) people living with dementia, their families, and care partners. In addition, our study aimed to map the current landscape of global research initiatives on DHTs on the prevention, diagnosis, treatment, and support of people living with dementia and their caregivers.

Methods: A bibliometric analysis was performed as part of a systematic review protocol using MEDLINE, Embase, Scopus, Epistemonikos, the Cochrane Database of Systematic Reviews, and Google Scholar for systematic and scoping reviews on DHTs and dementia up to February 21, 2024. Search terms included various forms of dementia and DHTs. Two independent reviewers

XSL•FO
RenderX

conducted a 2-stage screening process with disagreements resolved by a third reviewer. Eligible reviews were then subjected to a bibliometric analysis using VOSviewer to evaluate document types, authorship, countries, institutions, journal sources, references, and keywords, creating social network maps to visualize emergent research trends.

Results: A total of 704 records met the inclusion criteria for bibliometric analysis. Most reviews were systematic, with a substantial number covering mobile health, telehealth, and computer-based cognitive interventions. Bibliometric analysis revealed that the *Journal of Medical Internet Research* had the highest number of reviews and citations. Researchers from 66 countries contributed, with the United Kingdom and the United States as the most prolific. Overall, the number of publications covering the intersection of DHTs and dementia has increased steadily over time. However, the diversity of reviews conducted on a single topic has resulted in duplicated scientific efforts. Our assessment of contributions from countries, institutions, and key stakeholders reveals significant trends and knowledge gaps, particularly highlighting the dominance of high-income countries in this research domain. Furthermore, our findings emphasize the critical importance of interdisciplinary, collaborative teams and offer clear directions for future research, especially in underrepresented regions.

Conclusions: Our study shows a steady increase in dementia- and DHT-related publications, particularly in areas such as mobile health, virtual reality, artificial intelligence, and sensor-based technologies interventions. This increase underscores the importance of systematic approaches and interdisciplinary collaborations, while identifying knowledge gaps, especially in lower-income regions. It is crucial that researchers worldwide adhere to evidence-based medicine principles to avoid duplication of efforts. This analysis offers a valuable foundation for policy makers and academics, emphasizing the need for an international collaborative task force to address knowledge gaps and advance dementia care globally.

people living with dementia; digital health technologies; bibliometric analysis; evidence-based medicine

Introduction

Background

Dementia is a progressive neurocognitive syndrome currently cited as the seventh leading cause of death worldwide [1]. This degenerative disease is also one of the leading causes of disability or dependency for aging populations today [2]. Dementia places a substantial burden on health care systems, national economies, and families, who often bear the responsibility of caregiving. Beyond the financial and logistical strain, individuals with dementia endure profound cognitive and neurological challenges, significantly affecting their quality of life [3]. In 2019, dementia affected over 55 million people globally and cost the world economy US $1.3 trillion. Nearly half of the financial burden was borne by informal caregivers [4]. With no currently available cure [5], efforts are focused on disease management, improving quality of life, and providing well-being support [6].

In recent years, the health care landscape has undergone a profound transformation with the integration of digital health technologies (DHTs), particularly the technologies applicable in the care of people living with dementia and their health care providers (formal and informal). Digital solutions offer novel avenues for enhancing medical care by supporting early diagnoses and implementing better preventive strategies [7]. Furthermore, DHTs can potentially minimize the burden of care felt by family members, who often devote over 5 hours daily to providing care and supervision [8]. Digital health interventions can offer a multifaceted approach to dementia treatment and prevention and revolutionize the modern approach to health care delivery and support in daily living. This comprehensive group of interventions covers multiple modalities of technologies, including artificial intelligence (AI), computer-based cognitive interventions and digital platforms, GPS, sensors for remote care, smart devices, mobile health, instant messaging applications, wearable devices, virtual reality, and telehealth [9].

Recognizing the value of multidisciplinary research initiatives, the World Health Organization (WHO) Regional Office for Europe has taken a leading role in advancing scientific research in this area. Key initiatives have made significant contributions to exploring the intersection between digital health and healthy aging, including the United Nations Decade of Healthy Ageing (2021-2030) [10], the WHO Global Digital Health Strategy 2020 to 2025, the Regional Digital Health action plan for the WHO European Region 2023 to 2030, and the WHO European Framework for Action on Mental Health 2021 to 2025. Acknowledging the importance of its role, the WHO is committed to supporting the achievement of the sustainable development goals, specifically goal 3 (good health and well-being) and goal 9 (industry, innovation, and infrastructure) [11]. The research questions in this study aligned with 4 particular targets: reduce mortality from noncommunicable diseases and promote mental health (3.4), achieve universal health coverage (3.8), enhance research and upgrade industrial technologies (9.5), and universal access to information and communications technology (9.8) [11].

A protocol was published on February 19, 2024, which provided an overview of systematic and scoping reviews detailing how the analysis of different modalities of DHTs could improve the prevention, diagnosis, treatment, care, and support of (older) people living with dementia, their families, wider support network, and care partners [12]. The research insights were drawn from a series of reviews on the topic and the numerous

XSL•FO
RenderX

interventions for the holistic management of dementia, underscoring the necessity for compiling and summarizing the existing evidence in a solid and systematic document. As of April 2024, there has been a paucity of comprehensive, high-quality bibliometric analysis that examines the complete scope of research intersecting between the interface of DHTs and dementia care. Notably, compiling this bibliometric analysis provides valuable insights to identify areas for further investigation in granular detail, acting as a conduit for researchers working in areas of technology, gerontology, social science, gerontechnology, social research, and policy to initiate a route map based on the gaps in the literature.

This Review

This publication synthesizes the preliminary findings from the broad systematic search on February 21, 2024. This work will serve as a springboard for future investigations with a more detailed synthesis of specific modalities in digital health and how they relate to the 8 domains of the WHO's Age-friendly Cities and Communities Framework. We anticipate that this series of documents will yield evidence beneficial to clinicians and policy makers alike working with people living with dementia.

Methods

Overview

Our study combines 2 methodologies within the field of evidence-based medicine as follows: (1) overview of systematic reviews and (2) bibliometric analysis. We combined both methodologies to leverage their complementary strengths in analyzing the complexity and evolution of DHTs in dementia care [13]. We initially used the principles of systematic reviews to obtain a broader number of studies, enabling the execution of the bibliometric analysis. The integration of both approaches provided a comprehensive and in-depth understanding of the current state of DHTs in dementia care—insights that neither method could achieve alone. This combined approach ensured rigorous and replicable evaluation of existing evidence from systematic reviews and also positioned our research within the broader context of global research trends.

This bibliometric analysis originated as part of the protocol published before the start of the reviewing process under the PROSPERO tracking locator CRD42024511241 [12]. For this bibliometric analysis, we adhered to the guidelines for bibliometric studies, BIBLIO statement [14] and report the associated checklist as Multimedia Appendix 1. This analysis began with a large-scale review of 4839 articles retrieved from a comprehensive overview of systematic reviews, examining the current literature landscape at the interface of digital health and dementia. According to the international guidelines in evidence-based medicine, overviews of reviews are intended to evaluate the existing evidence from 2 or more reviews of different health interventions for a similar population or condition; they also assess these interventions across varying outcomes, settings, or time points [15].

Article Search and Selection Strategy

This publication is a part of the project protocol using 2 primary techniques—systematic review and bibliometric analysis. In the first phase, we systematically searched 5 leading medical databases (MEDLINE, Embase, Scopus, Epistemonikos, and Cochrane Database of Systematic Reviews) for eligible systematic and scoping reviews. In collaboration with an expert committee, our information specialist designed a search strategy based on Medical Subject Headings and nonstandardized technical terms. In addition, the search was complemented by obtaining the first 300 hits from the Scholar (Google LLC) platform (source for gray literature) for eligible reviews from database inception until February 21, 2024, regardless of publication language. Search terms involved, but were not limited to, "dementia," "Alzheimer disease," "Lewy body dementia," "mixed dementias," "Huntington disease," "multi-infarct dementia," "vascular dementia," and "major neurocognitive disorder." Full access to the search strategy used in these preliminary findings is available in Multimedia Appendix 2.

Most investigators participated in the study selection phase, which was conducted independently by at least 2 investigators using the Covidence Systematic Review Platform (Veritas Health Innovation). The screening process was conducted in two stages as follows: (1) paper title and abstract and (2) full-text screening. Disagreements were resolved by a third investigator not involved in the initial screening process by evaluating the raised discrepancies compared to the inclusion criteria in the published protocol. Interrater reliability was noted to be average with a mean (SD) of 0.66 (0.31) and 0.57 (0.28) and median (IQR) of 0.58 (0.48-0.79) and 0.66 (0.54-0.77) for the screening stages, respectively, indicating moderate to strong reliability.

Using the PICOS framework, the search criteria for review analysis are described below.

- Participants (P): reviews, including data from patients diagnosed with dementia (self-reported or clinically diagnosed by an individual or multidisciplinary team of medical and health care providers), regardless of the international classification used (for instance, *International Classification of Diseases, Tenth Revision*; *International Classification of Diseases, Eleventh Revision*; or *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*). In addition, those reviews focusing on the importance of DHTs for caregivers (formal or informal) of people living with dementia were shortlisted and evaluated.
- Intervention (I): we included any modality of DHTs, telemedicine, telehealth, computerized decision support systems, clinical reminders or alert systems, home automation and monitoring systems, sensor-based systems and ambient intelligence, AI, mobile health, big data, 4G or 5G, exergaming, and the internet of things.
- Comparator (C): no comparison group was prioritized. We included studies without any comparator, head-to-head comparisons, and placebo assessments.
- Outcome (O): the Crosslingual Optimized Metric for Evaluation of Translation initiative was used to evaluate the existing "core outcome sets."

XSL•FO
RenderX

- Study design (S): systematic, rapid, and scoping reviews.

Systematic reviews that included more than one database search, in either narrative or quantitative format, were eligible. Moreover, scoping and rapid reviews were considered, categorized as "a review aiming to identify and map the available evidence, but that utilized a systematic methodological approach for including studies" [16]. We excluded

narrative and integrative reviews (reviews without systematization of search and inclusion approaches) because they are more likely to report data in a highly biased pattern. Regarding the exclusion of narrative and integrative reviews, we would like to highlight several reasons [16,17]. First, narrative reviews are highly prone to selection bias, as they typically do not systematically cover all relevant studies. Similarly, integrative reviews often lack the rigorous, standardized search and inclusion criteria that are fundamental to systematic and scoping reviews [16,17]. Therefore, we excluded these types of publications to minimize potential inconsistencies and biases that could compromise the validity of our bibliometric analysis. [16,17].

Bibliometric Analysis and Data Management

Following the initial identification of eligible reviews, a bibliometric analysis was conducted on the records that met our inclusion criterion. First, we downloaded eligible data from Covidence in a cvs format file to create our "primary library." Raw cvs data were transformed into a relational Research Information System database, with the further exclusion of duplicates not primarily identified by Covidence ("secondary library"). After identifying unique records using their digital object identifier (DOIs), we created a matching "secondary library." We then downloaded a comprehensive cvs file, which was further used for the bibliometric analyses.

This review used VOSviewer (version 1.6.20; Leiden University) to analyze the type of documents, years, authors, countries, institutions, journal sources, references, and keywords, allowing the creation of social network maps. VOSviewer uses probabilistic-driven normalization to ensure that the strengthen of relationships between nodes is accurately represented, accounting for differences in publication volumes and citations practices across various fields [18]. The projected clusters, each represented by a different color, suggest groups of related items that frequently cooccur in the literature, indicating underlying thematic connections [18]. The importance of these clusters lies in their ability to identify trending research topics, emerging trends, and potential gaps in the literature [18]. The total number of citations each year was obtained from the Scopus citation report. Social network analysis was set as the primary method used to analyze co-occurrence. Data associated with the journal's impact factor (IF) were obtained from the Clarivate Journal Citation Reports (2022) and matched to the highlighted journals in our results section. From all variables prioritized in our study, corresponding data obtained from VOSviewer visualization analysis and calculations were also exported and tabulated on Microsoft Excel. VOSviewer uses probabilistic-based data normalization to create maps in fields like keywords, countries, and authors. These data were subsequently displayed in descriptive tables.

In bibliometrics, social network assessments are widely used to identify research hot spots and trends within specific scientific fields. The cluster findings were evaluated through VOSviewer to develop social network visualizations, demonstrating the relevance of the node size and line thickness. The nodes represent the number of occurrences or frequencies, while the observed lines between the nodes suggest relationships between nodes. A thicker line denotes a more substantial relationship between the nodal components, while a slimmer line denotes a weaker relationship and connection between nodes. The reported network analyses afford the visualization of trends in reviews on the interface between digital health and dementia.

Data management was performed predominantly in VOSviewer, which uses machine learning algorithms, processed input data related to study identification (title, authors, publication year, journal, and DOI), the number of citations and impact (citation count and IF of the journal in which the review was published), reported geographic regions attributed during indexation, departments and institutions declared during indexation, as well as main descriptors (standardized or nonstandardized indexation nomenclature).

Our bibliometric analysis is based on an overview of systematic and scoping reviews. Bibliometric analyses focus on quantifying publication patterns within a field, including the number of citations, authorships, coauthorship networks, institutional contributions, and keyword trends. Consequently, readers should not expect quality assessments of individual reviews, such as the use of AMSTAR tool.

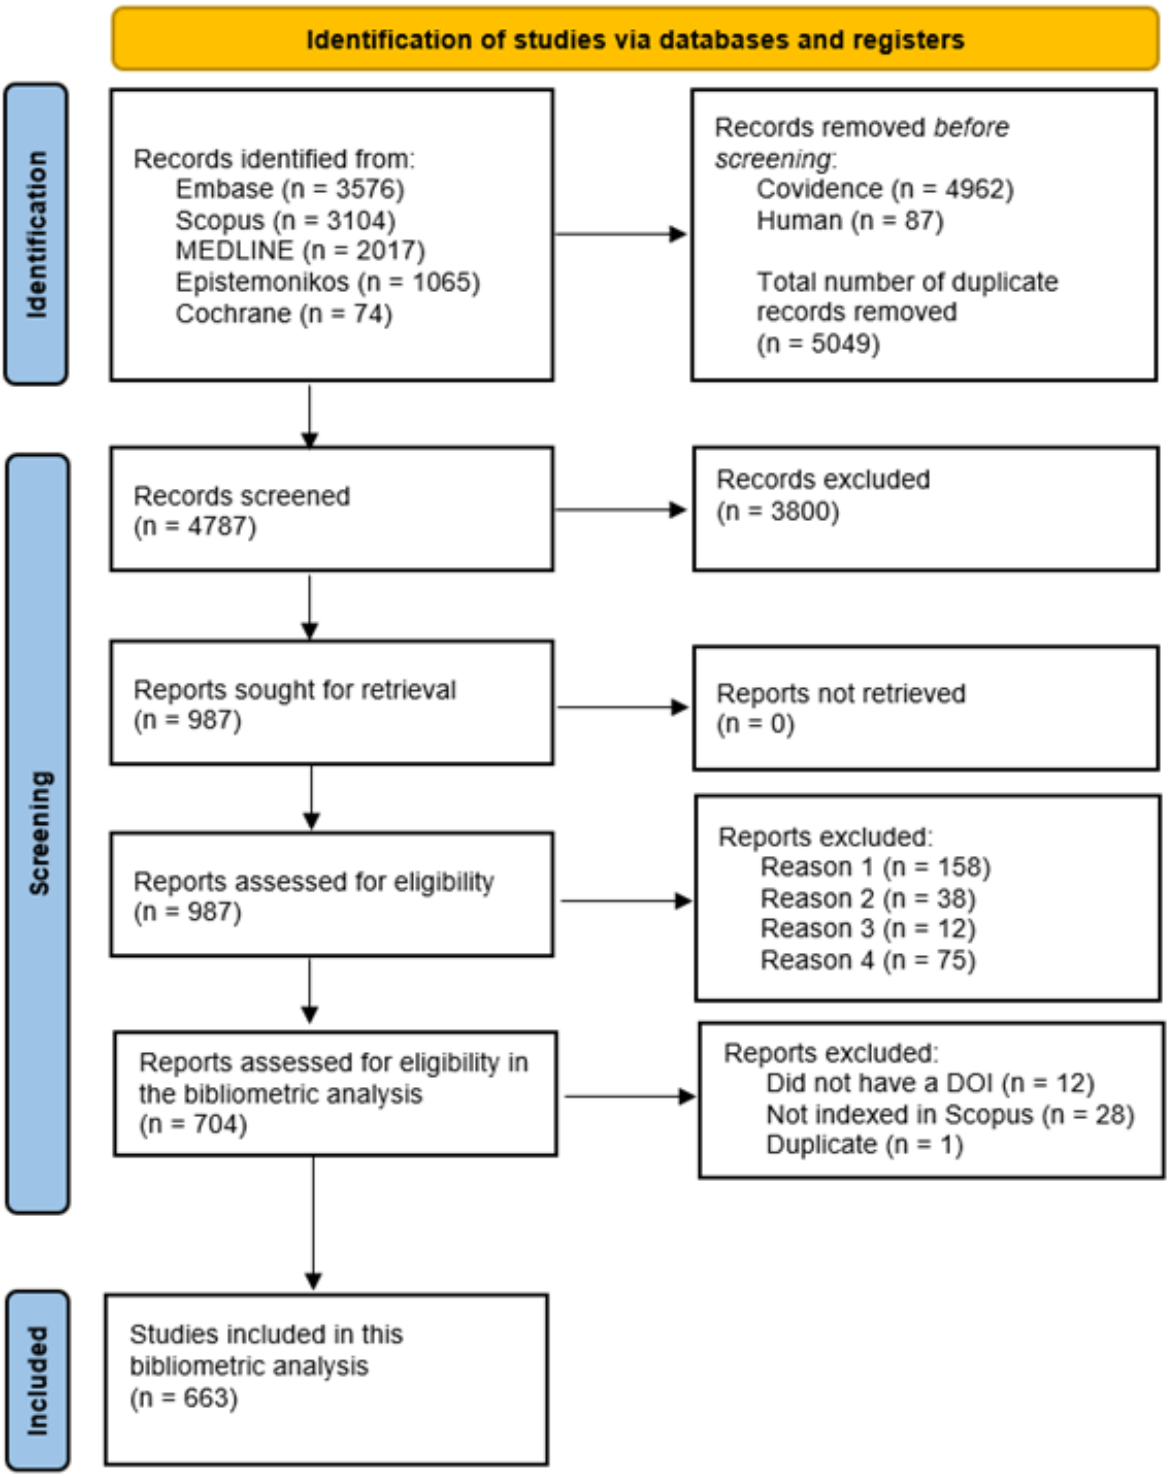
Additional Data Processing and Categorization and Data Synthesis

In addition to our bibliometric assessment, a further classification of included reviews using a 3-step data assessment plan was conducted independently using Covidence. Each review was tagged for the number of primary studies reported in the manuscript (for instance, 0-10, 11-30, 31-60, 61-90, and 91-infinity), the modality of DHT being reported within the review, and if the record was a "systematic" or "scoping" review. We designed a focused analytic step of shortlisted studies to identify overviews intersecting between digital health and dementia. An additional filtering step was applied to identify records that had already used an overview methodology in their assessment. This step was introduced to avoid duplicating research efforts and to prioritize a more detailed exploration of modalities that have historically been less examined in the literature. This resulted in the identification of 14 records with the identifier "overview" or "umbrella," as shown in Multimedia Appendix 3.

Ethical Considerations

Ethics approval was waived as we used secondary, publicly available data.

Results



Overview

A review flowchart diagram is shown in Figure 1. Complete details regarding the justification for the exclusion of the

XSL•FO
RenderX

shortlisted studies is available in Multimedia Appendix 4. Reasons for excluding shortlisted studies were primarily associated with conference papers (not published as full reports), protocols, reviews not focusing on DHTs, reviews of bioinformatics concepts, literature reviews, and studies not enrolling patients with dementia or cognitive impairment.

Figure 1. Review flowchart diagram. DOI: digital object identifier.

General Findings

Our results show the categorization of eligible reviews based on the number of primary studies, the modalities of DHTs reported within reviews, and the type of review (scoping or systematic review). Most of the included records were systematic reviews (537/663, 80.9%), while some scoping reviews were also registered (126/663, 19%). In addition, most reviews (346/663, 52.1%) included 11 to 30 primary studies (regardless of the study design). Notably, a lower number of records were allocated to the 31 to 60, 61 to 90, and ≥91 primary studies.

XSL•FO
RenderX

At the time of conducting the literature search, we ascertained that there were no published protocols of an overview of reviews (systematic or nonsystematic reviews), collating the available evidence of multiple modalities of DHTs pertaining to the integrated care of people living with dementia or any other related neurocognitive disorders or cognitive impairment disorders. This literature search is significant because of the volume of studies involved, including a substantial number of published overviews analyzing the relevance of DHTs in dementia care. While we assessed DHT modalities already covered in existing literature reviews, we placed particular emphasis on thoroughly examined less-explored modalities using our overview methodology. In doing so, we ensured a focused and detailed exploration of underrepresented areas. As part of this process, 14 records containing the term "overview" or "umbrella review" were identified in the tracked records (Multimedia Appendix 3). These overviews, published after 2022, have been undertaken on people diagnosed with dementia to understand the effect of DHTs, such as wearable sensors, AI, virtual reality, eHealth, and web-based interventions. We did not include studies without a clear clinical, radiological, or any other deterministic form of diagnosing dementia on the patients under investigation in our analysis.

Bibliometric Analyses

A total of 755 references were included, and 52 reviews were duplicated (not primarily identified through automatic exclusion using the reference manager software), resulting in 704 references eligible for the bibliometric analysis. Furthermore, 12 references did not have a DOI identifier (Multimedia Appendix 5), and 28 were not indexed in Scopus (Multimedia Appendix 6). Therefore, a total of 663 articles were downloaded into the cvs extension from Scopus, and visualization analysis was conducted.

Top Contributing and Co-Cited Journals

Table 1 and Figure 2 present our results on the authors with the most publications and the journals with the highest citations in the field of dementia and DHTs based on our included reviews. The Journal of Medical Internet Research had the highest number of reviews (34/663, 5.12%), with the highest citation count from all journals provided in the ranking (1052). Similarly, the Journal of Alzheimer's Disease and the Cochrane Database of Systematic Reviews showed substantial metrics regarding published reviews and citation count. Note that the average publication year widely varied across ranked journals. The Ageing Research Reviews (IF_2022=13.1) was the journal with highest IF, while the lowest was the Geriatric Nursing (IF=2.7). Six distinct clusters were identified represented in red, green, blue, yellow, purple, orange, and cyan, each corresponding to a unique collaborative or thematic pattern. A complete analysis of the identified clusters is reported as a legend to Table 1.

As seen in Figure 2, the analysis of clusters revealed that cluster 1 (in red) included journals like *Dementia, Disability and Rehabilitation: Assistive Technology*, and *Frontiers in Psychology*, which focus on psychological, social, and rehabilitation features of dementia care, particularly the integration of dementia to assistive technologies. Cluster 2 (in green) contained journals like *Healthcare (Switzerland)* and *Frontiers in Aging Neuroscience*, which were likely to be associated with health care delivery and neuroscience aspects of dementia care, providing a focused and tailored analysis using medical and biological components attributed to DHTs. In cluster 3 (in blue), we observed the presence of highly influential journals like the *Journal of Medical Internet Research* and *International Psychogeriatrics*, whose primary focus relates to internet-based research, psychogeriatrics, and perhaps the broader implications of DHTs in dementia care. Cluster 4 (in yellow) featured journals like the Cochrane Database of Systematic Reviews and *Ageing Research Reviews*, representing evidence-based reviews and systematic approaches to aging and dementia, emphasizing the fundamental role of rigorous evidence synthesis in the development and validation of DHTs in dementia care. In cluster 5 (in purple), journals like *International Journal of Nursing Studies* and *Journal of Clinical Medicine*, were found, which mainly publish research focused on the clinical and nursing aspects of dementia care as well as their integration with DHTs into routine clinical practice. Cluster 6 (in cyan) contained journals like the *Journal of Alzheimer's Disease* and *Sensors*, with a particular focus on the interface between dementia research and sensor technologies, potentially emphasizing the role of wearable and remote monitoring devices in dementia care. Finally, the small cluster 7 (in orange) represented a distinguished group of journals, highlighting specific thematic focus within the field of dementia care and DHTs.

Figure 2. Top contributing and co-cited journals.

Top Contributing Countries and Regions

Researchers from 66 countries published reviews on the intersection between dementia and DHTs, and Table 2 details the number of citations, documents, and the average number of publications per year, etc. The top 5 countries with evidence-based research in this arena are the United Kingdom (139/663, 20.9%), United States (105/663, 15.8%), Australia (66/663, 9.9%), Canada (61/663, 9.2%), and the Netherlands (53/663, 7.9%). Column 3 of Table 2 shows the country coauthorship networks, particularly evidencing the chord diagram of country cooperation networks ranked by total link strength (Figure 3). The United Kingdom had the highest number of total link strengths, followed by the United States, the Netherlands, Australia, and Switzerland (335, 155, 145, 142, 128, respectively). Countries with the highest number of citations included the United Kingdom (n=6004), United States (n=4911), Australia (n=3491), the Netherlands (n=2647), and Canada (n=1758). Cluster analysis identified 6 different research clusters within the intersection between DHTs and dementia care. Explanation related to identified clusters is available in Table 2.

As seen in Figure 3, cluster 1 (in red) shows that North America and East Asian countries are powerhouses on the research in the interface between DHTs and dementia care, cluster 2 (in green), represents diverse global contributors with a focus on European and South Asian countries, cluster 3 (in blue) suggests leaders in the European and Middle Eastern research hubs, cluster 4 (in yellow) flags Northern European and Nordic countries as research hubs, cluster 5 (in purple) represents Southern Europe and Middle Eastern countries as emerging players in research with growing interest in advancing research in the intersection of DHTs and dementia care, and cluster 6 (in cyan), represents smaller and more focused contributors with specific expertise (in terms of citations).

Figure 3. Most prolific countries in the field of dementia and digital health technologies.

Top Contributing Authors

Between 2002 and 2024, a total of 3076 authors have published reviews relating to the intersection between dementia and DHTs (Table 3), including authors who have published ≥3 papers. Seven (0.22%) researchers had published 5 documents based on the identified reviews (Rose-Marie Dröes, Julian Hirt, Minmin Leng, Meyer Gabriele, Ita Daryanti Saragih, Jing Wang, and Zhiwen Wang). Column 4 of Table 3 pertains to the author coauthorship networks, particularly related to the density visualization of the number of publications by the author (Figure 4). Some of the 63 (2.04%) authors in the network were not connected to each other, and the largest set of connected authors consisted of 31 (1%) authors. In Figure 4, the redder the color, the higher the number of publications from the determined investigator, and the closer the distance between authors, the greater the collaboration intensity. With regards to the total link strength between identified authors, the most substantial co-occurrence network was performed by Minmin Leng (n=11), Mingyue Hu (n=11), Julian Hirt (n=10), Li Chen (n=9), and Huiru Yin (n=9).

Figure 4. The most prolific authors in the field of dementia and digital health technologies.

Top Contributing Institutions

A total of 2218 institutions or academic departments (organizations) have produced reviews on the interface between dementia and DHTs (Table 4). The analysis evidenced that the College of Nursing, Kaohsiung Medical University, Kaohsiung in Taiwan (5/2218, 0.22% documents) and the Dementia Services Development Centre Wales, Bangor University, Bangor in the United Kingdom (4/2218, 0.18% documents) were the most productive centers in the field of digital health and telemedicine. In relation to the highest total number of citations from each organization, 3 (0.13%) institutions from the Netherlands had the highest citation number (n=396). These institutions are Delft University of Technology, Delft Bio-Robotics Lab, in Delft, Maastricht University, Care and Public Health Research Institute, in Maastricht, and Zuyd University of Applied Sciences, Research Centre for Technology in Care, in Heerlen. Column 5 presents the institution coauthorship networks and the chord diagram of the institution cooperation network. In Figure 5, it is worth reiterating that the size of the nodes represents the number of publications per institution. The distance between each node as well as the thickness of the link represents the strength of cooperation between institutions. Cluster analysis is fully described in Table 4. However, the identified clusters represent 1 (in red) institution leading in technological innovation and multidisciplinary research in DHTs; 2 (in green) institutions that focuses on health care implementation, gerontology, and ethics; and 3 (in blue) institutions at the intersection of nursing and applied psychology.

Analysis of Co-Occurring Keywords

On the basis of the co-occurrence network, a total of 2808 indexed keywords were found with each keyword being used at least 20 times. Table 5 illustrates the keyword co-occurrence network of reviews focusing on dementia and DHTs. The network map contains 5 clusters of 101 items, 4159 links, and 43,365 total link strengths. “Human” was the most frequently occurring keyword (523/2808, 18.63%), followed by “dementia” (385/2808, 13.71%), “systematic review” (327/2808, 11.65%), “review” (327/2808, 11.65%), and “aged” (181/2808, 6.45%). Table 5 presents the top 97 indexed keywords. These keywords are divided into 5 clusters (Figure 6), and its highlighted topographical zones.

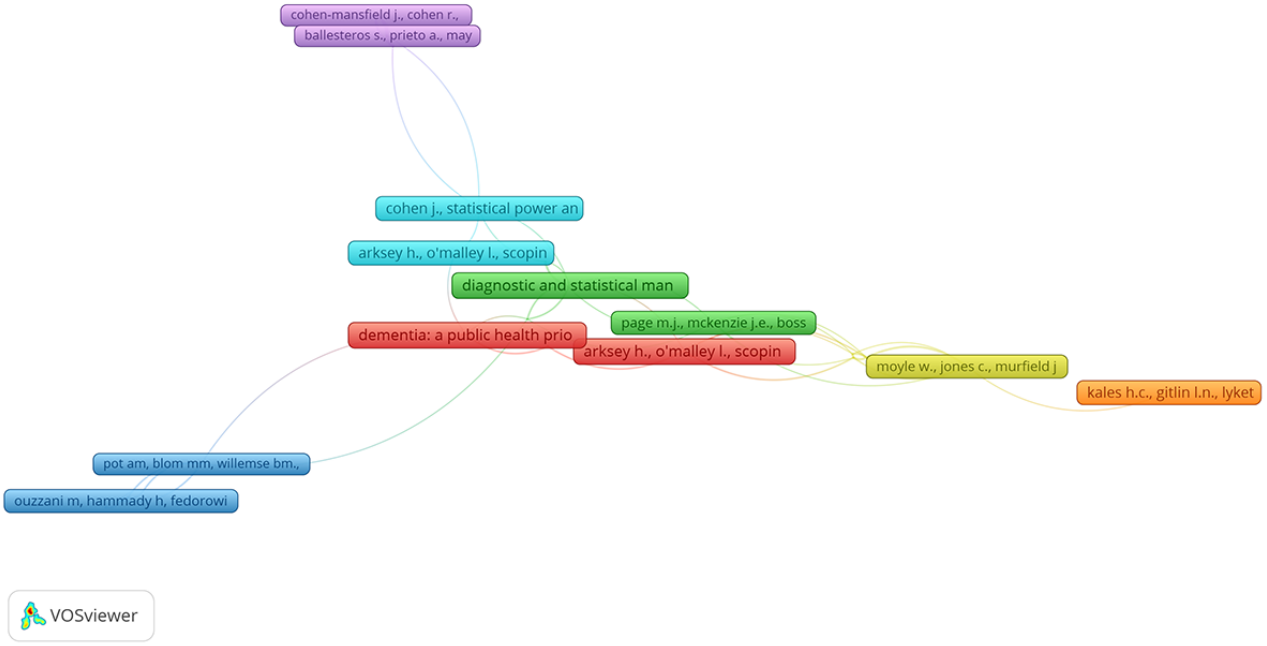
Figure 6. Analysis of co-occurring keywords.

As seen in Figure 6, cluster 1 (in red) represents all technological innovation and multidisciplinary research groups, characterized by groundbreaking institutions at the forefront of technological innovation in DHTs. Cluster 2 (in green) includes institutions that represent health care implementation, gerontology, and ethical considerations, while cluster 3 (in blue) represents evidence groups working on the interface of nursing and applied psychology groups.



Analysis of Reference Co-Citation Network

In 663 reviews analyzing the interface between dementia and DHTs, 42,758 references were cited **(**Figure 7). On the basis of the statistical assessments performed on VOSviewer to create our co-citation network (parameters: 3 for a minimum number of citations of cited references), 439 (1.02%) cited references were identified. Some of the 439 cited references in the obtained network were not connected. The most extensive set of connected references was 433 (1.01%) (Figure 7). Table 6

XSL•FO
RenderX

presents the top 15 most cited references among the 663 included reviews. The most cited reference was by the WHO, titled “Dementia: a public health priority,” published in 2012 [19].

[a]Of note, we observed the existence of duplicated references not primarily identified through the software use for performing our bibliometric analysis (VOSviewer). Thus, we consolidated the reported metrics accordingly whenever needed (links, total link strength, and citations) into a single entry to ensure the most accurate representation within the cocitation network assessment.

Discussion

Principal Findings

Overview

This primary review describes a high-level bibliometric insight into the literature on the existing DHTs and dementia care between 2002 and 2024. An increasing number of reviews (either systematic or scoping) have been published in medical- and technology-related scientific journals (704/704, 100% records). The included reviews suggest that the number of publications covering the intersection of digital health and dementia has increased steadily over time (compound annual growth rate of 26%), with some fluctuations. However, our observations highlight how several research initiatives released in indexed journals have covered similar modalities of digital technologies and research questions. Our findings align with trends reported in several studies, showing that the proliferation of reviews on a single topic leads to duplicated efforts and underscores the need for greater accountability to reduce research waste [34]. In addition, our data highlight the concentration of research originating from high-income settings, presenting an opportunity for broader reflection on the implications of population aging within these countries.

Implications for Dementia Care

The challenges associated with the care of people living with dementia, as well as their caregivers, highlight the need for policy makers to reinforce adequate interventions in dementia care delivery. This review serves as a primary, high-level resource for policy makers and academics to enable them to

XSL•FO
RenderX

understand and address the growing challenges in dementia care. As reported in the identified overviews of specific modalities of DHTs, multiple digital interventions pose as relevant tools for improving the health-related outcomes of people living with dementia and their caregivers. For instance, multidomain online lifestyle programs have been reported to not only positively affect population brain health outcomes but also potentially contribute to the prevention of dementia (based on findings from the Lifestyle Enrichment for Alzheimer Prevention program) [35]. One overview investigating the role of eye-tracking technologies in evaluating eye movements and pupillometry parameters during different stages of dementia (using machine learning algorithms) suggested the potential for early diagnosis and the monitoring of cognitive decline, in addition to predicting the risk of developing dementia long-term [36]. Likewise, wearable technologies and sensors (including environmental sensor-based systems and video systems) are suggested to reduce falls and fall risk for people living with dementia or mild cognitive impairment [37].

Limitations in Current Research Approaches

Findings from this bibliometric review have ascertained the high number of reviews evaluating the impact of DHTs on dementia care. However, we have considered that there are limitations pertaining to the evidence-making process, which might not prove adequate. We found several reviews covering similar research questions (such as reviews evaluating the use of exergaming or AI in dementia care), exploring equivalent methodological approaches (such as similar research questions and eligible populations), and even underlying parallel outcomes of interest. For instance, 3 systematic reviews published in 2017, 2020, and 2023 investigated the impact of exergames on individuals with cognitive impairment to minimize the thematic level [38-40]. While the selected cases held slightly different foci, the core elements proved virtually identical, particularly the results, interpretations, and future directions for research stakeholders. This finding echoes the concerns stressed by multiple evidence producers, highlighting the potential for research redundancy in the reported results [41-44]. We recommend several strategies to address this concern, emphasizing that future research on digital health in dementia care should build on existing evidence and explore complementary knowledge gaps. In addition, we advocate for the use of standardized guidelines for conducting systematic reviews, such as those in the Cochrane Handbook of Systematic Reviews and other authority sources in the field [45]. Avoiding research duplication can be facilitated by creating a centralized research database that serves as a repository for ongoing and complemented initiatives. This would help investigators worldwide to identify knowledge gaps and prevent redundant efforts [46,47]. Moreover, fostering research collaboration and communication through interdisciplinary partnerships and international online forums can further reduce duplication [46,47]. Preregistration of studies and the adoption of open science practices enhance transparency and allow researchers to identify existing projects.

We also highlight the critical role of scientific diplomats in fostering international collaboration and multilateral partnerships. By using concepts, norms, and values in scientific diplomacy, typically used in political diplomacy, we take actions to facilitate international scientific collaboration (eg, facilitating the negotiation of research and development agreements and exchange programs or services, or enabling the establishment of international research infrastructure) [48]. Although not frequently known by senior researchers, this labor class has becoming more frequently needed and common over the last years as scientific diplomats are a critical part of fostering and initiating discussions where science, innovation, and technological advancement intersect with international relations and policy [49]. These professionals are commonly active researchers who use diplomatic responsibilities to not only influence (locally or internationally), but to also represent national interests (commonly known as diplomat scientist) to other nations, or they might potentially become specialized in a particular domain of expertise (ie, science, technology, and innovation policies in international collaboration) [50]. In addition, scientific diplomats help establish shared and standardized protocols, promote the adoption of best practices, and ensure the long-term sustainability of international research network [51]. These efforts contribute to more efficient and impactful scientific strategies on a global scale.

Cluster Analysis and Research Trends

We selected specific clusters for detailed and comprehensive analysis. Notably, our analysis of these clusters reveals relevant and timely discussions, particularly regarding their alignment with current trends in DHTs for dementia care and their implications for future research directions.

First, regarding the clusters identified in our assessment of the most cited journals in the field of dementia and DHTs, we observed a diverse landscape. Interdisciplinary collaboration, evidence-based development, and personalized care emerged as major themes. Notably, the clusters highlight the integration of psychological, social, clinical, and technological aspects, with increasing emphasis on using DHTs for mental health support (for both patients or formal and informal health care providers), sensor technologies for real-time monitoring, and systematic reviews to evaluate the efficacy of these tools.

On the basis of these findings, future research should prioritize not only collaborative research development but also the synergic integration of DHTs into health care systems, particularly in nursing and clinical practice, while always considering ethical concerns, such as privacy and the specific implementation challenges for different labor sectors. Another cluster we analyzed involved the most prolific countries in the field of dementia and DHTs. This revealed a complex global network, with leading research hubs forming distinct clusters. High-income countries, such as the United Kingdom (cluster 3), and the United States and Australia (cluster 1), stand out with the highest number of reviews and citations, underscoring their central role in advancing scientific knowledge related to DHTs for dementia care. Emerging middle- or high-income countries, including India and South Korea, respectively, are becoming notable research hubs in Asia, expanding DHT-related research beyond traditional Western centers.

Our data also point to growing international collaboration, particular among European countries, likely driven by concerns

XSL•FO
RenderX

about populational aging in the region and the European Union funding programs that require a multicenter approach to research. This global distribution emphasizes the importance of fostering international research partnerships to ensure that DHT innovations are accessible and applicable worldwide, not just in high-income countries.

Finally, our cluster analysis highlighted key institutions and research groups active in the field of dementia and DHTs. These findings underscore the importance of a multidisciplinary approach to advancing dementia care through digital health, stressing the need for collaboration across technology, health care services, ethics, and human factors to design effective, sustainable solutions.

This review predominantly included studies conducted and produced by researchers located in high-income countries. The impact of dementia and neurocognitive impairment has been noteworthy in nations where the gross national income per capita is more than US $12,376 [52]. However, the rising prevalence of dementia is not limited to high-income settings. Recent estimates suggest that by 2030, more than 75 million individuals with dementia will reside in low- and middle-income countries [53]. While our analysis included studies from various nations, there remains a need for more global and collaborative effort beyond the regions currently leading this research. These efforts should focus on evaluating the diverse roles of DHTs in dementia care, taking into action regional specificities, needs, and expectations. Furthermore, this review highlights global regions that do not feature highly in the results; this is a call for action to researchers, organizations, and policy makers in the respective regions (Latin America, Asia, Africa, Central and Eastern Europe, and so forth) to explore and conduct research in this arena.

The coauthorship and collaboration network analysis highlighted the most prolific collaboration between authors and institutions with the most relevant reviews on DHTs for dementia care. Rose-Marie Dröes, Julian Hirt, and Minmin Leng emerged as critical global investigators. At the same time, institutional productivity showed that the College of Nursing, Kaohsiung Medical University, Kaohsiung, Taiwan, and the Dementia Services Development Centre Wales, Bangor University, United Kingdom are leading contributors in this arena. By understanding this trend in productivity over time, we can further evaluate their influence on this inter and multidisciplinary field.

Implications for Future Research, Clinicians, Researchers, and Policy Makers

Our study systematically evaluates the extent to which DHTs have been described as potential interventions in dementia care. For several DHT modalities, particularly those with substantial scientific output, these technologies have provided clinicians with a strong evidence base to inform their clinical practices, enabling them to integrate (or reject) these tools for people living with dementia [54]. However, further detailed assessments are needed to determine whether various digital interventions adequately address the physical, cognitive, and social needs of people living with dementia and their caregivers.

Our bibliometric analysis highlights the growing and evolving body of literature on the critical role of DHTs in advancing dementia care, particularly within the context of international health priorities, such as those endorsed by the WHO's Global Digital Health Strategy 2020 to 2025 [55]. Given the rising global incidence of dementia, there is an imperative demand for innovative solutions that can be scaled globally, especially in low- and middle-income countries, where the burden of dementia-related disorders is expected to significantly increase by 2030.

The WHO's strategy on digital health emphasizes the importance of leveraging DHTs through equitable process, aiming to achieve universal health coverage, enhance research, and improve the quality of care [55]. These principles align directly with the potential of DHTs for dementia care, as observed in our study. With most research initiatives concentrated in high-income countries, future research should focus on the tailored development, long-term evaluation, and implementation of DHTs in diverse settings, including resource-limited environments.

Policy makers must consider the implications of our research for establishing and sustaining international research collaborations, as well as the need for interventions specifically designed to address the challenges faced by different populations. Moreover, the "publish or perish" paradigm prevalent in academia contributes to research duplication, which should be mitigated through various strategies, as previously discussed [56]. These proposed actions are aligned with the WHO's initiatives for improving global research and advancing industrial technologies, under the Sustainable Development Goals 9. By aligning future research with the priorities outlined in the WHO Global Digital Health Strategy, stakeholders can support the development of comprehensive, evidence-informed public health policies that promote the equitable adoption of DHTs in dementia care.

Strengths and Limitations

This bibliometric review has provided evidence of the modalities of DHTs in the context of dementia. The findings highlight domains that still require further evaluation and geographic regions that are leading in this arena but also require further investigation at a local level. In addition, we did not observe any previous systematic reviews evaluating the role of telemedicine and remote telemonitoring interventions on dementia care. There is a paucity in the current body of literature pertaining to the appraisal of the applicability of big data analytics regarding health-related decision-making. These analytics have been shown to provide important clinical insights that have the potential to support the development of effective therapeutic strategies and preventive measures. There is a planned body of work relating to a series of papers whereby the authors intend to evaluate the potential of these 2 modalities of digital interventions, encompassing multiple prospective domains and influencing health, economic, or social outcomes. We believe that by identifying the knowledge gap, we will facilitate the provision of care for both people living with dementia and their caregivers. Moreover, we anticipate future results will alleviate the burden of dementia on international

XSL•FO
RenderX

health care systems and optimize resource allocation toward programs that adequately supply patients and social actors involved in care. This in turn has the potential to furnish national governments, local authorities, and municipalities with greater insights to tackle respective priorities and strategies. This too may aid policy makers in identifying financial resources [57] at a local level in the context of age-friendly cities and communities [58].

This review used a solid and comprehensive methodology, although there are limitations. First, in this bibliometric analysis, reviews were included if they were located in the Scopus database, and a few identified records were not indexed in this database. Because we solely focused on the Scopus database, we may have missed key literature that might hinder the generalizability of our findings. However, we believe that the core reported findings would not be significantly changed. Second, while the observed keywords and identifiers analysis offered important insights regarding research topics that have received scholarly attention over time, further detailed assessments of the shortlisted publications may provide more specific information associated with the interface between digital health and dementia care. Third, our study's selection criterion (exclusively focusing on systematic and scoping reviews) may have slightly introduced selection bias due to the exclusion of narrative and integrative reviews. Although commonly labeled as less rigorous in their methodology, they could still offer some additional perspectives and insights into emerging tendencies, particularly in a field such as digital health, which is constantly evolving. However, we believe that maintaining our work based on better methodologically designed records increases the validity and credibility of our study. In addition, potential publication bias must be acknowledged, especially, with the repeated similar reviews that may overrepresent certain technologies or outcomes. Finally, we did not assess the methodological quality of systematic reviews identified in our screening because of the high volume of eligible reviews. However, we will prioritize the quality appraisal in the process of evidence synthesis by following the PRISMA (Preferred Reporting Items for Systematic reviews and Meta-Analyses) guidelines to report the upcoming systematic review.

Conclusions

This review indicates that there has been an increase in both dementia- and DHT-related publications since the first review in 2002, with a more prominent growth observed after 2017. Despite the diverse approach of DHT modalities for dementia care, authors have focused on mobile health, virtual reality, AI, and sensor technologies. Analysis revealed prominent authors and institutions studying the intersection between digital health and dementia. High-income countries were identified as the leaders in publishing and maintaining research collaborations on this topic. Overall, this analysis provides an initial point of reference for policy makers and academics who wish to conduct research or collaborate on funding calls to understand the contemporary landscape in a bid to undertake innovative and applied research that will primarily benefit people living with dementia, their caregivers, and service provision and resources. We particularly recommend prioritizing the exploration of underrepresented DHTs for research questions and expanding research in low- and middle-income countries to ensure alignment with global equity principles. In addition, it is essential for the scientific and governmental communities to develop frameworks that effectively integrate DHTs into dementia care, guided by the principles of accessibility, affordability, and user friendliness. This review has illustrated emerging global trends and identified areas where future research should focus, especially considering the current emphasis on high-income countries and the remaining knowledge gaps.

Acknowledgments

Abstract

Background: Alcohol use disorder (AUD) is associated with cognitive impairments that are known to affect the outcomes of conventional treatment. Digital cognitive training programs have been examined as a possible way of addressing these overlooked challenges. Existing findings regarding the efficacy of such training programs are divergent, and further studies are warranted to examine more engaging cognitive training programs using the latest technology. Smartphone-based training built upon the principles of serious gaming would not only increase the accessibility of the program, but it could also increase the motivation of the patients, potentially maximizing adherence to the training program.

Objective: The aim of the present feasibility and efficacy study was to examine the feasibility and acceptability of the Brain+ Alco-Recover app (Brain+ A/S) with gamified elements among patients with AUD when delivered as an add-on to treatment-as-usual (TAU) and with minimal guidance from health care practitioners. In addition, the effects on cognitive and alcohol-related outcomes were examined.

Methods: A total of 72 outpatients were randomized into either group A, experimental + TAU (n=36), or group B, sham + TAU (n=36), and they had to complete a 1-month training program in addition to primary treatment. Self-reported experience at the 6-month follow-up as well as actual game usage was used to determine the feasibility of the training program. Cognitive performance and alcohol consumption were assessed as well.

Results: The patients in both groups reported a high level of acceptability, and up to 83% of the patients in the experimental group met the minimum requirements for the usage of the app. The experimental group also demonstrated significant improvements in working memory ($P<.001$). Although no significant differences were found between the 2 groups regarding clinical outcomes, a greater reduction in alcohol consumption was evident at the 6-month follow-up in the experimental group.

Conclusions: The acceptability and adherence to the minimum training requirements deems the gamified Brain+ app as a feasible tool for cognitive training when delivered as an add-on to TAU. Furthermore, the potential improvements in cognitive functions should be further replicated in a larger-scale trial to assess whether these could be used to improve the treatment of AUD in the future.

Introduction

Individuals who have experienced long-term exposure to the neurotoxic effects of alcohol may show signs of cognitive impairment [1,2]. Patients with alcohol use disorder (AUD) experience partial recovery after successfully completing alcohol treatment and sustaining abstinence, but recent findings also suggest that some cognitive deficits persist in the domains for processing speed and attention (PSA), working memory (WM), and executive functions (EF), and impairments in learning and memory may persist during periods with abstinence [3,4]. Even after a year of abstinence, patients with AUD still display a broad range of diffuse dysfunctions in controlled and effortful processes such as EF and WM [1,5,6].

Unimpaired effortful cognitive processes are important in the patients' everyday lives, but also in aiding them to exert control over their own impulses toward alcohol-related cues, which in turn could increase the likelihood of abstaining from alcohol [7]. This is corroborated by recent findings, where patients with AUD who had a lower score on the Montreal Cognitive Assessment compared to healthy individuals had an increased risk of relapse at 3 and 6 months after discharge [8]. In addition, impaired attention and task shifting by means of performance on the Trail-Making Test-B was associated with a higher number of drinking days at the 3- and 6-month follow-up. Systematic reports on AUD and other substance use disorder (SUD) have also found medium effect sizes for associations between general cognition and treatment adherence for cognitive behavioral therapy, as well as impaired decision making and increased risk of relapse [9,10]. Although these findings were heterogeneous and based on various populations with SUD, the negative impact on treatment outcomes underlines the importance of recovering a broad range of cognitive functions among patients with AUD.

Therapeutic approaches focusing on restoring cognitive functions often consist of recurring, behavioral tasks that, if maintained for a longer period, result in neuroplastic changes, which in turn may be exhibited as improvements in daily activities [11]. The effects of cognitive training can be assessed according to how closely the assessment resembles the training task. Increased performance in cognitive domains targeted by similar to those prespecified in the cognitive training program is indicative of a so-called near-transfer effect [12]. On the other hand, improved performance in domains that are not related to the domains actively targeted by the training program is known as far-transfer effects [12].

The evidence of near-transfer effects among patients with AUD has been demonstrated using a wide range of different digital and computerized cognitive training programs [2]. These interventions have been shown to be effective in improving different cognitive domains, but especially the domains for EF and WM have been scrutinized [13]. Although evidence suggests that cognitive training designed to target specific domains can provide near-transfer effects [14], an improvement in one domain may not optimally address the diffuse and heterogeneous cognitive deficits that are evident in patients with AUD. In keeping with this notion, only preliminary findings are evident demonstrating far-transfer effects of cognitive training among patients with AUD [13]. This suggests that cognitive training programs focusing on a single domain, or a few closely related domains, may be an inadequate strategy for targeting the wide range of cognitive impairments exhibited by patients with AUD. More complex programs consisting of a variety of training tasks, each targeting a set of specific cognitive processes, could thus be needed. These types of multidomain, cognitive training programs have been shown to be feasible as well as capable of improving performance on a variety of cognitive tasks among patients with AUD [15-18]. Although the studies were mainly centered around the effects on higher-order cognitive functions such as WM and problem solving, these findings suggest that using more multifaceted programs may be an effective method for improving a broader range of cognitive processes, which in turn could be beneficial for the abilities required for daily activities.

In the past decade, there has been a growing interest in uncovering whether the effects of cognitive training can be transferred to clinical outcomes [2]. So far, evidence suggesting that cognitive training can improve alcohol-related outcomes has been scarce [19]. A few studies on domain-focused cognitive training [20,21] have examined the effects on alcohol consumption, but no significant reductions were found when compared to the control groups. Contrasting the findings from domain-focused programs, 3 small efficacy randomized controlled trials used training programs targeting multiple cognitive domains [18,22,23], and 2 of these reported improved abstinence rates among patients [18,23]. Although these findings were observed in only 2 studies, the results suggest that interventions addressing a broader range of cognitive functions may hold promise for improving clinical outcomes.

One possible factor that might explain the diverging findings regarding clinical outcomes could be the level of motivation [24]. The patient's motivation to complete a training program can be optimized if the tasks are kept adequately challenging while not being too overwhelming [25]. Earlier versions of computerized cognitive training have relied on less engaging paradigms based on an experimental setting, where the patients were required to use proprietary software that could only be used on a stationary computer [22]. Not only did this limit the accessibility, but it would also mean that training days would need to be scheduled regularly with a researcher or clinician.

XSL•FO
RenderX

Early versions of goal management training and software targeting WM were also characterized by simple user interfaces with a minimum number of visual elements [5]. The lack of visually capturing features were outweighed by more text-based tasks that were closer in resemblance to standardized neuropsychological assessment batteries [17,22], and this could make the training at risk for being perceived as trivial and decreasing the treatment adherence [5]. Nonetheless, advancements in mobile health (mHealth) technology have made it easier to create a personalized experience and more visually engaging training programs that incorporate gamification [26] and serious gaming elements [27]. Contrasting previous training programs, the latest technological capabilities would also allow outpatients admitted to conventional treatment to access the training program from home, thus reducing the required visits to a treatment facility [27,28].

The aims of this feasibility and efficacy study were to assess the acceptability and feasibility of a semiguided, smartphone-based, serious gaming app administered as an add-on to conventional treatment among patients with AUD. As secondary objectives, we wanted to explore whether the training program could show improvements in cognitive performance and if potential benefits on alcohol consumption and craving could be observed.

Methods

Ethical Considerations

The present study was approved by the Research Ethics Committee for the Region of Southern Denmark (S-20200199), and it was conducted in accordance with the Declaration of Helsinki [29]. This study was not registered in a public trial registry, but a protocol for the trial was published prior to the inclusion of patients [30], and registered under the International Registered Report Identifier (IRRID; RR2-10.3389). No amendments were made to the original protocol, but minor changes to the total sample size and age criteria were incorporated into the study (see Multimedia Appendix 1). Further, the reporting of this study is in accordance with the Consolidated Standards of Reporting Trials (CONSORT) 2010 Statement: updated guidelines for reporting parallel randomized trials [31] and the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) checklist (see Multimedia Appendix 2 [32]).

There were no known harmful effects of the smartphone-based training program. As all patients in this study were offered either pharmacological or psychological treatment, the study was not evaluated as posing any ethical challenges. Finally, all patients were informed that they could withdraw their consent without it having any implications for their current or future treatment options. If the patients chose to withdraw their consent, all their data would be erased.

Trial Design

This pilot trial was conducted as a double-blinded, randomized controlled trial with 2 parallel groups. An urn randomization technique was used without any stratification [33], and the allocation of patients to the groups was performed by an independent statistician.

Recruitment

Patients from the publicly financed, outpatient alcohol treatment clinic in Odense, Denmark, were consecutively invited to take part in the study until a sample of 72 patients was obtained. The recruitment took place between September 2021 and September 2022. All patients attending the clinic in Odense undergo a 3-month treatment program consisting of either pharmacotherapy or psychotherapy or a combination of both, where the latter is based on manualized combined motivational interviewing and cognitive behavioral therapy [34]. During the primary treatment, a health care professional conducted a clinical assessment of the patients according to the *International Classification of Diseases, Tenth Revision(ICD-10)* [35]. The Addiction Severity Index (ASI) was used to assess sociodemographic characteristics to generate an addiction severity profile for each patient [36].

Eligibility Criteria

Patients were eligible to participate in the study if they: (1) had a confirmed diagnosis of AUD (ie, harmful use or abuse or dependence); (2) had access to a smartphone or tablet that met the requirements for using the gamified cognitive training app; (3) were between 18 and 70 years of age; (4) spoke Danish; (5) provided informed consent to participate; and (6) had completed detoxification prior to study inclusion if deemed necessary. Patients were excluded if they had a diagnosis of SUD other than AUD, a severe mental disorder with suicidal, manic or psychotic symptoms, a neurological disorder, or terminal illness.

Procedure

Eligible patients were informed about the study by their health care providers. Patients who expressed interest in participating were referred to a research assistant who provided verbal and written information about the study following a standardized procedure. The patients signed an informed consent form, and they were further screened for eligibility and randomly allocated to an experimental or sham training group. Following this, a pretreatment assessment of cognitive and clinical outcomes was conducted, and lastly the research assistant helped the patients with installing the app on their smartphone or tablet.

Allocation and Blinding

Eligible patients were consecutively randomized to one of 2 groups: (A) an experimental version of the cognitive training program + treatment as usual (TAU) (n=36), or (B) a sham version of the cognitive training program + TAU (n=36). The patients were blinded to their allocated group, and the research assistants who performed the randomization were also unaware of which version of the training app they helped to install on the patients' smartphones or tablets. This was achieved by assigning a random number to the 2 versions of the training app, and these 2 designated numbers were only known to an independent researcher who did not take part in the assessment of the patients.

XSL•FO
RenderX

Assessment and Outcomes

Sociodemographic and clinical data were extracted from the outpatient clinic's clinical database containing data from the initial clinical assessments performed by the health care professionals. Assessments were conducted by research assistants at study enrollment (T0), posttreatment (T1), and at 6-month follow-up (T2).

Acceptability and Feasibility Outcomes

The acceptability of the Brain+ Alco-Recover (Brain+ A/S) app was determined by means of the System Usability Scale (SUS) and was only administered at T2. This scale evaluates different elements of the user-interface and assesses the confidence of the user in using the training program [37]. The criterion for the feasibility outcome was based on the actual usage of the individual games in the training program. For the experimental group, a minimum requirement of 5 completed game trials for each of the individual game types was predetermined and this was equal to approximately 80 minutes of total training time (ie, 20% of the instructed duration for the predefined training program). It was expected that the adherence to the training program would be much lower than the instructions provided to the patients due to the lack of a notification system and that the patients trained at home. Thus, for the training program to be deemed as feasible, a criterion was set, where at least half of the patients in the experimental group had to meet these minimum requirements for each game type.

Cognitive and Clinical Outcomes

Cognitive performance was measured with assessment versions of the various training games in Brain+ Alco-Recover at T0 and T1. The performance scores in 2 cognitive domains were prespecified as PSA (ie, the in-games Perception Speed and Attention Island) and WM (ie, the in-games Memory Lane and Bulky Codes).

Alcohol consumption was measured at T0, T1, and T2 using the following 2 items derived from the alcohol module in the ASI: (1) days with any alcohol consumption in the past 30 days, and (2) days with excessive drinking (ie, 3 units or more) in the past 30 days [36]. Mean craving level and highest craving level during the past week and the past 30 days were measured at T0, T1, and T2 using the visual analogue scale (VAS) [38].

Intervention

The cognitive training app, Brain+ Alco-Recover, was adapted from the publicly available Brain+ Recover app [39], which was developed by neuropsychologists at the Centre for Traumatic Brain Injury, University of Copenhagen in collaboration with the company Brain+. To test the effects of the training program with high ecological validity, the Brain+ Alco-Recover app was used by the patients at home without any guidance from the researchers.

Experimental and Sham Version of the Cognitive Training Program

The experimental version of Brain+ Alco-Recover consisted of a personalized training program initially created from the preassessment, and the difficulty level was adjusted to fit the patient's performance level measured during the preassessment. The personalized, daily training sessions consisted of 6 different games (see Multimedia Appendix 1 for detailed information and screenshots of each game), which were combined in 2 blocks of 4 games each. The training blocks alternated between the selection of games, but all the games appeared with the same frequency. The in-game algorithm ensured that the 2 blocks were personalized in terms of the duration of each game, and the cognitive domains in which the patient underperformed during the preassessment were thus targeted for more intensive training. Each game took on average 2 minutes and 40 seconds to complete, but 1 training block lasted 10 minutes. The sham version of the training program was nearly identical to the experimental version, except for the omission of 1 game (see Multimedia Appendix 1 for details). While the games in the sham condition remained adaptive to the patient's performance, the level of difficulty was fixed to minimize the potential for cognitive improvement (eg, by preventing further reductions in exposure time). Importantly, we identified a discrepancy between the sham and experimental versions of the app that resulted in differences in baseline measurements (Table 1). To ensure this discrepancy did not bias our statistical analysis, we focused on within-group change by analyzing improvement from baseline to final measurement, rather than relying on absolute scores.

Previous studies have found an effect of training sessions lasting 45-60 minutes [16,20], but as we wanted to establish the feasibility of the Brain+ app in its early stages, we chose to incorporate short but frequent training sessions. Patients in the experimental and sham group were instructed to use the app for 20 minutes a day, 5 days a week, for 1 month (ie, a minimum of 400 minutes or 6 hours and 40 minutes of total in-game time for the entire intervention). This resulted in a daily training session that consisted of 2 blocks of 10 minutes each (ie, 2 blocks of 4 games each). As a notification system was not yet developed for the app, patients were reminded to complete their training sessions, when they had to visit the outpatient facility, but they were not guided any further. Thus, this was a semiguided training program in which patients were neither monitored for their actual game progress nor assisted with completing any games, which also meant that there were no implications if a patient failed to adhere to the training program. It was not possible to log the time spent on the training; instead, the total duration was estimated based on the number of completed game trials.

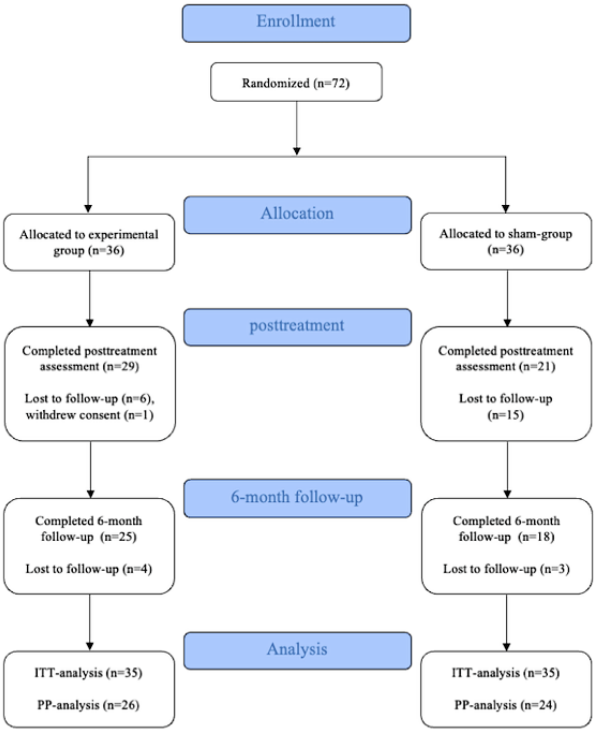
Statistical Analyses

The baseline characteristics of patients in both study arms were summarized using means and standard deviations (SD) for continuous variables, and frequencies and percentages (%) for categorical variables. Differences between the 2 arms were assessed using 2-tailed, independent samples *t* tests for continuous variables and chi-square tests for categorical variables.

To determine whether 50% of the patients in each group completed the minimum of 5 game trials for each game type, our feasibility was analyzed using Fisher Exact test under the intention-to-treat (ITT) principle, including all randomized participants. In terms of cognitive outcomes, the within-group

XSL•FO
RenderX

change from baseline to posttreatment in domain scores (ie, PSA and WM) as well as individual game scores, were analyzed using linear mixed-effects models with random intercepts for participants, fixed effects for time, and a group-by-time interaction. An unstructured covariance matrix and robust standard errors were used. These models inherently account for all available data under the assumption of missing at random and are consistent with the ITT principle. Analyses were also conducted per-protocol (PP), including only participants who completed ≥ 5 game trials for each game type.



Clinical outcomes, which included drinking days (DD), heavy drinking days (HDD), mean and highest craving level (MCL and HCL, respectively), were analyzed using similar linear mixed-effects models across baseline (T0), posttreatment (T1), and 6-month follow-up (T3), with a group-by-time interaction, unstructured covariance, and robust standard errors. These analyses followed the ITT principle. No formal power calculation was conducted; results are interpreted as efficacious. All analyses were performed using Stata 18 (StataCorp LLC). A 2-sided *P* value<.05 was considered statistically significant.

Results

Participants

A total of 72 patients were randomized to either the experimental group (n=36) or the sham group (n=36). One patient in the experimental group withdrew consent to participate after the baseline assessment and thus data for this person were deleted (see Figure 1). Fifty patients completed the posttreatment assessment (ie, experimental group: n=29; sham group: n=21), and 43 patients completed the 6-month follow-up assessment (ie, experimental group: n=25; sham group: n=18). It was not possible to reach any of the missing patients for the posttreatment assessment or at the follow-up after 6 months; thus, no further information on reasons for discontinuing the study could be retrieved.

Figure 1. Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) chart depicting the flow of participants from allocation to the last follow-up after 6 months. ITT: intention-to-treat; PP: per-protocol.

Baseline Characteristics

No significant differences were found between the experimental and sham groups regarding age, gender, alcohol consumption, and craving variables (see Table 1). There were 77% (n=27) male patients in the experimental group and 72% (n=26) were male in the sham group. The mean age of the patients in the experimental groups was 45.3 (SD 10.1) years, whereas the patients in the sham group were aged 41.4 (SD 11.5) years on average. The cognitive assessment revealed significant differences between the experimental and sham groups in the domain for PSA as well as the domain for WM (*P*<.001). Inspecting the individual mean domain scores, the experimental group had a higher cognitive performance when compared to the sham group.

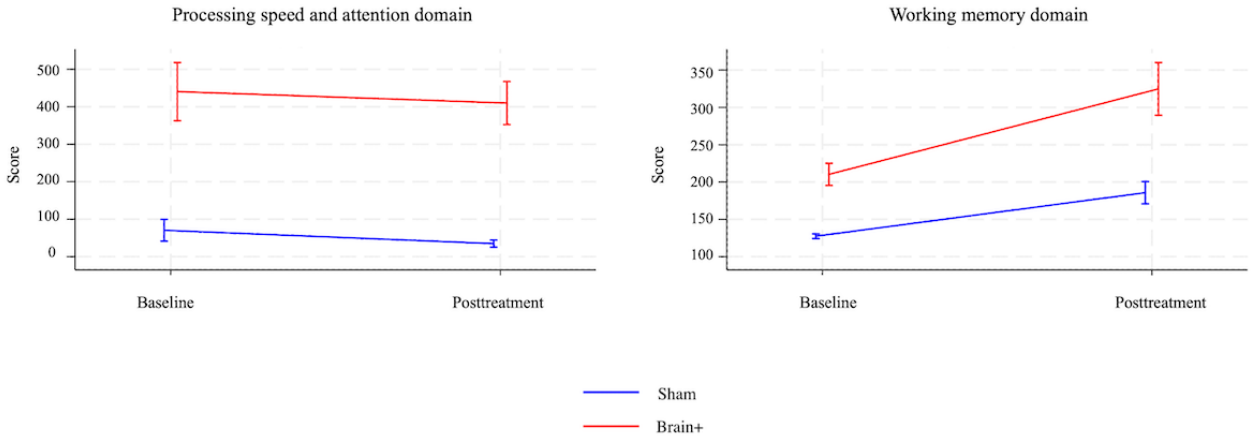
Feasibility and Acceptability of Brain+ Alco-Recover

Only 23.6% (n=17) of the patients completed the SUS at 6-month follow-up, but the overall experience with the Brain+ Alco-Recover app was well received by these patients in both groups, and no significant difference was found between the ratings of the 2 different versions of the app (*P*=.17). This was indicated by a good usability rating with a mean total score of 74.6 (SD 17.6) in the experimental group, while the sham group rated the usability of the training program as excellent with a mean total score of 81.5 (SD 11.9).

The criterion for determining the feasibility of the training program was reached in 5 out of the 6 games in the experimental version of the Brain+ Alco-Recover app, with a rate of patients completing the minimum requirements ranging from 51.4% to 82.9% (ie, corresponding to 18-29 participants) for the individual game type. The estimated average total time spent on the 1-month training program was 577 minutes for the experimental group and 919 minutes for the sham group (see Table S1 in Multimedia Appendix 1). The game that did not meet this criterion was Attention Island, where only 37.1% (n=13) of the patients completed the 5 required game trials. In the sham version of the app, the criterion was reached in 4 out of the 5 games. The game that did not meet the criterion was



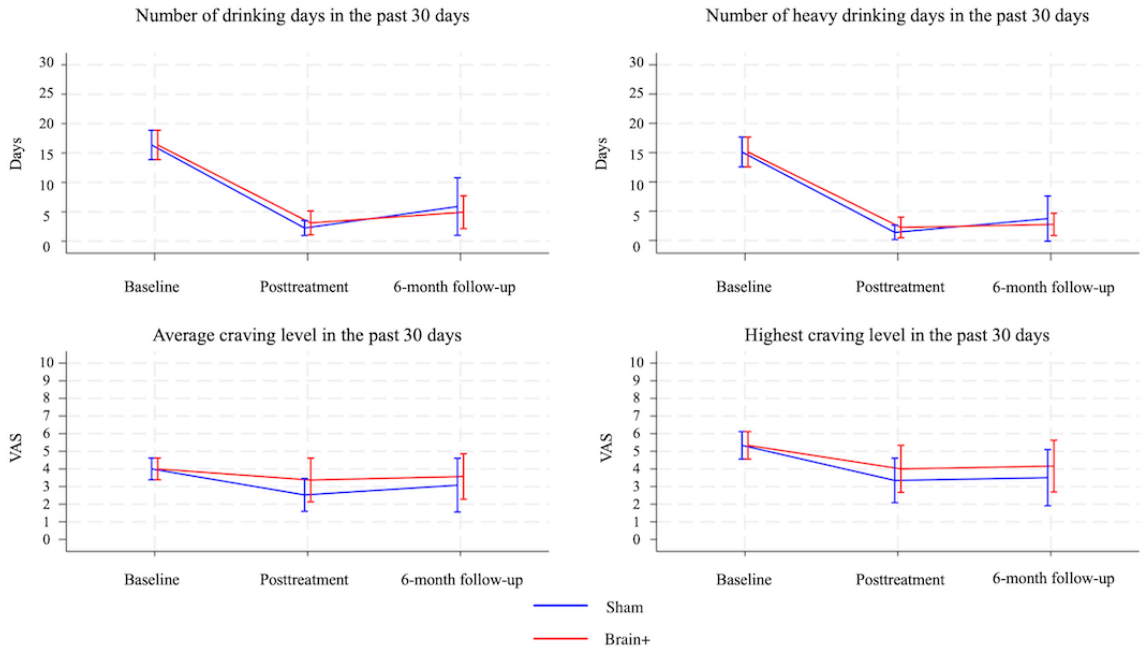
XSL•FO
RenderX

Bulky Codes, where 48% of the patients completed the 5 required game trials. There was no significant difference between the 2 groups regarding the number of completed game trials, except that significantly more patients in the sham group completed the minimum number of required game trials for Attention Island (n=13, 65.7%) compared to the experimental group (*P*=.04).

Effects on Cognitive Outcomes

Comparisons between baseline and posttreatment assessments (see Figure 2) showed a minor improvement in PSA in both groups, with no indication of a group difference (*P*=.90). A significant difference was observed between the 2 groups in the working memory (WM) domain (*P*=.002). This difference favored the experimental group, which demonstrated a higher mean change score (WM: mean 114.6, 95% CI 82.1-147.1) compared to the sham group (WM: mean 58.3, 95% CI 43.9-72.7). This significant effect remained consistent in the PP-analyses after adjusting for patients who met the minimum training requirements (see Multimedia Appendix 1 for PP analyses).

Figure 2. Change in mean domain scores from baseline to the posttreatment assessment for the experimental (ie, red line) and sham group (ie, blue line). A higher score indicates a better cognitive performance. The error bars depict the 95% CIs.



Effects on Alcohol Consumption and Craving

No significant differences between baseline, posttreatment, and 6-month follow-up assessments were observed between 2 groups regarding DD, HDD, MCL, and HCL (see Figure 3 and Multimedia Appendix 1).

By inspecting the mean difference at 6-month follow-up, there was a pattern favoring the experimental group for both DD (mean –11.44, 95% CI –15.00 to –7.88) and HDD (mean –12.37, 95% CI –15.54 to –9.19) when compared to the sham group (DD: mean –10.48, 95% CI –16.10 to –4.86; HDD: mean –11.38, 95% CI –16.13 to –6.62).

Discussion

Principal Findings

The present feasibility and efficacy study provides the most recent evidence on the acceptability and usability of a semiguided, smartphone-based, serious gaming app administered as an add-on to conventional treatment among patients with AUD. The Brain+ Alco-Recover app was deemed feasible and accepted by the patients. Further, the experimental group exhibited significant improvements in WM compared to the sham group; however, these secondary effects should be interpreted with caution due to the in-game cognitive assessment. Our analyses did not reveal any significant differences between the 2 groups regarding alcohol consumption and craving, presumably due to inadequate power. Nonetheless, the observed reduction in alcohol consumption in the experimental group suggests that this type of cognitive training might be beneficial for clinical outcomes.

The adherence and acceptability of the cognitive training in this study are corroborated by previous findings in studies that examined training programs with gamified elements [15,16,20,21] and studies that delivered the training program using mHealth technology [15,16]. Nonetheless, it should be stressed that these results regarding the acceptability were based on our minimum criterion for the usage of the training program, which was lower compared to other studies that instructed the patients to complete 45-60-minute training sessions [16,20]. Despite our decision on using shorter, 20-minute sessions, still only one third of the patients adhered to the preinstructed training program. This could be indicative of fundamental issues with the game design of the training program and the means of administration. It has been proposed that a constant display of frustrating training elements or a display of negative scores may induce a state of failure and disbelief and thereby reduce the patients' self-efficacy [24].

A reduction in self-efficacy could pose a potential threat to the effectiveness of the design of smartphone-based cognitive training programs, as one needs to balance the incentive to push the performance of the patients by constantly increasing the level of difficulty while ensuring that the patients receive an adequate amount of positive reinforcement. Although the differences in SUS scores should be interpreted with caution due to the low return rates, one could argue that the discrepancies between the two groups may be the result of one group encountering more challenging games. The lower SUS score in the experimental group could indicate that some of the games were perceived as too difficult, and thus patients could have experienced more frustration by being exposed to low scores and a high level of errors. In contrast, the level of difficulty in the sham version might have increased the completion rate, which in turn would decrease the number of self-perceived failures, resulting in more positive ratings on the SUS. This could highlight the importance of implementing the training into existing treatment programs, in which a health professional could encourage and coach the patient during the training program. Previous studies have shown that administering the cognitive training program in an environment in which the patient receives support to maintain his or her treatment goals can cultivate the effects of cognitive training [1,16,17]. Thus, balancing the optimal training conditions between a highly structured clinical setting and a more unguided approach could be imperative.

Albeit our findings of near-transfer improvements in WM were discovered using proprietary algorithms for assessment of cognition, they do corroborate findings from previous trials that demonstrated near-transfer effects using similar multifaceted

XSL•FO
RenderX

cognitive training programs for AUD [18,23]. The lack of EF and episodic memory training in the sham version also means that our preliminary findings cannot be fully extended to a broader range of cognitive domains. However, other studies that examined cognitive training focusing specifically on WM were able to demonstrate far-transfer improvements in episodic memory [40,41]. It has also been suggested that cognitive functions do not work independently of each other, and tasks designed to train verbal memory are still highly dependent on the ability to direct one's attentional resources to process and store information [2]. Thus, it could be hypothesized that even though the patients in the present study did not specifically train episodic memory, improvements in WM could manifest as improvements in other domains as well. However, relying solely on the in-game preassessment function for cognitive evaluation limits the ability to determine whether the observed near-transfer effects extend to distal domains not actively targeted by the current version of the Brain+ Alco-Recover app.

As expected, our findings showed that the cognitive training program did not result in statistically significant improvements in clinical outcomes. Notwithstanding, small and clinically relevant changes in alcohol consumption were observed. By inspecting the reduction in the mean number of DD and HDD, the experimental group did exhibit close to a 10% reduction in alcohol consumption.

Although a previous study by Kumar et al [18], with a comparable sample size (n=50) was able to detect improved abstinence rates, the cognitive training program was combined with yoga, breathing exercises, and psychoeducation. This resulted in a more guided intervention that could potentially have induced a synergistic effect of the different treatment elements. In contrast, other research groups have failed to demonstrate significant improvements in clinical outcomes [20,21,42,43], which corroborates the findings of the present study. Most of these studies included small sample sizes (n≤60), but one research group [20] did identify a trend for reduction in units per drinking day (P=.07). The training program used in the study by Khemiri et al [20], focused more on training tasks selectively targeting WM, and the patients also used the training program at home with minimal guidance. When aggregating these similarities, it could indicate that cognitive training programs, even when administered outside a treatment facility, may have clinically relevant effects among patients with AUD. However, the lack of evidence for clinical effects of the training program in the present study could also support the notion that cognitive training programs are too reductionistic to comprise the complexity needed for the induction of behavioral changes [2,12].

Limitations

The present study has some limitations. First, the development of the Brain+ Alco-Recover app was in its early stages, and as a result, more complex features as well as adaptations of specific games were omitted. The lack of a notification system made it more difficult to remind the patients about their training sessions, and this could have impeded on the number of completed game trials and adherence to the training program. To mitigate the implications of this missing feature, we ensured that the clinicians at the outpatient facility reminded the patients to complete the training sessions.

Second, previously mentioned fundamental differences in the way that cognitive scores were calculated in the preassessment phase in the Brain+ Alco-Recover app hindered the patients using the sham version to attain cognitive scores comparable to those in the experimental group. As such, the observed baseline differences in cognitive performance between the two groups were expected and are unlikely to reflect allocation bias. Furthermore, since our primary outcome focused on within-group change from baseline to posttreatment, the method of cognitive score calculation is unlikely to have substantially affected the results in the sham group.

Third, the usage of the in-game assessment meant that we were unable to detect far-transfer effects. This would also preclude bold comparisons to the effects of other cognitive training programs that were assessed with standardized instruments, thus reducing the external validity of the present findings. Nonetheless, the precision and extendibility of the cognitive assessment and training algorithms implemented in the Brain+ app have been established in studies for acquired brain injury and Parkinson's disease. Thus, it would be hypothesized that the findings in the present study could be indicative of benefits on cognitive performance.

Fourth, the present study did not examine the training effects on verbal learning and episodic memory due to technical restraints, making it impossible to cap the level of difficulty for the sham version. This should be addressed in future versions of the Brain+ Alco-Recover app, since learning and memory could be less susceptible to the spontaneous recovery occurring with continuing abstinence among patients with alcohol-related Wernicke-Korsakoff disorder [3]. However, as the included patients experienced less severe AUD and were not diagnosed with Wernicke-Korsakoff disorder, the additional benefits of implementing games targeting episodic memory could be questioned.

Last, as we in this study wanted to establish the usability and efficacy of the Brain+ app, it was not assumed that we could detect significant changes in the clinical outcomes between the experimental and sham groups. Therefore, the low sample size may have increased the risk of a Type 2. Nevertheless, in this study, potential improvement in clinical outcomes was examined to pave the way for a future, large-scaled trial, in which clinical effects could be ascertained.

Conclusions

The use of the semiguided, Brain+ Alco-Recover serious gaming app was found to be a feasible and acceptable way of delivering cognitive training to patients with AUD in conjunction with conventional treatment. Although the potential near-transfer effects in WM should be interpreted with care, this early version, adapted to patients with AUD, could be beneficial for cognitive performance even when the training sessions were performed at home with minimal to no support from a health professional. The prospect of potential effects of the cognitive training program on alcohol consumption could have valuable clinical implications and highlights the importance of exploring the

XSL•FO
RenderX

effects of the Brain+ app in large-scale trials. This would be an important step toward uncovering an effective way of ameliorating cognitive dysfunctions and improving clinical outcomes in the future treatment of AUD.

Acknowledgments

NM and AIM were involved in the design and conceptualization of the study, whereas LS and NM conducted the baseline interviews, only LS conducted the follow-up assessments of the patients. NM wrote the first version of the manuscript with help from AIM. The data processing was completed by NM, and the analyses were conducted and supervised by ANM during the first version. During the latest revision, ANM conducted the updated analyses, and ANM took part in finalising the manuscript. For the latest revision of the manuscript, LK assisted NM in editing and adapting the final manuscript. The latest revision was proof-read by LK, and AIM, ANM, LK, KA, AG, LS, and TM all approved the final version of the manuscript.

Financial funding for this pilot and feasibility trial was granted by the Psychiatric Research Foundation, which is a part of the Region of Southern Denmark. No additional financial support was received for conducting the trial.

Abstract

Background: Aerobic exercise (AE) training has been shown to enhance aerobic fitness in people with schizophrenia. Traditionally, such training has been administered in person at gyms or other communal exercise spaces. However, following the advent of the COVID-19 pandemic, many clinics transitioned their services to telehealth-based delivery. Yet, at present, there is scarce information about the feasibility, safety, and efficacy of telehealth-based AE in this population.

Objective: To examine the feasibility, safety, and efficacy of trainer-led, at-home, telehealth-based AE in individuals with schizophrenia.

Methods: We analyzed data from the AE arm (n=37) of a single-blind, randomized clinical trial examining the impact of a 12-week AE intervention in people with schizophrenia. Following the onset of the COVID-19 pandemic, the AE trial intervention transitioned from in-person to at-home, telehealth-based delivery of AE, with the training frequency and duration remaining identical. We compared the feasibility, safety, and efficacy of the delivery of trainer-led AE training among participants undergoing in-person (pre–COVID-19; n=23) versus at-home telehealth AE (post–COVID-19; n=14).

Results: The telehealth and in-person participants attended a similar number of exercise sessions across the 12-week interventions (26.8, SD 10.2 vs 26.1, SD 9.7, respectively; *P*=.84) and had similar number of weeks with at least 1 exercise session (10.4, SD 3.4 vs 10.6, SD 3.1, respectively; *P*=.79). The telehealth-based AE was associated with a significantly lower drop-out rate (telehealth: 0/14, 0%; in-person: 7/23, 30.4%; *P*=.04). There were no significant group differences in total time spent exercising (telehealth: 1246, SD 686 min; in-person: 1494, SD 580 min; *P*=.28); however, over the 12-week intervention, the telehealth group had a significantly lower proportion of session-time exercising at or above target intensity (telehealth: 33.3%, SD 21.4%; in-person: 63.5%, SD 16.3%; *P*<.001). There were no AE-related serious adverse events associated with either AE delivery format. Similarly, there were no significant differences in the percentage of participants experiencing minor or moderate adverse events, such as muscle soreness, joint pain, blisters, or dyspnea (telehealth: 3/14, 21%; in-person: 5/19, 26%; *P*>.99) or in the percentage of weeks per participant with at least 1 exercise-related adverse event (telehealth: 31%, SD 33%; in-person: 40%, SD 33%; *P*=.44). There were no significant differences between the telehealth versus in-person groups regarding changes in aerobic fitness as indexed by maximum oxygen consumption (VO_2max; *P*=.27).

Conclusions: Our findings provide preliminary support for the delivery of telehealth-based AE for individuals with schizophrenia. Our results indicate that in-home telehealth-based AE is feasible and safe in this population, although when available, in-person AE appears preferable given the opportunity for social interactions and the higher intensity of exercises. We discuss the findings' clinical implications, specifically within the context of the COVID-19 pandemic, as well as review potential challenges for the implementation of telehealth-based AE among people with schizophrenia.

KEYWORDS

schizophrenia; psychosis; exercise; aerobic fitness; VO2max; telehealth; telemedicine; COVID-19; clinical trial; safety; maximum oxygen consumption

Introduction

Sedentary lifestyle and low aerobic fitness are highly ubiquitous among individuals with schizophrenia [1,2] and are associated with a wide range of medical and psychiatric health indicators including cardiopulmonary and metabolic problems [3-5], high symptom burden, and depression [6], as well as poor neurocognition and daily functioning [1].

Emerging evidence over the past decade indicates that aerobic exercise (AE) training is effective in enhancing aerobic fitness in people with schizophrenia, along with improving multiple key clinical indicators [7,8]. Specifically, meta-analyses of studies of exercise in patients with schizophrenia point to significant improvements in positive, negative, and general symptoms; depressive symptoms; global functioning; quality of life (29 studies, 1109 patients) [9]; better sleep quality (8 studies, 1329 patients) [10]; as well as improved global and specific domains of neurocognition (ie, working memory, social cognition, and attention and vigilance; 10 studies, 385 patients) [7,11-13]. Aerobic exercise has also been shown to benefit daily living and social functioning (18 articles, 734 participants) [14]. Specifically, our group reported enhancements in maximum oxygen consumption (VO_2max)–indexed aerobic fitness that significantly predicted improvements in self-, informant-, and clinician-reported social functioning, predicting 47%, 33%, and 25% of the variance, respectively [15]. Consistent with these robust findings, the European Psychiatric Association recommended AE should be incorporated into the standard treatment of people with schizophrenia and related disorders [16].

Traditionally, AE interventions for people with schizophrenia have been administered in person (eg, exercising at a gym) [17-19]. However, following the advent of the COVID-19 pandemic and the ensuing shelter-in-place regulations, many clinics transitioned their services to telehealth-based delivery. Evidence suggests that such transitions have generally been successful—a recent report of treatment engagement with mental health services among outpatients with serious mental illness (n=116,497) indicated engagement was largely maintained during the COVID-19 pandemic [20]. The utilization of telehealth-based delivery of mental health services remained high after the cancellations of the COVID-19–related shelter-in-place regulations—data from 12,828 mental health treatment facilities in the United States indicated 88% offered telehealth services in September 2022 compared with 39% in April 2019 [21]. Yet, information about the employment of telehealth-based AE among people with schizophrenia is scarce. To address this gap in the literature, our aim was to examine the feasibility, safety, and efficacy of telehealth-based delivery of AE in this population.

Methods

Overview

Data were obtained from a multi-site, single-blind, parallel-group, randomized clinical trial examining the impact of AE on neurocognition in individuals with schizophrenia (ClinicalTrials.gov NCT03270098). Participants were randomized to one of two 12-week, 3 times per week, 1-hour interventions: AE training or a stretching and toning (ST) control intervention. All participants received their regular medical and psychiatric treatment during the 12-week interventions. Research assessments were completed at baseline (prior to randomization) and at 6 and 12 weeks after the start of the interventions. Detailed information on the trial's methodology has been published previously [22].

Following the onset of the COVID-19 pandemic, the interventions transitioned from an in-person format to telehealth, with identical training frequency and duration. This paper analyzes data from the AE arm of the study and compares the feasibility, safety, and efficacy of AE among participants in the in-person (pre–COVID-19) versus the telehealth AE (post–COVID-19).

Ethical Considerations

Data were obtained from 4 US sites in New York, North Carolina, California, and Georgia. The study was reviewed and approved by the Icahn School of Medicine at Mount Sinai's Institutional Review Board (STUDY-17‐00971); all sites approved the study, and all participants provided informed consent. Participants received up to US $720 compensation for completing all research assessments and study procedures.

Participants

Data were collected between April 2018 and January 2023. Inclusion criteria included the following: aged 18‐55 years; English-speaking; a *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (*DSM-IV*) diagnosis of schizophrenia or related disorders; taking antipsychotic medication for ≥8 weeks and on current doses for ≥4 weeks or injectable depot antipsychotics for ≥3 months; medically cleared by a physician to complete a VO_2max test and exercise; and has the capacity to understand study risks and benefits. Exclusion criteria were having a *DSM-IV* diagnosis of alcohol or substance abuse (except nicotine) within the past month or alcohol or substance dependence (except nicotine) within the past 6 months; initiation of any medication known to impact cognition in previous 4 weeks or any change in medication dosage during this period; a history of seizures or head trauma with a loss of consciousness greater than 10 minutes resulting in cognitive sequelae or rehabilitation; significant clinical abnormalities in physical examination, electrocardiogram, or laboratory assessments; medical or neurological conditions that could interfere with

XSL•FO
RenderX

study participation; untreated hyper- or hypothyroidism; BMI ≥40; pregnant or nursing; serious homicidal risk within the last 6 months; "moderate" or more severe conceptual disorganization (Positive and Negative Syndrome Scale score ≥4) [23]; poor English reading ability (Wechsler Test of Adult Reading score <7) [24]; and participation in a study involving neurocognitive assessment in the previous 3 months.

Description of In-Person and Telehealth-Based Interventions

Consistent with the American College of Sports Medicine (ACSM) guidelines [25], previous meta-analyses [26], and previous trials by our group [5,7,27,28], the AE interventions involved 12-week, 3 times per week, 1-hour exercise sessions. Sessions were led by an exercise trainer certified by the ACSM, the National Strength and Conditioning Association, or the American Council on Exercise. In-person AE sessions were held in small groups at site-affiliated exercise facilities. The in-person AE sessions began with a trainer-led 10-minute warm-up period, followed by a 45-minute exercise period using AE equipment, and ended with a 5-minute cool-down period. Participants were free to choose which AE equipment they wished to use, with the trainer encouraging participants to change equipment every 15 - 20 minutes to allow all participants to use all equipment and diversify exercise routines. All sites housed identical exercise equipment (eg, a treadmill, stationary bicycle, elliptical machine, and Xbox active play video-game console with a Kinect motion-sensing device) [27,28]. Participants who missed 3 or more AE sessions due to extenuating circumstances (eg, federal holidays, inclement weather) completed an additional week of AE.

Following the COVID-19 pandemic and the ensuing shelter-in-place orders, the interventions transitioned to telehealth-based delivery. This transition was necessary due to AE involving a high degree of ventilation and the potential of aerosolization of the SARS-CoV-2 virus from infected individuals. The AE sessions were completed at the participants' homes via teleconferencing software (CardaHealth) run on study-dedicated iPads. Telehealth AE sessions opened with a 10-minute trainer-led warm-up period, followed by 45 minutes of AE, and closed with a 5-minute cool-down period. During the 45-minute AE, participants completed common kinesthetic exercise activities (eg, jumping jacks, burpees), with a new set of exercises introduced every 3 weeks. In both AE formats, training intensity was set for each participant individually based on their maximal heart rate (HR; ie, Karvonen formula) [29] indexed during their baseline VO_2max test, with intensity set to 60% of maximal HR in week 1, 65% in week 2, 70% in week 3, and 75% in weeks 4 - 12.

AE training fidelity was indexed by the number of sessions attended and in-session training intensity recorded as the number of minutes per session participants trained with their HR at or above their designated weekly training intensity. The AE intensity was continuously monitored via Polar V800 HR monitors that participants wore during training. The trainer monitored the participant's HR via their HR monitor, which was preprogramed to beep when the participant's HR did not fall within the predetermined intensity window. If a participant's HR fell under their target HR intensity level, the trainer encouraged the participant to achieve their target goal.

Experimental Design

After fulfilling initial inclusion and exclusion criteria, participants completed a baseline assessment including demographic, diagnostic, and aerobic fitness tests (eg, VO_2max), along with clinical, neurocognition, and daily functioning measures (not reported in this manuscript). Following completion of baseline assessments and fulfilling medical clearance (completed in the same way during the in-person and telehealth-based phases), participants were randomized consecutively in the order they entered the study to either AE or ST and began training within 1 week of randomization (in person or at home, respectively). This study makes comparisons within the AE arm between those enrolled for in-person training (prior to the COVID-19 pandemic) and those enrolled for at-home training (after the pandemic started). All baseline and 6- and 12-week follow-up research assessments (including VO_2max tests) were completed in person during both phases of the study.

Key Measures

Demographic and Clinical Measures

Demographic data were collected at the baseline assessment, along with the Structured Clinical Interview for DSM-IV Axis I Disorders (SCID-I) [30] to confirm diagnoses.

Aerobic Fitness

Aerobic Fitness was indexed via VO_2max tests completed under physician supervision using electromagnetically braked cycle ergometers. Oxygen uptake and related parameters were measured at rest, during exercise, and during recovery. A 12-lead electrocardiography was used throughout all tests to index HR. Consistent with our previous studies [5, 7], the test procedure involved 3-5 minutes of resting baseline; 3-minute low resistance (10 watts) warm-up; a ramping exercise protocol of 10-50 watts (set by ACSM-predicted age, gender, and conditioning; maximal exercise norms reached in ~12 mins); and a ~3-minute active recovery period. During the VO_2max test, workload was increased by 5-10 watts every minute until 1 of the following criteria occurred: VO_2 plateau, 85% of maximal HR (220 beats per minute–age), a respiratory quotient ≥1.1, or reported exhaustion [31]. Pulmonary gas exchange and ventilatory variables were recorded breath-by-breath and averaged over 20 seconds.

AE Training Fidelity

AE training fidelity was indexed by the number of sessions a participant attended and the number of minutes per session participants trained with their HR at or above their designated weekly training intensity.

Safety Measures

Serious adverse events were recorded including death, hospitalization, emergency room visits, life-threatening events, disability or permanent damage, or other serious medical or psychiatric events.

XSL•FO
RenderX

Minor or moderate adverse events that are typically associated with AE were recorded weekly including blisters, chafing, fatigue, falls, muscle soreness or strain, joint pain, dyspnea, and angina.

Statistical Analyses

Demographic and baseline clinical data were summarized for the in-person and telehealth AE groups. Total exercise sessions, weeks with exercise, total time spent exercising, and proportion of time spent at or above target exercise intensity zone per participant were summarized using means and standard deviations and compared between groups using *t* tests. All serious adverse events were listed in tables. Proportions of patients with AE-related adverse events were compared between groups using Fisher exact tests, and mean weeks or days with exercise-related events were compared with *t* tests. A mixed-effects model with the mean-centered outcome VO_2max change from baseline was used to test for changes from baseline within each group and for differences between groups after weeks 6 and 12.

Results

Demographics and Sample Characteristics

One hundred and four participants enrolled in the study with 76 completing the baseline assessments and being randomized. Of the 37 randomized to the AE arm, 33 completed at least 1 exercise session (in-person: n=19; telehealth: n=14) and were included in the analyses. Table 1 presents the sample's demographic information. There were no significant group differences with regard to primary diagnosis, age, sex, race, ethnicity, or education.

Table . Sample demographics.

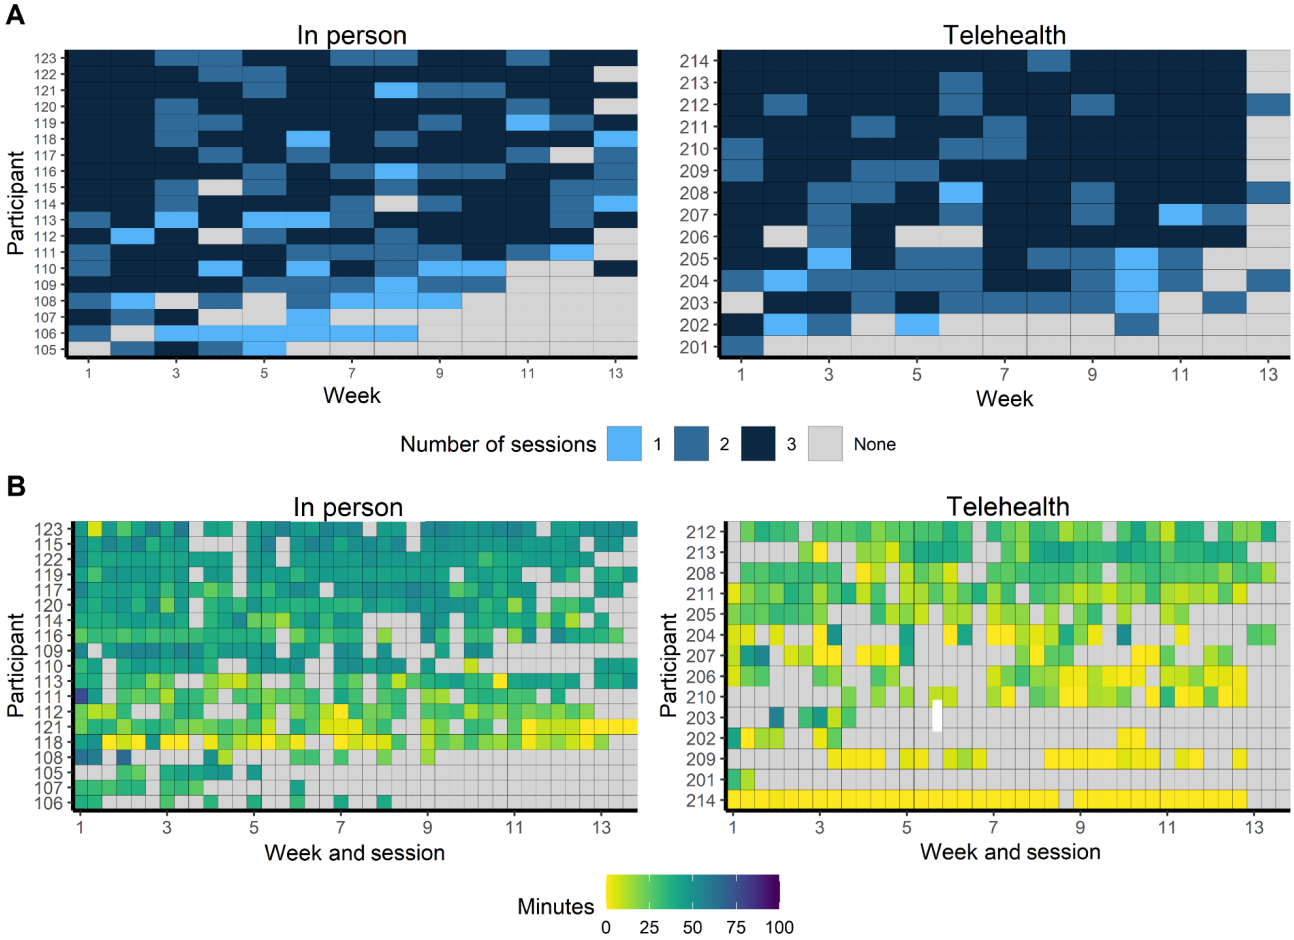
[a]GED: General Educational Development.

Exercise Fidelity



The telehealth-based AE was associated with a significantly lower drop-out rate (telehealth: 0/14, 0%; in-person: 7/23, 30.4%; *P*=.04). However, the telehealth and in-person participants attended a similar number of exercise sessions across the 12-week interventions (26.8, SD 10.2 vs 26.1, SD 9.7, respectively; *P*=.84) and the telehealth participants also had a similar number of weeks with at least 1 exercise session (10.4, SD 3.4) compared to the in-person participants (10.6, SD 3.1; *P*=.79).

The number of weekly exercise sessions and session duration over the course of the 12-week interventions are presented in

XSL•FO
RenderX

Figure 1. The telehealth participants exercised a total of 1246 (SD 686) minutes versus 1494 (SD 580) minutes among the in-person participants (P=.28). HR zone data were available for 96% of the exercise sessions—the in-person participants spent a significantly higher proportion of that time in the AE intensity target zone (in-person: 63.5%, SD 16.3%; telehealth: 33.3%, SD 21.4%; P<.001).

Figure 1. (A) Number of weekly exercise sessions and (B) session duration over the course of the intervention.

Safety: Serious and Minor or Moderate Adverse Events

None of the telehealth participants experienced any serious adverse events. The in-person AE group experienced a total of 5 serious adverse events by 2 participants (eg, exacerbation of psychotic symptoms), all resulting in psychiatric hospitalizations. All 5 adverse events were judged to be non–life-threatening and not related to the AE intervention. Data on weekly experiences of minor and moderate adverse events are presented in Figure 2.

The telehealth and in-person groups did not significantly differ in the percentage of participants with minor or moderate adverse events (telehealth: 3/14, 21%; in-person: 5/19, 26%; P>.99). The groups also did not differ significantly in the percentage of weeks per participant with at least 1 exercise-related adverse event (telehealth: 31%, SD 33%; in-person: 40%, SD 33%; P=.44) or with at least 1 moderate exercise-related adverse event (telehealth: 5%, SD 11%; in-person: 4%, SD 10%; P=.80).

The most common minor or moderate exercise-related adverse events experienced in at least 1 study week were soreness (n=21, 64%), fatigue (n=19, 58%), and joint pain (n=12, 36%; see Table 2). There was no significant difference between groups in the number of participants who experienced any minor or moderate exercise-related adverse events (P=.27). Among participants who experienced each of the minor or moderate exercise-related adverse events, the mean percentage of study days when that adverse event was experienced was highest for soreness (7.4, SD 7.4 days), fatigue (5.8, SD 6.9 days), and joint pain (3.3, SD 5.5 days), with no significant differences between groups (P=.15).

[a]Fisher exact test.

Aerobic Fitness

Baseline VO_2max was 19.1 (SD 7.25) and 21.4 (SD 7.50) for the in-person and telehealth groups, respectively. The mixed-effects model indicated an increase in VO_2max from baseline to weeks 6 and 12 in the in-person group and a decline in the telehealth group, but these changes did not reach significance, likely due to the study being underpowered. There was no significant change from baseline to weeks 6 nor 12 in either group, nor differences between groups—the in-person AE group showed 1-to-2-point change in VO_2max by 6 and 12 weeks that were not statistically significant. The telehealth AE group showed a 0-to-2-point decline in VO_2max that also was not statistically significant. These changes were not different between groups at week 6 or 12 (Table 3).

XSL•FO

Discussion

This study is the first investigation examining the feasibility, safety, and efficacy of telehealth-based AE among individuals with schizophrenia and related disorders. Our results suggest that a trainer-led administration of AE via telehealth is feasible in this population. Specifically, compared to in-person AE, telehealth-based AE was associated with a significantly lower drop-out rate and comparable total time spent exercising, though at a lower intensity as indexed by a smaller average proportion of session-time exercising at or above designated target intensity. This lower intensity may be related to the telehealth group's exercises being limited to calisthenics versus the participants in the in-person group being able to use a variety of gym equipment, including active-play videogames [27].

Our results provide support for the safety of administering AE via telehealth, as evident by the absence of any exercise-related serious adverse events during the 12-week intervention. Likewise, compared to in-person AE, there were no significant group differences in the proportion of patients with any AE-related minor or moderate adverse events (eg, joint pain, muscle strain, blisters, dyspnea). This notable safety record can be attributed to a number of factors: all participants were screened by a physician prior to initiating AE, including a complete physical, blood work, and a VO_2max test; attention was given to ensuring the telehealth group participants' exercise space at their home was unobstructed and safe; for each telehealth-based exercise session, participants had to provide contact information of someone in the household in case of a medical or psychiatric emergency; the target exercise intensity was set individually for each participant based on their VO_2max test; we employed a "start low and go slow" exercise strategy (eg, starting exercises at low intensity with gradual increases over time); a certified trainer led all training sessions and monitored participants' training intensity via "live" HR data displayed on their screen; and weekly experiences of minor or moderate AE-related adverse events were monitored.

Somewhat surprisingly, neither group showed significant changes in aerobic fitness. This could potentially be due to the small sample size or the inclusion of a more clinically diverse patient population compared to our previous studies (eg, patients with more severe depressed mood) [7]. Additionally, the decline in VO_2max (4.8%) in the telehealth group may reflect the impact of COVID-19 and its cardiovascular sequelae. Consistent with this view, a study of 86 nonclinical participants found a 14% decline in VO_2max over a 3-year period coinciding with the COVID-19 pandemic (a 4.6% annual decline) [32]. Thus, it is conceivable that without the AE intervention, the telehealth participants' aerobic fitness would have deteriorated even further. Alternatively, the lack of aerobic fitness benefits in the telehealth group may reflect having fewer opportunities to engage in physical activities outside the sessions due to the shelter-in-place guidelines. For example, an in-person AE participant who would attend 3 AE sessions per week and would walk 10 minutes to and from the gym for each AE session would engage in 60 additional minutes of physical activity per week (40% of the weekly ACSM-recommended 150 minutes of exercise). Future studies should examine the efficacy of telehealth AE during such periods without the shelter-in-place guidelines.

Telehealth-based AE presents several advantages compared to in-person AE, including (1) having a greater convenience and a potential for higher engagement; (2) allowing for AE interventions to be offered over larger geographic catchment areas, which may be particularly advantageous for delivery in rural areas or locales with limited in-person psychiatric services; (3) allowing for the delivery of AE training during periods of inclement weather that would limit travel (eg, snow storms), as well as in the event of another COVID-19–like pandemic; (4) being relatively low cost with no need for gyms, exercise equipment, or other physical infrastructure; and (5) having the digital infrastructure for its delivery already be available and in use in many hospitals and clinics, allowing it to be integrated with other clinical services (eg, use of MyChart by EPIC).

XSL•FO
RenderX

Yet, the delivery of telehealth-based AE requires consideration of some technological and logistical issues. As many individuals with schizophrenia may not have access to tablets or WiFi, we provided study participants with dedicated exercise iPads (eg, all iPad features were blocked, including internet use, email, and games). Nearly two-thirds of the devices had cellular capabilities, as most participants did not have access to home WiFi. Prior to training initiation, study personnel provided an initial introduction to iPad operations and addressed any follow-up technical or connectivity issues.

Altogether, while our findings provide preliminary support for the integration of telehealth-based AE into "real-world" clinical services for patients with schizophrenia, when available, in-person AE appears preferable given the opportunity for social interactions and the higher intensity of exercises. Additionally, the feasibility and efficacy of delivering telehealth-based AE over periods longer than 12 weeks is unknown. Thus, telehealth delivery of AE is an acceptable alternative when in-person AE is unavailable.

Our study had several limitations. First, the sample size of this study was relatively modest. Thus, any conclusions should be considered as preliminary until replicated by larger studies. Second, the delivery of AE in the present study was based in large academic medical centers with substantial medical, logistical, and other resources. Future studies should examine whether delivery in less resource-rich areas would provide comparable results. Finally, as noted, the present interventions were limited to 12 weeks, with exercise sessions completed under unique circumstances (eg, shelter-in-place orders). It is unknown whether delivery over longer periods or under normal circumstances would be similarly feasible and efficacious.

Abstract

Background: Evidence-based digital therapeutics represent a new treatment modality in mental health, potentially providing cost-efficient, accessible means of augmenting existing treatments for chronic mental illnesses. CT-155/BI 3972080 is a prescription digital therapeutic under development as an adjunct to standard of care treatments for patients 18 years of age and older with experiential negative symptoms (ENS) of schizophrenia. Individual components of CT-155/BI 3972080 are designed based on the underlying principles of face-to-face treatment. A positive therapeutic alliance between patients and health care providers is linked with improved clinical outcomes in mental health. Likewise, establishing a similar therapeutic alliance with a digital therapeutic (ie, digital working alliance [DWA]) may be important for engagement and treatment effectiveness of this modality.

Objective: This study aimed to investigate the establishment and maintenance of a DWA between a beta version of CT-155/BI 3972080 (CT-155 beta) and adults with ENS of schizophrenia.

Methods: Two multicenter, exploratory, single-arm studies (study 1: CT-155-C-001 and study 2: CT-155-C-002) enrolled adults with schizophrenia and ENS receiving stable antipsychotic medication (≥12 weeks). Participants had access to CT-155 beta and were presented with daily in-app activities during a 3-week orientation phase that included lessons designed to facilitate building of a DWA. In study 2, the 3-week orientation phase was followed by an abbreviated active 4-week phase. Digital literacy at baseline was evaluated using the Mobile Device Proficiency Questionnaire (MDPQ). The mobile Agnew Relationship Measure (mARM) was used to assess DWA establishment after 3 weeks in both studies, and after 7 weeks in study 2 to assess DWA maintenance. Participant safety, digital literacy, and correlations between negative symptom severity and DWA were assessed in both studies.

Results: Of the enrolled participants, 94% (46/49) and 86% (43/50) completed studies 1 and 2, respectively. Most were male (study 1: 71%, 35/49; study 2: 80%, 40/50). The baseline digital literacy assessed through MDPQ score was comparable in both studies (study 1: mean 30.56, SD 8.06; study 2: mean 28.69, SD 8.31) indicating proficiency in mobile device use. After 3 weeks, mARM scores (study 1: mean 5.16, SD 0.8; study 2: mean 5.36, SD 1.06) indicated that a positive DWA was established in both studies. In study 2, the positive DWA established at week 3 was maintained at week 7 (mARM: mean 5.48, SD 0.97). There were no adverse events (AEs) in study 1, and 3 nonserious and nontreatment-related AEs in study 2.

Conclusions: A positive DWA was established between participants and CT-155 beta within 3 weeks. The second 7-week study showed maintenance of the DWA to the end of the study. Results support the establishment and maintenance of a DWA between adults with ENS of schizophrenia and a beta version of CT-155/BI 3972080, a prescription digital therapeutic under development to target these symptoms.

KEYWORDS

therapeutic alliance; digital working alliance; experiential negative symptoms; schizophrenia; digital therapeutics; digital literacy

Introduction

The therapeutic alliance was defined by Bordin and colleagues in 1979 as a measure of the quality of the relationship between a patient and health care provider, and its pivotal influence on clinical outcomes is well documented and supported [1-3]. The following three main components constitute the therapeutic alliance: (1) the patient-provider bond, (2) a collaborative approach to assignment of therapeutic tasks, and (3) agreement on therapeutic goals [1]. In face-to-face therapy, the quality of this working alliance predicts clinical outcomes independently of the type of implemented psychotherapy or assessed outcome measures [2-6]. Several studies suggest that there is an association between a positive therapeutic alliance and improved outcomes in people with mental illness, including schizophrenia. For example, there is evidence that maintaining a positive alliance is associated with adherence to schizophrenia medication [7,8], that a positive alliance predicts improved overall psychotic symptomatic outcomes [9,10], and that strong alliances are associated with better treatment engagement and improvements in schizophrenia symptoms [11].

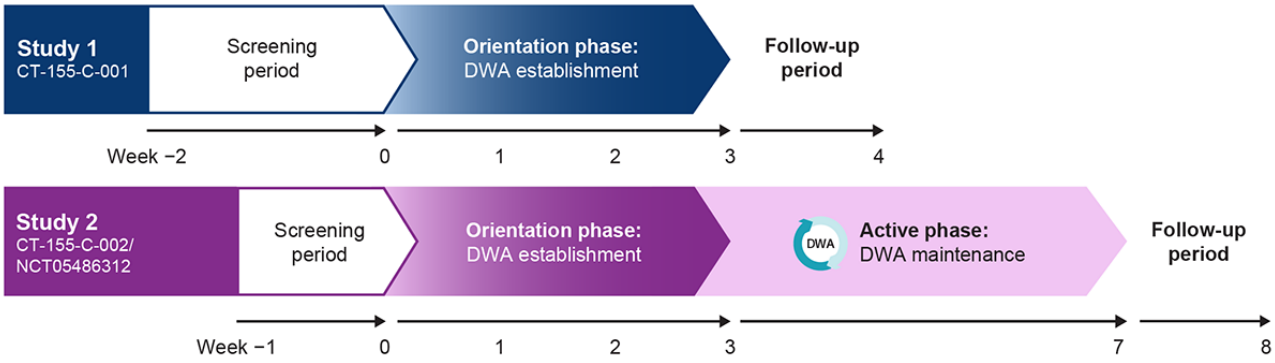
Schizophrenia is a chronic debilitating psychiatric disorder that occurs in approximately 1 in every 300 people worldwide [12]. Symptoms generally emerge in late adolescence or early adulthood and are categorized as positive, negative, or cognitive [13,14]. Positive symptoms, such as delusions, hallucinations and disorganized thinking, represent an excess or distortion of normal functions, and tend to relapse and remit. Negative symptoms involve reductions or absences in normal emotional and social functioning. Cognitive symptoms affect memory, attention and executive function. Both negative and cognitive symptoms being chronic in nature contribute substantially to the significant emotional and socioeconomic burden associated with schizophrenia [15-18]. Experiential negative symptoms (ENS) are a key subset of negative symptoms characterized by deficits in pleasure (anhedonia), motivation (avolition), and social interest (asociality), and have a profound impact on functional outcomes [19,20].

The American Psychiatric Association practice guidelines for the treatment of people with schizophrenia highlight the benefits of evidence-based psychosocial treatments, social skills training and psychoeducation as adjunct therapies to medication [21]. To date there is no treatment approved by the US Food and Drug Administration (FDA) for negative symptoms. Despite promising evidence for psychological approaches including cognitive behavioral therapy and cognitive remediation in treating negative symptoms [22-24], people with schizophrenia face significant barriers to engaging in psychosocial therapy. These include symptom-related barriers, stigma and social isolation, and insufficient health care resources [25-27], all of which may contribute to a low uptake of psychosocial therapy in people with schizophrenia [27-30].

Digital therapeutics (DTx) have the potential to bridge this gap by broadening access to adjunctive psychosocial therapies and facilitating greater frequency of exposure in a way that is flexible and convenient for those receiving treatment [31,32]. DTx are defined by the International Organization for Standardization as any evidence-based "health software intended to treat or alleviate a disease, disorder, condition, or that has a demonstrable positive therapeutic impact on a patient's health" [33]. For DTx intended as treatments for vulnerable populations such as those with serious mental illness, it is particularly important that they are regulated, rigorously tested, and found to have proven effectiveness and strong safety profiles. Recent studies evaluating novel DTx in the form of smartphone apps have shown this modality to be acceptable and feasible to implement in individuals with chronic psychiatric disorders such as schizophrenia [34-37]. While there is evidence to suggest that the therapeutic alliance can be established and maintained in remote online settings of psychotherapy [4,38,39] it is not fully understood if individuals with severe mental illness, such as schizophrenia, can establish and maintain a therapeutic alliance with a DTx [40-43]. Importantly, while recent studies in people with schizophrenia evaluated the feasibility of DTx they did not assess the establishment of a therapeutic alliance [34,35,44].

We conducted 2 independent studies to assess the establishment and maintenance of a digital working alliance (DWA) between adults with ENS of schizophrenia and a beta version of CT-155/BI 3972080 (hereafter referred to as CT-155 beta), a novel software accessible on mobile phones under development to treat ENS of schizophrenia adjunctive to standard of care. In December 2023, CT-155/BI 3972080 was granted breakthrough device designation by the FDA [45]. In the studies reported here, we assessed whether it is feasible to establish and maintain a positive DWA between people living with ENS of schizophrenia and CT-155 beta, and if the strength of the DWA correlates or differs according to severity of negative symptoms, age, or race.

Methods



Study Design

Two independent single-arm, multicenter, exploratory studies (study 1: CT-155-C-001 and study 2: CT-155-C-002/NCT05486312) were conducted across 10 sites in the United States. Patient informed consent was obtained at an initial in-person screening visit, during which site personnel assisted with the download and setup of CT-155 beta onto participants' personal smartphone devices. Eligibility was confirmed and CT-155 beta was activated at an in-person

XSL•FO
RenderX

baseline visit on Day 1. Both studies comprised a screening period, a treatment period, and a follow-up period (Figure 1). The treatment period comprised a 3-week orientation phase in study 1 and study 2, with an additional 4-week active phase in study 2 (further details in Intervention section). Both studies concluded with a follow-up period during which a remote teleconference follow-up visit occurred (Figure 1).

Figure 1. Study design. Two independent single-arm, multicenter, exploratory studies (study 1: CT-155-C-001, study 2: CT-155-C-002/NCT05486312) were conducted across 10 sites in the United States. [a]Schedules for the key assessments are presented. CAINS-MAP: Clinical Assessment Interview for Negative Symptoms–Motivation and Pleasure; DWA: digital working alliance; ENS: experiential negative symptoms; MAP-SR: Motivation and Pleasure–Self Report; mARM: mobile Agnew Relationship Measure; MDPQ: Mobile Device Proficiency Questionnaire.

Digital literacy	MDPQ	✓	✓										

Participants

Eligible participants were 18-64 years old (study 1) and ≥18 years old (study 2) with a primary diagnosis of schizophrenia for at least 1 year as per the *ICD-10* (*International Classification of Diseases, Tenth Revision*; study 1) [46], and the *DSM-5* (*Diagnostic and Statistical Manual of Mental Disorders* [Fifth Edition]; studies 1 and 2) [13], with moderate-to-severe ENS (defined as a score of ≤30 on the Motivation and Pleasure–Self Report [MAP-SR]) [47], and receiving a stable dose of a maximum of 2 different antipsychotic medications for at least 12 weeks before screening. Exclusion criteria included a *DSM-5* or *ICD-10* diagnosis other than schizophrenia, or a substance or alcohol use disorder, excluding caffeine and nicotine. People receiving clozapine, haloperidol, or who had received psychotherapy within 12 weeks of screening were also excluded. People with active prominent positive symptoms that, in the opinion of the investigator, would preclude effective engagement in treatment for negative symptoms were also excluded. The complete list of eligibility criteria for both studies is included in Table S1 in Multimedia Appendix 1.

Intervention

CT-155/BI 3972080 is a novel software accessible on mobile devices, designed to treat the ENS of schizophrenia and under development for use adjunctive to standard of care treatments for schizophrenia. As such CT-155/BI 3972080 is currently FDA regulated as an investigational device, more specifically, a software as a medical device [48]. The development of the software was informed by an iterative patient-centered design process, which consisted of 2 phases during which feedback was captured from 4 peer support specialists with lived experiences of schizophrenia, and 15 patient panel participants with a diagnosis of schizophrenia (refer to Supplementary Methods in Multimedia Appendix 1 for further details).

CT-155 beta has 3 core phases. First, the 3-week orientation phase in each study was designed based on the core features of in-person therapeutic alliance to encourage daily adherence to lessons and activities by providing schizophrenia-specific psychoeducation and introducing core therapeutic skills (Figure 2) [41]. An empathic style of communication informed by patient feedback, provision of schizophrenia-specific psychoeducation, and introducing core therapeutic skills are patient-centric features incorporated into CT-155. Like therapists getting to know their patient, this phase focuses on DWA establishment through asking questions and rapport building, followed by collaborative treatment approach and goal definition. These patient-centric features that support DWA are subsequently integrated into all therapeutic components to optimize the experience by infusing an interactive, empathic, knowledgeable, and personally meaningful nature to the in-app experience that builds confidence for achieving treatment goals and is critical to treatment outcome. Second, study 2 included an active phase, during which participants receive access to CT-155 beta for an additional 4 weeks after the 3-week

XSL•FO
RenderX

orientation phase (Figure 1), designed to reinforce orientation phase components and introduce adaptive goal setting [49,50]. The active phase comprises evidence-based digitized therapeutic techniques leveraging the underlying principles of face-to-face treatment [51-54]. Examples of the therapeutic techniques used include adaptive goal setting [49,50] and social skills training [21]. Adaptive goal setting is focused on delivering interventions known to target negative symptoms in important functional areas (ie, social items, work and school items, and recreation items). Finally, during a brief follow-up phase, participants from both studies complete qualitative exit interviews to help understand the user experience and inform further CT-155/BI 3972080 development.

Figure 2. CT-155 beta captures aspects of in-person therapeutic alliance. Individual components of CT-155 beta are designed based on the underlying principles of face-to-face treatment. These therapeutic techniques are intended to work synergistically to treat ENS and are supported by personalized engagement functionality that works in concert with the core therapeutic mechanisms. DWA: digital working alliance; ENS: experiential negative symptoms.

	Core aspects of in-person therapeutic alliance	Reflected in CT-155 beta
Bonds	• Collaboration between clinician and patient to establish an affective bond which facilitates the achievement of goals	• An empathic style of communication informed by patient feedback is used
Tasks	• A collaborative approach to assignment of therapeutic tasks	• Provision of schizophrenia-specific psychoeducation and introducing core therapeutic skills encourages daily adherence to lessons and activities
Therapeutic goals	• Agreement between clinician and patient about patient goals	• Design incorporates feedback from people with schizophrenia (N=358; ~670 hours) • Patient can select therapeutic goals

Protocol Deviations

In study 1, 12 major protocol deviations occurred with 10 participants (Table S2 in Multimedia Appendix 1). Deviations included assessment performed outside of protocol window (n=6), CT-155 beta was uninstalled (n=2), failed inclusion criteria (n=2), and visit occurred outside of protocol window (n=1). One participant with failed inclusion deviation was deemed ineligible and terminated the study early. One participant had 3 major deviations (uninstalled CT-155 beta before week 4, schizophrenia diagnosis confirmed <1 year before enrollment, and antipsychotic added <12 weeks before screening) was included in the intent-to-treat-population but excluded from the per protocol population. In study 2, 1 major protocol deviation occurred with 1 participant (visit outside protocol window; Table S2 in Multimedia Appendix 1).

Assessments

Patient Digital Literacy

The digital literacy of participants at baseline was assessed using the self-administered Mobile Device Proficiency Questionnaire (MDPQ). While developed for assessing mobile proficiency in older adults, the MDPQ has also been used in health studies to assess proficiency in individuals with subjective cognitive complaints and those with cirrhosis [55-57]. The MDPQ consists of 46 items rated on a 5-point Likert scale and assesses seven aspects of digital literacy: (1) mobile device basics, (2) communication, (3) data and file storage, (4) internet, (5) entertainment, (6) privacy, and (7) troubleshooting and software management [55]. Participants were asked to rate their ability to perform specific digital tasks on a scale of 1 (never tried it) to 5 (very easily performed). Subscale scores were obtained by averaging responses within each subscale and overall scores were calculated as the sum of mean subscale scores. The overall scores fall in a range of 8 (low) to 40 (great ability to perform a number of tasks with a mobile device). Internal reliability of the MDPQ was demonstrated with a Cronbach α score of 0.975.

XSL•FO
RenderX

Experiential Negative Symptom Severity Assessment

Participants completed the MAP-SR at screening. The MAP-SR is a 15-item validated self-administered tool that assesses the motivation and pleasure domain of negative symptoms in people with psychotic disorders and scores are rated on a 5-point Likert scale, where low scores reflect greater severity [47]. In addition, the Clinical Assessment Interview for Negative Symptoms–Motivation and Pleasure (CAINS-MAP) assessment was conducted at baseline in both studies, and at week 7 in study 2, to evaluate ENS symptom severity. The CAINS-MAP is a validated 13-item clinician-administered interview-based assessment with items scored on a 4-point scale, with lower scores indicating lower negative symptom severity [58].

Digital Working Alliance Assessment

The DWA was assessed using the self-administered 25-item mobile Agnew Relationship Measure (mARM) questionnaire. The mARM is a measure used to evaluate the DWA of mobile health interventions across 5 therapeutic alliance domains: bonding, partnership, confidence, openness, and initiative [59]. It provides an alliance measure with good content and face validity suitable for assessing alliance with DTx [59]. The mARM includes five subscales to represent the dimensions of the DWA: (1) the bond subscale focuses on the perceived acceptance, support, friendliness, and understanding the patient develops with the app, (2) the partnership subscale measures the extent of the perceived collaboration of the patient with the therapeutic tasks, (3) the confidence subscale focuses on patient optimism and their belief in the competency of the app, (4) the openness subscale assesses the perceived freedom to disclose personal concerns without fear of judgment or embarrassment, and (5) the client initiative subscale focuses on the client willingness to take responsibility for their treatment progress.

The mARM was administered at week 1, week 2, and week 3 in study 1 to assess the establishment of the DWA during the orientation phase. In study 2, it was administered at week 3 to assess DWA establishment and again at week 7 to evaluate the maintenance of DWA during the abbreviated active phase. The overall mARM score is calculated at each time point as the mean of all subscale scores and is interpreted along a Likert scale ranging from 1 (strongly disagree) to 7 (strongly agree), with 4 equating to “neutral,” and scores higher than the neutral midpoint suggesting a positive DWA [59-61]. The potential association between various factors including age, race, and ENS severity, and the DWA was also assessed.

Safety

Safety was assessed by recording adverse events (AEs), serious AEs, adverse device effects (ADEs), serious ADEs, and discontinuations from the study due to AEs, from signing of informed consent through to the end of study period.

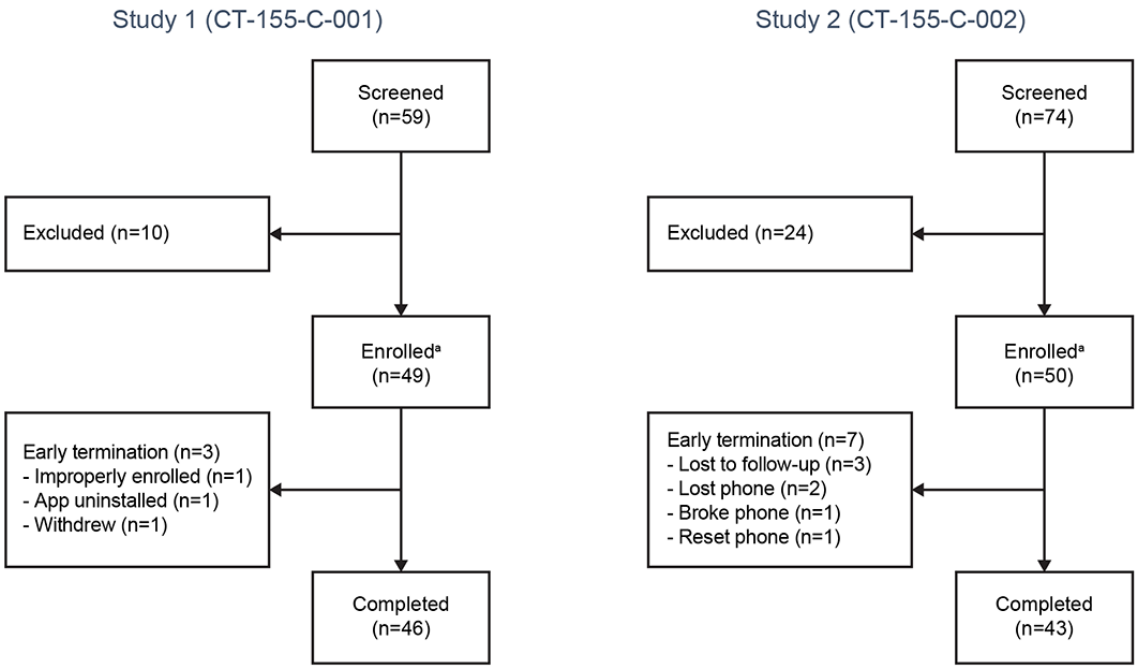
Sample Size and Statistical Analyses

Both studies were exploratory in nature and sample size and analyses were selected for optimal assessment of DWA establishment and maintenance between schizophrenia patients and CT-155 beta. Data presented are from the intent-to-treat population, defined as all participants who were enrolled in each study to receive treatment with CT-155 beta. Descriptive statistics were evaluated for all study variables. To determine if DWA was related to ENS, age, or engagement, correlation analyses between mARM scores and baseline CAINS-MAP, age at screening, and session completion were performed using a Spearman rank-order correlation analysis and correlation coefficients were calculated together with the 95% 2-sided confidence intervals. To investigate effects of race, variance of the mean overall mARM score between Black or African American and participants of all other races were compared using an F test. To assess whether digital literacy was related to ENS and engagement, correlation analyses between baseline MDPQ scores and CAINS-MAP and session completion scores were also performed using a Spearman rank-order correlation analysis. Engagement was assessed using the number of sessions completed during the study whereby a session was defined as any interaction within CT-155 beta for >60 seconds.

Ethical Considerations

The study protocols and study materials were reviewed by the Western Copernicus Group independent institutional review board (approval numbers: 20215315 [study 1] and 20220609 [study 2]). The studies were conducted in compliance with the respective clinical study protocols, in accordance with the principles of the Declaration of Helsinki [62], the International Council for Harmonisation of Good Clinical Practice [63], and applicable US regulatory requirements. Patient informed consent was obtained from all participants. Participants were deidentified and assigned a unique identifier to protect personal data and privacy throughout both studies. Throughout both studies, a study team maintained compliance with applicable laws and accepted security standards, including the Health Insurance Portability and Accountability Act of 1996, the U.S. National Institute of Standards and Technology Framework, and the Service Organization Control Type 2 controls. The compliance program was designed to (1) ensure the security, confidentiality, integrity, and availability of the assets and other sensitive information that was collected, used, and maintained; (2) protect against any anticipated threats or hazards to the security, integrity, or availability of such information; (3) maintain information security controls that were appropriate to Click Therapeutics size, scope, and business; (4) maintain safeguards and controls to protect information from loss, theft, destruction, unauthorized manipulation, disclosure, or unavailability. Participants were offered up to US $465 and US $735 for partaking in study 1 and study 2, respectively. Incentive values reflect fair market value; variance in incentive values is reflective of the differing observation periods between the 2 studies.

Results



Patient Demographics and Baseline Characteristics

In study 1, a total of 49 participants were enrolled and 46 (94%) completed the study. In study 2, a total of 50 participants were enrolled and 43 (86%) completed the study. Participant disposition is presented in Figure 3. The median age of enrolled participants was 46 (range 18-64) years in study 1 and 53.5 (range 23-64) years in study 2. Of those enrolled, most were male (study 1: 35/49, 71%; study 2: 40/50, 80%), and more than

XSL•FO
RenderX

half were Black or African American (study 1: 27/49, 55%; study 2: 29/50, 58%). The majority never attended college (study 1: 31/49, 63%; study 2: 32/50, 64%) and most had a self-reported annual income of <US $25,000 (study 1: 46/49, 94%; study 2: 47/50, 94%; Table 1). The median MAP-SR score at screening was 25.0 (IQR 17.0-28.0) in study 1 and 15.0 (IQR 7.0-23.0) in study 2. At baseline, the median overall CAINS-MAP score was 2.4 (IQR 2.0-2.9) in study 1 and 2.6 (IQR 1.6-2.9) in study 2. Baseline demographics and characteristics of study 2 participants are also being reported in another manuscript reporting separate outcomes.

[a]MAP-SR: Motivation and Pleasure scale–Self Report.

[b]MDPQ: Mobile Device Proficiency Questionnaire.

[c]CAINS-MAP: Clinical Assessment Interview for Negative Symptoms Motivation and Pleasure subscale.

The median overall MDPQ score was comparable in both studies at baseline (study 1: 32.01, IQR 23.20-39.07; study 2: 30.10, IQR 21.36-35.46), indicating proficiency in the use of mobile devices before accessing CT-155 beta. A summary of MDPQ overall and subscale scores is presented in Table 2. Overall, MDPQ subscales scores revealed proficiency across most operations from the basic task of "turning the device on and off" and communication tasks, such as "open emails" to the more advanced tasks such as those related to privacy "Setting up a password to lock/unlock the device," and tasks related to the troubleshooting and software management, such as "Restarting the device when it is frozen, or not working right." However, participants in both studies were slightly less proficient with data and file storage tasks, such as "Transfer information (files such as music, pictures, documents) from portable device to computer" (Table 2). There was no correlation between MDPQ and baseline CAINS-MAP in study 1 (ρ=0.01, 95% CI –0.31 to 0.34) and study 2 (ρ=–0.01, 95% CI –0.29 to 0.28). Furthermore, there was no correlation between MDPQ and degree of participant engagement with CT-155 beta (number of completed sessions) in study 1 (ρ=0.00, *P*=.99) and study 2 (ρ=–0.18, *P*=.22).

[a]MDPQ: Mobile Device Proficiency Questionnaire.

Digital Working Alliance Summary

The mean overall mARM score in study 1 was 5.15 (SD 0.74) indicating establishment of a positive DWA by week 1 that did not significantly change by week 3, 5.16 (SD 0.77). Similarly, in study 2, participants also formed a positive DWA by week 3, with a mean overall mARM score of 5.36 (SD 1.06; Table 3). Furthermore, the positive DWA in study 2 was maintained through the subsequent 4-week treatment period with mean overall mARM score of 5.48 (SD 0.97) at week 7 (Table 3). The individual mARM subscale scores (Bond, Partnership, Confidence, Openness, and Client initiative) remained consistent and above "neutral" (score of 4) at the end of the DWA and core-skills-building phase at week 3 in both studies demonstrating that participants successfully formed a positive DWA with CT-155 beta across all subscale categories (Table 3). In study 2, no significant difference in mARM subscale scores were seen from weeks 3 to 7 (refer to Table 3 for subscale scores). Overall, at the individual level, positive correlations (ρ=0.27-0.84) were observed between subscale scores at week 3 and those at week 7 (Table S3 in Multimedia Appendix 1).

Table 3. Evaluation of digital working alliance formation at week 3 and digital working alliance maintenance at week 7 as assessed by mobile Agnew Relationship Measure in study 1 and study 2.

mARM[a] scores	DWA[b] formation (week 3)		DWA[b] maintenance (week 7)
	Study 1, mean (SD) (n=40)	Study 2, mean (SD) (n=45)	Study 2, mean (SD) (n=44)
Overall	5.16 (0.77)	5.36 (1.06)	5.48 (0.97)
Subscale scores			
Bond	5.67 (1.03)	5.63 (1.31)	5.82 (1.19)
Partnership	4.83 (0.72)	5.67 (1.32)	5.85 (1.18)
Confidence	5.49 (1.04)	5.68 (1.27)	5.62 (1.23)
Openness	4.94 (1.06)	4.83 (1.25)	5.16 (1.04)
Client initiative	4.56 (0.75)	4.60 (0.99)	4.64 (0.93)

[a]mARM: mobile Agnew Relationship Measure.

[b]DWA: digital working alliance.

Correlations Between DWA and ENS Severity, Engagement, Age, and Race

In both studies, the strength of DWA at week 3, as assessed by the mean overall mARM score, was similar in participants with severe and moderate ENS (Table 4). In study 1, this finding was consistent at each week across the 3-week study. Accordingly, there was no significant correlation between mARM overall scores at week 3 and the baseline CAINS-MAP total score in study 1 (ρ=–0.16, *P*=.36) and study 2 (ρ=–0.13, *P*=.41; Table S4 in Multimedia Appendix 1).

[a]mARM: mobile Agnew Relationship Measure.

[b]To minimize participant burden, mARM was assessed at weeks 1 and 2 in study 1 only. Severity of negative symptoms based on CAINS-MAP score: moderate <29 points; severe ≥29 points.

Strength of DWA correlated positively with the number of completed sessions by participants at week 3 in study 2 (ρ=0.34, *P*=.02), but was not significantly correlated in study 1 (ρ=0.22, *P*=.19; Figure 4). Neither age (study 1, ρ=0.31, *P*=.05; study 2, ρ=0.15, *P*=.32) nor race significantly correlated with overall mARM scores (study 1, *F* test=1.1928, *P*=.72; study 2, *F* test=1.1615, *P*=.75; Table S4 in Multimedia Appendix 1). In this study population, there was no clear relationship between digital literacy and DWA scores. Assessed by quartile MDPQ scores, mean mARM scores in the highest and lowest quartiles were study 1: 4.9 (SD 0.9) and 5.7 (SD 0.4) and study 2: 5.8 (SD 0.9) and 4.8 (SD 1.2), respectively (Table S5 in Multimedia Appendix 1).

XSL•FO
RenderX

Figure 4. Correlations of mARM overall score at week 3 with number of sessions completed. mARM: mobile Agnew Relationship Measure; ρ: Spearman correlation coefficient.

Safety Data Across Two Studies

No ADEs, AEs, or serious AEs were reported during study 1. In study 2, three AEs were reported by 2 participants, none of which were considered severe or related to CT-155 beta use, nor led to study discontinuation. AEs reported were a sinus infection (n=1), arthralgia (n=1), and a rash (n=1). The sinus infection and arthralgia resolved after 6 days; the rash remained present at end of follow-up.

Discussion

Our findings from 2 independent single-arm multicenter exploratory studies show that a DWA can be established and maintained between people with schizophrenia and a smartphone-based digital therapeutic, namely the abbreviated beta version of CT-155/BI 3972080, a prescription digital therapeutic to target ENS adjunctive to standard of care treatments for schizophrenia. During the orientation phase in study 1, participants established a positive DWA with CT-155 beta. This was replicated in a separate and independent cohort of participants at the end of an equivalent orientation phase in study 2. Furthermore, the positive DWA was maintained during the additional 4-week active phase in study 2, as demonstrated by an equivalent positive mARM score at week 7.

While a strong therapeutic alliance is linked to successful clinical outcomes for in-person therapy, the relationship between DWA, engagement, and outcomes requires further investigation [2-6]. The concept of a therapeutic alliance with DTx is gaining

XSL•FO
RenderX

traction in line with the rapid expansion of digital mental health research and implementation; however, the role and relevance of the bond, a core feature of the in-person therapeutic alliance, is somewhat unclear for DTx [40] and not investigated in sufficient detail. Our results add to a growing body of evidence demonstrating that a therapeutic alliance can be established between people with serious mental illnesses and DTx. For example, in recent studies evaluating the benefits of conversational agents (or chatbots) that deliver cognitive behavioral therapy for symptoms of depression, anxiety, and substance use disorder, participants reported high acceptability and affective bond formation [64-67]. Another investigation of a digital health intervention for people with early psychosis, based on cognitive behavioral therapy principles and delivered through a smartphone app, demonstrated that engagement was significantly and positively associated with therapeutic alliance, as assessed by mARM [68]. However, measures to assess bond formation varied with a short-revised version of the Working Alliance Inventory and a Working Alliance Questionnaire (based on the Working Alliance Inventory) being used, making comparisons across studies difficult.

Although there are several lines of evidence demonstrating that a therapeutic alliance is possible for people with schizophrenia and is associated with improved outcomes, there are some factors related to the disorder itself, such as negative symptoms, lack of insight and self-stigma, that can adversely impact the therapeutic alliance between patient and therapist [69-71]. One could therefore speculate that patients who formed and valued a therapeutic alliance with a DTx may accept this additional therapeutic modality for the treatment of schizophrenia. Notably, in our studies, there was no correlation between the severity of negative symptoms at baseline and the establishment or maintenance of a DWA, indicating that even the participants with the most severe symptoms could form and maintain an alliance with CT-155 beta. In line with previous reports examining associations between age and therapeutic alliance we also did not observe any correlation between age and the DWA strength [11,39,71,72]. Similarly, we did not observe any correlation between race and strength of DWA. While some reports emphasize the importance of ethnic matching between patients and clinicians in improving therapeutic alliance [73,74], the lack of correlation with race here highlights the adaptable nature of a DTx modality to fit the needs of different communities.

Although not specifically assessed, the user-centered design process that guided the development of CT-155/BI 3972080 could have improved overall participant engagement and effectiveness. A recent systematic review showed that making end-users central to the product development process leads to enhanced cultural sensitivity, increased acceptance and engagement [75-77]. The review also provided some key recommendations for coproduction, including stakeholder involvement at all stages of development, which was implemented into the development of CT-155/BI 3972080. Considering the 3 pillars of the therapeutic alliance involve enhancing the patient-provider bond, shared goals and adopting a collaborative approach in the therapeutic approach, the patient-centered development process may have contributed to the establishment of a positive DWA achieved here.

The participants in both studies demonstrated a reasonable level of mobile device proficiency. This finding is aligned with recent data from the United States showing that 70%-80% among people with severe mental illness own a smartphone [78-80]. However, smartphone ownership does not necessarily equate with digital literacy [81]. In this study we confirmed that participating people with schizophrenia owning a smartphone showed digital literacy similar to that from the general population [82], but greater than that reported for people with serious mental illness [83]. Indeed, a study in the United Kingdom showed that 42.2% of people with serious mental illness had no foundation digital skills [83], while electronic health literacy has been described as either moderate or low in 2 independent cohorts of adults with schizophrenia spectrum disorders [84]. However, one should consider that the younger generation diagnosed with severe mental illness and schizophrenia are now digital natives and past research may not reflect current trends.

Limitations of these studies include their small sample size, single-arm design, and exploratory nature. While the sample size was limited, the demographics of participants were reflective of the general schizophrenia population including a higher incidence in males [85,86], the majority being Black or African American [87] and a level of education no greater than high school [88]. In addition, almost all (94%) participants in this study reported an annual income under US $25,000, which likely reflects low employment rates in people with schizophrenia [16]. Furthermore, while all participants met inclusion criteria, there was a difference in median MAP-SR score at screening between study 1 and 2. However, as no correlation between ENS severity and DWA was observed in both studies, the difference in baseline MAP-SR scores could be linked to broader population compared in 2 studies. While only a few out of protocol window deviations were recorded, they may impact the DWA assessments over time through asking questions and rapport-building. Preliminary data from these studies support the further evaluation of CT-155 in an ongoing large phase III trial (CONVOKE; NCT05838625). Although the mARM assessment possesses good face and content validity [59], further validation of this assessment for the measurement of DWA in severe chronic mental illness is essential to inform further optimization of this assessment for use in clinical trials [89]. In addition, establishment and assessment of therapeutic alliance between participants and digital devices or apps is relatively new. There is a need to use standardized and validated scales with psychometric validation to assess DWA in future studies which will also make it feasible to compare data and outcomes. Finally, it should also be noted that the eligibility criteria for the studies mandated that participants had a smartphone, an email address, and regular access to the internet through mobile data plan, Wi-Fi or both. Accordingly, the association of digital literacy measured by MDPQ with DWA and engagement should be interpreted in the context of this study population. The study inclusion criteria for participants to own their own mobile device may have biased toward a more digital proficient study population and therefore not reflective

XSL•FO
RenderX

of patients who do not own a mobile device and who potentially may have a lower device proficiency. As such, future studies are warranted to understand the impact of lower digital proficiency on adherence to a digital therapeutic and on establishing DWA. While recent evidence suggests that rates of smartphone ownership among adults with severe mental illness (including schizophrenia) are comparable to the general adult US population [78,80], it is encouraging to see high levels of mobile device proficiency in people living with schizophrenia and owning smartphones.

The results from these 2 studies confirm that a positive DWA can be formed within a 3-week period and this DWA was maintained for the entire 7-week duration of study 2, demonstrating that a therapeutic alliance can be formed with a DTx in people living with schizophrenia. Importantly, the formation of a positive DWA was not limited by severe ENS, supporting its potential benefits for those experiencing severe symptoms. Furthermore, people with schizophrenia who participated in these studies demonstrate good digital literacy and acceptance of CT-155 beta for the treatment of ENS. The development of a DTx with proven acceptability, safety, and effectiveness profiles as an adjunctive treatment for ENS of schizophrenia would represent a promising, accessible, scalable, and affordable treatment option for clinical and patient communities for whom the lack of effective treatments for ENS has presented significant challenges. These preliminary data support further evaluation of the potential importance of the patient-CT-155 DWA to therapeutic effectiveness in an ongoing large phase III trial (CONVOKE; NCT05838625). With the expansion of mobile device ownership, DTx offers a potential patient-centered, evidence-based therapeutic support 24 hours a day, 7 days a week. In addition, incorporated into standard of care, evidence based DTx may act as clinician extenders, increasing the breadth and depth of care provided. Understanding how best to engage and optimally implement DTx with people living with schizophrenia to have the greatest reach and impact is of great importance and may shape future clinical research. In addition, understanding who may benefit from a DTx, how to best introduce these tools to patients as part of the clinical workflow, and how to support continued engagement, are important future steps.

Acknowledgments

The authors would like to acknowledge and thank all study participants for contributing their time and effort to take part in these studies. The authors would also like to acknowledge Alankar Gupta and Eehwa Ung (employees of Click Therapeutics at the time of the study), as well as Uma Vaidyanathan (employee of Boehringer Ingelheim Pharmaceuticals, Inc., at the time of the study) for their respective contributions to the study. Editorial support in the form of initial preparation of the manuscript with input from all authors, and collation and incorporation of author feedback to develop subsequent drafts, assembling tables and figures, copyediting, and referencing was provided by Lieve Desbonnet, PhD, and Jonnie Plumb, PhD, of Avalere Health Global Limited, and was funded by Boehringer Ingelheim International GmbH. This work was funded by Boehringer Ingelheim (study identification numbers: study 1, CT-155-C-001; study 2, CT-155-C-002, ClinicalTrials.gov identifier: NCT05486312).

Data Availability

To ensure independent interpretation of clinical study results and enable authors to fulfill their role and obligations under the ICMJE (International Committee of Medical Journal Editors) criteria, Boehringer Ingelheim grants all external authors access to clinical study data pertinent to the development of the publication. In adherence with the Boehringer Ingelheim Policy on Transparency and Publication of Clinical Study Data, scientific and medical researchers can request access to clinical study data when it becomes available on Vivli - Center for Global Clinical Research Data [90], and earliest after publication of the primary manuscript in a peer-reviewed journal, regulatory activities are complete, and other criteria are met. Please refer to “Medical & Clinical Trials | Clinical Research | MyStudyWindow” [91] for further information.

Authors' Contributions

CS and CDC contributed equally as co-first authors. SEL and AP contributed equally as co-last authors. CDC, CS, MP, TC, and SEL contributed to the conceptualization of the study. CS, MP, OB, TC, and SEL were involved in the development of methodology. CS contributed to the software development. CS and OB contributed to data validation. AP, BDH, OB, and SEL were involved in formal analysis. AP, OB, and SEL contributed to study resourcing, and AP, BDH, CS, MP, OB, and SEL contributed to visualization of the work submitted for publication. OB contributed to data curation. AP, CS, CDC, and SEL supervised research activity and outputs. All authors contributed to the manuscript development and reviewed the final manuscript.

Conflicts of Interest

CT-155 beta was co-developed by Boehringer Ingelheim and Click Therapeutics Inc. This work was funded by Boehringer Ingelheim. CS, MP, OB and SEL are employees of Click Therapeutics, Inc. CDC is an employee of Boehringer Ingelheim International GmbH. TC was an employee of Click Therapeutics at the time of the study. AP and BDH are employees of Boehringer Ingelheim Pharmaceuticals, Inc; BDH was an employee of Click Therapeutics at the time of the study. AP is also affiliated with King’s College London, London, UK and the University of Washington, Seattle, WA, USA. Boehringer Ingelheim authors were involved in the study design, analysis and interpretation of the results, and the decision to submit.

Abstract

Background: Therapist-guided, internet-delivered cognitive behavioral therapy (guided ICBT) appears to be efficacious for depression, panic disorder (PD), and social anxiety disorder (SAD) in routine care clinical settings. However, implementation of guided ICBT in specialist mental health services is limited partly due to low referral rates from general practitioners (GP), which may stem from lack of awareness, limited knowledge of its effectiveness, or negative attitudes toward the treatment format. In response, self-referral systems were introduced in mental health care about a decade ago to improve access to care, yet little is known about how referral pathways may affect treatment outcomes in guided ICBT.

Objective: This study aims to compare the overall treatment effectiveness of GP referral and self-referral to guided ICBT for patients with depression, PD, or SAD in a specialized routine care clinic. This study also explores if the treatment effectiveness varies between referral pathways and the respective diagnoses.

Methods: This naturalistic open effectiveness study compares treatment outcomes from pretreatment to posttreatment and from pretreatment to 6-month follow-up across 2 referral pathways. All patients underwent module-based guided ICBT lasting up to 14 weeks. The modules covered psychoeducation, working with negative or automatic thoughts, exposure training, and relapse prevention. Patients received weekly therapist guidance through asynchronous messaging, with therapists spending an average of 10 - 30 minutes per patient per week. Patients self-reported symptoms before, during, immediately after, and 6 months posttreatment. Level and change in symptom severity were measured across all diagnoses.

Results: In total, 460 patients met the inclusion criteria, of which 305 were GP-referred ("GP" group) and 155 were self-referred ("self" group). Across the total sample, about 60% were female, and patients had a mean age of 32 years and average duration of disorder of 10 years. We found no significant differences in pretreatment symptom levels between referral pathways and across the diagnoses. Estimated effect sizes based on linear mixed modeling showed large improvements from pretreatment to posttreatment and from pretreatment to follow-up across all diagnoses, with statistically significant differences between referral pathways (GP: 0.97 - 1.22 vs self: 1.34 - 1.58, P<.001-.002) and for the diagnoses separately: depression (GP: 0.86 - 1.26, self: 1.97 - 2.07, P<.001-.02), PD (GP: 1.32 - 1.60 vs self: 1.64 - 2.08, P=.06-.02) and SAD (GP: 0.80 - 0.99 vs self: 0.99 - 1.19, P=.18-.22).

Conclusions: Self-referral to guided ICBT for depression and PD appears to yield greater treatment outcomes compared to GP referrals. We found no difference in outcome between referral pathway for SAD. This study underscores the potential of self-referral pathways to enhance access to evidence-based psychological treatment, improve treatment outcomes, and promote sustained engagement in specialist mental health services. Future studies should examine the effect of the self-referral pathway when it is implemented on a larger scale.

Introduction

Background

Depression and anxiety disorders are recognized as major contributors to global disability, carrying significant societal costs and having high personal impact [1]. In 2019, nearly 600 million people worldwide were affected by these conditions. Throughout life, depression and anxiety disorders are approximately 50% more common in women than in men [2]. Broadly accessible treatment is required to reduce this burden [3], yet a significant treatment gap remains between the need for and access to adequate care [4]. This gap is driven by a variety of factors, including limitations in available health care services, financial barriers, avoidance of help-seeking, lack of mental health literacy, and stigma [5]. The dominant model of treatment delivery—face-to-face treatment with trained mental health professionals in clinical settings—further restricts the widespread dissemination of mental health care [6]. Even in high-income countries, where access to care is more readily available, only about one-third of those with major depressive disorders receive formal mental health care [2].

Pharmacological and psychological therapies have demonstrated equal effects in treating depression and anxiety disorders [7,8]. However, psychological therapy is often preferred by patients over medication due to having fewer side effects and better long-term outcomes [9,10]. Cognitive behavioral therapy (CBT) is the psychological treatment with the strongest empirical support [11] and it is the recommended first-line treatment for these disorders [12,13]. Internet-delivered cognitive behavioral therapy (ICBT) delivers evidence-based CBT specifically targeting, but not limited to, depression and anxiety disorders [14]. ICBT offers several practical advantages that help address the treatment gap, including reduced travel time and expenses, greater flexibility to fit around individuals' daily schedules, and the potential to overcome stigma-related barriers through increased anonymity [2,15]. Additionally, the internet-delivered treatment format is less time-consuming for the therapist, thus it is scalable and affordable without compromising the quality of care [16]. These factors make ICBT an attractive option for expanding access to mental health treatment, particularly in areas with limited resources or where traditional face-to-face therapy is not readily available.

Systematic reviews have found the effect of guided ICBT for depression and anxiety disorders to be no different from that of face-to-face CBT [17-19]. Guided ICBT for depression and anxiety is found to work well in routine care clinics and tends to replicate results found in efficacy studies in Sweden, Denmark, Norway, Canada, and Australia [20-24] and to have long-term effects [25]. However, the implementation of guided ICBT in specialist mental health care has been slow, partly due to lack of knowledge, prejudice, and negative attitudes among health care professionals and general practitioners (GPs) [26]. This is concerning, as GPs in primary care often serve as gatekeepers and are responsible for initiating referrals to secondary care and specialist clinics.

The lack of referral from GPs to guided ICBT [26] has led to efforts enhancing access to care, with self-referral being proposed as a way to improve access to psychological therapies [27]. Self-referral implies that patients can seek the service from secondary care or specialist clinics, bypassing the need for referrals from GPs [27]. Self-referral to ICBT opens a pathway to evidence-based psychological care especially for individuals who never reach specialist clinics or mention their problems when consulting their GP [15]. Some have suggested that self-referral may attract more motivated patients [11], which could influence treatment engagement and improve outcomes [28]. Participants in guided ICBT trials tend to be more educated [15]. Since higher education is associated with better health literacy and access to and understanding of health information [29,30], patients self-referred to ICBT may thus be more responsive to treatment, which could help explain potential differences in treatment outcomes.

In addition, self-referral pathways are believed to empower patients by giving them greater control over their health care [31]. According to Self-Determination Theory (SDT), having greater control over the decision to seek care may foster autonomy, which in turn could enhance motivation and engagement with treatment [32]. For example, patients who self-refer may feel more motivated, ready, and confident in their choice to pursue ICBT, which can lead to greater engagement in therapy. When autonomy is supported by a sense of competence, such as patients feeling capable of managing their treatment, it can strengthen intrinsic motivation. This, combined with supportive feedback from ICBT therapists and a sense of relatedness, can also strengthen intrinsic motivation and may thus encourage continued participation and adherence to treatment plans [33].

However, while self-referral can improve access to psychological therapies, it also presents challenges. One concern is that self-assessment tools for depression and anxiety are not validated for lay self-diagnosis in this context. This is particularly important when accurate diagnosis is crucial for providing appropriate evidence-based treatment [34]. It has been argued that self-referral in general may result in unnecessary, costly, or even harmful interventions. Conversely, it could also lead to reduced patient responsibility, causing symptoms to be dismissed or action to be delayed, potentially leading to harm [35]. This reliance on individual health care–seeking behaviors has been identified as a factor that can contribute to widening socioeconomic inequalities [36]. Additionally, self-referral may lead to oversaturation of specialist health care and potentially widen already existing health inequalities by primarily attracting younger, well-educated woman. However, this concern remains underexplored and may be context-dependent [36].

The practice of using self-referral pathways to specialist care varies across countries and clinical domains, with physiotherapy and mental health services being among the most common [37]. Self-referral is well studied in the field of physiotherapy and is an available pathway to musculoskeletal care in many countries [38]. Consistent yet limited evidence suggests that self-referral for musculoskeletal care yields clinical outcomes comparable to GP referrals [39]. Research comparing different referral pathways to mental health services remains limited. In a recent systematic review examining who benefits from guided

XSL•FO
RenderX

internet-based interventions across mental health diagnoses, 88 predictors and moderators of treatment outcome were analyzed but referral pathway to treatment was not included [40]. A recent study recommends investigating referral pathways on patient outcomes [41]. However, some studies comparing referral pathways to psychological care already exist.

First, in a study on GP referral and self-referral to psychological treatment for patients with severe health anxiety, Hoffmann et al [11] examined the accuracy of these referral pathways in recruiting patients with treatment-demanding symptom levels. The accuracy was assessed by comparing the proportion of patients in each referral group who met the treatment criteria, with results significantly favoring self-referral. One reason for this difference was that several GP-referred patients did not attend the clinical diagnostic interview and therefore were excluded from the study. The findings suggest that self-referral may be a more accurate method for recruiting patients with severe health anxiety, as self-referred patients not only meet the criteria for treatment but also appear to be more motivated to participate in it [11].

Referral pathway has also been studied in relation to how consistently patients attend psychological therapy sessions within Improving Access to Psychological Therapies (IAPT) services [42]. When comparing GP referral, GP-initiated self-referral, and true self-referral to IAPT, no significant differences were found between referral pathways and attendance at the subsequent therapy sessions. Moreover, the study examined the patient's preferred pathway and found that those who had a GP-initiated self-referral later stated a preference for the GP to take full responsibility for the referral process. Accordingly, 60% of the true self-referrers stated that they preferred to self-refer again if they needed additional services from IAPT [42].

Although studies on treatment outcomes across referral pathways to psychological therapy are scarce, a notable exception is an observational study comparing GP referral and self-referral to 2 similar ICBT treatments for depression and/or anxiety [43]. In this study, patients from both referral pathways reported significant symptom reduction; however, those who self-referred showed larger effect sizes both at posttreatment and at the 3-month follow-up compared to those referred by their GPs [43].

No studies have yet investigated the role of referral pathway on treatment outcomes for guided ICBT for depression and anxiety disorders to a specialized routine care clinic. Based on the results from the comparison of GP referral and self-referral pathways to ICBT [11,43], we hypothesize that individuals who self-refer to specialized mental health care services will experience greater treatment effectiveness from pretreatment to posttreatment and for pretreatment to 6-month follow-up compared to those referred by GPs. Additionally, we will explore differences in treatment effectiveness across the specific diagnoses in relation to referral pathways.

Aim

The aim of this study was to compare the overall treatment effectiveness across different referral pathways—GP-referred and self-referred—in guided ICBT for moderate depression, panic disorder (PD), and social anxiety disorder (SAD). We also explore whether differences in treatment effectiveness between the referral pathways vary across the 3 diagnoses.

Methods

Ethical Considerations

This study was approved by the Regional Committee for Medical Research Ethics (REK) 2014/2175. The authors assert that all procedures contributing to this work comply with the ethical standards of the relevant national and institutional committees on human experimentation as well as with the principles of the Declaration of Helsinki [44]. The original written informed consent covers secondary analysis without additional consent. Data were deidentified, with direct personal identifiers removed and the key linking IDs stored separately on an inaccessible server. No compensation was provided for participation.

Setting

The data collection for this study was conducted at the eCoping clinic, a specialized routine mental health care clinic at Haukeland University Hospital in Bergen, Norway. All patients were referred to the eCoping clinic either from their GP or by themselves through direct contact with the eCoping team, resulting in both GP referrals and self-referrals. This study presents data from GP-referred patients included between September 2014 and May 2019 and self-referred patients included between September 2016 and May 2019.

Design

This study was a naturalistic open effectiveness study with repeated assessments for primary treatment outcomes and a 6-month follow-up for patients with moderate depression, PD, and SAD undergoing therapist-guided ICBT.

Referral to Treatment

Several approaches were used to increase knowledge about eCoping among the GPs. First, there were face-to-face educational visits conducted by the eCoping team. Second, GPs were provided with test-user accounts for the eCoping program to familiarize themselves with the treatment, however, none of the GPs logged in. Third, information about the treatment was presented in GPs' waiting rooms through flyers and short messages on information screens. In addition, promotion of eCoping was carried out through the local newspapers to highlight the new referral option. Finally, for a short period, Facebook ads about the possibility to self-refer were targeted at the local population.

GPs evaluated patients using their clinical judgment to assess symptom severity to determine the need for specialized care services; if deemed necessary, the GP authored a referral to the eCoping clinic. Patients who self-referred sent an email with their contact details to an address available on the eCoping website [45]. Subsequently, an eCoping therapist conducted a clinical interview by telephone to assess symptom severity and the treatment's relevance. A summary of the interview was generated as a self-referral.

XSL•FO
RenderX

A specialist in clinical psychology reviewed all referrals regardless of referral pathway in accordance with national priority guidelines [46] to determine eligibility for specialized care treatment.

As the study was conducted within routine care, the eligibility assessment and the inclusion and exclusion criteria were identical across referral pathways, ensuring that the sample was unbiased with respect to referral source. Inclusion criteria for all study patients were: (1) being 18 years of age or older; (2) diagnosed either with major depressive episode, SAD, or PD; (3) if using antidepressants, being on a stable dosage over the previous four weeks; and (4) fluent in oral and written Norwegian. Exclusion criteria for all study patients were: (1) current suicidal ideation, (2) current psychosis, (3) current substance abuse, (4) using benzodiazepines daily, (5) immediate need of other treatment, and (6) no access to the internet. Written informed consent was obtained from all study patients prior to data collection. We have no data on individuals who were screened out during the eligibility process as these patients did not sign informed consent forms. Patients who met the criteria for treatment received a scheduled appointment for a face-to-face consultation.

Procedure

During the face-to-face consultation, all patients underwent a diagnostic interview with the Mini-International Neuropsychiatric Interview (MINI) [47]. Based on the MINI, patients deemed unfit for eCoping were excluded and rereferred to a more suitable treatment option. The treatment program allocation was determined based on the MINI assessment.

Training

All therapists at the eCoping clinic were colocated for 1-2 days per week when working with guided ICBT, with an ordinary workload during the rest of the week. In addition to a 1-year continuing education program, the therapists received weekly peer supervision and monthly expert supervision from the Internet Psychiatry Clinic in Stockholm.

Treatment

For depression, the guided ICBT program included 8 text-based modules including psychoeducation, behavioral activation, and cognitive reappraisal and relapse prevention. PD was addressed with 9 text-based modules with psychoeducation, working with automatic thoughts, behavioral experiments, in vivo exposure, and relapse prevention. Similarly, SAD treatment comprised 9 text-based modules including psychoeducation, working with automatic thoughts, behavioral experiments, shifting focus, and relapse prevention. The treatments are described in detail in previous publications [22,48,49]. The therapists adhered to the treatment protocol and provided uniform treatment to all patients regardless of referral pathway. The treatment programs were provided on a secure web platform that was state-of-the-art when data collection started in 2014.

Treatment time for the 3 diagnoses was up to 14 weeks. Irrespective of treatment program, each patient was expected to spend 7 - 10 days per module; access to the next module was gained upon finishing the previous one. Each module required approximately 45 minutes to complete.

After each completed module or at least once per week, a therapist gave feedback and guidance tailored to individual patient needs based on their worksheets, symptom assessment, and emails, while also introducing them to the next module. All feedback and communication were enabled asynchronously through a secure email system. Therapists spent an average of 10 - 30 minutes per patient per week. Patients not heard from for 1 week were contacted by the therapist via an SMS text message to encourage them to continue to work through the program. When necessary, phone calls could be made to solve problems, discuss motivation, or simply get in touch with an inactive patient.

Primary Outcomes

All self-report measures and questionnaires were administered via the internet and made accessible at the end of each module. Patients completed the measures and questionnaires pretreatment, after each module, posttreatment, and at the 6-month follow-up. The programs for depression, PD, and SAD had the following primary outcome measures:

- Depression: Montgomery Åsberg Depression Rating Scale, Self-rating version (MADRS-S) [50]. The MADRS-S comprises 9 items rated on a Likert scale from 0 - 6 (total score range: 0 - 54), where higher scores indicate more severe depression. The scale has been found to be sensitive to change [50,51] and has shown high correlations between expert ratings and self-reports [50]. Internal consistency measured with Cronbach α yielded 0.77 for patients with GP referral and 0.82 for self-referred patients.
- Panic disorder: Body Sensation Questionnaire (BSQ) [52]. The BSQ has been found sensitive to symptom change during treatment [52]. The BSQ comprises 16 items rated on a 5-point Likert scale (total score range: 16 - 80), where higher scores indicate a higher level of fear and sensitivity to bodily sensations commonly experienced during autonomic nervous system arousal. Cronbach α yielded 0.84 for GP-referred patients and 0.88 for self-referred patients and showed good internal consistency reliability.
- Social anxiety disorder: Social Phobia Scale (SPS) [53]. The SPS measures social phobia and the distress of being observed or watched while performing daily activities in the presence of others [53]. The SPS entails 20 questions rated on a 5-point Likert scale (total score range: 0 - 100), where higher scores indicate higher anxiety of being observed or scrutinized. The scale has shown good reliability and validity [53,54], as well as discriminant validity in distinguishing individuals diagnosed with SAD from both healthy controls and individuals with other anxiety disorders [53]. Internal consistency measured with Cronbach α yielded 0.91 for GP-referred patients and 0.93 for self-referred patients.

To address the main aim of this study, we combined the outcome measures for the 3 treatment modalities. We harmonized the outcome total scores and computed a common harmonized outcome measure (see Equation 1), thereby increasing the net sample and the statistical power for the analyses [55]. To ensure

XSL•FO
RenderX

comparability across different measurements, this formula normalizes the total score by first subtracting the minimum possible value, then dividing by the range (maximum possible value minus minimum), and finally multiplying by 100. This transformation ensures that all scores are expressed on a common scale, reducing biases introduced by different measurement units. However, the harmonization removes the original scale's absolute meaning and assumes that all scales represent the same underlying construct in a comparable way, which may not always be true if the scales have different distributions or nonlinear relationships. Moreover, harmonization was only feasible at the total score level. At the item level, where variables were ordinal, no harmonization was possible since no patients could have information on all 3 outcome variables. Therefore, we were unable to calculate internal consistency for the harmonized outcome measure.

$$(1) H = \text{score} - \text{MIN} \text{MAX} - \text{MIN} * 100$$

Statistics

Data preparation and calculation of descriptive statistics and bivariate analyses, including percentages, means, standard deviations, and cross tabulations with χ^2 tests, were conducted using IBM SPSS (version 29; IBM Corp) [56]. Effect sizes from pretreatment to posttreatment and from pretreatment to 6-month follow-up are reported as Cohen *d*, based on pooled standard deviations [57]. All measurement points (completed modules) were used for the analyses; however, the focus is the between-group (GP-referred vs self-referred) difference in pretreatment levels and changes from pretreatment to posttreatment and from pretreatment to 6-month follow-up. We performed analyses of the treatment outcome using linear mixed modeling (LMM). LMM is a recommended statistical method for handling missing data under the assumption of missing at random and uses all available data for estimation [58]. We analyzed levels and changes in data with a random intercept and fixed slope model. First, unconditional models including the time variable were tested. Time was defined as modules, giving changes in outcomes per module. To compare group differences over time, we added the referral group, both as a main effect and in an interaction effect with time. The reliable change index (RCI) was calculated using individual-level changes from pretreatment to posttreatment and from pretreatment to the 6-month follow-up, based on observed data for patients in each referral pathway and diagnosis. The RCI calculates whether changes in symptoms are reliable and not caused by measurement error [59]. Symptom level was considered to have improved if the outcome measure indicated a reliable change, as defined by the RCI [59]. The RCI was calculated with the formula $1.96 \times SD \times \sqrt{2}(1\text{-Rel})$, where SD is the observed standard deviation and Rel is the internal consistency at pretreatment assessment for each referral pathway and outcome measure. Improvement was defined by a negative RCI change, while deterioration was defined by a positive RCI change. Sensitivity models based on multiple imputation (MI) were analyzed to explore possible differences in levels and changes related to missing data for the 2 groups, assuming missing data were missing at random [60]. Pretreatment and longitudinal information were used as predictors of plausible values, and 50 data sets were generated. To account for the clustered data structure in the imputation process, data were transformed into wide format and analyzed with latent growth curve models. These models were parameterized identically to the corresponding linear mixed effect models, ensuring the same number of parameters and constraints [61]. Imputations and analyses were conducted using Mplus 8.10 [62].

Results

Patients

A total of 460 patients provided informed consent across the 2 referral pathways. Patient characteristics are shown in Table 1. Of the total sample, approximately two-thirds were referred by a GP (GP-referred), while about one-third were self-referred. There were more females in both groups (GP-referred: 176/289, 60.9%; self-referred: 106/151, 70.2%). The mean age across the total sample was approximately 32 years, with an average duration of complaints of about 10 years in both groups. The only statistically significant difference between the 2 groups was that a higher proportion of those who self-referred had obtained a university-level education. The distribution across the diagnosis-specific treatment programs was approximately 22% depression, 38% PD, and 41% SAD. Among patients in the depression group, the referral pathway was approximately equally distributed. In contrast, the pathway distribution for both the PD group and the SAD group was about two-thirds GP referrals and one-third self-referrals.

Attrition and Adherence

In the depression group (N=101), 97 patients (96%) completed the MADRS-S assessment pretreatment, 66 (65.3%) completed it at posttreatment, and 41 (40.6%) completed it at the 6-month follow-up. The amount of missing data was found to be equal between the 2 groups (GP-referred: mean 4.9, SD 2.9; self-referred: mean 4.6, SD 3.3; t_{99}=0.50, *P*=.62). In the PD group (N=172), 156 patients (90.7%) completed the BSQ pretreatment, with 111 (64.5%) and 67 (38.9%) completing the assessment at posttreatment and follow-up, respectively. No difference in the amount of missing data was found between the 2 groups (GP-referred: mean 5.0, SD 3.5; self-referred: mean 3.9, SD 3.1; t_{170}=2.0, *P*=.051). For the SAD group (N=187), 177 patients (95.2%) completed the SPS pretreatment, followed by 99 (52.9%) at posttreatment and 59 (31.6%) at follow-up, with no difference in the amount of missing data between the groups (GP-referred: mean 5.7, SD 3.6; self-referred: mean 4.9, SD 3.8; t_{185}=1.50, *P*=.14). Details on the observed diagnosis-specific outcome measures are provided in Table S1 in Multimedia Appendix 1.

Primary Outcomes

LMM results showed that, when harmonizing the outcome measures for all 3 diagnoses, significant symptom reduction was evident for both referral pathways from pretreatment to posttreatment and pretreatment to 6-month follow-up. Overall, patients who self-referred demonstrated significantly greater estimated symptom reduction from pretreatment to posttreatment and pretreatment to 6-month follow-up compared to those referred by GPs. The estimated scores from the LMM showed that the MADRS-S level decreased over time (Table 2). Self-referred patients showed no significant difference in depression scores from GP-referred patients at the pretreatment assessment, but a statistically greater reduction from pretreatment to posttreatment and pretreatment to 6-month follow-up. More details on the level and change in the estimated outcome measures are provided in Table S2 in Multimedia Appendix 2. Table 3 shows estimated means at pretreatment, posttreatment, and follow-up together with estimated effect sizes. Overall, we found large effect sizes (>0.8) over time.

Figure 1 depicts the corresponding level and change in the LMM. Overall, the figure shows that the estimated harmonized levels for both referral pathways decreased over time, with statistically significant greater reductions from pretreatment to posttreatment and from pretreatment to 6-month follow-up for those who self-referred. The pattern of changes in MADRS-S showed a somewhat different picture compared to the other results, with a stronger reduction in the self-referred group in the pretreatment to posttreatment interval, but no further reduction from posttreatment to follow-up. BSQ levels for both referral pathways decreased over time. Self-referred patients showed a significantly greater reduction in BSQ scores from pretreatment to 6-month follow-up and a temporarily greater reduction after completing module 2. The LMM scores showed that the estimated SPS levels and changes did not differ between

XSL•FO
RenderX

the referral pathways from pretreatment to 6-month follow-up. Self-referred patients showed a temporary significantly greater reduction from pretreatment to module 3.

Reliable Change

Overall, of those who self-referred, statistically significantly more patients showed an improvement in reliable change index (RCI) from pretreatment to posttreatment compared to those referred by their GP (Table 4). From pretreatment to follow-up, we found statistically significant differences only for self-referred patients with PD. RCI improvement based on the observed data required a reduction of at least 8 and 9 points on the MADRS-S (GP and self-referred), 12 and 11 points on the BSQ (GP and self-referred), and 13 points on the SPS (both referral pathways). There were statistically significant differences in RCI improvement between referral pathways among patients with depression from pretreatment to posttreatment, as well as among patients with PD from pretreatment to posttreatment and from pretreatment to follow-up. In all cases, symptom improvement favored those who self-referred. Of patients with depression or PD who reported no change in symptom level at posttreatment and at the 6-month follow-up, the majority were GP-referred. In contrast, the reliable change in reported symptom level between the referral pathway among patients with SAD was minor at both posttreatment and the 6-month follow-up. The proportions of patients with symptom improvement and no change in SPS were evenly distributed between the referral pathways.

Missing Data Sensitivity Analyses

The sensitivity analyses using MI indicated that the estimated pretreatment MADRS-S mean score for the GP-referred group was identical to the full-information maximum likelihood (FIML) estimate (Multimedia Appendix 3) . However, the reduction in symptoms from pretreatment to 6-month follow-up was smaller in the MI analysis compared to the original analysis (FIML=–7.54 vs MI=–6.55). Additionally, we also found a difference in the group effect of self-referral at the 6-month follow-up (FIML=–4.80 vs MI=5.49). This suggests less reduction and less difference in reduction in depression symptom levels in the net population based on the sample with the observed information compared to the total population with intact information on all variables and all measurement points. Thus, the main results may have shown somewhat overestimated reductions. A similar pattern was found for BSQ (GP follow-up levels: FIML=–15.21 vs MI=–14.21). For SPS, the difference was smaller but in the opposite direction (GP follow-up levels: FIML=–14.40 vs MI=–15.26). Differences from pretreatment to posttreatment are also reported in Multimedia Appendix 3; however, since there were fewer missing data at this assessment point, the results closely matched those of the main analysis.

Discussion

This study compared the overall treatment effectiveness of guided ICBT across GP-referred and self-referred pathways for patients with moderate depression, PD, or SAD. We also explored whether differences in treatment effectiveness between the referral pathways varied across the diagnoses separately. All patients underwent guided ICBT in a specialized routine mental health care clinic.

Principal Findings

Overall, there were large effect sizes of guided ICBT from pretreatment to posttreatment and from pretreatment to 6-month follow-up, aligning with the large effects reported in a systematic review of routine care practice on the effectiveness of guided ICBT for depression and anxiety [63], and further aligning with treatment results from previous investigations from the same specialized routine care clinic [22,48,49].

Our overall results support the hypothesis that patients who self-refer have significantly larger treatment effectiveness compared to those referred by their GP. This is evident from the relatively large estimated effect sizes in the harmonized scores in the self-referred group (effect sizes: 1.34 - 1.58) compared to the GP-referred group (effect sizes: 0.97 - 1.22). Additionally, there was a significant difference in reliable change between the self-referred and GP-referred groups. These results are noteworthy, especially since no difference in pretreatment symptom level was found across referral pathways. Our results favoring self-referral are consistent with those of Staples et al [43] where self-referred patients showed greater effect sizes compared to GP-referred patients both from pretreatment to posttreatment and from pretreatment to the 3-month follow-up. Neither our study nor previous studies on

XSL•FO
RenderX

referral pathway to ICBT [43] investigated the potential mechanisms behind the findings that self-referred patients have better treatment effectiveness, leaving open the possibility that unaccounted-for factors may influence the results.

One such factor could be differences in motivation and autonomy among patients across the referral pathways. According to SDT, internal motivation thrives when individuals experience autonomy, capability, and relatedness [32]. Self-referred patients may feel a greater sense of empowerment and autonomy by actively choosing to seek help through guided ICBT [31], which could enhance their motivation to engage with treatment more effectively compared to GP-referred patients [11]. The hope of recovery and the desire to gain control over one's life, identified as internal motivators in a study by Wilhelmsen et al [64], may be particularly strong among self-referred patients, who make the decision to undergo therapy independently. This increased autonomy may enhance their motivation to engage with treatment [32]. In turn, higher motivation may lead to more effective engagement with ICBT tasks, which could boost self-referees' sense of competence [33].

Other potential factors that may influence differences in treatment outcomes include both GPs' beliefs about treatment and patients' own beliefs and expectations. The assumption that "gold standard" psychotherapeutic treatment requires long-term, weekly face-to-face sessions with a therapist to be effective may shape how both GPs and patients perceive ICBT [65]. Patients often rely on their GPs for guidance in navigating the health care system, including for treatment recommendations [66]. A recent systematic review found that GPs' negative attitudes toward ICBT can transfer to patients and potentially undermine treatment outcomes [67]. GP-referred patients who expected or preferred face-to-face therapy may have engaged less with ICBT, influencing their outcomes in this study. In contrast, self-referred participants actively chose ICBT, suggesting they may have had greater knowledge, motivation, and readiness for this treatment. Accordingly, patients' perceptions of ICBT's usefulness—and potential lack of awareness of its effectiveness—may impact patients' engagement and treatment outcomes [68].

Guided ICBT relies on the patient's ability to actively engage with the treatment and implement changes into their everyday life. Since sustained behavior change is more effective when driven by autonomous motivation [69], fostering this motivation may enhance treatment engagement. Enhancing patients' sense of competence and connection may may further improve their engagement with homework, compliance with exposure exercises, and relapse prevention. These factors are crucial to therapy effectiveness, but have also been identified as major challenges in ICBT [70]. However, because technology is central to ICBT, factors like low computer self-efficacy, lack of basic computer skills, or computer anxiety may undermine perceived competence and hinder engagement with treatment [71], although previous studies have found that patients with lower levels of computer anxiety tend to show greater interest in ICBT [72]. Although these factors were not explicitly analyzed in our study, they may help contextualize the significant differences in treatment outcomes we found between the referral pathways.

Another factor potentially related to increased effectiveness in self-referred patients is educational level, as people with higher education report greater acceptance of digital mental health interventions than those with lower education [68]. Thus, the difference in education levels between referral pathways may contribute to differences in treatment outcomes. More self-referred patients had higher education, such as university degrees, compared to those referred by GPs. This is a pattern commonly observed across ICBT clinics and studies [20,24,73,74]. A key challenge in this context has been demonstrating that ICBT can effectively support individuals with fewer resources and lower education levels [24].

As education may develop capacities on many levels including increased sense of personal control, mastery, and self-direction [29], education may enhance engagement with ICBT by promoting autonomy and self-determination, as outlined in SDT [32,75]. Additionally, the treatment format in our study relies on text-heavy modules that guide patients through psychoeducation, working with negative or automatic thoughts and exposure therapy, a format known as bibliotherapy [76]. Patients with higher education levels may find it easier to process and apply these materials effectively, potentially contributing to their greater improvements.

Beyond comprehension, education is also linked to digital literacy, health literacy, and problem-solving skills, which may further support active engagement with the treatment format [29,30]. However, a recent systematic review found inconsistent evidence regarding the relationship between higher education and treatment outcomes in guided internet-delivered therapy, including ICBT [40]. This suggests that, while education may facilitate certain aspects of engagement, other factors such as motivation and readiness for digital interventions may play an equally important role.

Exploring the difference in treatment effectiveness between depression, PD, and SAD revealed large effect sizes of guided ICBT from pretreatment to posttreatment and from pre-treatment to the 6-month follow-up, regardless of referral pathway. These findings align with the large effects reported in systematic reviews for depression [63,77], PD [78,79], and SAD [80]. Our results indicate statistically significant differences in effect sizes between referral pathways across the 3 diagnoses.

In our study, both referral pathways led to significant symptom reduction, consistent with findings from research comparing GP referral and self-referral in psychological care [43] and musculoskeletal care [39]. Considering self-referral in a broader context, the United Kingdom's IAPT program was introduced in 2007 within primary care to expand access to treatment for common mental health problems. Self-referral within IAPT has improved access to care, particularly for individuals who might not seek help through traditional GP referrals [27]. However, concerns have been raised about equity, as factors such as education, digital literacy, and ethnicity influence who engages with the program [81]. Recent research suggests that digital solutions, such as artificial intelligence–driven self-referral chatbots, may help reduce these disparities by increasing referrals from underrepresented groups, including ethnic minorities and nonbinary individuals [82]. Building on the IAPT,

XSL•FO
RenderX

the Norwegian Prompt Access to Mental Health Care program provides adults with quick, low-threshold access to evidence-based treatment for anxiety and depression through self-referral. Situated within primary care, the program offers both short-term face-to-face therapy and guided internet-delivered treatment [83]. A randomized controlled trial comparing these modalities found that the digital option improves accessibility, requires significantly less therapist time, and has the potential to reach a larger population [84]. Sweden permits self-referral directly to specialized mental health care. A study of young Swedish adults who self-referred to a specialized mental health clinic found no evidence of overutilization of specialized services. Additionally, most self-referrers had not previously sought professional help for their psychiatric symptoms. This suggests that self-referral lowers the threshold for accessing specialized care especially for those who for various reasons do not contact their GPs for mental health problems [85].

Limitations

First, the attrition was high, particularly at the 6-month follow-up, potentially introducing bias into the results, as indicated by the results from the missing data sensitivity analyses. This may, in part, reflect the limitations imposed by conducting the study within routine care, where ethical approval from the Regional Ethical Committee restricted patient contact to what was considered natural for the treatment process, and offering incentives for survey completion was not permitted. Future studies conducted outside these constraints could explore strategies such as using multiple contact methods or offering incentives to improve follow-up rates. Second, since we did not assess patients' motivation for treatment, we can only speculate whether underlying patient characteristics such as those outlined by SDT [32] contributed to variations in effectiveness across referral pathways. Third, as we were only able to assess primary outcome measures for the diagnoses and did not assess secondary outcomes such as comorbidity disorders or quality of life, we cannot document a broader impact of the results. Fourth, although all data in this study were collected through the same secure web platform, technological advancements since data collection began in 2014 have surpassed the platform's capabilities. Although extracting user data from the platform's backend to examine engagement patterns and completion speeds would be valuable, this is not supported by the platform.

Implications

Overall, our results showed that both referral pathways led to significant symptom reduction in guided ICBT. However, for patients with SAD, treatment effectiveness did not differ between referral pathways. These results underscore the importance of maintaining both referral pathways, as they attract distinct patient populations and serve complementary roles in facilitating access to mental health care. Although self-referral may be a more effective route for some, GPs remain crucial as gatekeepers, gate-openers, and trusted guides in navigating the health care system for others. Therefore, raising awareness among GPs and other health care providers about the viability and effectiveness of guided ICBT is essential to ensuring more patients benefit from this evidence-based treatment.

Delayed help-seeking remains a major challenge in mental health care [2,82]; our finding that the patients had been experiencing symptoms for an average of 10 years underscores the urgent need to increase help-seeking behavior. Improving mental health literacy could help reduce stigma and encourage help-seeking behavior [86], while public information campaigns may further raise awareness of the benefits of guided ICBT and self-referral. Additionally, our results suggest that motivation plays a key role in treatment success. Addressing potential barriers such as lower motivation in GP-referred patients through targeted engagement strategies could help optimize outcomes.

Beyond increasing accessibility, self-referral offers an essential pathway for individuals who may not seek help through traditional means [27,82]. Technology-driven solutions, such as artificial intelligence–powered self-referral chatbots, could further enhance access by reducing stigma, guiding users to appropriate services, and providing personalized interactions that support motivation and engagement [82]. Notably, chatbots have been shown to reduce negative attitudes and stigma toward mental health, potentially improving help-seeking behaviors [87]. Taken together, these findings highlight the need for a multifaceted approach that ensures timely and equitable access to mental health care while also addressing patient engagement and systemwide awareness.

Future Directions

Future research could focus on conducting cost-effectiveness analyses of different referral pathways to provide policymakers and health care providers with a systematic comparison for prioritizing resource allocation. Additionally, exploring qualitative aspects of patient experiences with referral pathways may offer a more comprehensive understanding of the factors influencing treatment outcomes. Together, these approaches could guide the development of more effective and accessible ICBT services. Further, investigating the influence of potential mediators and moderators could clarify the relationship between referral pathways and treatment outcomes. Adjusting for factors like baseline characteristics may provide valuable insights into the mechanisms underlying guided ICBT effectiveness.

Conclusion

This study demonstrates that both GP referral and self-referral pathways to guided ICBT are effective for moderate depression, PD, and SAD when delivered in a specialized routine care clinic. Notably, self-referred patients experienced significantly greater treatment outcomes both from pretreatment to posttreatment and from pretreatment to 6-month follow-up compared to those referred by a GP. We suggest that this additional improvement may stem from differences in internal motivation, with self-referred patients being more motivated to engage with the treatment, leading to greater long-term benefits. Our results highlight the vital role of self-referral and patient autonomy in driving sustained progress, particularly for depression and PD. At the same time, the comparable outcomes for SAD suggest that referral pathways may be less influential for this condition. These findings underscore the need for a health care system that

XSL•FO
RenderX

supports both referral pathways, ensuring timely and equitable access to evidence-based psychological treatment while also fostering patient engagement and long-term recovery. Further research is needed to examine the effect of self-referral to guided ICBT when the pathway is implemented on a larger scale.

Acknowledgments

The authors would like to express their gratitude to all patients in the study. A special thank you goes to eCoping's clinical coordinator, Hanne Halseth Lund Gulbrandsen, and clinical psychologist, Reidar Nævdal, for their valuable insights and contributions to this paper. This study was part of the Center for research-based innovation on Mobile Mental Health (ForHelse), which is funded by the Norwegian Research Council (NFR 309264).

Abstract

Background: The Evaluation of Digital Addiction (EVADD) study investigates problematic smartphone use in the digital age, as global smartphone users reached 55.88 million in France in 2023. With increased screen time from digital devices, especially smartphones, the study highlights adult use issues and associated risks.

Objective: The aim of the study is to assess the prevalence of compulsive smartphone use among French adults and identify patterns of problematic behaviors, including their impact on daily activities, sleep, and safety.

Methods: The EVADD study used a cross-sectional, nonprobability sample design, conducted from May 3 to June 5, 2023. Participants were recruited through the French mutual insurance company PRO-BTP. Data were collected anonymously via a digital questionnaire, including the Smartphone Compulsive Use Test, capturing information on social network engagement, device ownership, and daily screen use.

Results: A total of 21,244 adults (average age 53, SD 15 years; 9844 female participants) participated. Among 21,244 participants, 8025 of 12,034 (66.7%) respondents exhibited compulsive smartphone use (P<.001). Additionally, 7,020 (36.7%) participants scored ≥8 on the Smartphone Compulsion Test, indicating addiction. Younger participants (18 - 39 years) were significantly more likely to show signs of addiction (2504/4394, 57%; odds ratio 2.5, 95% CI 1.9 - 3.2) compared to participants aged ≥60 years. Problematic behaviors included unsafe smartphone use while driving (5736/12,953, 44.3%), frequent smartphone use before bedtime (9136/21,244, 43%), and using smartphones in the bathroom (7659/21,244, 36.1%). Sleep disturbances and risky behaviors correlated strongly with higher compulsion scores (P<.01).

Conclusions: The EVADD study highlights the complex relationship between adults and smartphones, revealing the prevalence of compulsive behaviors and their impact on daily life, sleep, and safety. These findings emphasize the need for public awareness campaigns, preventive strategies, and therapeutic interventions to mitigate health risks associated with excessive smartphone use.

Introduction

Background and Digital Addiction

The term “digital” encompasses the use of digital technology for communication through intangible devices. This includes activities such as browsing social networks, playing video games, or engaging in digital gambling using computers, smartphones, and tablets.

The proliferation of screens is a relatively recent phenomenon, with the number of smartphone users in France estimated to

XSL•FO
RenderX

have reached 55.88 million in 2023, marking a doubling since 2013 [1]. Screen selection is often dictated by various contexts, including sedentary lifestyles, mobility, and personal or professional use. Consequently, the time spent on screens, known as screen time, has witnessed a steady increase over the years. This trend has contributed to a notable rise in the prevalence of excessive screen behavior among individuals across age groups, including children, adolescents, and adults [2].

Problematic smartphone use is characterized by 3 primary consumption problems: addictive consumption habits (eg, symptoms of addiction), antisocial consumption patterns (eg, prohibited use), and adverse use patterns (eg, phone use while driving and going to the toilets or to bed with a smartphone), leading to a negative impact on academic, professional, or social functioning. This negative influence can manifest in disrupted interpersonal relationships, social withdrawal due to limited face-to-face contact, and an increased preference for solitary activities over group interactions. While smartphone addiction does not equate to substance or gambling addiction, screens can indeed foster addictive processes through activities like video gaming, social networking, and engaging in sexual content [3].

The widespread adoption of smartphones has given rise to a new digital clinical terminology. “Nomophobia,” or “no-mobile-phone-phobia,” refers to the compulsive and time-intensive use of smartphones, coupled with anxiety when the device is unavailable. It encompasses symptoms such as a constant need for availability, a preference for mobile communication over face-to-face interaction, and financial challenges related to excessive mobile use. “Ringxiety,” a specific manifestation of nomophobia rather than a standalone construct, describes the sensation of hearing phantom phone rings or notifications. Meanwhile, “fear of missing out” (FoMO) drives attentional distraction, as individuals strive to stay connected and engaged with the positive digital experiences portrayed in others’ content [4]. Both nomophobia and FoMO reinforce the need for constant connection, perpetuating excessive smartphone use. “Phubbing,” a blend of “phone” and “snubbing,” refers to ignoring others by focusing on one’s phone during social interactions [5]. “Athazagoraphobia” refers to the fear of being forgotten or ignored, often manifesting as anxiety when messages, posts, or comments go unnoticed, while “smombie,” a contraction of “smartphone zombie,” describes individuals walking while absorbed in their phones, oblivious to their surroundings. These behaviors often result in compulsive checking of messages or social networks [6].

Research has highlighted the fine line between habitual, nonproblematic use of social networks and potentially addictive behavior. Users exhibiting symptoms and consequences akin to substance addiction, such as salience, mood changes, tolerance, craving, withdrawal, and relapse, may indeed be addicted to social networks. Our objective is not to pathologize everyday behaviors excessively but to gather valuable insights that can help prevent risky behaviors and provide support for those in need of therapeutic intervention [7].

These digital behaviors have thus become a growing public health concern. Moreover, several recent studies conducted after the most acute phases of the COVID-19 pandemic have highlighted evolving digital use patterns. These include increased reliance on smartphones for communication, remote work, entertainment, and social networking, potentially reflecting longer-term shifts in digital habits [8-10]. Such postpandemic data provide a more contemporary context for understanding current problematic smartphone use trends.

Study Objectives

The objective of this study is to evaluate the extent and patterns of problematic smartphone and social media use among adults in France using validated assessment tools. Specifically, we aim to identify the prevalence of compulsive behaviors, their associations with demographic factors, and the potential health and social consequences.

Methods

Ethical Considerations

This study was conducted in accordance with the ethical principles of the Declaration of Helsinki and the French Public Health Code (Article L.1123-7). The research protocol was reviewed and approved by the Comité de Protection des Personnes Sud-Est I (reference 2023-A00312-43, national number 23.00519.000257). The approval was granted on March 6, 2023, and remains valid for 2 years. Participants were provided with detailed information regarding the study objectives, data collection process, confidentiality measures, and their rights, including the ability to withdraw at any time without consequences. Written informed consent was obtained from all participants before their inclusion in the study. To ensure compliance with the General Data Protection Regulation and French data protection laws, the study was designed to protect participant confidentiality. Data were anonymized and securely stored. Participants had access to the data protection officer for any inquiries or concerns regarding their data rights. No financial or material compensation was provided to participants in this study.

Study Design and Participant Characteristics

The Evaluation of Digital Addiction (EVADD) study used a cross-sectional, nonprobability sample design from May 3 to June 5, 2023. The use of nonprobability sampling was dictated by the practical constraints of recruiting participants through the PRO-BTP network, which provided access to a large population of insured members. To ensure comprehensive and transparent reporting of our web-based data collection, we have adhered to the CHERRIES (Checklist for Reporting Results of Internet E-Surveys) guidelines.

A total of 800,000 members of the French mutual insurance company PRO-BTP were invited to participate via email. The email provided information about the survey’s objectives, contents, and confidentiality protections, along with access to a completely anonymous digital questionnaire through a provided link. Upon clicking the link, participants were automatically redirected to a web platform hosted by the researchers, where they could complete the questionnaire anonymously. No personal data such as email or IP addresses were collected. Participants were required to be at least 18 years

XSL•FO
RenderX

of age and proficient in French; no other eligibility criteria were applied. The study followed the CROSS (Checklist for Reporting of Survey Studies) for reporting survey studies, as recommended by the Enhancing the Quality and Transparency of Health Research network. Considering an expected response rate of 1% - 5% among PRO-BTP members, corresponding to 8000 to 40,000 responses, a sample size of 16,302 participants was determined necessary to achieve a reliable representation of PRO-BTP members with a 99% CI and a 1% error margin.

Participant characteristics collected included age, sex, socioprofessional category, education level, and family status. Age was categorized into 3 groups: 18 - 39, 40 - 59, and ≥60 years. Socioprofessional categories were classified into 8 groups based on the French national classification system.

Measurement Tools: Smartphone Compulsion Scores

Data were obtained through a combination of a standardized test and author-formulated questions. The primary outcome measure was the degree of participants' smartphone compulsive use, assessed using the Smartphone Compulsive Use Test score [11], consisting of 15 yes or no questions. Scores indicated normal behavior (1 - 2 yes), leaning toward excessive use without problems (3 - 4 yes), problematic or compulsive use (5 or above), and obvious behavioral addiction (8 or higher).

The Smartphone Compulsion Test (SCT) was selected, as it broadly evaluates the clinical aspects of problematic smartphone use and its consequences. While no validated tools currently exist in French for this purpose, the SCT has been extensively used in our clinical practice. The trends observed in this study will serve as a basis for formal psychometric validation of this tool in the near future.

The SCT was administered to participants who reported owning and regularly using a smartphone. Respondents who did not own a smartphone or did not report regular use were excluded from this portion of the survey. This criterion ensured the relevance of the questions to the participants' experiences.

Measurement Tools: Problematic Smartphone Behaviors

A total of 4 yes-no questions assessed smartphone use while driving. In total, 10 questions evaluated nomophobia, while 1 question each assessed athazagoraphobia, phubbing, and smombie behavior. Additionally, participants were asked how frequently they took their smartphone or tablet to the toilet or bed, with response options of never, rarely, often, and always.

Measurement Tools: Social Media Use Patterns

All participants were asked whether they used social media networks. Those who confirmed using at least 1 social network were subsequently directed to questions about their use patterns.

The 5 addiction-related questions were then administered to a subset of participants (approximately 4800) who reported frequent use of social media and behaviors indicative of potential problematic use, as identified through initial screening questions. The 5 yes-no questions related to the activity on networks, and 5 others, to be answered by never, rarely, often, and always, related to a possible problem with network use.

Participants reported the number and types of electronic devices they owned (smartphone, tablet, laptop, desktop, and game console) and their primary use (social network, messaging, SMS text messages, emails, television series seasons, video games, and digital gambling). Daily leisure time spent on these devices was also estimated.

The questionnaire was pretested by a small group of researchers to ensure clarity, coherence, and technical functionality before wide distribution. No forced responses or completeness checks were implemented, allowing participants to proceed without answering all questions. Respondents were not able to return to previous pages to modify their answers once they advanced. Additionally, no statistical weighting or adjustments were performed to correct for the potential nonrepresentativeness of the sample.

Statistical Analysis

Descriptive statistical analyses were performed using R software (version 4.2; R Foundation for Statistical Computing). Descriptive statistical analyses were conducted to summarize participant characteristics and responses. Continuous variables were analyzed using nonparametric tests (eg, Kruskal-Wallis and Mann-Whitney-Wilcoxon) due to the nonnormal distribution of data, which was confirmed through the Shapiro-Wilk test. Categorical variables were analyzed using chi-square tests, appropriate for the distribution and nature of the data. Comparisons of median compulsion scores across groups used nonparametric methods due to the ordinal nature of the data and the violation of normality assumptions. Homogeneity of variances was assessed using the Levene test, and where assumptions were violated, appropriate adjustments were made (eg, robust statistical methods).

Categorical variables were presented as frequencies and percentages, while continuous variables were described using means and SDs. The number of missing data for each parameter was reported. Median compulsion scores were compared across age groups and digital activities using appropriate statistical tests such as Kruskal-Wallis or Mann-Whitney-Wilcoxon tests.

Results

Participant Characteristics

Overall, 21,244 (2.7% of the solicited panel) persons responded to all or parts of the questionnaire. Their overall characteristics are shown in Table 1. Their mean age was 53 (SD 15 years), and 9844 (46.3%) were female participants. The majority of participants were retirees or employees, and 14,293 (72%) were married or lived in a couple. More than 10,622 (50%) participants had 2 or 3 devices, mainly smartphones and laptops. The favorite device was the smartphone, and 14,871 (70%) participants admitted that they could no longer do without it.

[a]OR: odds ratio.

[b]Not applicable.

Sociodemographic Analysis

In addition to age differences, significant variations in smartphone and social media use patterns were observed across sociodemographic groups. For example, socioprofessional categories such as managers and high intellectual professionals reported higher rates of smartphone use for work-related purposes (1,570 out of 2,708; 58.0%) compared to retirees (1,625 out of 6,501; 25.0%) and employees (2,104 out of 5,260; 40.0%), who predominantly used smartphones for entertainment. Similarly, participants with higher education levels (university graduates) demonstrated a greater prevalence of compulsive smartphone use (4,320 out of 6,000; 72.0%) compared to those with secondary education or less (5,490 out of 9,000; 61.0%). These findings underline the complex interplay between demographic factors and digital behaviors.

Smartphone Compulsion Scores

Among the participants, 19,103 answered the SCT. A total of 8025 of 12,034 (66.7%) participants (odds ratio [OR] 2, 95% CI 1.90-2.11) exhibited compulsive smartphone use, and 7,020 (36,7%; OR 0.61, 0.58-0.64) scored ≥8, indicating obvious behavioral addiction (Table 2).

Sleep disorder if smartphone not near	1063 (7.8)	0.05 (0.05-0.06)	13,596
Athazagoraphobia	940 (7.3)	0.05 (0.04-0.05)	12,865
Phubbing	1818 (14)	0.05 (0.04-0.05)	12,865
Smombie	1452 (11)	0.09 (0.09-0.10)	12,865

[a]OR: odds ratio.

The percentage of participants according to the total number of positive responses by age class is displayed in Table 3.

Table . Smartphone Compulsion Test.

Total number of positive responses	18 - 39 years, n (%)	40 - 59 years, n (%)	≥60 years, n (%)
0	35 (0.8)	268 (3.5)	352 (4.6)
1 - 2	338 (7.7)	842 (11)	766 (10)
3 - 4	923 (21)	1301 (17)	1762 (23)
5 - 7	1362 (31)	2066 (27)	2068 (27)
≥8	2504 (57)	2907 (38)	1609 (21)

The highest scores were seen in the youngest class of age: 57% (2504/4394) of those less than 40 years had a score of 8 or more. Around 45% of participants spent 1 - 2 hours of their leisure time on screens, 7659 of 21,244 (36.1%) participants acknowledged going often or always to the toilets with their smartphone, and 9136 (43%) going to bed with it, although only 3186 (15%) said they fell asleep with it (Table 4).

[a]OR: odds ratio.

[b]Not applicable.

A total of 12,102 (57%) participants (95% CI 56.0 - 58.0) used social networks, primarily Facebook. Logging in to simply watch, without making comments, was reported by 8412 (70%) participants (OR 5.15, 95% CI 4.99-5.32), and 6916 (57%) scrolled through news feeds without paying attention. However, 4800 (40%) participants thought they spent too much time on social media. Questions relative to the problematic use of social networks were answered by fewer participants and generally acknowledged as not being a significant problem.

Discussion

Summary of Key Findings

Our EVADD study offers valuable insights into the various characteristics associated with frequent smartphone use, which has become a cornerstone of multitasking activities in modern life. By examining the problematic and potentially addictive aspects of this trend, we surveyed a significant sample of 21,244 adults in France, with an average age of 53 (SD 15) years, of whom 48% (n=9844) were female participants. This study revealed a high prevalence of problematic smartphone and social media use among French adults, with 8025 of 12,034 (66.7%) participants exhibiting compulsive behaviors and 4569 (38%) showing signs of addiction. These behaviors were more pronounced in younger age groups and were associated with activities such as unsafe driving and nighttime smartphone use. This work stands as a pioneering effort in France, shedding light on a topic of growing concern. The questions on problematic social media use were adapted from a combination of existing clinical frameworks and insights from the international literature. These were further refined through expert consensus to capture the primary characteristics of problematic social media behaviors. However, we acknowledge that these questions have not yet undergone formal validation.

Our findings underscore the widespread dependence on smartphones, with over two-thirds of participants exhibiting compulsive behaviors and a substantial portion devoting their free time to screen-based activities. While smartphones offer undeniable benefits for communication and information access, these patterns highlight the clinical and societal concerns associated with excessive use [11].

These findings should be viewed within the current post–COVID-19 landscape, where recent research indicates that digital behaviors have intensified and diversified, partly due to remote work, digital learning, and a broader shift toward digital entertainment and communication [8-10]. Such trends suggest that the patterns we observed may not merely reflect an exceptional period but rather a continued adaptation to new digital norms. The COVID-19 lockdown further exacerbated concerns about screen time, particularly among children, as evidenced by a study conducted by the French Public Health Agency. Almost 25% of respondents reported spending 7 hours a day, or even longer, on screens. Increased screen time, especially among young, educated individuals and urban dwellers, underscores the need for a nuanced understanding of its impact on physical and psychological well-being. However, it is essential to note that while screen time is a factor, its correlation with problematic smartphone use remains inconclusive [12].

Clinical and Public Health Implications

Screen exposure has increased substantially, with nearly half of the participants dedicating over 1.5 hours daily to digital devices, reflecting a marked shift in leisure patterns. These findings align with broader societal trends observed during the pandemic. Parental concern regarding children's screen time has escalated, a sentiment echoed by a study from the French Public Health Agency. This study highlighted a marked rise in average screen time during the COVID-19 pandemic, with nearly a quarter of the participants reporting screen engagement for 7 hours or more per day. This increase was predominantly observed among the youths, individuals with higher education levels, those working from home during the lockdown, and residents of urban areas [13]. Furthermore, a recent investigation indicated that individuals with a pronounced inclination toward smartphone use exhibit a higher propensity to consume video content on their devices, thereby accruing more screen time compared to their less engaged counterparts [14].

It is crucial to acknowledge that screen time is one of the several factors to consider in the discourse on problematic or excessive smartphone use. The current body of evidence regarding its impact on the physical and psychological well-being of young individuals remains mixed. While this study focuses on adults, we have included references to research on adolescents and children for several reasons. Adolescent populations have been the subject of most existing research on digital behaviors, offering critical insights into the psychological and behavioral consequences of smartphone use. These behaviors often persist into adulthood, making this research relevant for understanding patterns observed in adult populations. Additionally, intergenerational influences, such as how parents' and children's digital habits affect one another, further justify the inclusion of this literature. Addressing findings from adolescent-focused studies also enables us to draw attention to the life-course perspective of problematic smartphone use and its long-term implications. Recent comprehensive reviews and meta-analyses have found no significant link between screen time that surpasses the American Academy of Pediatrics guidelines and adverse health outcomes in youths [15]. The adage "everything in moderation" arguably serves as pragmatic counsel for parents navigating discussions on screen time with their children. However, the efficacy of screen time regulation as a strategy to curb problematic behaviors among youths does not consistently align with this principle [16].

Based on our findings, we propose the following actionable recommendations:

- For policy makers: Develop and implement public awareness campaigns that emphasize the risks of excessive smartphone use, particularly among younger adults.

XSL•FO
RenderX

Consider incorporating educational modules on digital well-being in school curricula.
- For mental health professionals: Integrate screening for problematic smartphone use into routine mental health assessments, particularly for individuals reporting anxiety, sleep disturbances, or compulsive behaviors. Provide targeted interventions, such as mindfulness-based stress reduction, sophrology, or therapeutic yoga, to address underlying factors contributing to excessive smartphone use. These approaches have demonstrated efficacy in reducing compulsive behaviors, improving emotional regulation, and promoting digital well-being.
- For employers: Encourage balanced digital use among employees by promoting "tech-free" breaks and fostering a culture that prioritizes mental well-being over constant connectivity.

These recommendations aim to support a multistakeholder approach to mitigating the health and social risks associated with problematic smartphone use.

Impact on Habits and Behaviors

Our investigation shed light on notable shifts in habitual behaviors, particularly concerning smartphone use in various contexts. A significant finding was that 36% of participants reported frequent or constant smartphone use in the bathroom. Beyond the hygiene concerns and the potential for bacterial contamination associated with this practice, it has emerged as a compulsive behavior for some individuals [17]. A survey from the United Kingdom disclosed that 57% of respondents confessed to using their phones in the bathroom, with 8% doing so "always" and an additional 14% "most of the time" [15]. In France, a study conducted in September 2019 with a representative sample of 1024 individuals found that 46% bring their mobile phone or tablet into the bathroom [18]. Younger participants exhibited significantly higher rates of compulsive smartphone use, likely driven by greater reliance on social media and constant connectivity. These findings highlight the need for targeted interventions addressing age-specific patterns of use. Furthermore, socioprofessional categories displayed distinct patterns: managers and high intellectual professionals reported higher screen time dedicated to work-related activities, while retirees and employees showed greater use of digital devices for entertainment and social purposes. These differences emphasize the importance of designing tailored public health interventions to address the specific risks and needs of each group. The sociodemographic differences observed in smartphone and social media use patterns provide important insights for tailoring public health interventions. For instance, the higher prevalence of compulsive smartphone use among individuals with advanced education and socioprofessional categories suggests the influence of work-related pressures and digital connectivity on these behaviors. In contrast, retirees and employees primarily using smartphones for entertainment highlight a different set of needs and risks. These distinctions emphasize the necessity of demographic-specific strategies to address problematic smartphone use effectively.

The intersection between smartphone use and sleep disturbance warrants close examination. Research in this area has predominantly focused on adolescents and young adults [19]. Our results reveal that smartphone engagement prior to sleep, including exposure to bright blue light and the use of applications, adversely affects sleep quality. A notable 43% of participants indicated that they go to bed accompanied by their smartphone or tablet, with 15% falling asleep while still engaging with these devices. Additionally, 53% reported awakening alongside their phones. Exposure to blue light emitted by smartphones during evening hours can inhibit melatonin synthesis, disrupt circadian rhythms, and reduce total sleep duration [20]. "Doomscrolling" further exacerbates these issues, delaying sleep onset and increasing daytime fatigue. Nighttime social media use, particularly when emotionally engaging with content, is linked to poorer sleep quality [20].

Our findings reveal concerning behaviors: 44% of respondents conceded to using their smartphones while operating a vehicle, with 14% engaging in SMS text messaging and 33% reading messages. It is important to note, however, that this figure includes the use of smartphones for GPS navigation. When the phone is securely mounted and not manipulated during driving, this use may not constitute a dangerous behavior and is more akin to traditional GPS device use. Such practices not only compromise the safety of the individuals involved but also pose significant risks to public safety [21]. A study elucidated that the propensity for distraction during driving is prevalent, particularly among drivers below 50 years of age [22]. Insights from the French Road Safety Observatory highlight that smartphone use while driving amplifies accident risks 3-fold and increases the likelihood of accidents by 23 times when reading messages [23].

Strengths and Limitations

Our cohort, while substantial, does not fully represent the diversity of the French population due to its size and the uniformity of its participants. The reliance on a nonprobability sample limits the generalizability of the findings. While the large sample size ensures statistical power, the respondents may not be representative of the broader French population, particularly in terms of socioeconomic and cultural diversity. Future studies should consider probability sampling methods to address this limitation and enhance external validity.

While this study captures essential behaviors through adapted clinical frameworks, the lack of validated tools in French limits generalizability, highlighting the need for future validation studies. Additionally, a limitation of this study is the reliance on several single-item measures to assess specific behaviors, such as smartphone use during nighttime or while driving. Although these measures provide valuable insights, they may lack the reliability and depth of multi-item scales. Future research should aim to develop and validate more comprehensive tools to assess these constructs with greater precision and reliability.

The study focused on adults, excluding children and adolescents. Dissemination via a private internet link may have introduced selection bias, potentially affecting participation among less technology-savvy individuals. Additionally, individuals with a pre-existing interest in digital technologies may have been overrepresented in the sample.

XSL•FO
RenderX

The choice of nonparametric methods was driven by the observed nonnormal distribution of the data, as indicated by the Shapiro-Wilk test. These methods ensure robust analysis for ordinal and nonnormally distributed data but may limit the generalizability of the findings compared to parametric approaches. Future research with larger and more representative datasets could explore additional statistical methods to further validate these results. While the study provides valuable insights into demographic differences in digital technology use, further research is required to examine cultural, psychological, and contextual factors influencing these behaviors across diverse populations.

A limitation of this study is the lack of validated tools in French for assessing problematic smartphone and social media use. While the SCT has been widely used in clinical practice and provides a broad evaluation of problematic smartphone behaviors, its psychometric properties require formal validation. Similarly, the questions on problematic social media use were adapted from a combination of existing clinical frameworks and insights from the international literature. These were further refined through expert consensus to capture the primary characteristics of problematic social media behaviors. However, we acknowledge that these questions have not yet undergone formal validation. Future research should prioritize the psychometric validation of these tools to ensure their reliability and generalizability across diverse populations.

A key challenge in the study of smartphone and digital technology use is the proliferation of overlapping constructs and terminologies, which can lead to fragmentation in the field. Terms such as problematic smartphone use, smartphone addiction, and compulsive smartphone use often describe similar phenomena. Similarly, behaviors like FoMO and specific manifestations such as phantom ringing or notification behavior overlap with broader constructs like nomophobia. Standardization of terminology and constructs in future research will be essential for advancing understanding and developing unified measures.

Future Directions

The EVADD study provides an epidemiological and clinical perspective on smartphone use and its consequences within an adult demographic aged 18 to 60 years. The impact on older populations remains largely unexplored [24]. In light of the growing concern over digital device use, the French government recently announced the commissioning of an expert report to address appropriate screen use in domestic and educational settings. Concurrently, the Canadian Paediatrics Society Working Group has highlighted several potential research paths [25].

Acknowledgments

The study is promoted by the Institute Rafael Center for Research with the support of the PRO BTP observatory for health.

Abstract

Background: Increasing observation and evidence suggest that the process of digitalization could have profound impact to the development of human mind and self, with potential mental health consequences. Self-differentiation is important in human identity and self-concept formation, which is believed to be involved in the process of digitalization.

Objective: This study aimed to investigate the relationship between digitalization and personal attributes in the actual selves in the physical and virtual worlds.

Methods: A community cohort of 397 participants aged 15 to 24 years old was recruited consecutively over about 3 months. Assessment was conducted upon the indicators of digitalization (smartphone use time, leisure online time, and age of first smartphone ownership), smartphone addiction, 14 selected personal attributes in the actual selves in the physical and virtual worlds, psychiatric symptomatology and personality traits. Euclidean distance analysis between the personal attributes in the actual selves in the physical and virtual worlds for the similarities of the 2 selves was performed in the analysis.

Results: The current primary findings are the negative correlations between the similarity of the personal attributes in the physical actual self and virtual actual self, and smartphone use time, smartphone addiction as well as anxiety symptomatology respectively ($P<.05$ to $P<.01$).

Conclusions: The current findings provide empirical evidence for the importance of maintaining a congruent self across the physical and virtual worlds, regulating smartphone use time, preventing smartphone addiction, and safeguarding mental health.

Introduction

Background

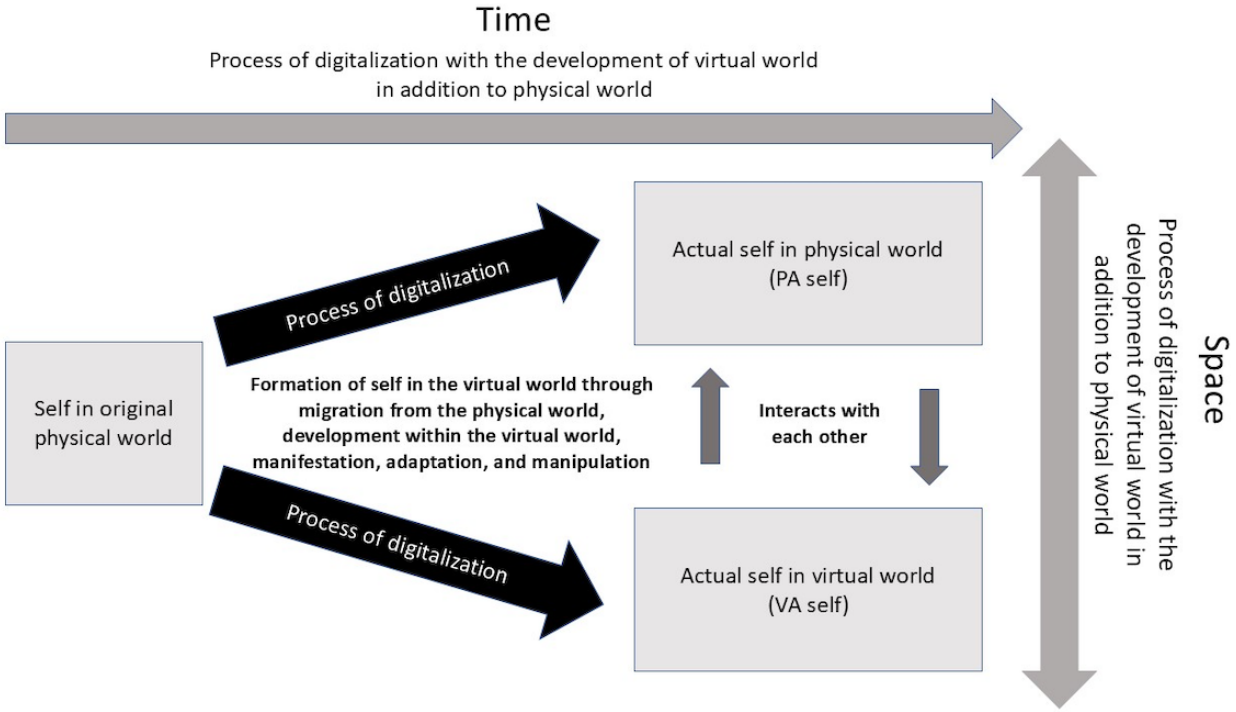
The internet and digital devices have been infiltrating rapidly into the world, human society and culture as well as everyday living, especially after the global popularization of the smartphone, which is a personalized communication tool with full computer functions and 24/7 accessibility. Across the millennium, there has been postulation of "Digital Natives" as well as "Digital Immigrants," depicting the potential influence of digitalization across the generations [1]. In recent decades, it has witnessed growing evidence of the impact of digitalization on the human brain, mind, cognition, and behavior [2]. Such observations and neurobiological findings imply that our brain, mind, and self can be modified in the process of digitalization in a direct and profound way. To delineate the active and overall process of digitalization upon the human self, there is a postulation of a "Digitalized Self" [3].

Concepts and Theories of Self, Identities, and Personal Attributes

There has been ongoing development of different conceptualization and theorization of the self according to contemporary knowledge and evidence. Based on the classic work by James [4], recent views tend to regard the self as both a unity and a multiplicity [5,6]. Subsequent works have been further exploring the properties of the self, such as structural properties of the self and their potential relationship with psychological well-being, as well as separate self-schemas [7]. Among various theories about the differentiation of the self according to different conditions and contexts, there comes the self-concept differentiation [8], which involves adaptation to the different requirements of different social roles by specialization and fragmentation [9]. Regarding different types of self-states, under the self-discrepancy theory [10], there are "actual self," "ideal self," and "ought self." Relevant to mental health, potential mismatches of these different kinds of self-states from the perspectives of oneself and others would be associated with different emotional states.

Concerning identities and personal attributes in different roles, for social identities, they are representation of self in social settings while for personal attributes, they are features or qualities of individuals. According to the integration model, they are organized in terms of several clusters, each of which combines identities and attributes [11]. According to the segregation model, personal attributes are organized under 2 major clusters of social identities, namely the collective self and the private self [12].

Based on these various theories, the development of self can be regarded as a continuous interaction of one's mind with the environment at different levels and with different facets according to different situations and roles, through the processes of differentiation and integration, leading to different selves with specific identities and personal attributes for that particular individual. Hence, the similarities and differences between different selves of an individual might be a reflection of the processes of self-development, which would be related to various mental health and behavioral outcomes [13].



Relationship Between Digitalization, Self, and Personal Attributes

It has been theorized under different perspectives that construction of online self-presentation and online identities would be subject to the specific aspects of self and the specific characteristics of the virtual world as well as their interaction, which would involve different mechanisms, functions, and outcomes [14,15]. To explore the evidence timely, recent reviews [16-18] and researches [19-22] have explored the issues of online presentation, self-discrepancy, as well as online identity reconstruction in the social media and virtual world with reference to the impact in human and social development as well as well-being. Preliminary findings have been found in different aspects such as self-esteem, personalities, and behaviors, which would in turn have fundamental implications to humankind adaptation in the changing environment as well as human development and mental health. As the development of research in the area is at an early stage, the knowledge and evidence so far are diverse and fragmented. In order to integrate various theoretical frameworks into existing evidence for further exploration, based on the concept of "Digitalized Self" [3], we postulated there would be a dual process involving both transition of the physical self into the virtual self as well as the indigenous birth virtual self when the boundary between the physical and virtual worlds become blurred. So far, we cannot find a study about the differentiation of the physical self and virtual self in the physical and virtual worlds which takes these 2 environments with associated interactions into account. That is the purpose of the current study to timely fill in the current knowledge gap. In this study, we chose personal attributes related to social context among the different components of the self for examination, which can highlight the interactive processes between humans and social environment in shaping the self.

Based on the postulated processes in the formation of "Digitalized Self" [3], it is postulated that the self in the original physical world would develop into actual selves in the physical and virtual worlds through self-migration from the physical world and formation of additional self in the virtual world, leading to the similarities and differences between the actual selves in the physical and virtual worlds (Figure 1). As far as the formation of personal attributes is concerned, while it can be the direct shaping, modulation and manifestation of the personal attributes in the physical world and virtual world in the process of digitalization, it can also be the adaptation of a particular personal attribute to that particular environment which determines its level of expression in the physical world and virtual world. In the end, the personal attributes in the physical and virtual worlds could also interact with each other, further shaping each other.

Figure 1. Differentiation of self in the process of digitalization: transition and interaction between physical actual self and virtual actual self across physical world and virtual world. PA: physical actual; VA: virtual actual.

Study Conceptualization and Hypothesis

Based on the aforementioned conceptualization and theorization, in this study, we aim at exploring the relationship between digitalization-related measurements (smartphone use time, leisure online time, age of first smartphone ownership, and smartphone addiction), the similarity of personal attributes in the actual selves in the physical world and virtual world as well as mental health outcomes. We would further discuss the postulation about the underlying mechanisms and development process of the impact of digitalization on the differentiation of personal attributes in the physical and virtual worlds. The primary hypothesis of our study is that there would be a correlation of the similarity of the 14 personal attributes in the physical actual (PA) self and the virtual actual (VA) self with different measurements of digitalization (including smartphone addiction) and psychiatric symptomatology.

Methods

Study Design

This study is a cross-sectional study, which is a consecutive cohort within the Hong Kong Youth Epidemiological Study of Mental Health (HK-YES), the epidemiological study for young people in Hong Kong with a sample size of 3340 [23-25]. A random stratified method was adopted to select participants with the addresses provided by the Census and Statistics Department of the Hong Kong Special Administrative Region (HKSAR), based on the geographical location and type of quarters. Further details of the HK-YES have been reported elsewhere [23-25].

Settings

As a part of a large epidemiological study in Hong Kong, the setting of this study is in the community, which was conducted upon a consecutive cohort recruited between June 10, 2021, and August 30, 2021. As a community sample, the exposure of the participants would be the influence of digitalization in the community.

Data Collection

All participants provided written informed consent before enrollment in the study. Informed consents from parents or legal guardians were obtained for participants aged 18 years or younger. Afterwards, the participants were interviewed by a trained research assistant who would provide clarity and guidance on answering questions. Interviews were conducted in both online and offline formats due to the social distancing policies during the COVID-19 pandemic.

Participants

The inclusion and exclusion criteria are presented in Textbox 1. A total of 397 participants were recruited during the study period.

XSL•FO
RenderX

Textbox 1. Participant inclusion and exclusion criteria.

Inclusion criteria:

- Aged between 15 to 24 years old at the time of recruitment.
- Ability to give consent for participation.
- Hong Kong resident.

Exclusion criteria:

- Not having Chinese as a first language.

Variables and Measurements

Personality Attributes in Selves

To measure different types of personal attributes, 14 personal attributes related to different identities were selected from a list of personal attributes in a previous study [26]. The method in measuring a person's self-concept has been described [27], while specific personal attributes were chosen to reflect changes in self-concept [26]. The list includes the dimensions of different roles of oneself and others in a relevant and meaningful way validated by the idiographic and hierarchical classes analysis model. The 14 personal attributes include "Aggressive," "Calculating," "Capable," "Compromising," "Deceiving," "Excluding," "Helpful," "Gossiping," "Hostile," "Investigative," "Manipulative," "Powerful," "Trustworthy," and "Vengeful" [26]. It covers the nonprosocial, prosocial, and competence personal attributes, which would develop under different self-identities in the physical and virtual worlds in order to survive, socialize, and achieve.

Measurements of Digitalization

The degrees of digitalization in the environment were captured by smartphone use time (in terms of hours per day), leisure online time (in terms of hours per day), and age of first smartphone ownership (in terms of years). In addition, smartphone addiction is also measured to reflect the influence of digitalization within individuals where the pathological process and individual vulnerabilities would also be involved. For smartphone addiction, the Revised Chen Internet Addiction Scale (CIAS-R), a 26-item self-reported questionnaire on a 4-point Likert scale [28], measures one's level of smartphone addiction on 5 different factors. They are withdrawal symptoms, compulsive use, tolerance, interpersonal and health-related problems, and time management problems. All 26 items are included to create a total CIAS-R score. Psychometrics of the CIAS-R were previously examined in the Hong Kong population [29]. A higher CIAS-R score indicates a higher severity of internet addiction. Based on previous studies, a diagnostic cutoff point of 67/68 would be adopted, indicating that individuals scoring 68 or above in CIAS-R would be diagnosed as internet addiction [30]. In the current study, the CIAS-R was used to capture smartphone addiction by referring to smartphone use behavior.

Other Variables and Measurements

Demographics information, symptomatology of stress and common emotional issues as well as personality traits were also examined. Symptomatology of stress and common mental health problems was measured by Depression Anxiety Stress Scale [31,32]. General personality traits were measured by the Big Five Inventory, which consists of 44 items rated on a 5-point Likert scale [33]. Both of these scales have been validated and used in youth samples in Hong Kong [34,35].

Calculation of Euclidean Distances

In this study, to measure the difference of formation of personal attributes in the physical and virtual worlds, the calculation of their Euclidean distance [36] was done by squaring the differences between respective code values in the physical world (q) and virtual world (p) for each of the 14 personal attributes (codes 1 for presence of a particular personal attribute and 0 for absence of a particular personal attribute) followed by taking the square roots of the final summation. The formula is summarized as follows (n=14):

Biases

Potential biases in the primary epidemiological study were minimized by random stratified sampling, which was addressed in the paper of the primary study. For current study, our bias was minimized by consecutive sampling over a period of almost 3 months in the primary study.

Study Size

As this is a pilot study of its kind, we did not have previous data to estimate the sample size. The current sample size was estimated according to the number of variables.

Statistical Methods

Data analyses were conducted using SPSS (version 27.0; IBM Corp), with statistical significance at the $P<.05$ level. The assumptions of the relevant data are that they are in normal distribution and variances between different variables do not differ from each other. To adjust for multiple comparison problems, Benjamini–Hochberg procedure was performed for all correlation analyses to control for the false discovery rate (FDR). Likewise, Bonferroni correction was performed for all independent *t* test analyses to adjust for multiple comparison problems.

Data Analyses

First, correlations between smartphone addiction, smartphone use time, leisure online time, age of first smartphone ownership, personality traits, and symptomatology of stress and common emotional issues as well as the Euclidean distance between the

XSL•FO
RenderX

14 personal attributes in the PA self and the VA self (PA/VA distance) were examined. Second, partial correlations between constructs, where potential confounders were held constant, were done to ascertain the exact relationship between digitalization and mental health with the Euclidean distance between the 14 personal attributes in the PA self and the VA self (PA/VA distance).

Ethical Considerations

Approval from the institutional review board of the University of Hong Kong/ Hospital Authority Hong Kong West Cluster (UW 19-017) was obtained.

Results

Overview

A consecutive cohort of 397 eligible participants participated in this current project, with 24 having missing data. The missing data were excluded during analysis.

Descriptive Data and Comparisons of Demographics, Indicators of Digitalization, and Smartphone Addiction

Table 1 shows descriptive statistics for age, sex, smartphone use time, leisure online time, age of first smartphone ownership, and smartphone addiction as an overview.

Table 1. Basic information of age, sex, smartphone use time, leisure online time, age of first smartphone ownership, and smartphone addiction both for all and between sex groups.

Variables	All participants (N=397), mean (SD)	Sex	
		Male (n=183), mean (SD)	Female (n=214), mean (SD)
Age (years)	19.43 (2.77)	19.41 (2.76)	19.45 (2.78)
Smartphone use time (hours per day)	5.90 (3.27)	5.59 (3.41)	6.17 (3.14)
Leisure online time (hours per day)	6.05 (3.26)	6.67 (3.51)	5.53 (2.93)
Age of first smartphone ownership (years) (n=392)	11.91 (2.28)	12.06 (2.36)	11.78 (2.22)
CIAS-R[a] score (smartphone addiction) (n=395)	59.55 (11.66)	57.46 (11.31)	61.36 (11.75)

[a]CIAS-R: Revised Chen Internet Addiction Scale.

For the bivariate correlation between age, smartphone use time, online leisure time, age of first smartphone ownership, and smartphone addiction, smartphone use time is significantly positively correlated with leisure online time (r_{395}=0.439, P<.001). Smartphone addiction score CIAS-R is significantly positively correlated with smartphone use time (r_{393}=0.261, P<.001). Age of first smartphone ownership is significantly positively correlated with age (r_{390}=0.560, P<.001). Because of significant correlation between age and age of smartphone ownership as well as the potential generation-related cohort effect, a partial correlation analysis was done for correlation analysis of age of first smartphone ownership with other variables to control for the effect of age. Age of first smartphone ownership (controlled for effect of age) is significantly negatively correlated with smartphone use time (r_{390}=–0.151, P<.01), and significantly negatively correlated with smartphone addiction (r_{390}=–0.114, P=.03).

Furthermore, an independent t test was done for the difference in smartphone use time, leisure online time, age of first smartphone ownership, and CIAS-R between male participants and female participants, using Bonferroni method with adjusted P value of .02. Independent t test suggested that female participants (mean 61.36, SD 11.75) had higher smartphone addiction scores than male participants (mean 57.46, SD 11.31; t_{393}=3.36; P<.01), but female participants (mean 5.53, SD 2.93) had lower leisure online time than male participants (mean 6.67, SD 3.51; t_{395}=3.51; P<.001).

The above basic information of the current cohort would also be reported in other research papers of the same series by the first author.

Distribution of Euclidean Distance Between Personal Attributes in the Physical Actual and Virtual Actual Selves

For the Euclidean distance between personal attributes in the PA and VA selves (PA/VA distance), the mean is 1.716 (SD 0.761), the median is 1.732 (range 0-3.317).

Correlations of Demographics, Indicators of Digitalization, and Smartphone Addiction With Euclidean Distance Between Personal Attributes in Physical Actual and Virtual Actual Selves

In Table 2, the Euclidean distance between personal attributes in the PA and VA selves (PA/VA distance) is significantly positively correlated with age (r_{392}=0.111, P=.03), significantly positively correlated with smartphone use time (r_{392}=0.116, P=.02), significantly positively correlated with smartphone addiction (r_{390}=0.233, P<.001), significantly positively correlated with stress symptomatology (r_{390}=0.186, P<.001), significantly positively correlated with anxiety symptomatology (r_{390}=0.235, P<.001), and significantly positively correlated with depressive symptomatology (r_{390}=0.165, P<.01). All correlations remain statistically significant after the FDR correction.

XSL•FO
RenderX

Table 2. Correlation matrix of Euclidean distance of personal attributes between PA/VA selves with demographics, indicators of digitalization, smartphone addiction, and psychiatric symptomatology.

Variables	Euclidian distance
Age (n=394)	.111[a]
Smartphone use time (n=394)	.116[a]
Leisure online time (n=394)	.045
Age of first smartphone ownership (Controlled for age) (n=389)	–.008
CIAS-R[b] (Smartphone addiction) (n=392)	.233[c]
DASS-S[d] (n=392)	.186[c]
DASS-A[e] (n=392)	.235[c]
DASS-D[f] (n=392)	.165[c]

[a]*P*<.05, 2-tailed (remaining significant after FDR correction).

[d]DASS-S: Depression Anxiety Stress Scale-Stress.

[e]DASS-A: Depression Anxiety Stress Scale-Anxiety.

[f]DASS-D: Depression Anxiety Stress Scale-Depression.

In Table 3, for the bivariate correlation between the Euclidean distance of personal attributes between the PA and VA selves (PA/VA distance) and Big Five personality traits, the Euclidean distance is significantly negatively correlated with agreeableness (r_{392}=–0.284, *P*<.001), and significantly positively correlated with neuroticism (r_{392}=0.228, *P*<.001). Both correlations were statistically significant after the FDR correction.

Table 3. Correlation matrix of Euclidean distance of personal attributes between physical actual and virtual actual selves and Big Five Personality Traits.

Variables	Euclidean distance
Openness (n=394)	.003
Conscientiousness (n=394)	–.058
Extraversion (n=394)	–.040
Agreeableness (n=394)	–.284[a]
Neuroticism (n=394)	.228[a]

[a]*P*<.01, 2-tailed (remaining significant after false discovery rate correction).

Controlling for Potential Confounders in Partial Correlation

In Table 4, partial correlation analyses have been done in view of the intercorrelations between demographics, indicators of digitalization, smartphone addiction, Big Five personality traits, and psychiatric symptomatology, and hence potential confounding effects. Controlling for effect of age, sex, age of first smartphone ownership, Big Five personality traits, and psychiatric symptomatology, smartphone use time and CIAS-R are still significantly positively correlated with the Euclidean distance between the PA self and the VA self (PA/VA distance; r_{359}=0.121, *P*=.02 and r_{359}=0.145, *P*<.01, respectively). Controlling for age, sex, age of first smartphone ownership, Big Five personality traits, and smartphone addiction, anxiety symptomatology remains significantly positively correlated with the Euclidean distance between the PA self and the VA self (PA/VA distance; r_{361}=0.146, *P*<.01).

Discussion

Principal Findings

The primary findings of the current study are that the Euclidean distance of the 14 personal attributes between the PA self and VA self (PA/VA distance) correlates positively with smartphone use time, smartphone addiction and anxiety symptomatology respectively, even after controlling for the effects of potential confounders. That would mean that there is a negative correlation between the similarity of 14 personal attributes between the PA self and VA self, and smartphone use time, smartphone addiction as well as anxiety symptomatology respectively. In general, it would be rated as small effect size under usual statistical standards [37], but the current primary findings of positive correlations (0.121 to 0.146) would be considered as significant in view of the abstract and conceptual nature of the parameters.

Based upon these findings of correlations, we further attempt to infer the causality between the similarity of the 14 personal attributes between PA self and VA self, and smartphone use time, smartphone addiction, and anxiety symptomatology respectively. For the first possible direction, people with higher similarity of personal attributes between the PA self and the VA self could cause lower degree of smartphone use time, smartphone addiction, and anxiety symptomatology, as it would induce less cognitive dissonance [38] and self-incongruence [39] of actual selves between the physical and virtual worlds. In turn, it would be related to less maladaptive behavior such as excessive smartphone use, smartphone addiction, and psychological distress such as anxiety symptomatology.

On the contrary, people with lower similarity of personal attributes in the PA self and the VA self might cause higher degree of smartphone use time, smartphone addiction and anxiety symptomatology, as it would induce more cognitive dissonance and self-incongruence, which would be related to more maladaptive behavior and psychological distress. As a matter of fact, it is generally agreed that self-congruence is associated with mental well-being [40]. On the other hand, noncongruence of the self can be associated with negative mental health outcomes such as emotional and behavioral problems.

For the second possible direction of causality, it can be in the opposite direction in that excessive smartphone use and smartphone addiction might induce a higher differential migration of original personal attributes from the physical world to the virtual world as well as a more active birth and different formation of personal attributes in the virtual world, which might be advantageous for the adaptation and survival of oneself to the different environments and requirements in the physical and virtual worlds. The pathological process within vulnerable individuals in smartphone addiction in addition to the process of digitalization might further enhance this process of differentiation of the self.

For the negative correlation between anxiety symptomatology and the similarity of the PA self and VA self, it is possible that the feature of perceived threat in anxiety might induce a more active formation of different personal attributes in different environments to cope with the stressors in different environments with different requirements in the physical and virtual worlds.

We would believe the aforementioned mechanisms involved in these 2 opposite directions are different operating to different extent in different youth with different vulnerabilities, which eventually can be interrelated in vicious cycles. These explanations would lead to the importance of maintaining a congruent self between the physical and virtual worlds to reduce cognitive dissonance and self-incongruence and hence less maladaptive online behavior such as smartphone addiction and psychiatric symptomatology. On the other hand, regulating smartphone use time, prevention of smartphone addiction and safeguarding mental health would maintain self-congruence between the physical and virtual worlds.

For the third possibility, a confounding third factor could influence smartphone use time, smartphone addiction and anxiety symptomatology, and the similarity of the personal attributes in the VA self to the PA self at the same time. For example, personality traits can affect them simultaneously.

XSL•FO
RenderX

However, this is not likely as these factors have been controlled appropriately in the analysis by partial correlation.

Strengths and Limitations

The strength of the study is the quantitative capture of the abstract construct of personal attributes by using a set of researched personal attributes from a previous relevant study. The methodology is based on theory-informed construct. We have also performed partial correlation for our primary results to control for the potential effect of potential confounders to make our conclusion valid.

To capture the degree of digitalization in the environment in a quantitative and comprehensive way, we measured smartphone use time, leisure online time, age of first smartphone ownership and smartphone addiction. As there is a positive correlation of the age with the age of first smartphone ownership, the effect of age has been removed in the analysis of age of first smartphone ownership to improve its accuracy to reflect digital nativity.

Another strength of our study is the innovative and comprehensive measurement of personal attributes in both the physical and virtual worlds, which can capture and compare the formation and development of different selves of personal attributes in the original physical world and the emerging virtual world in order to postulate the possible processes and mechanisms.

The limitations of the study would include the subjective self-reporting of abstract personal features, which would be subject to the recollection, matching and projection of personal features based on values and concepts of individuals and would affect the validity of measurements. To address this issue, we have trained research assistants to explain the meanings of research questions for standardized clarification. For the interpretation of results about smartphone addiction, we need to take into account the underlying pathological component and individual vulnerabilities in addition to the process of digitalization within individuals. We have adopted the use of Euclidean distance [41] between the personal attributes in actual self in physical and virtual worlds as a quantitative comparison of the similarity of the complex constructs of personal attributes, which might not be able to fully reflect and compare the exact psychometric properties for such constructs. Furthermore, we have only included the social and competence aspects of personal attributes, which can limit the generalizability of the results.

In addition, as our participants were aged between 15 and 24 years, it would be necessary to conduct similar studies in the older age group of digital immigrants and compare them to delineate the effect of generations. In view of the nature of the cross-sectional study, the causal relationship between digitalization with the similarity of 14 personal attributes between the PA self and VA self cannot be ascertained, which would warrant longitudinal studies to explore.

Conclusion

Personal attributes are individual traits and assets with different expression and manifestation in different self-identities in different settings and environments, the congruence of which would be essential to mental well-being and mental health. The current primary findings are the negative correlations between the similarity of the personal attributes in the PA self and VA self, and smartphone use time, smartphone addiction as well as anxiety symptomatology respectively. Hence, the key message to the public is the importance of maintaining a congruent self across the physical and virtual worlds, regulating smartphone use time, preventing smartphone addiction, and safeguarding mental health before possible irreversible changes. That can be achieved by advocating healthy and regulated smartphone use, keeping a clear boundary between humans and digital devices and items as a tool, advocating youth mental health as well as advocating self-congruence across the physical and virtual worlds, especially for the young generations. Of course, this should be coupled by enhancing age-appropriate digital literacy and safety in the virtual world, as different manifestations of selves in the physical and virtual worlds might have served a self-protective function for defense and survival in the midst of the 2 changing worlds. However, it is easier said than done, which would require further discussion and timely consensus of different stakeholders including community people, young people, Information Technology entrepreneurs, scientists and researchers, academics, clinicians as well as mental health professionals.

Authors' Contributions

KTC contributed to conceptualization, data collection and analysis, writing, review. CLMH, YNS, and SMYW performed the review. CC and CSMW handled conceptualization and review. BPHK conducted data collection, analysis, and writing. EYHC contributed to conceptualization, data collection, analysis, and writing.

Abstract

Background: Digital mental health interventions (DMHIs) are a promising approach to reducing the public health burden of mental illness. DMHIs are efficacious, can provide evidence-based treatment with few resources, and are highly scalable relative to one-on-one face-to-face psychotherapy. There is potential for DMHIs to substantially reduce unmet treatment needs by circumventing structural barriers to treatment access (eg, cost, geography, and time). However, epidemiological research on perceived barriers to mental health care use demonstrates that attitudinal barriers, such as the lack of perceived need for treatment, are the most common self-reported reasons for not accessing care. Thus, the most important barriers to accessing traditional psychotherapy may also be barriers to accessing DMHIs.

Objective: This study aimed to explore whether attitudinal barriers to traditional psychotherapy access might also serve as barriers to DMHI uptake. We explored the relationships between individuals' structural versus attitudinal barriers to accessing psychotherapy and their indicators of potential use of internet-delivered guided self-help (GSH).

Methods: We collected survey data from 971 US adults who were recruited online via Prolific and screened for the presence of psychological distress. Participants provided information about demographic characteristics, current symptoms, and the use of psychotherapy in the past year. Those without past-year psychotherapy use (640/971, 65.9%) answered questions about perceived barriers to psychotherapy access, selecting all contributing barriers to not using psychotherapy and a primary barrier. Participants also read detailed information about a GSH intervention. Primary outcomes were participants' self-reported interest in the GSH intervention and self-reported likelihood of using the intervention if offered to them.

Results: Individuals who had used psychotherapy in the past year reported greater interest in GSH than those who had not (odds ratio [OR] 2.38, 95% CI 1.86-3.06; *P*<.001) and greater self-reported likelihood of using GSH (OR 2.25, 95% CI 1.71-2.96; *P*<.001). Attitudinal primary barriers (eg, lack of perceived need; 336/640, 52.5%) were more common than structural primary barriers (eg, money or insurance; 244/640, 38.1%). Relative to endorsing a structural primary barrier, endorsing an attitudinal primary barrier was associated with lower interest in GSH (OR 0.44, 95% CI 0.32-0.6; across all 3 barrier types, *P*<.001) and lower self-reported likelihood of using GSH (OR 0.61, 95% CI 0.43-0.87; *P*=.045). We found no statistically significant differences in primary study outcomes by race or ethnicity or by income, but income had a statistically significant relationship with primary barrier type (ORs 0.27-3.71; *P*=.045).

Conclusions: Our findings suggest that attitudinal barriers to traditional psychotherapy use may also serve as barriers to DMHI use, suggesting that disregarding the role of attitudinal barriers may limit the reach of DMHIs. Future research should seek to further understand the relationship between general treatment-seeking attitudes and attitudes about DMHIs to inform the design and marketing of DMHIs.

Introduction

Background

Over 50 million Americans experience mental illness in a given year [1,2], but only one-third of those diagnosed with a mental health condition receive treatment from a specialist mental health care provider [3]. Individuals with common mental disorders face many barriers to adequate care, including limited numbers of specialist mental health care providers, geographic barriers due to therapists living mostly in urban areas, and an inability to pay for or use insurance [3,4]. In recent years, there has been an increasing interest in the potential of low-cost, digitally delivered psychological treatments (eg, internet-based guided self-help [GSH] and smartphone apps) to provide treatment remotely and for low cost, such that they can be disseminated at a larger scale than "traditional" treatments, such as one-on-one face-to-face therapy [5]. These digital mental health interventions (DMHIs) may have the potential to expand access to effective psychological treatment [6] with a potentially revolutionary impact on public health, spurring a surge of attention across clinical research [7,8], the private sector [9,10], and government initiatives [11-13]. Robust evidence has now supported the efficacy of DMHIs in various formats, including internet-delivered cognitive behavioral therapy [14], both GSH and unguided self-help formats [14-16], and smartphone apps [16-18]. However, less research has focused on evaluating the potential *reach* of DMHIs [7,8].

Evidence suggests that public use of DMHIs may be lower than is required for broad public health impact. For example, DMHIs may be difficult for the public to access [19], underused by mental health care providers [20], or simpler and less appealing to the public than treatment developers might predict [21]. Therefore, it is vital that DMHI researchers afford sufficient attention to the actual implementation of DMHIs. Indeed, Ramos et al [7] cautioned that DMHI research risks mimicking the pitfalls of the "Decades of the Brain," where large volumes of funding and time were spent on seemingly exciting innovations that made virtually no public health impact. Excellent work is underway to address this issue by identifying successful implementation strategies to maximize the reach of DMHIs, drawing from theoretical models and previous successes in implementation and dissemination science [7,22-24]. However, it may also be important to consider factors in individuals' decisions to uptake and adopt DMHIs, drawing from literature on treatment-seeking behavior and mental health service use [25-28].

Attitudinal Barriers to Treatment Access

The scale of impact of DMHIs is dependent on the extent to which individuals with unmet treatment needs are broadly *interested in* and *would use* DMHIs. Although DMHIs are designed to circumvent *structural barriers* to treatment access (eg, cost, geographic availability of mental health care providers, need for transportation, and time commitment), their reach may still be limited by *attitudinal barriers* to treatment uptake. Attitudinal barriers are beliefs held by individuals that may affect their treatment-seeking behavior, such as the lack of perceived need for treatment, stigma, beliefs about the efficacy of psychotherapy, and the desire to handle a problem on one's own. Importantly, attitudinal barriers are at least as common as structural barriers [25-29]. For example, across 24 countries in the World Health Organization (WHO) World Mental Health surveys, only 38% of the individuals with a 12-month mental disorder diagnosis reported a perceived need for treatment, making low perceived need the most commonly reported barrier to treatment use [25]. Therefore, the most common barriers to accessing traditional treatment may not be addressed by the innovations of DMHIs, which could greatly limit their potential public health impact.

Because most common attitudinal barriers (eg, stigma) are likely to impact *any* form of mental health treatment seeking, it may be likely that barriers commonly reported for traditional psychotherapy will generalize to DMHIs. However, this has rarely been studied directly. A small, promising body of literature currently provides some information on attitudinal barriers that are specific and often unique to DMHIs. However, much of this research often focuses on the acceptability of using DMHIs [20,30], especially pertaining to issues with technology specifically rather than revealing the impact that attitudinal barriers to general mental health treatment seeking might have on DMHI uptake. In a 2021 systematic review, Borghouts et al [31] identified common barriers to user engagement with DMHIs across a variety of study types and DMHI formats (including telehealth treatment), in which information about barriers was often indirectly reported as secondary components of studies, such as clinical trials, or extracted from user reviews. Many of the reviewed studies investigated adherence and retention of participants receiving a DMHI rather than potential uptake among the general population. Across the studies, concerns specific to the use of technology were among the most commonly reported barriers for both participants and mental health care providers, such as privacy, digital literacy, and the ease of use. This literature advances our understanding of users' experience of using DMHIs, which is essential for the design and dissemination of DMHIs that are acceptable and engaging from both user and provider perspectives. However, among 208 relevant articles, the authors identified only 5 studies that had assessed the relationship between participants' broader mental health–related beliefs and engagement in DMHIs. For example, in a trial of a smartphone app for relationship stress among adolescents, perceived treatment needs and belief in treatment effectiveness were each associated with greater likelihood of use [32].

These findings provided some support for the idea that attitudinal barriers to mental health treatment seeking may generalize to DMHIs. However, none of these studies were conducted with the primary purpose of investigating this relationship. They did not gather comprehensive data surveying

XSL•FO
RenderX

commonly experienced access barriers, as is typically done in studies of perceived barriers to mental health care [25-28]. Therefore, this work did not explore the relative impacts of reduced structural barriers versus remaining attitudinal barriers when considering the potential reach of DMHIs. More research is needed to understand the extent to which attitudinal and structural barriers to help seeking may limit the reach of DMHIs to individuals with unmet treatment needs.

Low-Income Groups and Racial and Ethnic Minorities

In addition to hopes that DMHIs may expand treatment access in the general population, there is also an often-stated assumption that DMHIs have the potential to reduce racial, ethnic, and socioeconomic disparities in access to mental health care [33-35]. These groups are often underserved due to multifaceted, often systematic sets of access barriers. The relationship between income and actual treatment use may be more complex than is often assumed. For example, middle-income families may have lower access than low-income families due to the latter's ability to use government-funded mental health services [36]. Nonetheless, the ability to pay for treatment or use insurance is one of the most commonly reported perceived barriers to mental health treatment seeking [5,25,26], especially in the United States [27]. In addition to the ability to pay [4], lower-income individuals face associated structural barriers, such as geographic restrictions, for example, specialty mental health care providers are twice as likely to be available in the highest-income communities relative to the lowest-income communities [37]. Socioeconomic disadvantages disproportionately impact racial and ethnic minorities, who are overrepresented in lower-income communities. In 2012, the rate of access to mental health care for non-Hispanic White American individuals was 20%, whereas the rates for Black, Hispanic, and Asian American individuals were 10%, 9%, and 5%, respectively [38]. It is very reasonable to assume that making DMHIs available can reduce these disparities by reducing the structural barriers that often contribute to them. However, only a limited body of research has collected data to substantiate this assumption, particularly in regard to racial and ethnic minorities [33], suggesting that the reach of DMHIs risks replicating the same inequities seen in traditional treatments [8,33,39].

It is essential to consider the role of attitudinal barriers in the ability of DMHIs to ameliorate mental health care disparities, given their great influence on treatment use in the general population. First, the impact of DMHIs on mental health disparities may be limited by attitudinal barriers because attitudinal barriers can limit the extent to which services are used even if they are made accessible. Second, some literature suggests that certain attitudinal barriers may disproportionately affect underserved groups, raising the concern that targeting disparities via the dissemination of DMHIs may disregard potential contributions of attitudinal barriers as an important mechanism of these disparities. For example, some studies suggest that individuals with lower incomes and lower educational attainment have a lower perceived need for treatment than individuals with higher incomes [40]. Similar findings regarding racial and ethnic minorities are mixed, partially because attitudes vary both across different minority groups and intersectionally within them. For example, Asian American and Black American individuals report lower perceived need for treatment than non-Hispanic White American individuals, but Hispanic American individuals report approximately the same level of need as non-Hispanic White American individuals [41]. This picture is further complicated by intersectional differences. For example, despite those group-level differences, Hispanic men report *greater* need for treatment than non-Hispanic White men, and Black women report approximately the same level of need as non-Hispanic White men [41]. Cultural beliefs about mental health treatment seeking also vary by immigration status (immigrant vs US born) and country of origin, often, despite similar racial identities [40,41].

Existing literature exploring racial differences in perceived barriers to treatment use is severely limited [31]. Some data exist regarding racial differences in interest in DMHIs. For example, Hispanic adults may be more interested in DMHIs than non-Hispanic White adults [34,42-44]; however, researchers have suggested this may be attributable to greater rates of smartphone use rather than greater willingness to use treatment overall. Unfortunately, there is limited data to further clarify these patterns because individuals from both lower-income and racial and ethnic minoritized groups are often left out of DMHI trials, such that their preferences and attitudes may be overlooked in the design delivery and content of DMHIs [33,34,39,45]. Neglecting to understand actual interest in DMHIs among underserved and marginalized groups may limit the potential of DMHIs to attract members of these groups and serve their mental health needs [33,34,46]. Because attitudinal barriers are such a significant deterrent to treatment seeking and treatment access, paying special attention to how attitudinal barriers may translate to DMHIs in these groups will be key to ensuring DMHIs reach them as intended.

This Study

Existing literature has focused on developing innovative approaches to address structural barriers (ie, DMHIs), leaving a substantial gap in the effort to address attitudinal barriers. Therefore, it is unclear to what extent attitudinal barriers that limit access to traditional psychotherapy might generalize to also limit access to DMHIs, reducing the potential reach of DMHIs to populations with unmet treatment needs. In this study, we aimed to conduct an exploratory investigation of the relationship between attitudinal barriers to traditional psychotherapy access and potential use of DMHIs. We placed an emphasis on currently underserved populations such as racial and ethnic minorities and low-income groups in order to focus on those whom DMHIs are most intended to target. We captured both participants' *interest* in GSH and their self-reported likelihood of *using* it. This allows us to parse the appeal of the intervention from its actual potential to engage participants. Research applying the theory of planned behavior [47] supports the use of behavioral intentions as a reliable predictor of mental health help seeking [48,49], and behavioral estimates may be an even stronger predictor than intentions [50].

Methods

Ethical Considerations

Study procedures were approved by the Indiana University Human Subjects and Institutional Review Board (#14172). Participants were provided with an informed consent document with information about our laboratory, the study's purposes and procedures, payment, risks and benefits, confidentiality and data security, and their right to withdraw consent at any time. The document was written at an approximately seventh-grade reading level to ensure accessibility across differing literacy or English fluency. Participants were required to attest that they were aged ≥18 years before proceeding. Participants were paid at a rate of approximately US $10 per hour (US $3.02 total for a median time expenditure of 17 minutes and 59 seconds; IQR 13 minutes 53 seconds to 24 minutes and 18 seconds). First, we chose Prolific over other platforms such as Amazon Mechanical Turk (MTurk) due to its stated commitment to ethical treatment of its online workers, including its "ethical reward" payment policy [51-53]. Second, we designed our study to address established ethical considerations in DMHI research. For example, we used liberal inclusion and exclusion criteria in order to capture a broad population of individuals with treatment needs (eg, no suicidality exclusion) [54,55]. Finally, online DMHI research must carefully consider clinical risk monitoring [56]. We provided participants with crisis resources for suicidality as well as information about how to find noncrisis treatment and direct access to a free online self-help booklet (refer to the subsequent sections) [57].

Web-Based Data Collection

Data Collection Platform

Participants were US adults recruited via the web-based crowdsourcing data collection platform Prolific (accessed from July 25to July 26, 2022) [58]. We chose Prolific because it is designed to improve upon common problems in internet-based human subjects research with crowdsourcing platforms, such as "bots" [59], the lack of engagement, repeat responders, and nongenuine responses, which can create serious issues in the quality of health research [60]. In this regard, Prolific's quality control is superior to other platforms such as MTurk. Studies show that responders from Prolific are mostly rated as "high quality," significantly outperforming MTurk and even undergraduate students [61,62].

Data Quality Checks

We used a series of methods, informed by previous literature, to reduce the risk that "fraudsters" and low-quality responders would pose a threat to the integrity of the data [59,60]. First, participants were required to pass a reCAPTCHA task (version 1; Google LLC) [63]. Second, participants completed a series of reading comprehension questions designed to screen out nonhuman or inattentive responders (refer to the Survey Procedure section). Participants who answered >1 question wrong after 2 attempts were eliminated in the data cleaning process. After data collection, we also removed responders who completed the survey too quickly (ie, 2 SDs below the mean completion time).

Survey Procedure

Overview

Participants provided the data for this study in 2 separate surveys, which is the procedure required in order to implement a nondemographic eligibility requirement on Prolific. The first survey was primarily for screening purposes but also included several demographic characteristics, a measure of psychological distress used as the screening criterion (the Kessler-6 Psychological Distress Scale [K6]; refer to the Measures and Variables section [64]), and 2 other brief self-report measures not used in the present analyses. Participants who met the K6 eligibility criterion (scoring >5) were invited to complete the second survey, which included the following: (1) further demographic characteristics, (2) a description of a particular GSH intervention described in the subsequent sections, (3) questions about their past-year mental health treatment use, and (4) several other self-report measures not analyzed in this study.

GSH Intervention Description and Questions

Participants were provided information regarding a transdiagnostic GSH, Doing What Matters in Times of Stress (DWM), as it is delivered in clinical trials run by our laboratory. In the DWM intervention, trial participants are provided with a booklet developed by the WHO [57] that teaches principles and skills from acceptance and commitment therapy (ACT) [65]. They are provided the option to either access the booklet online (via a publicly posted PDF on the WHO website) or receive a paper copy in the mail. Guidance is provided by "coaches" (trained research assistants and graduate students in our laboratory), who meet with trial participants weekly via Zoom (Zoom Communications Inc) for 15- to 30-minute sessions across 3 to 6 weeks [66,67]. All survey participants were shown an advertisement used in our laboratory's clinical trials and an additional description of basic information about DWM.

Participants were then asked to predict their likelihood of using the DWM intervention in the following series of questions:

- First, participants were asked if they believe that they would click on the advertisement and complete a 15-minute survey if they saw it on social media ("Do you think you would click on the link in the ad..."; "Most likely yes" or "Most likely no").
- Those who answered "Most likely yes" to the aforementioned question were asked if they believed that they would then answer a call from a researcher and stay on the phone for approximately 30 minutes ("Do you think you would answer the call..."; "Most likely yes" or "Most likely no").
- Those who answered "Most likely yes" to the phone call question were provided information about the trial. Those who answered "Most likely no" were provided the same information before rating their interest in the intervention later in the survey. All participants were required to pass a set of comprehension questions.
- After learning the information typically shared in the trial's welcome call, participants were asked if they believed they would be likely to enroll in the intervention portion of the

XSL•FO
RenderX

trial ("Do you think you would sign up for the treatment?"; "Most likely yes" or "Most likely no").
- Those who answered "Most likely yes" were asked how many GSH sessions they believed they would attend ("How long do you think you would most likely stay in the treatment [how many weeks of calls with the coach do you think you would do]?"; "I would probably not attend any of the sessions" or "I would probably do the first few calls with the coach [1 to 2 weeks] but not finish all the ones I scheduled" or "I would probably do all the calls with the coach that I signed up for [3 to 6 weeks]").

Measures and Variables

Psychological Distress

Psychological distress was measured via the K6 [64], a 6-item measure assessing frequency of emotional distress over the past 30 days (eg, "During the past 30 days, about how often did you feel...Nervous," "...Hopeless," "...Worthless"), where higher scores indicate greater distress. The K6 is a reliable and valid measure of distress [68,69] that has been reported to have excellent internal consistency in previous work (Cronbach α=0.89) [70]. It appeared internally consistent in this study (ω=0.79). The K6 can be used to screen for both serious mental illness at a score of ≥13 [64] and milder forms of emotional distress with lower thresholds [71]. While investigators differ in describing the lower cutoffs as mild, moderate, or mild moderate, evidence generally supports the interpretation of a score >5 as indicating at least mild mental health needs [66,67,71].

Demographic Characteristics

Participants answered questions about age, race, ethnicity, gender, sex, sexual orientation, income, and education level (refer to the Results section).

Self-Reported Likelihood of GSH Use

After reading about the GSH intervention, participants answered a series of questions about their hypothetical use of the intervention. The *self-reported likelihood of GSH use* or "likely GSH use" outcome reflects endorsement that a participant believes that they would be likely to complete at least 1 GSH session if offered the intervention (ie, either "I would probably do the first few calls with the coach [1 to 2 weeks] but not finish all the ones I scheduled" or "I would probably do all the calls I signed up for"). Participants who did not reach this question due to denying that they believed they were likely to click on the advertisement, answer the phone call, or agree to enroll in the trial were coded as deniers of likely GSH use.

Interest in GSH

After answering the GSH use questions, participants were asked to rate their overall interest in the intervention on a 4-point scale ("Overall, does this treatment sound like something you would be interested in?"; "Not at all interested," "Somewhat interested," "Moderately interested," or "Very interested"). The ordinal value on this 4-point scale is the *GSH interest* outcome.

Past-Year Psychotherapy Use

Following the survey section regarding the GSH intervention, participants proceeded to a survey section focusing on their actual past-year mental health treatment experiences. Participants indicated whether they had attended psychotherapy in the past year ("I went to therapy: seeing a mental health professional such as a psychologist, counselor, therapist, or social worker") from a checklist of various forms of help (medications, informal social support, self-help, and other).

Perceived Need for Psychotherapy

Participants who denied any past-year psychotherapy use were asked whether there was any point in the past year at which they "thought [they] might benefit" from psychotherapy ("Yes, therapy: seeing a mental health professional like a counselor, psychologist, or social worker"), in the same checklist format as mentioned earlier. Selecting this answer choice was considered an endorsement of the *perceived need for psychotherapy* barrier; leaving it blank was considered to indicate the *lack of perceived need* barrier.

Barriers to Psychotherapy Use

Individuals who endorsed perceived need for psychotherapy were then presented with questions regarding their reasons for not receiving psychotherapy despite believing that they might need it. They were asked to select all contributing barriers for not accessing psychotherapy ("Please check *all* reasons that were part of why you did not go to therapy"). The answer choices included 11 common barriers to mental health treatment adapted from the National Comorbidity Survey [25,29]. A list of the 11 barriers is given in the Results section. The full text of each answer choice is provided in Multimedia Appendix 1. Text entry responses under "other" were manually coded to either match an existing answer choice (eg, "don't have the money" into the "money/insurance" answer choice) or remain in the "other" category if no obvious match was present.

Primary Barrier and Primary Barrier Type

After selecting all barriers that contributed to their lack of past-year psychotherapy use, participants were presented with the same list of barriers and asked to indicate their *primary* barrier for not accessing psychotherapy ("Which was the *biggest* reason you didn't go to therapy?"). We generated a *primary barrier type* variable by grouping individual primary barrier choices into 3 categories according to previous literature [25-28] and the authors' judgment: attitudinal (eg, "Didn't think it would work"), structural (eg, "Issues with money or health insurance"), and other (eg, "The problem went away by itself"). Denial of *perceived need for psychotherapy* was considered an attitudinal primary barrier. When participants selected "other" as their primary barrier, the text that they entered was coded into one of the existing categories for *primary barrier type.* They were recoded to be (1) *attitudinal* (eg, "too much history. how could I even begin to get a new person up to [speed]"), (2) *structural* (eg, "no privacy at home guaranteed for phone appointment"), or (3) *other* if did not clearly fit either category (eg, "anxiety").

Analyses

All analyses were performed in R software (version 4.3.2; R Foundation for Statistical Computing) [72]. First, we generated descriptive statistics for sociodemographic characteristics, psychological distress severity, and each of the primary outcomes (GSH interest and likely GSH use). We analyzed the relationship of individual characteristics (sociodemographic characteristics and psychological distress) with GSH interest via multivariate polychoric regression in the *MASS* package (version 7.3-60) [73] and the relationship of these predictors with likely GSH use via multivariate logistic regression. For all analyses involving income as a predictor, 1 participant was omitted due to a missing value for income. We additionally conducted univariate analyses for race and income, in order to isolate these key sociodemographic variables emphasized in the DMHI literature via 2 univariate polychoric regressions for GSH interest and 2 univariate logistic regressions for likely GSH use. These univariate analyses were informative in addition to the multivariate analyses of sociodemographic characteristics because we were substantively interested in the potential for DMHIs to reach low-income groups and marginalized racial-ethnic groups regardless of whether other demographic characteristics (eg, education) account for the difference.

Next, we generated descriptives for past-year psychotherapy use and analyzed its relationship with individual characteristics via logistic regression. We analyzed past-year psychotherapy use as a predictor of each GSH interest and likely GSH use via polychoric regression and logistic regression, respectively, controlling for psychological distress in both analyses. For all polychoric regressions, *P* values are not reported because the analysis does not directly generate *P* values, and simulated *P* values may not be reliable; our interpretations of statistical significance were made from CIs. Next, for participants who denied past-year psychotherapy use, we generated frequency statistics regarding endorsement of (1) perceived need for psychotherapy, (2) all contributing barriers to psychotherapy use, (3) primary barrier to psychotherapy use, and (4) primary barrier type. We only compared the frequency of lacking perceived need versus other *primary* barriers, rather than versus the frequency of all contributing barriers, due to the structure of our survey. Because participants who denied perceived need were not given the opportunity to select additional barriers, the level of detail collected about this subgroup's access barriers was lower than for the subgroup that selected multiple contributing barriers.

Finally, we grouped the primary barriers into 3 categories: attitudinal, structural, and "other" (refer to the Primary Access Barriers and Barrier Type section). We analyzed sociodemographic characteristics and psychological distress as predictors of primary barrier type via multinomial regression in the *nnet* package (version 7.3-19) [73] to accommodate the 3-category outcome. Next, we analyzed primary barrier type as a predictor of each GSH interest and likely GSH use via polychoric regression and logistic regression, respectively, controlling for psychological distress in both analyses. Finally, we analyzed the relationship between each contributing barrier and each outcome via a series of univariate linear regressions.

Due to the high number of statistical tests, we applied Benjamini-Hochberg adjustment to *P* values across all analyses.

Transparency and Openness

We report on how we determined our sample, all data exclusions, all manipulations, and all measures in the study. All data, analysis code, and research materials are available on the Open Science Framework website online [74]. This study's design and its analysis were not preregistered. No other papers currently use these data.

Results

Descriptives and Sociodemographic Characteristics

Most of the 971 participants identified as non-Hispanic White (n=665, 68.5%) and heterosexual (n=688, 70.9%), with an approximately even gender split (women: n=538, 55.4%) and a median age of 32 (IQR 25-41) years. The median K6 score was 11 (IQR 8-15) of 0 to 24 possible points. Full sample characteristics are reported in Table 1.

Psychological distress (K6[a]: 0-24), median (IQR)	11 (7)

[a]K6: Kessler-6 Psychological Distress Scale.

Most of the 971 participants (n=782, 80.5%) reported that they were at least "somewhat interested" in GSH. Nearly half (n=458, 47.2%) of the participants were at least "moderately interested," and 17.1% (n=166) were "very interested." However, a slightly greater proportion (n=189, 19.5%) of participants was "not at all interested." We found that 38.6% (n=375) of the participants reported that they believed they were likely to complete at least one GSH session if it were offered to them.

Individual Characteristics as Predictors of GSH Interest and Self-Reported Likelihood of GSH Use

None of the sociodemographic characteristics, including psychological distress, were statistically significant predictors of self-reported interest in GSH. For self-reported likelihood of GSH use, only age met statistical significance at $P<.05$ after Benjamini-Hochberg adjustment (odds ratio [OR] 1.02, 95% CI 1-1.03; $P=.045$). Table 2 gives full results for both outcomes.

XSL•FO

Past-Year Psychotherapy Use

Descriptives and Demographics for Past-Year Psychotherapy Use

We found that about one-third (331/971, 34.1%) of the participants reported past-year psychotherapy use. Among sociodemographic characteristics, only educational attainment (P<.001) and sexual orientation (P=.04) had statistically significant relationships with past-year psychotherapy use (refer to Table 3 for full results). Higher psychological use distress severity was significantly associated with greater odds of endorsing past-year psychotherapy use (OR 1.07, 95% CI 1.03-1.1; P<.001).

XSL•FO
RenderX

Interest in GSH by Past-Year Psychotherapy Use

Among those (n=640) who denied past-year psychotherapy use, 77.7% (n=497) were at least "somewhat interested" in GSH, 39.8% (n=255) were at least "moderately interested," and 11.3% (n=72) were "very interested." Nearly one-fifth (n=143, 22.3%) of the participants were "not at all interested." By contrast, among those (n=331) who endorsed past-year psychotherapy use, 86.1% (n=285) were at least "somewhat interested" in GSH, 57.7% (n=191) were at least "moderately interested," and 28.4% (n=94) were "very interested." Only 13.9% (n=46) of these participants were "not at all interested." The difference in GSH interest between groups was statistically significant, that is, those who had used psychotherapy in the past year were significantly more interested in GSH than those who had not (OR 2.38, 95% CI 1.86-3.06; *P*<.001). This effect was not accounted for by psychological distress severity, which was not a statistically significant predictor of GSH interest in this model (OR 1.02, 95% CI 0.99-1.04; *P*=.43). Refer to Multimedia Appendix 1 for complete descriptive statistics and Multimedia Appendix 2 for a visualization.

Self-Reported Likelihood of Using GSH by Past-Year Psychotherapy Use

Among those denying past-year psychotherapy use, approximately one-third (205/640, 32%) reported that they would be likely to complete at least one GSH session, whereas over half (170/331, 51.4%) of those endorsing past-year psychotherapy use reported that they would be likely to do so. This difference was statistically significant (OR 2.25, 95% CI 1.71-2.96; *P*<.001). This effect was not accounted for by psychological distress severity, which was not a statistically significant predictor of self-reported likelihood of GSH use in this model (OR 1, 95% CI 0.97-1.03; *P*=.92). Refer to Multimedia Appendix 1 for complete descriptive statistics and Multimedia Appendix 2 for a visualization.

Barriers to Psychotherapy Access

Descriptives for Barriers to Psychotherapy Access

Approximately one-third (206/640, 32.2%) of the participants denied that they "might benefit" from psychotherapy (ie, no perceived need). When the subgroup that endorsed perceived need (434/640, 67.8%) was given the opportunity to select multiple contributing reasons for not using psychotherapy, the most commonly endorsed barrier was "issues with money or insurance" (323/434, 74.4% of those endorsing perceived need). "Didn't know where to go or who to see" (230/434, 53%) and "too busy/not enough time" (190/434, 43.8%) were the second- and third-most commonly endorsed barriers in this subgroup (refer to Table 4 for frequencies of all barriers and Multimedia Appendix 2 for a visualization).

Table 4. Frequency of endorsement of all contributing barriers to past-year psychotherapy use in a checklist format among participants who endorsed perceived need for psychotherapy and denied past-year psychotherapy use (n=434), presented by barrier type.

All contributing barriers to past-year psychotherapy use by barrier type	Participants, n (%)[a]
Structural	
Problems with money or insurance[b]	323 (74.4)
Not enough time or too busy	190 (43.8)
Need to stay home or cannot get transportation	123 (28.3)
Could not get an appointment	53 (12.2)
Attitudinal	
No perceived need for psychotherapy	—[c]
Want to handle the problem alone	180 (41.5)
Do not want to share private information	169 (38.9)
Psychotherapy will not work	101 (23.3)
Worried about what others might think	84 (19.4)
Other	
Did not know who to see or where to go	230 (53.0)
Care provider might be culturally insensitive	84 (19.4)
Other reason	43 (9.9)
The problem went away	30 (6.9)

[a]Participants were given the opportunity to select multiple barriers, such that individual participants may be counted several times in this table.

[b]Each barrier description is abbreviated from the original answer choice presented to participants. See Multimedia Appendix 1 for full text of each answer choice.

[c]Participants were queried about perceived need for treatment before being presented a checklist of other potential barriers to treatment access. Those who denied perceived need were not given the opportunity to select multiple barriers and therefore are excluded from this table.

XSL•FO
RenderX

Interest in GSH by Individual Access Barriers

The lack of perceived need for psychotherapy was significantly associated with lower interest in GSH (for endorsing relative to denying perceived need: OR 2.11, 95% CI 1.55-2.88; *P*<.001). This effect was not accounted for by the effect of psychological distress severity, which was not a statistically significant predictor of GSH interest in this model (OR 0.99, 95% CI 0.96-1.03; *P*=.83). None of the other individual barriers had a statistically significant univariate relationship with interest in GSH. Refer to Table 5 for results of all univariate models, Multimedia Appendix 1 for full descriptive statistics, and Multimedia Appendix 2 for a visualization.

Table 5. Results of univariate logistic regressions for outcomes (1) interest in guided self-help (GSH) and (2) self-reported likelihood of guided self-help, by endorsement of each self-reported barrier to past-year psychotherapy use in a sample of adults with psychological distress (n=640).

Barrier[a]	GSH interest		Self-reported likelihood of GSH use[b]	
	OR[c] (95% CI)	Adjusted *P* value[d]	OR (95% CI)	Adjusted *P* value[d]
Psychotherapy will not work[e]	0.71 (0.47-1.06)	.28	0.99 (0.62-1.58)	.97
The problem went away	0.76 (0.4-1.44)	.59	0.93 (0.41-2)	.92
Want to handle the problem alone	0.84 (0.59-1.19)	.55	0.97 (0.65-1.45)	.92
Do not want to share private information	0.76 (0.54-1.08)	.35	0.93 (0.62-1.39)	.83
Worried about what others think	1.51 (0.97-2.36)	.23	1.19 (0.72-1.95)	.67
Did not know who to see or where to go	0.98 (0.7-1.38)	.92	0.88 (0.6-1.31)	.72
Not enough time or too busy	0.94 (0.67-1.33)	.83	1.08 (0.73-1.61)	.83
Problems with money or insurance	1.27 (0.85-1.91)	.47	0.93 (0.59-1.47)	.83
Need to stay home or cannot get transportation	1.52 (1.04-2.23)	.13	1.17 (0.76-1.81)	.67
Could not get an appointment	1.13 (0.66-1.92)	.83	1.39 (0.76-2.48)	.51
Care provider might be culturally insensitive	0.97 (0.63-1.5)	.92	1.05 (0.63-1.72)	.92
Other reason	0.75 (0.43-1.31)	.55	0.62 (0.29-1.22)	.43

[a]Participants were given the opportunity to choose multiple answer choices. Each row in the table represents 2 independent univariate regressions (1 for each GSH-related outcome), where the single predictor is binary endorsement of the barrier in column 1. The reference level for the predictor variable is nonendorsement, such that OR >1 reflects an association with endorsing the barrier.

[b]The reference level is denying likely GSH use, such that OR >1 reflects an association with endorsing likely GSH use.

[c]OR: odds ratio.

[d]Benjamini-Hochberg adjustment was performed across all analyses.

[e]Each barrier description is abbreviated from the original answer choice presented to participants. See Multimedia Appendix 1 for full text of each answer choice.

Self-Reported Likelihood of GSH Use by Individual Access Barriers

By contrast, the relationship between the lack of perceived need and self-reported likelihood of GSH use did not reach statistical significance after Benjamini-Hochberg adjustment (for endorsing relative to denying "benefit:" OR 1.51, 95% CI 1.05-2.2; *P*=.12). None of the other individual barriers had a statistically significant relationship with interest in GSH. Refer to Table 5 for results of all univariate models, Multimedia Appendix 1 for full descriptive statistics, and Multimedia Appendix 2 for a visualization.

Primary Access Barriers and Barrier Type

Descriptives and Demographics for Primary Barriers and Primary Barrier Type

When participants endorsing perceived need selected their primary barrier to past-year psychotherapy use, "issues with money or insurance" (170/640, 26.6%) was most commonly endorsed. Therefore, among all participants, this was the second-most common primary barrier relative to the lack of perceived need (206/640, 32.2%). The frequency of these 2 primary barriers far exceeded the frequency of the third-most common primary barrier, "wanted to handle the problem alone," which was endorsed as primary barrier by only 7.3% (47/640) of the participants.

When barriers were grouped, attitudinal primary barriers were reported by over half of the participants (336/640, 52.5% of those without past-year psychotherapy use) and were more common than structural primary barriers (244/640, 38.1%). The remaining 9.4% (60/640) of the participants' primary barriers fell into the " other" category (refer to Table 6 for frequencies of all primary barriers).

The only individual characteristic that was a statistically significant predictor of primary barrier type was gender (*P*=.002), such that women had lower odds of reporting an attitudinal primary barrier relative to men (OR 0.46, 95% CI 0.32-0.67; refer to Table 7 for full results).

[a]The reference level for the outcome variable is endorsement of a structural primary barrier.

[b]OR: odds ratio.

[c]*P* values are omnibus values across all levels of the outcome variable (ie, structural, attitudinal, and other). For categorical predictors, the *P* value shown is an omnibus *P* value calculated across all levels of the predictor variable.

[d]Benjamini-Hochberg adjustment was performed across all analyses.

[e]Reference level.

[f]K6: Kessler-6 Psychological Distress Scale.

Interest in GSH by Primary Barrier Type

Among the participants with an attitudinal primary barrier, 69.3% (233/336) were at least "somewhat interested" in GSH, whereas among those with a structural primary barrier, 87.3% (213/244) were at least "somewhat interested." Approximately one-third (108/336, 32.1%) of those with an attitudinal primary

XSL•FO
RenderX

barrier were at least "moderately interested" in GSH versus nearly half (118/244, 48.4%) of those with a structural primary barrier. Only 8.3% (28/336) of the participants with an attitudinal primary barrier were "very interested" in GSH versus 14.8% (36/244) of those with a structural primary barrier. Finally, less than one-third of the individuals with an attitudinal primary barrier reported that they were "not at all interested" in GSH (103/336, 30.7%) compared to 12.7% (31/244) of the individuals with a structural primary barrier. Refer to Multimedia Appendix 1 for full descriptive statistics and Multimedia Appendix 2 for a visualization. Overall, the effect of primary barrier type on GSH interest was statistically significant (P<.001), such that individuals who reported an attitudinal primary barrier were less interested in GSH than those who reported a structural primary barrier (OR 0.44, 95% CI 0.32-0.6). This effect was not accounted for by the effect of psychological distress severity, which was not a statistically significant predictor of GSH interest in this model (OR 0.99, 95% CI 0.96-1.02; P=.72). The effect of reporting an "other"-type primary barrier was not statistically significant (OR 0.93, 95% CI 0.56-1.55), relative to reporting an attitudinal primary barrier.

Self-Reported Likelihood of GSH Use by Primary Barrier Type

Whereas 37.3% (91/244) of those with a structural primary barrier reported that they would be likely to complete at least 1 GSH session, 26.8% (90/336) of the participants with an attitudinal primary barrier reported that they would be likely to do so. This difference met statistical significance at P<.05 (OR 0.61, 95% CI 0.43-0.87; P=.045). This effect was not accounted for by psychological distress severity, which was not a statistically significant predictor of self-reported likelihood of GSH use in this model (OR 0.99, 95% CI 0.95-1.03; P=.43). Among those endorsing a primary barrier in the "other" category, 40% (24/60) reported that they would be likely to complete at least 1 GSH session. The effect of endorsing an "other"-category primary barrier relative to a structural primary barrier was not statistically significant (OR 1.11, 95% CI 0.62-1.98; P=.83).

Univariate Analyses for Income and Race

Race and Ethnicity

Our sample consisted of just under one-third (306/971, 31.5%) people of color: 6.5% (63/971) non-Hispanic Black, 10.8% (105/971) Hispanic, 8.8% (85/971) Asian, and 5.5% (53/971) other races or multiracial. See Multimedia Appendix 1 for full descriptive statistics for GSH interest and likely GSH use by racial and ethnic group. In a series of univariate analyses, race did not have a statistically significant relationship with each past-year psychotherapy use (ORs 0.53-1.26; P=.59), primary barrier type (P=.43; for attitudinal relative to structural, ORs 0.75-2.18; for other relative to structural, ORs 1.54-1.97), interest in GSH (ORs 0.72-1.23; P=.58), or self-reported likelihood of using GSH (ORs 0.56-1.07; P=.45).

Income

Income had a statistically significant relationship with primary barrier type at P<.05 (P=.045), but did not have a statistically significant relationship with each past-year psychotherapy use (ORs 0.54-1.44; P=.45), interest in GSH (ORs 0.66-1.3; P=.43), or self-reported likelihood of GSH use (ORs 0.63-1.6; P=.13). The pattern of the effect of income on primary barrier type was inconsistent across income levels. For example, compared to the group at the lowest income level (<US $15,000), individuals with slightly greater incomes had greater odds of reporting an attitudinal primary barrier (eg, US $15,000-US $24,999; OR 3.4, 95% CI 1.59-7.28), but individuals with much greater incomes did not significantly differ from individuals in the lowest income level (eg, >US $150,000; OR 1.05, 95% CI 0.7-1.59). Refer to Multimedia Appendix 1 for full descriptive statistics for GSH interest and likely GSH use by income level, and Multimedia Appendix 2 for a visualization.

Discussion

Principal Findings

In this study, we found reasons to question the extent to which DMHIs may reach individuals with unmet needs by circumventing structural barriers alone. In a sample of individuals with psychological distress, those who did not use psychotherapy in the past year were *less* interested in GSH and *less* likely to predict that they would use GSH relative to those who had used psychotherapy. This difference might be explained by the high prevalence of attitudinal (vs structural) barriers observed among those without past-year psychotherapy use, especially the lack of perceived treatment need. Attitudinal barriers were the most commonly reported barriers to past-year psychotherapy use and were associated with lower interest in GSH and lower self-reports of likely GSH use. Taken together, these results suggest the potentially 3 substantial role of these barriers in limiting DMHI uptake for individuals with unmet treatment needs. Interestingly, we did not find support for differences in any of the major study variables by racial-ethnic identification, and results for differences by income were mixed.

Limitations

A limitation of this study is that our analyses are restricted to participants' opinions drawn from a brief description of a single DMHI. Our results about an internet-delivered GSH bibliotherapy might not generalize to other DMHI formats if barriers to DMHI use vary across digital delivery formats [31]. For example, privacy could be a greater concern when using a smartphone app, and attitudes might differ when human guidance is not included [25,31].

Our sample also presents limits to generalizability. First, this study focused exclusively on US residents, which limits generalizability to other countries, for example, due to different health care systems [27]. In addition, because all participants were recruited online, it is possible that unique features of this population might alter our sample's interest in DMHIs relative to the general population (eg, they may have higher digital literacy [75,76]). Future work extending this research to varying samples will be required to establish generalizability.

Our measurement methods may have introduced error. Self-reported likelihood of GSH use may overestimate actual likelihood of GSH use, and future research should measure

XSL•FO
RenderX

observable behavior instead. Our measure of interest in GSH may also have lost sensitivity in its format as a 4-point scale [77]; however, Leung [78] presented a discussion of psychometric performance relative to 5-, 7-, and 11-point scales. Finally, our survey design also imposes some limitations on the interpretability of these data. Participants without a perceived need for psychotherapy were not queried about any other barriers, obscuring the possible role of multiple barriers for this group. We also queried participants about their experience of multiple specific barriers via a checklist-format question, which may distort results by encouraging participants to overendorse answer choices [48]. Therefore, this work might be stronger if measurement allowed participants to rate the relevance of each barrier dimensionally to capture greater complexity.

Strengths

This study's major novel contribution is its direct investigation of the relationship between perceived barriers to accessing "traditional" psychotherapy and potential DMHI use. Previous literature has extensively reported barriers to general mental health treatment seeking [25-28,79,80] and DMHI interest and adherence [81] separately but often neglected to measure them together. Barriers to DMHI acceptability and engagement have often been studied inductively, often among participants in clinical trials or institutional settings *already using* DMHIs [30,31]. By contrast, our approach offered a unique contribution to the literature by reflecting potential barriers to the *uptake* of DMHIs. First, we captured a wide range of both attitudinal and structural barriers, rather than focusing on only those commonly addressed in the DMHI literature (eg, cost and geography). This allowed us to capture common barriers to help seeking in general, derived from robust existing literature [25-28] rather than technology-specific concerns. In addition, we sampled from a general population of individuals with potential treatment needs rather than trial participants who have already "overcome" barriers to uptake.

Importantly, we avoided the common negligence to investigate racial and ethnic differences in DMHI research [33,39,45], placing special emphasis on both racial and ethnic minorities and low-income individuals. In addition, we designed our sample to focus on individuals with unmet treatment needs by (1) requiring at least mild psychological distress and (2) conducting primary analyses on the subsample that had not accessed psychotherapy.

Finally, another unique strength of this study is that we parsed participants' *interest* in GSH from their self-reported likelihood of *actually using* GSH**.** The predictors of these outcomes were similar across analyses, but their differing base rates contributed unique information. For example, among individuals who did not access psychotherapy in the past year, the percentage of the participants who predicted that they would use GSH (205/640, 32%) was approximately half the percentage of the participants who were at least somewhat interested (497/640, 77.7%). According to the theory of planned behavior, participants' estimates of their likely treatment-seeking behavior should be a stronger predictor of actual treatment use than attitudes [47,49,50]. Understanding factors that lead to differences in attitudes versus perceived likelihood of using DMHIs may be informative for dissemination efforts.

Implications

Our results suggest that the attitudinal barriers that limit traditional psychotherapy use may also limit DMHI use. Individuals who are not in treatment due to the lack of perceived need for *any* treatment are likely to forgo use of DMHIs. Our results were also consistent with previous literature by suggesting that attitudinal barriers to psychotherapy use may be more common than the structural barriers that DMHIs may target [25,27]. Failing to address attitudinal barriers may substantially limit the potential public health impact of DMHIs if this obstacle is left unaddressed.

In addition, our results suggest that individuals who *already have access to* psychotherapy may be *more* likely to use DMHIs than those with unmet needs. This is concerning because a major aim of DMHIs is to reach individuals who cannot access traditional treatments. However, this finding does not contradict all models of DMHI dissemination. For example, DMHIs may improve access by expanding the spectrum of care intensities available [7]. If individuals with lower-intensity needs rely on lower-intensity treatments, they may free up "higher-intensity" resources (eg, specialized clinicians) for others. Whereas institutional systems of stepped care enforce this model (eg, Improving Access to Psychological Therapies program of the United Kingdom [13]), the public's use of stand-alone DMHIs may not always follow this pattern. The hope that individuals using publicly available DMHIs (eg, commercially available apps [9]) might then forgo traditional treatment is only a hypothesis. Our results suggest that the contrary is possible, such that, individuals with positive treatment attitudes may use *both* DMHIs *and* traditional treatment. This would risk widening, rather than reducing, the treatment gap by benefiting those with existing access rather than those without it. However, stand-alone DMHIs may have particular public health utility when they offer services that are difficult to access in the community (eg, specialty treatments such as cognitive behavior psychotherapy for insomnia [82]).

We did not find evidence supporting racial and ethnic differences in our study's indicators of potential DMHI use, supporting the broad appeal of DMHIs. This is consistent with previous literature, which has generally found little support for differences in interest and engagement in DMHIs across racial and ethnic groups, although research is still limited [33]. We also did not find racial-ethnic differences in the relative rate of attitudinal versus structural barriers to treatment access. This contrasts with previous findings that attitudinal barriers to general help seeking may vary by race [41,83], especially stigma [84]. However, results are inconsistent and suggest that these patterns may be nuanced across individual minority groups and by treatment type (eg, medications vs psychological treatment [34]). In addition, we found some evidence for differences in attitudinal barriers and GSH interest by income, but the results were mixed, such that it is difficult to interpret a pattern. Future research should clarify the potentially complex relationship between income, access barriers, and help seeking [36].

XSL•FO
RenderX

Finally, our findings have implications for DMHI development research. DMHI trials may primarily attract participants who are *already interested* in psychological treatment but unable to access traditional psychotherapy due to structural barriers. Therefore, these samples might underrepresent individuals facing attitudinal barriers to treatment. This biased sample would not reflect the total target population of individuals with unmet needs. Therefore, the estimates of DMHI use could be inflated, and design elements intended to increase DMHI use might not be generalizable to the total population. This would be particularly concerning because the rates of DMHI use are already low, and much work has been devoted to testing the effectiveness of design alterations intended to increase engagement [81].

Future Directions

Future work should first substantiate this exploratory research by investigating these questions in additional samples [60]. Recruiting dedicated samples of racial and ethnic minorities may also be key to developing a clearer picture of this phenomenon (eg, capturing intersectional effects). The lack of representation of racial-ethnic minorities is a well-documented problem in DMHI research [8,33,34,39,45], so this should be prioritized in future DMHI work. In addition, evidence suggests that attitudinal barriers may vary across countries [27], and treatment-seeking pathways vary across countries according to their health care systems [85]. Therefore, research with international samples and replication across research groups in several countries is essential for broad applicability and public health impact on a global scale. Finally, community-based sampling may improve upon potential generalizability and data integrity issues introduced by online recruitment [62]. Community-based sampling might also facilitate improved measurement approaches, such as observed uptake of clinical services, rather than relying on self-report.

In addition, future research should seek to better understand the lack of perceived need for treatment. Our results and previous literature [26] suggest that a lack of perceived need may be the most common reason individuals do not access treatment. Therefore, using measurement approaches that are able to parse the components of perceived need (and lack thereof) may be particularly informative. For example, low mental health literacy [86] may contribute to a lack of perceived need when an individual does not have sufficient understanding of mental health concerns to recognize their symptoms. In addition, reporting a lack of perceived need for treatment may reflect a cultural preference for other types of help, such as informal community support [87]. Developing a more nuanced understanding of perceived need may be the first step toward understanding how lacking perceived need for treatment might generalize to DMHIs as well as how perceived need might differ across treatment modalities.

Future work should also endeavor to synthesize barriers to general treatment seeking with findings about barriers to DMHIs specifically. Indeed, both barriers to help seeking in general [25,29] and barriers specific to DMHIs [30,31] cumulatively serve as bottlenecks in DMHIs' ability to reach individuals with unmet needs. Therefore, attempts to ameliorate these issues and expand the reach of DMHIs will need to address both types of barriers. In addition, individuals may sometimes seek treatment *despite* attitudinal barriers [88]. Therefore, in addition to interventions aimed at modifying attitudes, future research might also seek to promote factors that circumvent perceived barriers. For example, research informed by the theory of planned behavior [47] suggests that subjective social norms and perceived behavioral control predict treatment-seeking behavior [48,49].

Finally, future work might pay greater attention to existing approaches to increasing mental health treatment seeking. Help-seeking interventions [89,90] are often designed to target barriers such as stigma [79] and mental health literacy [91]. In addition to encouraging general treatment seeking, interventions could be tailored to encourage the use of DMHIs. For example, models for "direct-to-consumer marketing" of evidence-based psychological interventions have been proposed as an adjunct to treatment innovation and implementation efforts [92]. Tailoring such interventions to build public awareness of the diverse "portfolio" of treatment options [7] available for their direct access [93] could potentially increase the reach of DMHIs. Raising awareness of DMHIs' existence and efficacy [89] could empower treatment seekers to choose the options that are most fitting for their attitudes and preferences [86].

Conclusions

Overall, this work suggests the importance of questioning assumptions about how potential solutions to the mental health treatment gap will reach those who most need them. DMHIs clearly have an advantage over traditional psychotherapy in their scalability because their low resource requirements and low intensity of use can circumvent structural barriers. However, understanding the wide range of obstacles to DMHIs' dissemination and uptake may be essential to maximizing their impact. In the quest to expand treatment access, the *first* hurdle that DMHIs face is the willingness to seek mental health treatment *of any kind*. Our work suggests that addressing individuals' attitudinal barriers may be an important step to ensure that DMHIs maximally achieve their promise of expanding access to treatment and reducing the public health burden of psychopathology. Devoting resources to help-seeking interventions [89] may be key to addressing the treatment gap [6] rather than focusing on developing solutions to structural barriers alone (ie, scalable treatments). Importantly, adequate representation of the underserved groups most in need of accessible interventions is vital throughout this research [8,33].

Acknowledgments

Abstract

Background: Individuals with dementia, especially those in later stages, have difficulties with verbally reporting their experience of pain. This results in both underassessment and undertreatment of pain, signaling the need for better pain recognition in persons with dementia. A promising form of pain assessment is digital monitoring, which can concurrently and more objectively detect and use numerous relevant pain cues.

Objective: This review aimed to identify observable cues of pain, which could be used for digital pain monitoring. A total of 2 research questions (RQs) were formed as we set out to examine which digital cues offered a valid insight into pain in people with dementia (RQ1) and identify how these cues were originally measured (RQ2).

Methods: A standard methodological approach for scoping reviews was used. Relevant research papers were chosen based on SCOPUS and Web of Science databases, and relevant data on pain cues were extracted from all papers that satisfied the inclusion criteria. The gathered data were analyzed using a thematic analysis, which involved categorizing the observable cues into higher-order categories.

Results: Of the 3705 publications identified in the search, 34 satisfied the inclusion criteria and were closely examined. Addressing RQ1, we identified 7 categories of behavioral and physiological cues associated with pain, most frequently facial expressions (20/34, 59%) and body movements or expressions (15/34, 44%). Several subcategories for each main category of pain cues were also identified, each involving between 1 and 28 relevant specific pain cues. Addressing RQ2, 29/34 (85%) studies assessed pain cues via human observation only, while 5/34 (15%) combined human observation with either facial recognition software, PainChek app, or computer vision.

Conclusions: The review provides a comprehensive list of the most relevant cues that signify pain in persons with dementia and offers a foundation for the use of artificial intelligence and digital monitoring for the screening of pain in dementia.

Introduction

Dementia presents a global health concern, with some estimates suggesting that it affects over 50 million people worldwide, and this figure is predicted to triple by 2050 [1,2]. The course of dementia can span from 5 to 12 years, during which the patient's ability to function independently gradually decreases with the progression of the disease [3]. With this progression, there is also an increase in communication problems [4]. In a clinical setting, this can lead to the underassessment of many co-occurring health conditions or states, especially for patients with moderate to severe dementia [5,6]. One of these underrecognized states is pain [7]. Pain is frequently experienced by patients with moderate to severe dementia but is often undetected and consequently untreated because of their inability to self-report [8]. Since reliable recognition and assessment of pain are essential for effective treatment, observational pain tools that emphasize observable cues have become increasingly important for the accurate assessment of pain in people with dementia [9].

While self-reporting is generally considered the most reliable method for assessing pain [9], a different approach is needed when assessing patients with dementia. There are numerous observational scales available, such as the Abbey Pain Scale (APS) [10], Doloplus-2 [11], the Pain Assessment Checklist for Seniors with Severe Dementia (PACSLAC) [12], and The Pain Assessment in Advanced Dementia Scale (PAINAD) [13]. The problem with this type of assessment, however, is that the scales have poor or unproven reliability, insufficient evidence for validity, and untested sensitivity to change. Additionally, their implementation in practice is often poor [14,15]. It is usually nurses or caregivers who assess and report on the

XSL•FO
RenderX

patient's pain, and they do not always rely on observational scales. Even when they do, their ratings of pain are not always related to any specific pain behaviors, which results in inadequate pain assessment [16-18].

As an alternative, digital monitoring of pain could be very effective in assessing pain in patients with dementia, as it promises to provide objective evidence of the presence and intensity of pain [5,8,19]. The method could use a combination of different technologies, such as automated facial recognition and analysis, smart computing, affective computing, and cloud computing (ie, Internet of Things) for identifying the presence of pain in patients with advanced dementia [20]. As an example, Atee and colleagues [5] recently developed an electronic Pain Assessment Tool (ePAT), an application that uses facial recognition technology to detect facial microexpressions indicating pain and to record pain-related behaviors. A similar system is also used in health care—Internet of Things—enabled surveillance cameras capture real-time video data and can enhance patient care with features like sentiment analysis and emotion detection [21]. Digital monitoring has the potential to change pain assessment in individuals who are unable to verbalize their inner states, as it can be used by clinicians and caregivers in everyday clinical practice [5,8,20].

A critical foundation for effective digital monitoring is a thorough overview and categorization of cues associated with pain that can be measured using digital technologies (ie, digital cues). These are essential for identifying pain in individuals unable to directly report it themselves. However, despite previous efforts in identifying and categorizing pain cues (eg, by the American Geriatrics Society [22]), which identified broad categories of facial expressions, verbalizations and vocalizations, body movements, changes in interpersonal interactions, changes in activity patterns or routines, and mental status changes, the categorizations of pain cues remain inconsistent and segmented. If we want to develop better, technology-supported ways of monitoring pain, a systematic and thorough set of digital pain cues is needed.

Therefore, the main goal of this paper was to identify specific cues that could help identify pain in patients with dementia by way of digital monitoring. Despite many studies that identify common pain behaviors (eg, [22,23]), there is a lack of specific information about how certain cues are measured, or how identified behaviors are linked with pain. This scoping review aimed to address this gap by identifying pain cues that could potentially be intercepted using artificial intelligence (AI). Among other potential applications, results will be directly used to develop an AI-based pain identification system within the project Artificial intelligence–based health, optimism, purpose, and endurance in palliative care for dementia (AI4HOPE [24]). A total of 2 research questions (RQs) were formed for the purpose of this study. The first aimed to investigate which digital cues offer a valid insight into pain in patients with dementia, and the second focused on determining how these cues were measured. To address the RQs, we conducted a scoping review.

Methods

Overview

This scoping review was carried out following the framework established by Arksey and O'Malley [25], which involves 5 key stages: formulating the RQs, finding relevant studies, selecting studies, organizing the data, and finally, synthesizing, summarizing, and reporting the results. The findings from our review are presented in accordance with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines for scoping reviews [26,27]. The protocol for the review was established in detail beforehand and no changes were made to it once the study was initiated.

Identifying the Research Questions

To begin working toward a comprehensive list of digital cues that can help identify pain in people with dementia, 2 RQs were formed. The first RQ, "Which digital cues offer a valid insight into pain in people with dementia," aimed to identify crucial digital cues that can provide reliable insights into pain experienced by people with dementia. The second RQ, "How are these cues measured?" served to identify tools, methodologies, and techniques used to detect and measure the cues.

Identifying Relevant Studies

To address the RQs, we used 2 databases, Web of Science and Scopus. These databases were selected due to their comprehensive coverage of peer-reviewed journals, conference proceedings, and other scholarly publications across various disciplines. Only the 2 databases were chosen, considering that this was a scoping review and because this ensured a thorough and reliable search, as outlined by López-Illescas et al [28] and Zhu and Liu [29]. They complement each other well [30] and overlap largely with other databases [31]. We first conducted preliminary test searches to optimize our search string [32]. The main search was conducted on April 11, 2024.

The finalized search string included keywords identifying various types of dementia and cognitive impairment (dementia OR Alzheimer* OR Frontotemporal OR Korsakoff OR Creutzfeldt OR "Posterior Cortical Atrophy" OR "Normal Pressure Hydrocephalus" OR "Chronic traumatic encephalopathy" OR "Lewy Bod*" OR "HIV* neurocognitive disorder" OR "Corticobasal syndrome" OR "neurocognitive disorder"), cues (sign OR signs OR signal* OR cue* OR symbol* OR pattern* OR clue* OR manifestation* OR express* OR feature* OR indicator* OR cue* OR "digital biocue*" OR "electronic biocue*" OR sensor* OR "observable cue*" OR "physiological cue*" OR "behavioral cue*" OR "behavioral data" OR "physiological data" OR index OR indices OR property OR reaction* OR characteristic* OR pattern* OR "behavioral cue*" OR "behavioral data" OR behavior* OR behavior* OR change* OR expression* OR respons* OR observ*), modality of cues (text OR video OR image OR audio OR speech OR language OR paralinguistic OR prosodic OR semantic OR acoustic OR lexical OR facial OR visual OR appearance-based OR vocal* OR written OR verbal OR

XSL•FO
RenderX

nonverbal OR conversational OR behavior* OR behavior* OR movement OR soft OR motor OR psychomotor OR somatic OR word* OR social OR mood OR eat* OR sleep* OR physiologic* OR body OR communicat* OR noise* OR breath* OR activit*) additional specific observable cues ("sore areas" OR rubbing OR bracing OR restlessness OR consolability OR appearance OR "startle response" OR trembling OR palpitation* OR hyperventilat* OR sweat* OR dizziness), and excluding studies with nonhuman subjects (mouse OR mice OR rat* OR animal*).

Inclusion criteria for the initial search were for the paper to be (1) in English and (2) a peer-reviewed empirical study, published in scientific journals or conference proceedings as full papers (excluding abstracts-only proceedings, preprints, and unpublished work). We restricted the search to publications in the English language, considering the language proficiency of the authors as well as the evidence that this does not have a significant impact on the conclusions of reviews [33]. We did not restrict the papers based on the year of publication.

Study Selection

All identified citations were exported to Microsoft Excel spreadsheets. The study selection procedure was then performed in 2 review phases. In the first phase, 6 researchers (IM, US, SMB, AM, MK, and another colleague) independently screened titles and abstracts to determine eligibility. A small sample of papers was screened before the first phase and reviewed by 2 researchers (SMB and US) to ensure the agreement on inclusion criteria among all the researchers. In the second phase, the same authors reviewed full articles, each reviewing a different set of articles from phase 1. In the second phase, we excluded records based on predetermined exclusion criteria, that is, those that (1) were not an empirical study (eg, reviews and meta-analyses), (2) were not performed on human participants, (3) were not focusing on adults, (4) did not report associations between observable cues and pain, (5) focused on self-reported cues, (6) focused on cues that required specialized equipment (eg, magnetic resonance imaging [MRI] and electroencephalogram [EEG]), (7) did not provide data on individual cues (eg, only a composite score of a questionnaire), (8) were single-case studies, (9) did not focus on people with dementia, and (10) were not in English. In the case of studies using observational scales, to avoid unnecessary duplication, only the most relevant papers with unique information on cues were used, typically the original validation of each scale. No restrictions were placed on the age of publication or methodological quality.

Charting the Data

After the 2 screening phases, 4 authors (US, SMB, AM, and MK) independently extracted data from the included articles using a standardized Microsoft Excel spreadsheet, containing several headings that correspond to our RQs, namely: reference of paper (authors, year, and DOI), type of study (eg, cross-sectional and randomized control trial), sample characteristics (total number of participants [N], target sample number and characteristics, and comparison group, if there was one, number of participants [n] and characteristics), information on dementia in the study (diagnosis and criteria or assessment), information on pain in the study (definition of pain and criteria or assessment), comorbidities (eg, other psychiatric or somatic data provided), observed cues of pain, with each cue recorded on a separate line, relation of cue to pain (direction of association), statistics provided (if available), method of observation (eg, phone, wristband, and observation), and who observed the cue (eg, caregiver or nurse).

Collating, Summarizing, and Reporting Results

The gathered data were analyzed by 2 authors (US and SMB) using thematic analysis, in accordance with the Braun and Clarke [34] approach. This process involved categorizing closely related observable cues into higher-order categories. Several iterations were performed to refine the number of themes.

Results

Overview

Figure 1 shows that our search identified 3705 publications (1508 from Web of Science and 2197 from Scopus). After removing 745 duplicate records, 2960 records were screened in phase 1. The majority of those (n=2714) were excluded, leaving 246/2960 (8.3%) eligible for full-text retrieval. Additionally, 12 records were not obtainable, leaving 234/2960 (7.9%) records to be screened in phase 2. A total of 206 records were excluded based on criteria outlined in the Study Selection section. We additionally used other databases (eg, Google Scholar and PubMed) to find original validation studies for scales or questionnaires outlined in other articles, which led to the inclusion of 6 additional articles. The final sample thus consisted of 34 articles, or 1.1% of the original sample, after duplicates were removed.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart depicting the study selection process.

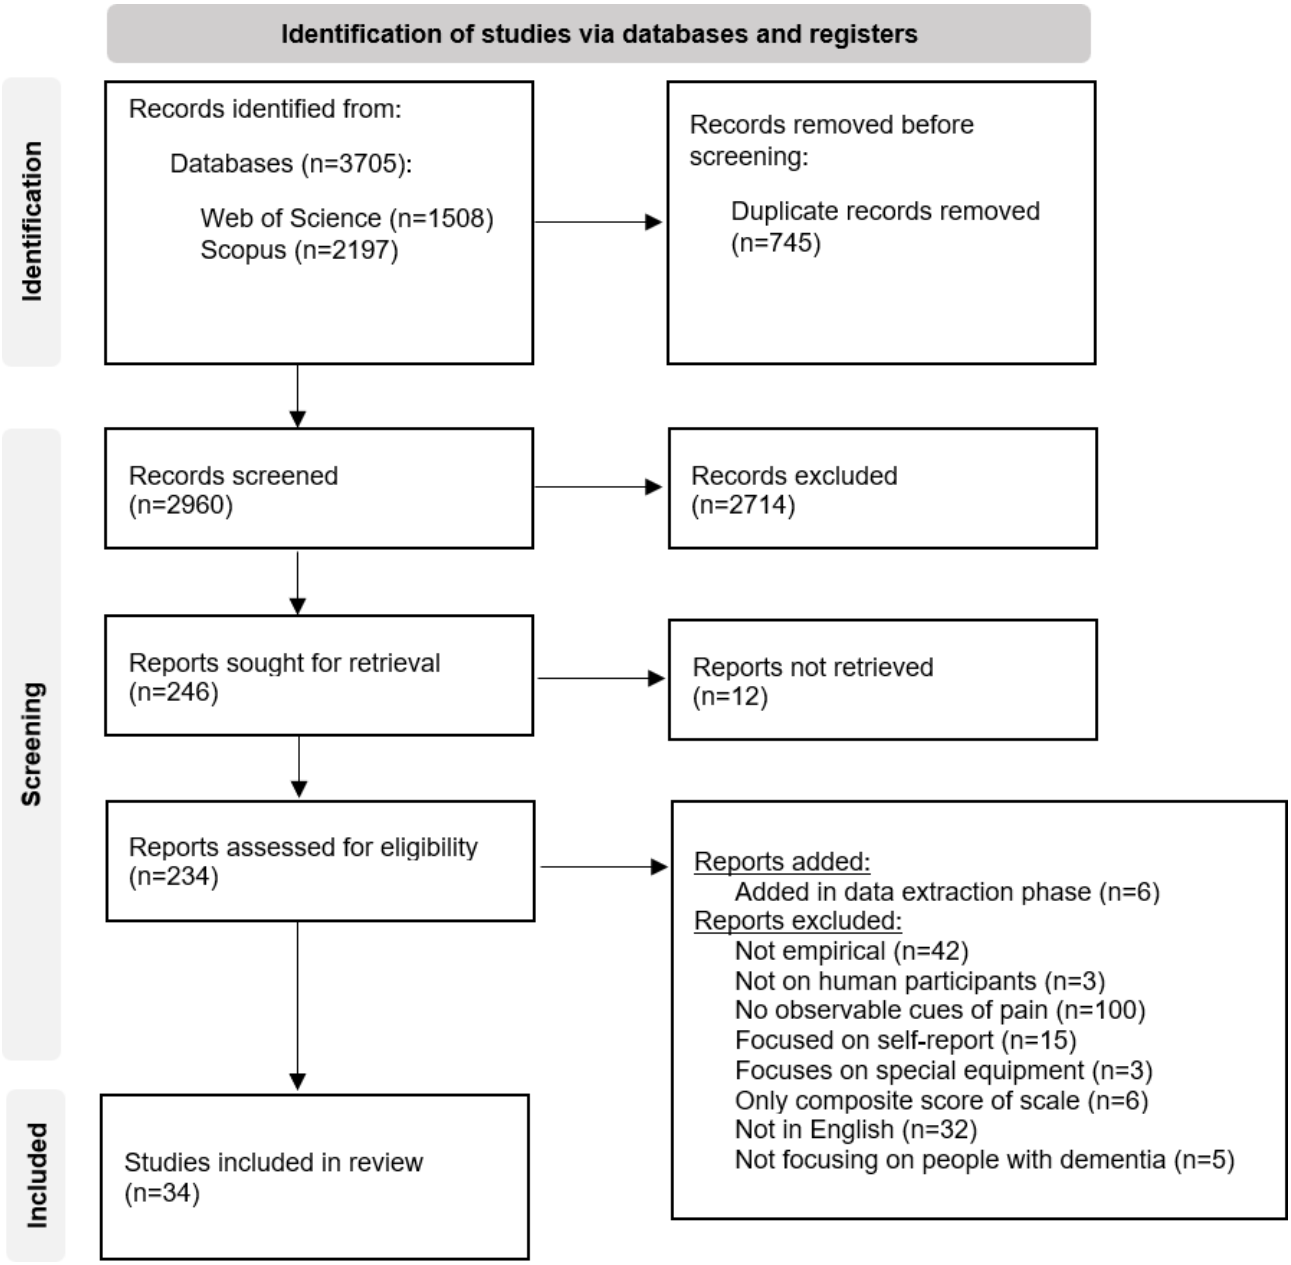

Figure 1 shows that our search identified 3705 publications (1508 from Web of Science and 2197 from Scopus). After removing 745 duplicate records, 2960 records were screened in phase 1. The majority of those (n=2714) were excluded, leaving 246/2960 (8.3%) eligible for full-text retrieval. Additionally, 12 records were not obtainable, leaving 234/2960 (7.9%) records to be screened in phase 2. A total of 206 records were excluded based on criteria outlined in the previous paragraph. We additionally used other databases (eg, Google Scholar and PubMed) to find original validation studies for scales or questionnaires outlined in other articles, which led to the inclusion of 6 additional articles. The final sample thus consisted of 34 articles, or 1.1% of the original sample, after duplicates were removed.

This study analyzed 34 research articles on cues of pain in people with dementia (for details, see Table 1). Half of the studies (17/34, 50%) were published within the last decade (from 2014 onward), while most of the remaining studies (14/34, 41.2%) were published between 2004 and 2014. The largest portion (11/34, 32.4%) consisted of evaluation and validation studies. Cross-sectional studies accounted for 17.6% (6/34), while prospective observational studies and tool development studies each made up 11.8% (4/34). Most of the studies (26/34, 76.5%) did not report comorbidities in the sample or did not specify what the comorbidities were.

The median sample size in the reviewed studies was 116 (range: 12-52,996). The target sample (excluding control groups) across the studies included between 12 and 45,568 participants (mean 1537.25, SD 7581.9), predominantly older adults aged 60 years and older. Most participants (36,525/52,996, 69%) resided in long-term care facilities or nursing homes. The majority of studies (28/34, 82.4%) focused on individuals with moderate to severe dementia, including those unable to express pain. About half of the studies (18/34, 52.9%) involved participants with a history of pain-related conditions. Additionally, a subset of studies (5/34, 14.7%) involved caregivers, health care providers, or family members as study participants. About a third (11/34, 34.4%) of the included studies used comparison groups in their research design. Most of those (6/34, 54.5%) included control groups composed of cognitively intact individuals, with or without pain symptoms. Among the studies that mentioned the type of dementia (28/34, 82.4%), unspecified dementia (such as "dementia," "advanced dementia," and "moderate dementia") was the most frequently mentioned (20/34, 58.8%).

A total of 211 distinct pain-related cues (485 overall instances) were extracted and categorized into 7 broad categories, each consisting of one or more subcategories. The main categories and their corresponding number of cues were: behaviors (49/211, 23.2%), body movement or expression (55/211, 26.1%), facial expressions (47/211, 22.3%), medical status–somatic (5/211, 2.4%), mental state (14/211, 6.6%), physiology (10/211, 4.7%), and speech, language, and sounds (31/211, 14.7%). The following sections describe each category in detail.

Behaviors

We identified 5 subcategories within the "Behaviors" category: "Active behavior," "Behavioral change," "Inappropriate behavior," "Mood-related behavior," and "Social behavior" (see Table 2 for a summary, and Table S1 in Multimedia Appendix 1 for detailed information). Cues without any statistical information (ie, general behavior change) are listed in Table S8 in Multimedia Appendix 1.

Table . Summary of relevant cues of pain in the behavior category.

Pain cue		Relevance of the cue
Categories and subcategories		Direction of the association to pain[a] and relevance of the pain cue[b]
Behavior		
Active behavior		
	General	+ (strong) [19]
	Falls	+ (weak or medium) [39]
	Impulsive behavior	+ (strong) [12]
	Normal behavior	– (strong) [37]
	Wandering	+ (strong) [5,12,54]
	Washing and/or dressing	+ (weak or medium) [52]
	Washing and/or dressing	+ (not specified)[c] [58]
Behavioral change		
	General	+ (not specified) [51] + (strong) [57]
	Changes in appetite	+ (strong) [12,54] + (weak or medium) [39]
	Changes in communication	+ (weak or medium) [52] + (not specified) [58]
	Changes in routines	+ (strong) [5]
	Changes in sleep	+ (strong) [5,12] + (weak or medium) [52] + (not specified) [58]
	Decrease in activity	+ (strong) [6,12] + (weak or medium) [39,52] + (not specified) [58]
	Lethargy	+ (weak or medium) [39] + (strong) [5]
	Stopping an activity	+ (weak or medium) [41]
Inappropriate behavior		
	General	+ (strong) [5,36] + (weak or medium) [52] + (not specified) [58]
	Combativeness	+ (weak or medium) [39]
	Handling things inappropriately	+ (weak or medium) [42]
	Refusing medications	+ (strong) [12]
	Resisting care	+ (strong) [5,12,48]
	Throwing things	+ (strong) [12]
	Trying to leave or get to a different place	+ (strong) [12]
Mood-related behavior		
	Aggressive behavior	+ (strong) [5,12,54]
	Whiny	+ (weak or medium) [37]
Social behavior		
	Argumentativeness	+ (strong) [7]

XSL•FO
RenderX

Pain cue		Relevance of the cue
Categories and subcategories		Direction of the association to pain[a] and relevance of the pain cue[b]
	Consolability	– (strong) [13]
	Disruptive behavior	+ (strong) [54]
	Interpersonal changes	+ (strong) [6]
	Not allowing people near	+ (strong) [12,38]
	Not wanting to be touched	+ (strong) [12,38,54]
Requesting attention		+ (weak or medium) [42]
	Social life	+ (weak or medium) [52] + (weak or medium) [58]
	Striking out	+ (strong) [54]
	Unsocial behavior	+ (strong) [5]
	Withdrawn	+ (strong) [54]

[a]"+"=positive and "–"=negative.

[b]Relevance of the pain cue was determined as follows: "Strong"=large effect size and "Weak or medium"=small to medium effect size [61].

[c]Not specified: study reported only on the significance and direction of the association, without statistical coefficients.

In the subcategory of active behavior, general active behavior, impulsive behavior, normal behavior, and wandering were associated with pain. Falls and washing and/or dressing had mixed associations, while scratching was not significantly related to pain. Active behavior, measured using ePAT, was positively associated with APS [19]. Falls were rated as an important indicator of pain but did not show a direct relationship with pain [39,42]. Impulsive behavior, measured by PACSLAC, was associated with global pain intensity ratings [12]. Wandering, measured using the Pain Assessment Tool in Cognitively Impaired Elders (PATCIE) or PACSLAC, was linked to the Checklist of Nonverbal Pain Indicators (CNPI), APS, and global pain intensity ratings [5,12,54]. Washing or dressing behavior, measured using Doloplus-2, was associated with the Visual Analog Scale (VAS) rating [52,58].

In the behavioral change subcategory, change in communication, change in sleep, and lethargy were associated with pain, while behavioral change in general, changes in appetite or routine, decreased activity, and stopping an activity showed mixed associations. In the general behavioral change category, APS distinguished pain intensity across MMSI categories [57] and a significant difference in behavioral pain observation was found during aversive versus pleasant activities [51]. Decreased appetite was rated as important [39], and appetite changes in general, measured using PACSLAC or PATCIE, were associated with CNPI and global pain intensity ratings [12,54]. Communication changes, measured using Doloplus-2, were associated with VAS [52,58], while routine changes and sleep changes, measured using ePAT, were associated with APS [5]. Sleep changes, measured using Doloplus-2 or PACSLAC scores, were also associated with VAS or global pain ratings during events [12,52,58]. Decreased activity was rated somewhat important by nursing staff [39] and was associated with global pain intensity, as well as with Assessment of Discomfort in Dementia (ADD), CNPI, Non-Communicative Patient's Pain Assessment Instrument (NOPPAIN), PACSLAC, Pain Assessment for the Dementing Elderly (PADE) and PAINAD, when measured using PACSLAC-II or PACSLAC [12,38,52,58]. Activity changes showed large effect sizes for both influenza vaccination and movement-exacerbated pain [6]. Lethargy was considered important by nursing staff [39], and prolonged resting, measured using ePAT, was associated with APS [5]. Pain intensity was predictive of stopping an activity pre-activity, but not during an activity [41].

In the inappropriate behavior subcategory, cues such as inappropriate behavior in general, combativeness, handling inappropriate things, refusing medication, and resisting care were associated with pain, while throwing things and trying to leave showed mixed associations. There was no association between pain and biting, eating inappropriate substances, grabbing, hiding, hitting, hoarding, hurting self or others, kicking, pushing, disrobing, spitting, or tearing things. Inappropriate behavior in general, measured using ePAT or Doloplus-2, showed a positive association with APS and VAS and predicted pain in a regression model [5,36,52,58]. Combativeness was rated as important by nursing staff [39]. Handling inappropriate things, refusing medication, resisting care, throwing things, and trying to leave were all related to pain [5,12,43,48].

In the mood-related behaviors subcategory, aggressive and whiny behavior were associated with pain, while pleasant behavior showed no association. Aggressive behavior, measured using ePAT, PATCIE, and PACSLAC, was associated with APS and CNPI [5,12,54]. Whiny behavior indicated the presence of pain [37].

In the social behavior subcategory, argumentativeness, disruptive behavior, interpersonal changes, not allowing people near, not wanting to be touched, requesting attention, social life, striking out, unsocial behavior, and being withdrawn were associated with pain. Consolability showed mixed associations, while sexual advances showed no association with pain.

XSL•FO
RenderX

Argumentativeness was associated with reported pain frequency [7]. Consolability, disruptive behavior, not allowing people near, avoiding being touched, social life, striking out, unsocial behavior, and being withdrawn were associated with pain measures, such as CNPI, VAS, and APS, when measured using PAINAD, ePAT, PATCIE, PACSLAC-II, PACSLAC, or Doloplus-2 [5,12,13,38,52,54,58]. Interpersonal changes, measured using PACSLAC, showed higher effect sizes for both influenza vaccination and movement-exacerbated pain [6], while a decrease in constant need for attention was linked with decreased pain [42].

Body Movements or Expressions

We identified 5 subcategories within the "Body movements or expressions" category: body language, body movement, body parts and cues, body positions or postures, and physical cues (see Table 3 for a summary, and Table S2 in Multimedia Appendix 1 for more detailed information). Cues without any statistical information (ie, general body language, decreased movement, reluctance to move, rubbing, tense body, and guarding) are listed in Table S8 in Multimedia Appendix 1.

XSL•FO
RenderX

Table . Summary of relevant cues of pain in the body movement or expressions category.

Pain cue Categories and subcategories	Relevance of the cue Direction of the association to pain[a] and relevance of the pain cue[b]
Body movement or expressions	
Body language	
General	+ (weak or medium) [60] + (strong) [13] + (not specified) [51]
Change in body language	+ (weak or medium) [57,60]
Body movement	
General	+ (strong) [6,19]
Bracing	+ (weak or medium) [39-41] + (strong) [41]
Difficulty chewing	+ (strong) [39]
Fidgeting	+ (strong) [12]
Flinching and/or pulling away	+ (strong) [12,38]
Freezing	+ (weak or medium) [48] + (strong) [5]
Gait changes	+ (strong) [54]
Handwringing	+ (weak or medium) [37]
Leg or arm movement	+ (strong) [5]
Limping	+ (strong) [12,38,39] + (weak or medium) [39]
Pacing	+ (weak or medium) [42] + (strong) [12]
Pulling or moving away	+ (strong) [5,12]
Reluctance to move	+ (strong) [12,38,54] + (weak or medium) [39]
Repetitive movements	+ (weak or medium) [39] + (strong) [36,39]
Restlessness	+ (strong) [5,12,42,48,54,59] + (weak or medium) [7,39,59]
Rigidity	+ (weak or medium) [37,39] + (strong) [12,38,41]
Rocking motion	+ (strong) [54]
Rocking motion–head	+ (weak or medium) [39]
Rubbing	+ (mixed results) [40,56] + (strong) [38,41,48,54] + (weak or medium) [41,59]
Shaking or trembling	+ (strong) [12,38]
Shifting	+ (strong) [41] + (weak or medium) [41]
Slow movement	+ (strong) [12,38]
Tense body	+ (weak or medium) [37] + (strong) [54]

Pain cue Categories and subcategories	Relevance of the cue Direction of the association to pain[a] and relevance of the pain cue[b]
Thrashing	+ (strong) [12,38]
Tossing and/or turning	+ (weak or medium) [39] + (mixed results) [43]
Touching a body part or area	+ (strong) [12,39,54]
Trembling	+ (weak or medium) [39]
Wincing	+ (weak or medium) [39] + (strong) [39]
Body parts and cues	
General	+ (weak or medium) [36] + (strong) [19]
Abdomen	+ (mixed results) [43,55]
Arms	+ (mixed results) [43] + (strong) [55]
Hands	+ (mixed results) [43] + (weak or medium) [55]
Head, mouth, and neck	+ (mixed results) [43] + (weak or medium) [55]
Heart, lung, and chest wall	+ (weak or medium) [55] + (mixed results) [43]
Legs	+ (mixed results) [43,55]
Pelvis and genital organs	+ (mixed results) [43] + (strong) [55]
Skin	+ (mixed results) [43,55]
Turn over	+ (weak or medium) [55]
Body positions or postures	
Abnormal or awkward sitting or standing or walking	+ (strong) [5,39] + (weak or medium) [39]
Clenched fist	+ (strong) [12,38]
Fetal position	+ (strong) [12,38]
Guarding	+ (weak or medium) [41,52,56] + (strong) [5,12,38,41,48,54] + (not specified) [58]
Poor posture	+ (weak or medium) [39]
Protective posture at rest	+ (weak or medium) [52] + (not specified) [58]
Sitting	+ (mixed results) [43] + (strong) [55]
Physical cues	
Abnormal skin color	+ (strong) [39]
Blood stains	+ (weak or medium) [39]
Heat from specific body part	+ (strong) [39]
Swollen joints	+ (strong) [39]

RenderX

Pain cue Categories and subcategories	Relevance of the cue Direction of the association to pain[a] and relevance of the pain cue[b]
Tight belly	+ (strong) [39]

[a]"+"=positive and "−"=negative.

[b]Relevance of the pain cue was determined as follows: "Strong"=large effect size and "Weak or medium": small to medium effect size [61], "Mixed results"=study reported inconsistent findings, and "Not specified" =study reported only on the significance and direction of the association, without statistical coefficients.

In the body language subcategory, general body language had mixed associations, while changes in body language showed a moderate association with pain. General body language was associated with pain via behavioral pain observations, high interrater agreement, and positive association with VAS, when measured using PAINAD [13,51,60]. Changes in body language (eg, fidgeting, rocking, etc) also demonstrated high interrater agreement, as well as a connection with APS in the group exhibiting pain [57,60].

In the body movement subcategory, general body movement, and cues such as difficulty chewing, fidgeting, flinching and/or pulling away, freezing, gait changes, handwringing, leg or arm movement, limping, pulling or moving away, reluctance to move, restlessness, rocking motion, shaking or trembling, shifting, slow movement, thrashing, touching a body part, and wincing were associated with pain. Bracing, pacing, repetitive movements, rigidity, rubbing, tense body, tossing, turning, and trembling had mixed associations, while ease of movement was not associated with pain.

General movement, measured using ePAT, CNPI, NOPPAIN, PAINAD, PADE, or PACSLAC, was associated with APS or pain across conditions [6,19]. Bracing, measured using CNPI, was associated with the Verbal Descriptor Scale (VDS), linked to overall pain intensity pre- and during activity, and rated as important by nursing staff [39-41]. Difficulty chewing was rated as important by nursing staff [39], while fidgeting and flinching/pulling away, measured using PACSLAC and PACSLAC-II, showed associations with global pain ratings, CNPI, PADE, PAINAD, and NOPPAIN [12,38]. Freezing, measured using ePAT, showed an association with APS and was supported by interrater reliability [5,48]. Gait changes, assessed with PATCIE, were associated with CNPI [54]. Handwringing was associated with the presence of pain [37] and leg or arm movement, measured using ePAT, was associated with APS [5].

Limping was rated as important by nursing staff and associated with global pain ratings, NOPPAIN, CNPI, PADE, and PAINAD, when measured using PACSLAC or PACSLAC-II [12,38,39]. Pacing was associated with global pain ratings, when measured using PACSLAC, and was reduced following intervention [12,42]. Pulling or moving away, measured using ePAT or PACSLAC, was associated with global pain ratings and APS [5,12]. Reluctance to move, measured using PACSLAC, PACSLAC-II, or PATCIE, was associated with global pain intensity, CNPI, NOPPAIN, PADE, and PAINAD, and was rated as important by nursing staff [12,38,39,54].

Repetitive movements, measured using the Minimum Data Set Resident Assessment Instrument 2.0 (MDS-RAI 2.0), were linked to pain and rated as important by nursing staff [36,39]. Restlessness, measured using the caregiver report, the Cohen-Mansfield Agitation Inventory (CMAI), ePAT, PACSLAC, PATCIE, and the Observational Pain Scale – Non-Verbal Indicators (OPS-NVI), was associated with APS, CNPI, National Institutes of Health Research Evaluation and Commercialization Hubs (NIH-REACH), global pain ratings, and self-reported pain. It was also present in situations where pain was more likely and rated as important by nursing staff [5,7,12,39,43,48,54,59].

Rigidity and muscle tensing were associated with global pain intensity, NOPPAIN, CNPI, PADE, and PAINAD, when measured using PACSLAC, PACSLAC-II, or caregiver observation [12,37-39,41]. Rocking motions, assessed using PATCIE, were associated with CNPI and rated as important by nursing staff [39,54]. Rubbing, observed via caregiver observation, CNPI, OPS-NVI, or PATCIE, was associated with VDS, CNPI, or self-reported pain and was supported by interrater agreement during painful situations [40,41,48,54,59]. Shaking or trembling, trashing and slow movement, measured using PACSLAC or PACLAC-II, were associated with global pain ratings during pain events, as well as with NOPPAIN, CNPI, PADE, and PAINAD [12,38]. Shifting predicted pre-activity pain [41].

Tense body was rated as important by nursing staff and was associated with CNPI when measured using PATCIE [37,39,54]. Tossing and/or turning was also rated as important and was associated with CMAI and Neuropsychiatric Inventory—Nursing Home version (NPI-NH), when measured using Mobilization-Observation-Behavior-Intensity-Dementia-2 (MOBID-2) [39,43]. Touching a body part, measured using PACSLAC or PATCIE, was associated with global pain intensity and CNPI. It was frequently reported by nursing staff [12,39,54]. Trembling and wincing were rated as important by nursing staff [39].

The body parts and cues subcategory in general, measured using ePAT or MOBID-2, showed associations with APS, CMAI, and NPI-NH, and predicted pain in a regression model [5,36,43]. Pain in the abdomen, arms, hands, head, mouth, neck, heart, lung, chest wall, legs, pelvis, genital organs, or skin was associated with CMAI and NPI-NH, when measured using MOBID-2. Total MOBID-2 scores improved after a pain intervention [43,55].

In the body positions and postures subcategory, abnormal or awkward sitting, standing, or walking, clenched fists, fetal

XSL•FO
RenderX

position, guarding, poor posture, and protective posture at rest were associated with pain, while sitting showed mixed associations. Abnormal movements or posture, measured using ePAT, were associated with APS and rated as important by nursing staff [5,39]. Clenching fists, fetal position, and guarding, measured using PACSLAC or PACSLAC-II, all had a positive association with global pain ratings, NOPPAIN, CNPI, PADE, and PAINAD [12,38]. Guarding, assessed via caregiver observation, ePAT, PATCIE, or Doloplus-2, was associated with APS, VAS, self-reported pain, or CNPI. It was supported by interrater reliability for predicting pain [5,41,48,52,54,56,58]. Poor posture was rated as important by nursing staff [39], while sitting, measured using MOBID-2, was associated with CMAI and NPI-NH [43].

Finally, Cohen-Mansfield and Creedon [39] reported that physical cues ratings by nursing staff, abnormal skin, blood stains, heat from a specific body part, swollen joints, and tight belly were all rated as important indicators of pain by nursing staff.

Facial Expressions

We categorized facial expressions into 8 distinct subcategories: brows, cheeks, eyes, forehead, jaw, lips and mouth, nose, and whole face (see Table 4 for a summary, and Table S3 in Multimedia Appendix 1 for more detailed information). Cues without statistical information (ie, brow lowering, cheek raising, blinking, closing eyes, specific eye movement (up, down, left, or right), tightening of eyelids, jaw drop, parting lips, specific facial expression, grimacing, and sudden jerk) are listed in Table S8 in Multimedia Appendix 1.

XSL•FO
RenderX

Table . Summary of relevant cues of pain in the facial expressions category.

Pain cue Categories and subcategories	Relevance of the cue Direction of the association to pain[a] and relevance of the pain cue[b]
Facial expressions	
Brows	
Brow lowering	+ (strong) [5,8,9]
Frowning	+ (weak or medium) [48] + (strong) [12,38,54,59]
Cheeks	
Cheek raising	+ (strong) [5]
Eyes	
Changes in eyes	+ (strong) [12]
Closing eyes	+ (strong) [5,8,9,38]
Dirty look	+ (strong) [12]
Increased eye movement	+ (strong) [38]
Narrowing and/or closing eyes	+ (weak or medium) [48,59] + (strong) [59]
Teary eyes	+ (strong) [12]
Tightening of eyelids	+ (strong) [5,8]
Forehead	
Creasing forehead	+ (strong) [12,38]
Jaw	
Restricting jaw movement while chewing	+ (strong) [59]
Lips and mouth	
Clenching teeth	+ (strong) [12,54]
Drooling	+ (strong) [59]
Horizontal mouth stretch	+ (strong) [5,8] + (weak or medium) [9]
Opening mouth	+ (strong) [12,38] + (weak or medium) [48,59]
Parting lips	+ (weak or medium) [8] + (strong) [5,9]
Pulling at the corner lip	+ (strong) [5] + (weak or medium) [8]
Raising of the upper lip	+ (strong) [5,8,9,48]
Nose	
Screwing up nose	+ (strong) [12]
Wrinkling nose	+ (weak or medium) [8] + (strong) [5,9]
Whole face	
General	+ (strong) [8,19]
Change in color	+ (strong) [39]
Facial expression	+ (not specified) [51,58] + (strong) [6,13,57,60]

XSL•FO
RenderX

Pain cue Categories and subcategories	Relevance of the cue Direction of the association to pain[a] and relevance of the pain cue[b]
Facial expression–specific	+ (strong) [38,60]
Fearful expression	+ (weak or medium) [37]
Flushed or red face	+ (strong) [12]
Gloomy facial expression	+ (strong) [54]
Grim face	+ (strong) [12]
Grimacing	+ (weak or medium) [39] + (mixed results) [40,56] + (strong) [12,38,41,54]
Looking tense	+ (weak or medium) [48]
Pain expression	+ (weak or medium) [52] + (strong) [12,38]
Pale face	+ (strong) [12]
Pale or flushed or red face	+ (strong) [5]
Prkachin and Solomon Pain Index	+ (weak or medium) [53]
Sad expression or look	+ (strong) [36] + (mixed results) [12]
Scared expression	+ (weak or medium) [37]
Tighter face	+ (strong) [12,38]
Wincing	+ (strong) [12,38]

[a]"+"=positive and "–"=negative.

[b]Relevance of the pain cue was determined as follows: "Strong"=large effect size, "Weak or medium"=small to medium effect size [61], "Mixed results"=study reported inconsistent findings, and "Not specified"=study reported only on the significance and direction of the association, without statistical coefficients.

The brows subcategory included brow lowering and frowning, with frowning strongly associated with pain, and brow lowering showing mixed associations. Brow lowering, measured using ePAT, was associated with APS and linked to higher pain scores in the PainChek app [5,8,9]. Frowning, measured with PACSLAC, PACSLAC-II, PATCIE, or OPS-NVI, was associated with global pain intensity, NOPPAIN, CNPI, PADE, PAINAD, and self-reported pain [12,38,48,54,59]. Cheek-raising, measured with ePAT, was associated with APS [5].

In the eyes subcategory, eye changes, closing eyes, dirty look, increased eye movement, narrowing and/or closing of eyes, and teary eyes were associated with pain, while specific eye movements (eg, looking to the left), blinking, and tightening of eyelids had mixed associations. Eye changes, measured using PACSLAC, were associated with global pain intensity [12]. Closing eyes, measured using ePAT or PainChek app, was associated with APS and observed pain and predicted pain when it was present [5,8,9]. Eye closure and increased eye movement, measured using PACSLAC-II, were associated with NOPPAIN, CNPI, PADE, and PAINAD [38]. Dirty look and teary eyes, measured using PACSLAC, were associated with global pain intensity ratings [12]. Narrowing eyes, measured using OPS-NVI and supported by interrater agreement, was associated with observational or self-reported pain [48,59]. Tightening of eyelids, measured with ePAT, was associated with APS and predicted higher pain [5,8].

In the forehead subcategory, creasing of the forehead, measured using PACSLAC or PACSLAC-II, was associated with global pain intensity, NOPPAIN, CNPI, PADE, or PAINAD [12,38]. In the jaws subcategory, restricting jaw movement was associated with self-reported pain when measured using OPS-NVI [59].

In the lips and mouth subcategory, clenching teeth, drooling, horizontal mouth stretch, opening mouth, pulling at corner of the lip, and parting lips were associated with pain, while raising of upper lip had mixed associations. Clenching teeth, measured using PACSLAC or PATCIE score, was associated with global pain intensity and CNPI [12,54]. Drooling, measured using OPS-NVI, was associated with self-reported pain [59]. Horizontal mouth stretching and parting of lips, measured using ePAT or the PainChek app, were associated with APS or observational pain scores and were more likely to predict pain when present [5,8,9].

Opening mouth, measured using interrater agreement, PACSLAC, PACSLAC-II, or OPS-NVI, was associated with self-reported pain, global pain intensity, NOPPAIN, CNPI, PADE, and PAINAD [12,38,48,59]. Pulling at the corner of lips and raising of the upper lip, measured using ePAT, were

XSL•FO
RenderX

associated with APS and more likely to predict higher pain when present [5,8]. Raising the upper lip, measured using the PainChek app, OPS-NVI, or interrater agreement also had an association with observational pain scores and self-reported pain [9,48,59].

In the nose subcategory, screwing the nose and wrinkling the nose were linked with pain. Screwing the nose, measured using PACSLAC, was associated with global pain ratings [12], while wrinkling the nose, measured using ePAT or the PainChek app, was associated with APS or observational pain scores and was more likely to predict higher pain when present [5,8,9].

In the whole face subcategory, the general face domain, facial expression, fearful expression, flushed face, gloomy expression, grim face, looking tense, pain expression, pale face, Prkachin and Solomon Pain Intensity, scared expression, tight face, and wincing were associated with pain, while change in color, grimacing, sad expression, and sudden jerks had mixed associations. A relaxed expression had no association with pain. The face domain, measured using ePAT, was associated with APS. Whole-face domain scores were significantly associated with pain, with upper face action units (eg, brows, eyelids, and eyes) noted more frequently than lower face action units (eg, nose and lips) during moderate and severe pain [8,19]. Change in face color was rated as important by nursing staff [39].

Facial expressions measured using APS, Coloured Analogue Scale (CAS), ADD, CNPI, Mahoney Pain Scale (MPS), PACSLAC, PADE, PAINAD, and NOPPAIN differentiated pain conditions and levels of dementia. When measured using Doloplus-2, PAINAD, or PACSLAC-II, facial expressions were associated with caregiver-reported pain, VAS, NOPPAIN, CNPI, PADE, and PAINAD. Facial expressions were also rated as reliable indicators of pain by interrater agreement [6,13,38,51,57,58,60]. Specifically, brow lowering, lid tightening, cheek raising, and jaw clenching, looking tense, frowning, grimacing, or appearing frightened were identified as pain indicators based on caregiver report or interrater agreement [60]. A fearful expression had a significant association with the presence of pain [37]. Flushed, red face and grim face, measured using PACSLAC, were associated with global pain ratings [12], while gloomy facial expression, measured using PATCIE, was associated with CNPI [54]. Grimacing, measured using PACSLAC, PACSLAC-II, PATCIE CNPI, or observation, was associated with global pain rating, self-rated pain, VDS, NOPPAIN, CNPI, PADE, or PAINAD. It was rated as important by nursing staff and was more frequent in patients with chronic low back pain than in pain-free participants [12,38-41,54,56]. Looking tense was present in situations where pain was more likely, based on interrater agreement or intraclass correlation coefficient [48]. Pain expression, measured using PACSLAC, PACSLAC-II, or Doloplus-2, was associated with global pain intensity, NOPPAIN, CNPI, PADE, and PAINAD [12,38,52]. Pale face, measured using PACSLAC, was associated with global pain intensity [12], while pale and/or flushed (red) face, measured using ePAT, was associated with APS [5].

Prkachin and Solomon pain estimation model outperformed a baseline model in pain estimation [53]. Scared expression, measured using Computerized Pain Assessment Tool (CPAT), was associated with the caregiver's report of pain [37], while sad expression predicted pain in a regression model and was associated with pain intensity when measured using PACSLAC [12,36]. Tighter face and wincing, measured using PACSLAC or PACSLAC-II, were associated with NOPPAIN, CNPI, PADE, PAINAD, and global pain intensity [12,38].

Medical Status: Somatic

The "Medical status—somatic" category included 2 subcategories, injuries and medical conditions (see Table 5 for a summary, and Table S4 in Multimedia Appendix 1 for more details).

Table . Summary of relevant cues of pain in the medical status—somatic category.

Pain cue	Relevance of the cue
Category and subcategories	Direction of the association to pain[a] and relevance of the pain cue[b]
Medical status–somatic	
Injuries	
Dislocated limbs	+ (strong) [39]
Injuries	+ (strong) [5]
Physical changes	+ (weak or medium) [60]
Medical conditions	
One leg shorter	+ (weak or medium) [39]
Painful medical conditions	+ (strong) [5] + (mixed results) [51]

[a]"+"=positive and "−"=negative.

[b]Relevance of the pain cue was determined as follows: "Strong"=large effect size, "Weak or medium"=small to medium effect size [61], and "Mixed results"=study reported inconsistent findings.

In this category, all cues were associated with pain, except for painful medical conditions, which had mixed associations. Dislocated limbs and having one leg shorter were rated as important by nursing staff [39]. Injuries in general, and painful

XSL•FO
RenderX

medical conditions, when measured using ePAT, were associated with APS [5], but the latter showed no connection to pain, when measured using MPS [51]. Physical changes such as skin tears, pressure areas, and arthritis were reported as good indicators of pain based on high inter-rater agreement [60].

Mental State or Mood

The mental state or mood category had 2 subcategories: mental states and mood indicators (see Table 6 for a summary, and Table S5 in Multimedia Appendix 1 for more details). Cues that were reported without any statistical information (ie, depression) can be found in Table S8 in Multimedia Appendix 1.

Table . Summary of relevant cues of pain in the mental state and mood categories.

Pain cue Category and subcategories	Relevance of the cue Direction of the association to pain[a] and relevance of the pain cue[b]
Mental state or mood	
Mental state	
Changes in mental status	+ (strong) [6,38,39]
Confusion	+ (strong) [5,12,54]
Delusions	+ (weak or medium) [7]
Distressed	+ (strong) [5]
Mood indicators	
Agitation	+ (weak or medium) [7,39] + (strong) [12]
Anger	+ (strong) [12]
Anxiousness, nervousness	+ (weak or medium) [7,12] + (strong) [7,12]
Depression	+ (weak or medium) [39]
Fear	+ (strong) [5]
Frustrated	+ (strong) [12]
Irritable	+ (strong) [12,39,54]
Mood changes	+ (weak or medium) [36]
Moodiness	+ (weak or medium) [39] + (strong) [12]

[a]Direction of the association to pain: "+"=positive and "−"=negative.

[b]Relevance of the pain cue was determined as follows: "Strong"=large effect size and "Weak or medium"=small to medium effect size [61].

Mental state cues, such as changes in mental status, confusion, delusions, and distress, were associated with pain. Changes in mental status, when measured using PACSLAC, ADD, CAS, CNPI, PADE, PAINAD, and NOPPAIN, differentiated between pain conditions. When measured with PACSLAC-II, mental status changes were also associated with NOPPAIN, CNPI, PADE, and PAINAD [6,38]. Increased agitation, moodiness, and irritability were frequently reported by nursing staff [39]. Confusion, measured using ePAT, PATCIE, or PACSLAC, was associated with APS, CNPI, and global pain ratings [5,12,54]. Delusions and distress, measured using ePAT or behavioral report items, were associated with APS and NIH-REACH [5,7].

Mood indicators, such as agitation, anger, anxiety, depression, fear, frustration, irritability, mood changes, and moodiness were associated with pain. Agitation was rated as important by nursing staff and was associated with NIH-REACH and global pain intensity, measured using items on behavioral report and PACSLAC [7,12,39]. Both anger and anxiety, measured using PACSLAC, were associated with global pain intensity [12]. Anxiety, measured by behavioral items, was associated with NIH-REACH [7].

Depression was rated as important by nursing staff [39]. Fear, measured using ePAT, was associated with APS [5], while frustration and irritability, measured using PACSLAC, were associated with global pain intensity [12]. Irritability was associated with CNPI when measured using PATCIE and was rated as important by nursing staff [39,54]. Mood changes, measured with MDS-RAI 2.0, were moderately connected to pain in a regression model [36]. Moodiness, measured using PACSLAC, was associated with global pain intensity and rated as important by nursing staff [12,39].

Physiology

In the "Physiology" category, we identified 4 subcategories: body temperature, breathing, other indicators, and several vital signs (see Table 7 for a summary, and Table S6 in Multimedia

XSL•FO
RenderX

Appendix 1 for more details). Cues without statistical information (ie, general changes in vital signs) can be found in Table S8 in Multimedia Appendix 1.

Table . Summary of relevant cues of pain in the physiology category.

Pain cue Category and subcategories	Relevance of the cue Direction of the association to pain[a] and relevance of the pain cue[b]
Physiology	
Body temperature	
Cold or feverish	+ (strong) [5]
Cold and clammy	+ (strong) [12]
Sweating	+ (strong) [5,12,39]
Breathing	
Ease of breathing	– (not specified) [51] – (strong) [13]
Gasping or breathing loudly	+ (weak or medium) [39] + (strong) [38]
Rapid breathing	+ (strong) [5]
Other	
Physical change	+ (weak or medium) [57]
Vomiting	+ (weak or medium) [39]
Vital signs–several	
	+ (strong) [39,57]
Changes in vital signs–general	+ (mixed results) [51]

[a]Direction of the association to pain: "+"=positive and "–"=negative.

[b]Relevance of the pain cue was determined as follows: "Strong"=large effect size, "Weak or medium"=small to medium effect size [61], "Mixed results"=study reported inconsistent findings, and "Not specified"=study reported only on the significance and direction of the association, without statistical coefficients.

Within the body temperature subcategory, being cold, clammy, feverish, and/or sweating, measured using ePAT or PACSLAC, was associated with global pain intensity and APS. Sweating was also rated as important by nursing staff [5,12,39].

Within the breathing subcategory, ease of breathing, measured using MPS or PAINAD, differentiated aversive and pleasant activities and was associated with VAS [13,51]. Gasping or breathing loudly, measured using PACSLAC-II, was associated with NOPPAIN, CNPI, PADE, and PAINAD and was rated as important by nursing staff [38,39]. Rapid breathing measured using ePAT was associated with APS [5].

In the other indicators subcategory, vomiting was rated as important by nursing staff [39], while physical changes, measured using APS, were associated with self-reported pain and differentiated pain and dementia groups [57].

For the several vital signs subcategory, associations with pain were mixed. General changes in vital signs were rated as important by nursing staff. When measured using MPS or APS, they were associated with functional deviations and self-reported pain [39,51,57].

Speech, Language, and Sounds

In the speech, language, and sounds category, 7 subcategories were identified: complaining, inappropriate verbal behavior, language, nonverbal expression, speech, verbal expression, and other (see Table 8 for summary, and Table S7 in Multimedia Appendix 1 for more details). Cues without any statistical information (ie, nonverbal expression in general and negative vocalizations) are listed in Table S8 in Multimedia Appendix 1.

XSL•FO
RenderX

Table . Summary of relevant cues of pain in the speech, language, and sounds categories.

Pain cue	Relevance of the cue
Category and subcategories	Direction of the association to pain[a] and relevance of the pain cue[b]
Speech, language, and sounds	
Other	
General	+ (strong) [19]
Pain frequency	+ (weak or medium) [36]
Pain intensity	+ (weak or medium) [36]
Quietness	+ (weak or medium) [39]
Complaining	
Somatic complaints	+ (weak or medium) [52] + (not specified) [58]

Pain cue	Relevance of the cue
Category and subcategories	Direction of the association to pain[a] and relevance of the pain cue[b]
Yelling	+ (strong) [54]
Speech	
Loud talk	+ (strong) [5,35]
Verbal expression	
Specific pain sounds or words	+ (strong) [5,12,35,38,46,48]

[a]Direction of the association to pain: "+"=positive and "−"=negative.

[b]Relevance of the pain cue was determined as follows: "Strong"=large effect size, "Weak or medium"=small to medium effect size [61], "Mixed results"=study reported inconsistent findings, and "Not specified"=study reported only on the significance and direction of the association, without statistical coefficients.

In the complaining subcategory, somatic complaints, measured using Doloplus-2, were associated with pain [52,58]. Verbal complaints, measured using CNPI, observation, or interrater agreement, were associated with pain, as measured with VDS or self-report. Verbal complaints significantly decreased after a pain-reducing intervention [40,41,43,48].

In the inappropriate verbal behavior subcategory, verbal aggression and verbally offensive behavior were associated with pain, while verbal sexual offenses showed no association. Verbal aggression and offensive behavior, measured using PACSLAC, CMAI, or ePAT, were associated with pain intensity, APS, and were reduced following a pain-reducing intervention [5,12,42].

In the language subcategory, both negative statements or negativism and repetitive verbalizations predicted pain in a regression model and were reduced after pain treatment [36,42].

In the nonverbal expression subcategory, crying, groaning, grunting, howling, moaning, mumbling, negative vocalizations, shouting, whining, and yelling were associated with pain. Vocalizations and screaming had mixed associations, while making strange noises had no association with pain.

Nonverbal expressions in general, measured using APS, CNPI, CAS, ADD, PACSLAC, PADE, PAINAD, or NOPPAIN, were associated with VDS and self-reported pain and distinguished between different pain conditions [6,40,57]. Crying and groaning, measured using ePAT, MDS-RAI 2.0, PACSLAC, PACSLAC-II, or PATCIE, were associated with global pain intensity, APS, NOPPAIN, CNPI, PADE, or PAINAD. They were rated as important by nursing staff and had a high effect size for predicting pain [5,12,35,36,38,39,54]. Grunting, measured using PACSLAC, PACSLAC-II, or PATCIE, was associated with global pain intensity, NOPPAIN, CNPI, PADE, or PAINAD [12,38,54].

Howling, measured using ePAT, was associated with APS and had a high effect size in predicting pain [5,35]. Moaning, measured using ePAT, PATCIE, or CPAT, was associated with APS, CNPI, and general pain presence. It also had a high effect size in predicting pain [5,35,37,54]. Combined with groaning and mumbling, it was associated with NOPPAIN, CNPI, PADE, and PAINAD, or global pain intensity, when measured using PACSLAC or PACSLAC-II [12,38]. Mumbling was present in pain-like situations, supported by interrater agreement [48].

Negative vocalizations had high interrater agreement as pain indicators, were rated as important by nursing staff, and were associated with pain behaviors across conditions, and with VAS, when measured with MPS, the Pain Assessment Checklist for Seniors with Limited Ability to Communicate (PACI) or PAINAD [13,39,46,51,60]. Screaming, measured using ePAT or PACSLAC, was associated with global pain intensity or APS. It was rated as important by nursing staff and had a large effect size in predicting pain scores when present [5,12,35,39].

Shouting was present in pain-like situations, as rated by interrater agreement [48], while sighing, measured using ePAT or PATCIE, was associated with APS or CNPI. It had a large effect size for predicting pain and pain behaviors in general [5,35,41,54]. Whining and yelling, measured using PATCIE, were associated with CNPI [54].

In the speech subcategory, loud talk, measured using ePAT, was associated with APS and predicted pain scores when pain was present with a large effect size [5,35]. Calling out, measured using CPAT or PACSLAC, was associated with pain presence or global pain intensity [12,37].

In the verbal expression subcategory, specific pain sounds or words (eg, "ow" and "ouch") and requesting help repeatedly, measured using ePAT, were associated with APS and had a large effect size in predicting pain scores when present [5,35]. Additionally, pain sounds measured using PACI, PACSLAC, or PACSLAC-II were associated with global pain intensity, caregiver report, NOPPAIN, CNPI, PADE, or PAINAD. They were also present in situations where pain was more likely, as supported by interrater agreement [12,38,46,48].

In the "other" subcategory, the voice domain, measured using ePAT, was associated with APS [19]. Pain intensity and frequency, as described or displayed by the patient, showed moderate effects in regression models [36], and unusual silence was rated as important by nursing staff [39].

Methods of Measuring Pain Cues

Most cues were assessed through human observation, either directly or from recorded footage. A total of 2 studies combined human observation with facial recognition software [8,19], another used both human observation and the PainChek App on a tablet [9], and 1 study reported integrating computer vision with human observation [53].

Discussion

Principal Findings

Individuals with dementia often have difficulties or are unable to self-report the experience of pain [8], which frequently results in its underassessment, especially for patients with moderate to severe dementia [5,6]. Recognition and assessment of pain could significantly improve with the use of digital monitoring, which would help identify pain cues in patients with (advanced) dementia [5,8,19,20]. This review aimed to identify such observable cues that could be used to detect pain in patients with dementia by way of digital monitoring. More specifically, we wanted to examine, "which digital cues offered a valid insight into pain in people with dementia" (RQ1) and identify "how these cues were originally measured" (RQ2).

A total of 34 relevant articles on observable cues of pain were closely examined in this scoping review. Addressing the first RQ, we could identify several behavioral and physiological cues associated with pain, which were categorized into 7 main categories. For each of the main categories, several subcategories of pain cues were identified, each involving between 1 and 28 specific pain cues. In the category of behavior, observing wandering [5,12,54], changes in appetite [12,54], inappropriate [5,36], aggressive [5,12,54], and disruptive behavior [54], as well as not wanting to be touched [12,38,54], was most strongly associated with the experience of pain, according to the available data. Considering body movements and expressions, the most relevant cues for identifying pain were flinching and/or pulling away [12,38], shaking or trembling, clenching one's fists or adopting a fetal position [12,38], and swollen joints [38,39]. In the category of facial expressions, lowering the brows [5,8,9], closing the eyes [5,8,9,38], creasing the forehead [12,38], clenching one's teeth [12,54], or raising one's upper lip [5,8,9,48], as well as wincing [12,38], were most relevant for pain identification. Further identified observable pain cues were dislocated limbs [39] and injuries [5], falling into the category of medical or somatic pain cues. Within the category of mental state and mood, changes in mental status [6,38,39], being confused [5,12,54], and distressed [5] or irritable [12,39,54] were the most important cues for identifying pain. Within physiology-related cues, being cold or feverish [5] or cold and clammy [12], sweating [5,12,39], or breathing rapidly [5], strongly signified the experience of pain. Finally, considering speech, language, and sounds, the most relevant pain cues were being verbally offensive [5], requesting help repeatedly [5,35], groaning [5,35,48,54], moaning [5,35,37,54], talking loudly [5,35], and using specific pain sounds or words [5,12,35,38,46,48].

Individuals with dementia often experience pain but may not know how to express it or may be unable to do so. Several methods of observing pain exist, but they often lack objectivity, differ in reliability and validity—leading to inconsistent assessments—or focus only on certain cues, thereby failing to account for all relevant ones, mainly due to time constraints and the effort required for a comprehensive assessment [5,6,14,15]. This review focused on recognizing various observable pain cues, and the most relevant cues were identified. They align with and extend previous frameworks, such as the American Geriatrics Society guidelines, which categorize nonverbal pain cues to be considered when identifying pain in people with dementia into facial expressions, verbalizations, vocalizations, body movements, changes in interpersonal interactions, in activity patterns or routines, and in mental status [22,62].

Findings of this review can serve as a basis for an objective identification of pain, especially in individuals with moderate or severe dementia. Even though several identified cues correspond to, for instance, already established pain-related facial action units identified in nondementia populations, for example, in the study by Prkachin and Solomon [63], pain expression can potentially be altered in people with dementia due to impaired cognitive and communicative abilities [64]. Therefore, focused, in-depth investigations of pain cues in people with dementia are of utmost importance.

While several observable cues of pain in individuals with dementia were identified, further investigation into this topic is necessary, as support for some cues is inconsistent. Specifically, the strength of pain associations with some cues varied between strong and weak or medium, or mixed results. A potential explanation of inconsistent results lies in the suggestion of previous studies regarding the variability in pain expressions, which depend on the contextual influences (eg, pain type), dementia type, and its severity [65], as well as the potential of some cues being misattributed to psychiatric causes rather than pain (eg, behavioral cues like wandering and aggression that overlap with agitation symptoms in dementia) [66]. These reasons deem the in-depth exploration of the topic even more important.

Some reviewed studies also failed to report the strength or statistical significance of the reported associations. Additionally, many of the cues were quite broadly defined or lacked a detailed description, hindering insight into the specifics of certain observational cues.

Addressing the second RQ, most of the reported pain cues were assessed through human observation, although some studies also included a facial recognition software [8,19], the PainChek app [9,20], or combined human observation with computer vision [53]. Human observation certainly improves reliability, especially when patients are not able to express pain themselves, as shown by the very validation studies we examined for relevant pain cues (eg, [12,13,38]). Nevertheless, human observation introduces a certain amount of bias and, more importantly, requires significant time and effort. It is also important to point out that a large proportion of the included papers consisted of validation studies of specific (observational) questionnaires. Although these questionnaires were designed for the purpose of others (eg, caregivers or nurses) assessing levels of pain in individuals with dementia, such studies do not provide information on how such cues could be digitally monitored—an important issue for future studies or efforts for digital pain identification. Nevertheless, a few of the identified pain cues were assessed with facial recognition software or computer vision. A prominent example of facial recognition, the PainChek app, uses automated facial recognition and analysis

XSL•FO
RenderX

to detect facial action units associated with pain. It also incorporates user-fed clinical data to generate a pain intensity score. Additionally, the app offers various features, including pain assessment, monitoring, patient profiling, and data synchronization, although these require active human participation and human cue observation [20]. As such, the PainChek app represents a solution that could potentially be further developed with the use of findings from this paper, with the ultimate goal of automatic digital pain detection. Specifically, automatic recognition of pain cues could be extended beyond the use of only facial action units to include a broader scope of cues that were identified in this review. Incorporating such multimodal approaches, relying on various types of pain cues for its detection, AI systems could provide greater consistency in pain recognition and potential for real-time monitoring, enhancing the diagnostic accuracy and accessibility of reliable pain assessment in people with dementia. In the AI4HOPE [24] project, we intend to exploit the findings of this review for the development of explainable AI able to capture and interpret cues of pain that are spontaneously expressed.

Implications

To the best of our knowledge, this review serves as a first overview of cues for the purpose of digitally monitoring cues related to pain. To utilize these cues in pain assessment, it is necessary to explore ways to design efficient algorithms and to investigate which cues are better or worse predictors of pain. The findings of this paper show that potential cues of pain exist in many different categories (eg, behavior, body movements, facial expressions, and language). This is particularly important for the development of algorithms for the purpose of identifying or classifying the identified cues of pain, as it has been found that algorithms, which consider multiple modalities, tend to be more successful than those focusing on a single modality in identifying other conditions, for example, depression [67,68]. The identified pain cues could also be used to develop digital solutions that are on the rise for supporting people with dementia [69], for example, based on AI algorithms, to help identify pain in individuals with dementia. AI-based systems could offer a more efficient and cost-effective method for clinicians to assess pain. These solutions would also allow for continuous, real-time pain monitoring, which is not feasible with traditional observational or self-reported measures. For individuals with dementia, AI would provide a discreet and accessible way to monitor pain. It would benefit clinicians by not requiring much conscious effort and allowing for continuous assessments, as well as help patients by reducing the reliance on self-reporting, which can be especially challenging for those unable to communicate their pain. Additionally, such solutions could be incorporated into broader platforms collecting various disease-related cues over longer periods of time, benefiting researchers and clinicians in gaining insight into disease progression, in order to improve prevention strategies, interventions, and personalized care for patients with dementia (eg, [70]).

Limitations

This scoping review provides a valuable synthesis of research on the observable cues of pain in individuals with dementia and their measurement. However, certain limitations must be acknowledged. Since we focused exclusively on English-language publications, predominantly involving Anglophone participants from industrialized nations, our findings may not be fully generalizable across different cultural contexts. Another limitation lies in the fact that the largest proportion of the included papers consisted of evaluation and validation studies, which may have led to a narrower focus, as these studies concentrate on the effectiveness or reliability of specific interventions or tools, but do not address all relevant aspects of the phenomenon in question. This limitation of the study distribution may have resulted in a less comprehensive understanding of the topic, particularly in terms of causality and breadth of applications. However, it is important to note that there is a general lack of studies that evaluate observable cues indicative of pain, which is why such a large proportion of evaluation and validation studies were used in this review. Finally, as a scoping review using established methodology [25] was conducted to provide a comprehensive overview of the research related to our RQs, the quality of included articles was not assessed. Future research could additionally perform a risk of bias assessment.

Conclusions

This review examined the relevant literature for the purpose of identifying observable cues that could be used to detect pain in people with dementia with the use of digital monitoring. We focused on cues that can be measured without the use of specialized equipment unavailable to the general public. The review resulted in a comprehensive set of observable cues that could be used to help identify pain in persons with dementia. We also identified inconsistencies regarding the relevance of some identified cues, as well as a lack of studies that evaluate observable cues indicative of pain, beyond the scope of evaluation and validation studies of specific pain questionnaires. The conducted review could help future advancements aiming to objectively and efficiently identify and manage pain in persons with dementia, potentially via the use of AI and digital monitoring. Our findings could also inform the design of accessible devices (eg, smartwatches and smartphones), to incorporate features that monitor and assess pain.

Acknowledgments

Abstract

Background: Cognitive behavioral therapy (CBT)–based chatbots, many of which incorporate artificial intelligence (AI) techniques, such as natural language processing and machine learning, are increasingly evaluated as scalable solutions for addressing mental health issues, such as depression and anxiety. These fully automated or minimally supported interventions offer novel pathways for psychological support, especially for individuals with limited access to traditional therapy.

Objective: This narrative review synthesized evidence on the clinical efficacy, therapeutic mechanisms, and technological features of CBT-based chatbots designed to alleviate depressive and anxiety symptoms.

Methods: Fourteen peer-reviewed studies published between January 2015 and March 2025 were identified through systematic searches and met predefined inclusion criteria. The studies were analyzed to extract information on intervention structure, therapeutic components, outcomes, and implementation characteristics.

Results: Across the included studies, CBT-based chatbots consistently demonstrated short-term reductions in depressive symptoms, whereas findings for anxiety outcomes were mixed, with some studies reporting improvements and others showing nonsignificant or unreported effects. Moderate effect sizes were observed for depression. Reported therapeutic features included cognitive restructuring, behavioral activation, relaxation and mindfulness strategies, emotional support, self-monitoring and feedback, and therapeutic alliance. Technological characteristics such as real-time feedback and adaptive goal tracking were associated with enhanced engagement and adherence.

Conclusions: CBT-based chatbots appear to be a promising and scalable modality for delivering psychological support, particularly for underserved populations. However, variability in study designs, heterogeneity of outcome reporting, and limited long-term evidence pose challenges for generalizability. Emerging evidence from generative AI chatbots (eg, Therabot and Limbic Care) highlights both opportunities and risks. Future work should examine long-term efficacy, adaptive personalization, cross-cultural adaptation, and rigorous ethical oversight.

(JMIR Ment Health 2025;12:e78340) doi:10.2196/78340

KEYWORDS

CBT chatbot; artificial intelligence; depression; anxiety; digital psychotherapy

Introduction

Cognitive behavioral therapy (CBT) is a well-established and evidence-based psychological intervention for treating depression and anxiety. CBT alleviates emotional distress using structured techniques, such as cognitive restructuring and behavioral activation, which aim to modify negative thought patterns and maladaptive behavioral responses. Although face-to-face CBT has demonstrated efficacy across a wide range of mental health conditions [1,2], numerous individuals remain untreated because of barriers such as limited access to trained clinicians, high treatment costs, and social stigma [3,4].

In response to these barriers, conversational artificial intelligence (AI)–based chatbots have recently emerged as scalable tools for delivering CBT-informed support in digital contexts. A chatbot is a software agent that simulates interactive conversations with users through text or voice interfaces, functioning as a virtual coach or guide by delivering psychoeducational content and guiding therapeutic dialogue. Early prototypes such as ELIZA (developed at the Massachusetts Institute of Technology in the 1960s) [5] were limited to rule-based scripts and reflective mirroring.

CBT chatbots can be broadly categorized into 3 architectures, often described as an AI taxonomy of chatbots. Rule-based systems rely on preprogrammed scripts and decision trees,

XSL•FO
RenderX

ensuring safety and consistency but limiting personalization. Hybrid models combine rule-based safeguards with natural language processing (NLP) and machine learning classifiers, enabling greater flexibility while maintaining clinical oversight (eg, Wysa and Youper). Generative models, powered by large language models, can produce open-ended responses and more naturalistic dialogue (eg, Therabot and Limbic Care) but require strict safeguards to mitigate risks of misinformation or hallucinated outputs. In this review, 'chatbot' is used as the primary term; 'conversational agent' is treated as a synonym.

Several CBT-based chatbot platforms, such as Woebot [6], Wysa [7], Tess [8], and Youper [9], have been specifically developed to alleviate symptoms of depression and anxiety. Unlike static mental health apps that merely present information, these chatbots actively engage users in therapeutic activities. For instance, users are guided to identify automatic negative thoughts and practice cognitive reframing strategies to challenge maladaptive cognitions [8,10]. These systems also recommend behavioral tasks, such as scheduling pleasant events or performing breathing exercises, within ongoing conversations. Some platforms incorporate advanced features, such as real-time mood tracking and personalized feedback in Youper [9], or crisis keyword detection in Wysa [7], enabling timely responses and adaptive guidance.

Despite the absence of a human therapist, several studies suggest that users may develop a sense of working alliance with these tools, as reported for Woebot [6] and Wysa [7]. Research indicates that chatbot interactions are often perceived as empathetic and emotionally supportive [7]. Techniques such as name personalization, affirming language, and nonjudgmental tone contribute to user engagement and perceived support. Although this alliance may be limited in depth compared to human-delivered therapy, studies indicate that it can be sufficient to enhance adherence and user satisfaction, as observed in studies that used Woebot [6] and Tess [8].

Preliminary findings from randomized controlled trials (RCTs) suggest that CBT chatbots can yield significant reductions in depression and anxiety over short-term interventions (typically 2‐8 weeks), particularly when compared to passive or information-only controls [6,8]. However, the mechanisms through which these outcomes are achieved—whether cognitive, behavioral, or relational—have not been systematically reviewed. Moreover, there remains a lack of synthesis regarding how technological design and implementation features contribute to therapeutic impact.

To address this gap, this narrative review synthesizes empirical findings from 14 studies on CBT-based mental health chatbots published between 2015 and 2025. It evaluates (1) the effectiveness of these interventions in reducing depressive and anxiety symptoms over short and long durations; (2) the therapeutic mechanisms, defined as CBT-consistent techniques, such as cognitive restructuring, behavioral activation, relaxation, mindfulness, emotional support, self-monitoring and feedback, and therapeutic alliance; and (3) the implementation features, defined as the design and deployment characteristics of chatbot platforms, including AI architecture (eg, rule based, hybrid, and generative), protocol structure (eg, modular vs open-ended), usability, acceptability, and user engagement. By integrating findings across clinical and technological domains, this review aims to inform the development of more effective, engaging, and ethically robust CBT-based mental health tools.

Methods

Narrative Review Approach

This narrative review aimed to synthesize empirical evidence on the clinical efficacy, therapeutic mechanisms, and implementation features of CBT-based mental health chatbots.

Given the field's early stage and heterogeneity, we used a narrative synthesis. This approach allowed for theoretical integration and contextual interpretation across diverse interventions situated at the intersection of clinical psychology, AI, and digital health.

The narrative format enabled a broad, theory-informed synthesis, meaning that we not only summarized empirical outcomes but also interpreted them in light of established CBT theory and digital health implementation frameworks. This approach allowed us to integrate therapeutic mechanisms, user experiences, and platform characteristics across heterogeneous study designs.

Search Strategy

A comprehensive literature search was conducted in March 2025 across 4 academic databases—PubMed, Scopus, PsycINFO, and Web of Science—using the following Boolean query: (chatbot OR "conversational agent" OR "dialogue system") AND ("cognitive behavioral therapy" OR CBT) AND (depression OR anxiety OR "mental health"). Searches were applied to titles, abstracts, and keywords and were restricted to English-language, peer-reviewed articles published from January 1, 2015, to March 31, 2025.

The 2015 start date was selected because the first empirical evaluations of CBT-based chatbots appeared in 2015. Before 2015, chatbot-related publications were largely conceptual discussions, technical prototypes, or rule-based systems (eg, ELIZA) that did not constitute empirical clinical trials. In addition, we performed backward and forward citation chasing (manual screening of reference lists and Google Scholar citation tracking) to identify any studies missed by the database search.

Inclusion and Exclusion Criteria

Articles were included if they met all the following criteria. First, the intervention used a predominantly automated conversational agent delivering CBT-based techniques without real-time input from a human therapist. For this review, *fully automated* was defined as interventions where the chatbot itself delivered the therapeutic content. Minimal human involvement (eg, technical support and automated reminders) was permitted. Hybrid models were included only if the human role was limited to nonclinical tasks, such as technical assistance or scheduling, but excluded if a human provided real-time therapeutic decision-making, coaching, or guidance. The second inclusion criterion was that the study reported quantitative outcomes related to depression, anxiety, or other closely related mental health indicators. Third, the study used an RCT,

XSL•FO
RenderX

quasi-experimental design, or uncontrolled pilot trial. Fourth, the article was written in English and published in a peer-reviewed journal.

Articles were excluded if they met any of the following criteria: (1) the intervention addressed only depression or anxiety without incorporating a chatbot; (2) the study lacked a clearly articulated evidence-based rationale for the chatbot's therapeutic framework; (3) the chatbot was unrelated to mental health or used therapeutic approaches not grounded in CBT (eg, mindfulness alone, psychoanalysis); and (4) the study was a literature review, meta-analysis, protocol, or theoretical paper without original intervention data.

Study Selection

After removing duplicates, both authors independently screened the titles and abstracts to identify studies relevant to the review objectives. Full texts of potentially eligible articles were then independently assessed against the inclusion criteria. Disagreements were first discussed between the 2 reviewers; if consensus could not be reached, a third reviewer was consulted to adjudicate. This multistep procedure ensured methodological rigor and minimized subjective bias.

Data Extraction and Synthesis

For each included study, data were extracted using a standardized coding template developed a priori in Microsoft Excel to enhance reproducibility. Two authors piloted the form on 2 studies to ensure consistency and then applied it across the full dataset. Extracted data included target population, sample size, chatbot name and platform, intervention duration, core therapeutic components, outcome measures, and key findings on depression and anxiety.

We also reviewed process-related indicators, such as user satisfaction, engagement metrics, and dropout rates. On the basis of thematic coding of intervention descriptions, we identified and synthesized core therapeutic mechanisms and representative dialogue examples from the chatbots. This inductive thematic approach allowed key CBT strategies to emerge from the data.

Finally, we conducted a comparative analysis of technological and clinical features of the included chatbot platforms, focusing on AI architecture, protocol structure, usability, and user engagement outcomes. All coding and synthesis procedures were independently conducted and jointly reviewed by both authors to ensure rigor and conceptual alignment.

Quality Assessment

The methodological quality of the included studies was assessed using the Cochrane Risk of Bias 2.0 (RoB 2.0) tool for RCTs and the Appraisal Tool for Cross-Sectional Studies (AXIS) for observational studies. Two reviewers (ie, the 2 authors) independently appraised each study, and disagreements were resolved through discussion. The quality ratings were incorporated into the synthesis to contextualize study findings and highlight areas where stronger evidence is needed.

Results

Study Selection

This narrative review was conducted to synthesize evidence on the effects of CBT-based chatbots for depression and anxiety. The literature search covered peer-reviewed journal articles published between March 1, 2015, and March 31, 2025, across 4 electronic databases: PubMed, Scopus, Web of Science, and PsycINFO.

The search initially yielded a total of 347 records (PubMed=71, Scopus=174, Web of Science=86, and PsycINFO=16). After removing 83 duplicates using a reference management tool, 264 records remained for title and abstract screening. At this stage, 211 records were excluded for reasons such as being unrelated to the research topic, not involving CBT-based interventions, or not applying chatbot technologies.

The full texts of the remaining 53 articles were then reviewed for eligibility. A total of 39 articles were excluded at this stage for the following reasons: interventions not based on CBT (n=14); nonchatbot or insufficient automation (n=10); no depression or anxiety outcomes reported (n=9); or reviews, meta-analyses, or protocols without original empirical data (n=6).

Ultimately, 14 studies met all inclusion criteria and were included in the narrative review for qualitative synthesis.

Overview of Included Studies

A total of 14 studies met the inclusion criteria and were synthesized in the final review (Table 1). Of these, 10 were RCTs, 1 was a single-group pre-post trial, and 3 were observational or naturalistic studies. The studies were conducted across diverse countries, including the United States, the United Kingdom, China, Poland, Sweden, Canada, and South Korea, reflecting a broad international scope.

Sample characteristics varied considerably. Several RCTs recruited college or university students, including 70 students in the United States [6], 75 in the United Kingdom [8], 148 in China [10], and 28 in Sweden [11]. Other RCTs targeted specific populations, such as 192 postpartum women in the United States [12], 68 adults with chronic medical conditions such as arthritis or diabetes in Canada [13], and 98 adults with insomnia in South Korea [14]. Two trials were conducted in subclinical or community samples, including 81 young adults in Poland [15] and 103 young adults in the United States [16]. The most recent RCT tested a generative AI chatbot in 210 adults with major depression, generalized anxiety disorder, or eating disorder risk in the United States [17].

Observational and pre-post studies included large-scale naturalistic samples. Mehta et al [9] analyzed data from 4517 paying users of the Youper app (United States/global), whereas Inkster et al [7] examined 129 Wysa users worldwide. Prochaska et al [18] tested Woebot-SUD in 101 US adults with substance use problems, and Habicht et al [19] evaluated the Limbic Care tool in 244 patients undergoing group CBT within the UK NHS Talking Therapies program.

XSL•FO
RenderX

Intervention delivery formats also varied. Most chatbots were mobile app based (eg, Woebot, Wysa, XiaoE, Fido, Youper, Limbic Care), whereas Tess and CBT-txt were delivered via SMS text messaging or text message. The duration of chatbot use ranged from 1 to 8 weeks, with some trials incorporating longer follow-ups, such as 3 to 4 months [14,16] or 8 weeks [17].

Core therapeutic elements were consistent with CBT. Across the 14 studies, commonly implemented techniques included psychoeducation, cognitive restructuring, mood monitoring, behavioral activation, relaxation training, and emotion regulation strategies. Depression and anxiety were the primary outcomes, most frequently assessed with validated instruments, such as the Patient Health Questionnaire-9 (PHQ-9) and the Generalized Anxiety Disorder-7 (GAD-7).

Collectively, these studies provide evidence that CBT-based chatbots are being tested across diverse populations, countries, and delivery formats, demonstrating both scalability and adaptability in digital mental health care.

Quality Assessment

The quality appraisal of included studies revealed variability in methodological rigor. Among the RCTs, 2 studies [10,14] were judged to have an overall low risk of bias, supported by robust randomization procedures, preregistration, and appropriate handling of missing data. In contrast, the majority of RCTs were rated as having some concerns, largely attributable to open-label designs, limited blinding, or moderate levels of attrition [6,8,11-13,15-17].

For the nonrandomized and observational studies, the overall judgment was moderate to high risk of bias. Recurring limitations included self-selected or convenience sampling frames, absence of randomization and control groups, high attrition, and reliance on self-reported outcomes [7,9,18,19]. Despite these methodological weaknesses, these studies provided valuable evidence regarding feasibility, acceptability, and real-world engagement with CBT-based chatbots.

A detailed summary of risk of bias judgments across domains for each study is presented in Figure 1 and Table 2.

XSL•FO
RenderX

Figure 1. Risk of bias summary.

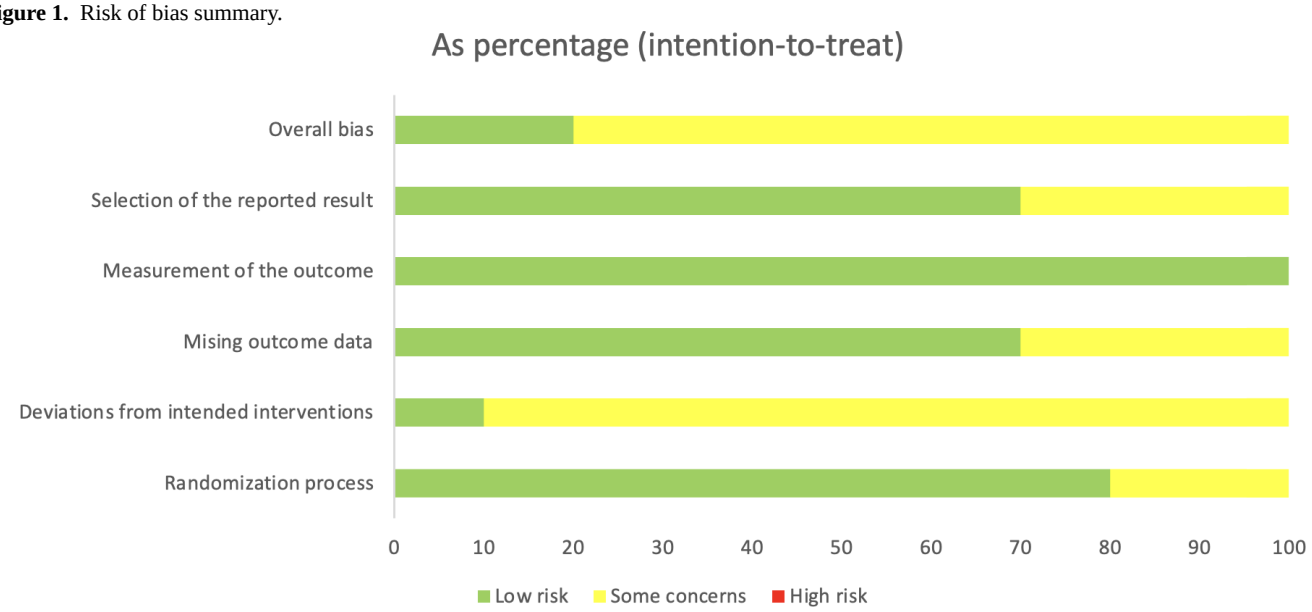

Table . Quality appraisal of observational studies using the AXIS[a] tool.

Study (Chatbot)	Total score (out of 20)	Overall risk	Notes
Prochaska et al [18] (Woebot-SUD)	11/20	Moderate–high	Strength: clear aims, validated tools, ethics approval; weakness: convenience sampling, high attrition (~50%), no control group
Inkster et al [7] (Wysa)	10/20	Moderate–high	Strength: validated PHQ-9[b], transparent reporting; weakness: self-selected users, inclusion only of ≥2 datapoints, high attrition, limited ethics reporting
Mehta et al [9] (Youper)	13/20	Moderate–high	Strength: very large N (4,517), multilevel models, validated GAD-7[c]; weakness: modified PHQ-9, female-dominant, self-selected paying users
Habicht et al [19] (Limbic Care)	15/20	Moderate–high	Strength: NHS[d] service setting, routine PHQ-9/GAD-7, regression with covariate adjustment, ethics via NHS audit; weakness: self-selection of tool use, nonrandomized design

User Engagement and Acceptability

To provide context for interpreting efficacy, engagement outcomes are presented first. Engagement was defined variably across studies as program completion, threshold number of sessions, weekly active use/retention, or service-level attendance and dropout.

Completion rates in RCTs generally ranged from ~50% to 85%. For example, the postpartum Woebot trial [12] reported a 74% completion rate and 91% satisfaction, whereas Tess [8] reported virtually no attrition over 2 to 4 weeks. In contrast, Woebot-SUD [18] showed high attrition (~50%). Observational studies demonstrated dose–response relationships, such as Wysa users engaging ≥2 times per week experiencing >5-point reductions in PHQ-9 [7] and Youper users (n=4517) achieving an average 3.6-point PHQ-9 reduction within 2 weeks with higher usage intensity [9]. In a service context, the NHS evaluation of Limbic Care [19] found attendance increased by 42% and dropout decreased by 23% compared to usual care.

Detailed engagement definitions and metrics for each study are summarized in the *Main findings* column of Table 1, with "NR" indicated when not reported.

XSL•FO
RenderX

Therapeutic Alliance

Therapeutic alliance was not uniformly assessed across studies. When measured, standardized or study-specific instruments were used. For example, Heinz et al [17] applied the Working Alliance Inventory–Short Revised and reported moderate alliance scores (mean ≈3.6). He et al [10] used study-specific items and found significantly higher alliance for XiaoE compared to an e-book control. Most other studies, including the postpartum Woebot trial [12], did not directly assess alliance but instead reported satisfaction or usability.

For transparency, alliance measurements are indicated in the *Main findings* column of Table 1, with "NR" used when not reported.

Safety and Adverse Events

No study reported any serious adverse events directly attributable to chatbot use. Several platforms incorporated basic safety protocols, such as crisis keyword detection (eg, suicidal ideation) and automated referral messages to emergency resources. However, adverse event reporting was inconsistent and often not provided and is therefore indicated as NR. These details are summarized in the *Main findings* column of Table 1.

Efficacy of CBT Chatbots for Depression and Anxiety

To ensure consistency across studies, efficacy outcomes are reported in a standardized manner: effect sizes with 95% CIs are presented when available; when not reported in the original study, point reductions on validated measures (eg, PHQ-9 and GAD-7) are included; if neither were available, findings are described narratively. This convention is reflected in Table 1, where studies with unreported data are indicated as NR.

Across the 14 included studies, CBT-based chatbots consistently demonstrated short-term reductions in depressive symptoms, whereas findings for anxiety symptoms were mixed: some trials reported improvements, whereas others found no significant effects or did not report anxiety outcomes. Table 1 provides an overview of each study's sample, intervention, and outcomes. In the first RCT of a mental health chatbot, college students who interacted with Woebot for 2 weeks showed a greater decrease in depression (PHQ-9 scores) compared to an information-only control group [6]. Woebot delivered CBT strategies, including psychoeducation, cognitive restructuring, and behavioral activation. The between-group effect size for depression was moderate (d≈0.44), whereas anxiety symptoms did not differ significantly between groups. Similarly, Fulmer et al [8] found that students using the SMS text messaging–based chatbot Tess for 2 to 4 weeks reported significantly lower depression and anxiety levels postintervention than those using a psychoeducational e-book. The observed effect size for depression in that study was moderate-to-large (d=0.68), and no attrition was reported in the chatbot group.

Subsequent RCTs supported these findings. A 3-arm trial in China demonstrated that XiaoE, a CBT chatbot, produced significantly greater reductions in depressive symptoms compared to both a minimal control (e-book) and a nontherapeutic chatbot control, with a between-group effect size of d≈0.5 [10]. Users also reported higher therapeutic alliance and acceptability than those in the control groups. In Poland, Karkosz et al [15] evaluated the Polish-language chatbot Fido, which yielded significant reductions in both PHQ-9 and GAD-7 scores among subclinical young adults.

More recent RCTs extended this evidence. Shin et al [14] tested Somzz, a CBT for insomnia (CBT-I) chatbot, among Korean adults with insomnia and found large improvements in insomnia severity index (ISI, d>1.0) with modest or nonsignificant changes in depression and anxiety. Mason et al [16] reported that symptom improvements from an 8-week SMS text messaging–based CBT chatbot (CBT-TXT) were sustained at 3-month follow-up, whereas MacNeill et al [13] found that initial gains in adults with chronic conditions were not maintained without ongoing support.

Most recently, Heinz et al [17] conducted the first RCT of a generative AI therapy chatbot, Therabot. In this 4-week trial with 210 US adults presenting with depression, anxiety, or eating concerns, Therabot users showed significantly greater symptom improvements compared to a waitlist control group. The effect sizes were large for depression (d≈0.85), anxiety (d≈0.84), and eating concerns (d≈0.82), demonstrating the potential of generative AI to achieve clinical benefits comparable to traditional CBT.

Beyond controlled trials, real-world observational studies confirmed the feasibility of CBT chatbot use. In a large naturalistic sample (n>4500), Mehta et al [9] reported that Youper users experienced an average 3.6-point reduction in PHQ-9 scores within the first 2 weeks. Similarly, Inkster et al [7] found that Wysa users who engaged with the chatbot at least twice per week over 2 weeks reported PHQ-9 reductions of more than 5 points, suggesting a dose–response relationship between chatbot engagement and symptom improvement.

In the UK NHS Talking Therapies program, Habicht et al [19] evaluated Limbic Care, a generative AI (GenAI)–enabled support tool integrated with group CBT. In this multisite observational cohort (n=244), patients who used the AI tool demonstrated a 25-percentage-point higher recovery rate, 21-point higher reliable improvement, and 23% lower dropout compared to those receiving standard care alone.

In summary, CBT-based chatbots appear to offer meaningful short-term relief for depressive symptoms, whereas the evidence for anxiety outcomes remains mixed, with some studies reporting benefits but others showing nonsignificant or unreported effects. Evidence from both RCTs and real-world implementations supports their feasibility and acceptability. Emerging evidence also highlights the potential of generative AI chatbots (eg, Therabot and Limbic Care) to achieve substantial clinical effects and improve engagement, although further research is needed to confirm long-term safety and efficacy.

Therapeutic Mechanisms and Implementation Characteristics of CBT Chatbots

Beyond symptom outcomes, included studies revealed 6 consistent therapeutic mechanisms used by CBT chatbots, as detailed in Table 3. These mechanisms align with the

XSL•FO
RenderX

foundational components of face-to-face CBT and have been adapted for digital delivery through structured conversation modules and affect-sensitive prompts.

XSL•FO
RenderX

Table . Therapeutic mechanisms implemented in cognitive behavioral therapy–based chatbots, corresponding psychological effects, representative chatbot platforms, and illustrative examples of user-chatbot dialogue scripts.

Therapeutic mechanism	Main effect	Applied chatbot	Example of specific conversation script	Study
Cognitive restructuring	Depression; anxiety reduction; and decrease in negative thinking and cognitive distortions	Woebot, XiaoE, Youper, Fido, Therabot	*Woebot: Was there a hard time today?* *User: I made a mistake at the meeting and thought everyone believed I was incompetent.* *Woebot: Is there evidence that supports that idea is true?* *User: Nobody said that.* *Woebot: Can you interpret this situation from a different perspective?* *User: I guess one mistake doesn't mean I'm incompetent.*	[6,9,10,12,15,17,18]
Behavioral activation	Increased activity and improved mood; reduction in depression and insomnia	Woebot, Wysa, Somzz, XiaoE, Youper, Therabot, Shim, CBT-TXT, Fido	*Wysa: Let's set a small activity that can make you feel better today.* *User: I'm going to walk every morning.* *Wysa: It's a good choice! Let's decide what time you want to walk tomorrow.* *User: I'll go out at 7 o'clock.* *Wysa: It's a nice plan. Shall we record your feelings tomorrow?*	[6,9-18]
Relaxation and mindfulness	Reduced anxiety and stress; improved sleep quality and emotional calmness	Somzz, XiaoE, Wysa	*Somzz: What have you tried to reduce tension before sleep?* *User: I haven't done much.* *Somzz: Good. Let's take a deep breath together for 5 minutes. Inhale deeply and slowly exhale.* *(After practice)* *Somzz: Are you a little more comfortable?*	[10,13,14]
Emotional expression and support	Reduction in depression and anxiety; enhanced alliance; and reduced isolation	Woebot, Tess, Wysa, XiaoE	*Tess: What happened today?* *User: I argued with my friend and feel lonely.* *Tess: It's natural to feel that way. Thank you for telling me.* *Wysa: Can you talk more about the feelings you felt in that*	[6-8,10,12,13]

XSL•FO
RenderX

Therapeutic mechanism	Main effect	Applied chatbot	Example of specific conversation script	Study
Self-monitoring and feedback	Reduction in depression and anxiety; and improved self-efficacy	Woebot, Youper, XiaoE, Limbic Care, Wysa	*Woebot: Did you have a moment today when you experienced emotional changes?* *User: I felt bad after I quarreled with my friend this morning.* *Woebot: What if you express your feelings in words?* *User: Anger.* *Woebot: Good. Let's think about the message that feeling conveys. Perhaps you want to be understood.*	[6,7,9,10,18,19]
Therapeutic alliance formation	Increased user participation, sustainability, symptom relief, and reduced loneliness	Woebot, Tess, Wysa, XiaoE, Therabot	*User: I can't talk to anyone these days. I feel so lonely.* *Wysa: It's natural to feel lonely. I understand that feeling.* *Wysa: This space is safe for you to express all your emotions. Let's get through this together.* *User: Thank you. Just being listened to helps me feel a little better.* *Wysa: I'm always here. You are not alone.*	[6-8,10,12,13,17]

Cognitive Restructuring

Cognitive restructuring is a central element in CBT, involving the identification and correction of maladaptive thinking. CBT chatbots such as Woebot and XiaoE, Fido, Youper, and Therabot facilitated the identification and reframing of negative thoughts using Socratic questioning. For example, users were prompted with questions such as "Is there evidence for that belief?," which led them to reframe maladaptive cognitions. Studies confirmed that this process significantly contributed to symptom improvement [6,10]. Mason et al [16] further showed that reductions in cognitive distortions were associated with improvements in depressive symptoms, consistent with mediation, although formal mediation analyses were not conducted. Cognitive distortions were measured using the Cognitive Distortions Scale.

Behavioral Activation

Another key therapeutic component is behavioral activation, aimed at increasing engagement in goal-directed activities. Woebot encouraged weekly goal setting, whereas Wysa and Fido suggested personalized tasks, and other platforms such as XiaoE, Somzz, Youper, Therabot, Shim, and CBT-TXT also integrated behavioral activation strategies (eg, planning pleasant events, scheduling exercise, or assigning weekly activity tasks). These interventions promoted daily structure, increased activity levels, and reduced avoidance behaviors, contributing to improvements in affect and functional outcomes [6,10,13,15]. Mason et al [16] also found that increases in behavioral activation were associated with improvements in depressive symptoms, in a manner consistent with mediation, although formal mediation analyses were not performed. Behavioral activation was assessed using the Behavioral Activation for Depression Scale.

Relaxation and Mindfulness

Several CBT chatbots (eg, Somzz, XiaoE, Wysa, and Tess) incorporated structured stress-regulation techniques, including breathing exercises, mindfulness prompts, and grounding strategies. These tools promoted autonomic calming and attentional shift. User feedback emphasized the utility of such exercises for managing anxiety and enhancing emotional calmness [7,8,11]. He et al [10] further reported that the inclusion of mindfulness modules was linked to higher satisfaction and stronger alliance scores.

Emotional Expression and Support

CBT chatbots provided a psychologically safe environment where users could articulate emotions without judgment. Woebot, Tess, Wysa, and XiaoE all featured empathetic design elements that validated user emotions and reduced feelings of isolation. Wysa users frequently reported feeling emotionally supported, often citing phrases such as "You're not alone" as impactful [7]. Fulmer et al [8] showed that supportive SMS text messaging design in Tess increased positive affect, and XiaoE trials demonstrated similar benefits through empathic dialogue.

XSL•FO
RenderX

Self-Monitoring and Feedback

Self-monitoring and feedback were common features in Woebot, Youper, XiaoE, Wysa, and Limbic Care. These platforms incorporated mood check-ins, symptom tracking (eg, PHQ-9 and GAD-7), and personalized feedback loops. Such features helped users recognize symptom patterns and reinforced self-management behaviors. For instance, Youper's regular mood check-ins contributed to a 3.6-point PHQ-9 reduction within 2 weeks [9], and Wysa data showed that higher engagement was linked to PHQ-9 reductions of over 5 points [7]. The NHS evaluation of Limbic Care also highlighted its role in providing between-session monitoring and feedback in real-world care pathways.

Development of Therapeutic Alliance

Although chatbots lack human warmth, several studies demonstrated the formation of moderate therapeutic alliance, which promoted sustained engagement and adherence. Alliance was reported or inferred in Woebot, Tess, Wysa, XiaoE, and Therabot. For example, XiaoE users reported higher alliance scores compared to e-book controls [10], whereas Therabot measured alliance using the standardized Working Alliance Inventory–Short Revised and showed moderate levels (mean≈3.6). Wysa users also described a strong sense of rapport, and Woebot/Tess used supportive and empathetic language that fostered trust. Although not equivalent to human-delivered therapy, these alliances contributed to a virtuous cycle of engagement and symptom improvement.

Comparative Analysis of Technological and Clinical Features of CBT Chatbots

CBT-based mental health chatbots vary widely in their technological design, therapeutic protocols, usability, and patterns of user engagement. A systematic comparison of these characteristics is essential for evaluating their clinical feasibility and technical robustness while also informing the development of next-generation digital mental health interventions. Table 4 presents a comparative summary of key CBT chatbot platforms, including launch year, core AI methods, therapeutic strategies, evidence from empirical studies, and user engagement indicators.

XSL•FO
RenderX

Table . Comparison of major AI[a]-based mental health chatbots in terms of developer or organization, core AI technologies, implemented CBT[b] therapeutic protocols, usability, and user engagement. All listed chatbots deliver CBT-based content but differ in conversational style, technical architecture, and adaptivity. "Usability/acceptability" is summarized from user feedback, satisfaction surveys, and system usability scales. "User engagement" reflects indicators such as program completion rates, frequency of use, retention, and dropout. "Partial" indicates limited or indirect implementation of a feature. "NR[c]" denotes information not reported in the study.

Chatbot (developer)	AI technology	Therapeutic protocol						Usability/acceptability	User engagement
		Cognitive restructuring	Behavioral activation	Relaxation mindfulness	Emotional support	Self-monitoring	Therapeutic alliance		
Woebot (Woebot Health, USA)	NLP[d], emotion recognition, RNN[e]/transformer-based language model, ML[f]	✓	✓	✓	✓	✓	✓	Very high	Very high
Tess (X2AI/Cass, USA)	NLP, emotion analysis, rule-based system	✓		✓	✓	✓	✓	High	Moderate

AI Architecture and Language Design

Early CBT chatbots such as Woebot and Tess were built on rule-based frameworks using decision trees and clinician-authored dialogue scripts. These systems rely on predefined response options triggered by user input, often supported by keyword or sentiment recognition algorithms [6,8]. For example, Woebot used natural language pattern matching to select the most relevant therapist-approved response, ensuring therapeutic consistency and risk minimization. Tess operated similarly, delivering structured interventions via SMS text messaging. While this rule-based approach promotes safety and reliability, it limits scalability and often results in repetitive or nonpersonalized conversations.

Recent developments have introduced more flexible hybrid models. Wysa, for instance, applies sentiment analysis and intent recognition to select responses from a large database, balancing variation with control [7]. Youper combines structured CBT strategies with more advanced NLP, enabling emotionally attuned and dynamic dialogue. To mitigate clinical risks, these hybrid systems still incorporate rule-based safeguards for screening user input and directing users to emergency services when necessary. Youper's successful deployment, with more than 4500 users retained within 1 month [9], demonstrates the scalability of such hybrid approaches.

Structure of Therapeutic Protocols

CBT chatbots differ in the structure and flexibility of their therapeutic content. Woebot offers structured, sequential modules (eg, a 2-week program focusing on cognitive restructuring followed by behavioral activation). In contrast, Wysa and Tess provide nonlinear, user-initiated conversations that allow for spontaneous topic switching and indefinite usage duration. Fido represents a hybrid model with an 8-week structured CBT program supplemented by on-demand conversational support between sessions [13].

These structural variations influence research methodology: modular interventions are typically evaluated through RCTs, whereas open-ended chatbots are assessed in real-world observational studies or mixed-method designs [7,9]. Each design has inherent trade-offs—modular programs offer higher experimental control and fidelity, whereas open-ended systems may provide enhanced ecological validity but present challenges for standardization. These findings highlight that the structural format of chatbot protocols interacts meaningfully with both clinical outcomes and user engagement metrics.

Usability and User Engagement

User-centered design and ease of access are critical to the success of chatbot-based interventions. Across platforms, most CBT chatbots received high usability ratings. For instance, in a postpartum trial, 91% of Woebot users reported satisfaction and 74% completed the full 6-week program [12]. Tess showed near-zero dropout among university students [8]. Longitudinal usage data from Wysa revealed that 33% of users remained active after 2 weeks, and approximately 20% engaged with the chatbot at least twice weekly [7]. These retention figures exceed those of most stand-alone wellness apps and underscore the importance of accessible design and behavioral nudges (eg, reminders and supportive messages).

However, several challenges remain. Users in multiple studies cited limitations such as repetitiveness and reduced emotional depth [6,7]. Some users expressed a preference for more emotionally intelligent and context-aware dialogue. Moreover, while most chatbots include safety protocols to detect crisis keywords (eg, suicidal ideation), these responses are often basic and lack localized nuance or empathic richness. Chatbots operating in linguistically under-resourced contexts, such as Korean, Arabic, or Swahili, face additional challenges due to the limited availability of annotated NLP corpora, which may compromise semantic accuracy and emotional responsiveness. Nonetheless, promising evidence supports their cross-linguistic viability. For example, Shin et al [14] evaluated a Korean-language CBT-I chatbot and found high levels of satisfaction alongside significant reductions in insomnia symptoms. This underscores the importance of ongoing investment in multilingual NLP development to promote global mental health equity.

Discussion

Key Findings and Implications

This review of 14 studies indicates that CBT-based chatbots can produce measurable short-term reductions in depressive symptoms, with mixed evidence for anxiety outcomes. These findings align with prior evidence [6,20,21] while also resonating with recent developments in the field of digital mental health. In particular, emerging GenAI chatbots, such as Therabot [17] and Limbic Care [19], have demonstrated substantial clinical benefits and improved engagement, providing complementary evidence that automated conversational agents can be effective in diverse settings. Taken together, these results suggest that CBT-based chatbots may hold promise as adjuncts to mental health care while also underscoring significant challenges that need to be addressed before widespread integration into routine practice.

Consistent with previous research, CBT-informed chatbots generally outperformed passive controls, such as waitlists or psychoeducational apps, in terms of symptom reduction, emotional relief, and user engagement. While results against

XSL•FO
RenderX

active comparators (eg, human-guided therapy or coaching apps) were mixed, these tools consistently demonstrated moderate effect sizes for depressive symptoms, underscoring their potential as first-line or supplementary digital interventions.

The therapeutic mechanisms observed across studies closely mirrored the foundational components of CBT, including cognitive restructuring [16], behavioral activation, mindfulness-based stress regulation, and simulated empathic interaction [8,10]. These features were delivered through structured, interactive dialogue that enabled users to challenge maladaptive cognitions, build adaptive behavioral routines, and receive emotionally validating responses. Many chatbots implemented a CBT-consistent therapeutic loop in which cognitive change facilitated symptom relief and behavioral re-engagement—a digital analog of the traditional CBT model [21]. Conceptually, such systems can be described as "cognitive-affective artifacts"—designed tools that modulate cognitive and affective states to support therapeutic processes.

In addition to clinical effectiveness, CBT chatbots offer advantages in scalability, anonymity, and 24/7 accessibility. Their use has been successfully demonstrated in diverse populations, from college students to postpartum women [8,12]. These platforms may serve not only as symptom management tools but also as low-threshold entry points for psychological support—functioning as digital companions during acute distress or between therapy sessions [7].

Nevertheless, several challenges remain. Although no study reported serious adverse events, most samples involved individuals with mild-to-moderate symptoms, raising concerns about applicability in more severe cases. For individuals with severe depression, psychosis, or suicidal ideation, chatbots should be integrated into a broader care plan with robust crisis intervention protocols [22]. Variability in study designs, comparator conditions, outcome measures, and chatbot platforms further complicates direct comparisons, a challenge also noted in recent reviews such as Zhong et al [20]. Standardized evaluation frameworks are needed to address this heterogeneity.

Future Research Priorities

First, longitudinal studies are essential to determine whether short-term benefits persist over time. Some findings suggest that gains diminish after the intervention period [13,22], whereas others indicate sustained effects when usage is extended or supplemented with booster sessions. Second, adaptive machine learning could enhance personalization by tailoring content, pacing, and dialogue dynamically to user characteristics, thereby improving alignment and retention. Third, the integration of generative large language models such as ChatGPT or GPT-4 may deepen conversational empathy and alliance but must be paired with rule-based safeguards and clinical oversight to prevent misinformation or ethical risks [21]. Finally, broader policy and implementation issues require attention, including regulatory oversight (eg, FDA SaMD frameworks), privacy and data security (Health Insurance Portability and Accountability Act/General Data Protection Regulation compliance), and financial sustainability models to support scalable integration into health care systems.

Attention should also be directed to linguistic and cultural inclusivity. Encouraging results from non-English platforms, such as the Korean-language CBT-I chatbot studied by Shin et al [14], demonstrate that CBT-based interventions can be adapted effectively to diverse sociocultural contexts. Investment in multilingual NLP and culturally sensitive design will be critical for equitable global dissemination.

Limitations

This review has several limitations. First, the evidence base remains limited in scope and quality: many studies involved small samples, short intervention periods, and heterogeneous outcome reporting, with moderate risk of bias in several cases. Moreover, most included chatbots were rule-based systems, with only a few recent platforms (eg, Therabot and Limbic Care) incorporating generative AI, constraining generalizability. Second, as a narrative review, this synthesis is inherently subject to selection bias, interpretive subjectivity, and potential publication bias, despite the use of predefined inclusion criteria and dual-reviewer procedures. Future research should examine whether emerging generative AI chatbots differ in efficacy, engagement, and safety compared with traditional rule-based designs.

Conclusions

CBT-based chatbots represent a clinically grounded, scalable, and contextually adaptable modality for mental health care delivery. They hold particular promise for increasing access to evidence-based support in underserved populations. As this technology continues to mature, future efforts should emphasize long-term efficacy, adaptive personalization, clinician-guided integration, and rigorous ethical oversight. Recent advances in generative AI chatbots (eg, Therabot and Limbic Care) further highlight both opportunities and challenges for implementation. Rather than replacing human therapists, chatbot systems are best positioned to augment existing services and bridge care gaps in increasingly strained global mental health systems.

Abstract

Background: Mood monitoring and ambulatory assessment offer improvements in measuring mood and behavior for mental health research and clinical practice. However, concerns about adverse effects and usability may hinder their implementation.

Objective: This systematic review and meta-analysis assessed the prevalence of adverse events, barriers and facilitators to use, and suggestions for improvement in quantitative mood monitoring studies involving people with depression and bipolar disorder.

Methods: We conducted a systematic review and meta-analysis of 77 quantitative studies that used mood monitoring or ambulatory assessment in depression and bipolar disorder, assessing adverse events, barriers and facilitators to use, and suggestions for improvement. Adverse events data were pooled to identify prevalence.

Results: Of the 77 studies, 15 (19%) reported adverse events, and 20 (26%) reported usability issues. Pooled prevalence of adverse events was 0.04 (95% CI 0.03-0.06; *P*<.001). Specific adverse effects included increased burden or stress (0.04, 95% CI 0.02-0.07; *P*<.001), mood worsening (0.02, 95% CI 0.01-0.02; *P*=.001), self-harm (0.05, 95% CI-0.02 to 0.10; *P*=.007), and hospitalization (0.06, 95% CI 0.04-0.09; *P*=.26). The top facilitators were perceived helpfulness and ease of use, the top barriers included technical challenges and the time-consuming nature of the interventions, and the top suggested improvement was personalization.

Conclusions: A small number of mood monitoring or ambulatory assessment users experienced negative psychological effects; however, we were unable to infer causality. Due to the severe underreporting of adverse events as well as heterogeneity and publication bias in the included studies, there was limited certainty in the prevalence, duration, and severity of these adverse events. More systematic monitoring of adverse events is needed to optimize safety and usability. Many mood monitoring protocols may require additional development to decrease adverse events and improve acceptability.

Introduction

This review analyzes adverse effects associated with mood monitoring, mood tracking, and ambulatory assessment in people with unipolar depression and bipolar disorder (BD). Ambulatory assessment encompasses a diverse set of methods that use mobile technology to collect repeated measurements from participants, often in real time and in natural settings [1]. It includes mood monitoring, remote measurement technologies (eg, wearables that passively collect data), and ecological momentary assessment (EMA; a more intensive form of data collection involving multiple reports per day [2]). Some studies of mood monitoring also fall under EMA, remote measurement, or ambulatory assessment, and there is definitional overlap

XSL•FO
RenderX

among these approaches. Mood monitoring can be used as an intervention (in both randomized controlled trials [RCTs] and nonrandomized studies) or as a method of outcome assessment (also in both RCTs and nonrandomized studies).

Technological advances (eg, wearables and smartphone sensors) have improved the potential of mood monitoring via novel methods of active (manual input) and passive (automatic) data collection [3]. These measures have many promising potential use cases, but smartphone-based ambulatory assessment tools may present unique risks, particularly in populations considered vulnerable [4]. While ambulatory assessment, mood monitoring, and EMA are performed in diverse populations for a wide variety of reasons (eg, dietary studies in healthy volunteers [5]), we chose to focus on people with unipolar depression and BD because evidence suggests that the risks in this population are unique [6,7]. Ambulatory assessment in psychiatric disorder also presents unique opportunities as well as challenges, given the difficulty of measuring rapidly shifting psychopathology with conventional measurement scales [8].

The risks of mood monitoring can be higher in self-guided apps, which have fewer built-in safety mechanisms to monitor user safety in real time [9]. Research on psychological treatments has historically focused on benefits rather than any negative psychological experiences [10]. Awareness of adverse events from internet- or app-based interventions is growing, and key academics have proposed consensus statements to guide future research on adverse events in this context [9,11,12]. This includes how to report, assess, and define adverse effects. The occurrence of adverse events may or may not be directly related to the treatment being used, and this review cannot assess causality [9,10]. Adverse effects of psychological interventions can range from mild experiences (eg, privacy concerns and frustration) to severe outcomes (eg, hospitalization, suicidality, and self-harm) [10].

Previous research has raised concerns that self-monitoring protocols could contribute to the maintenance of depression in some participants due to a variety of mechanisms [6,13,14]. The protocols could worsen negative processing bias, as participants confront their distressing experiences on a daily basis. It could be a painful reminder of their mental health problems, for example, or cause them distress if they realize that their mood is worsening and feel powerless to change it. The process could also be a time-consuming burden to them that diverts energy from more therapeutic activities. This could partially explain the occasionally occasionally high attrition rates and poor adherence observed in some interventions [15]. There has been little research examining adverse events from ambulatory assessment use or self-monitoring activities. Fundamental questions remain about the negative effects of mood monitoring interventions and how they might be improved to maximize their usefulness for people with depression or BD. Mixed methods research offers good potential to elucidate some of these factors [16,17].

It is important to consider the risks to maximize the potential benefits of these advanced technologies. The promising potential applications of these electronic tools are summarized briefly here. They may improve on existing research methods by decreasing participant burden and allowing for a higher quality and granularity of mood assessment at decreased economic cost. They may also improve the recall bias associated with some measures of psychopathology [18]. They may help in the treatment of depressive illness by detecting early behavioral change and allowing earlier intervention, potentially allowing individuals with depression to self-manage their condition. They may also help define clinical goals collaboratively with clinicians or be used as research tools to identify digital depressive phenotypes to potentially improve treatment personalization in mental health care. While compliance and acceptability have been studied extensively [7,15,19], there is limited understanding of the adverse effects of these ambulatory assessment approaches in clinical mental health care or research [20].

This is the first systematic review, to our knowledge, that assesses and quantifies adverse events in ambulatory assessment and mood monitoring studies. Specifically, we aimed to quantify the prevalence of adverse events and explore barriers and facilitators to use as well as any suggested improvements to identify common themes that may aid or hinder engagement with mood monitoring protocols. We chose to examine adverse events in studies where mood monitoring was used as an intervention (in both RCTs and nonrandomized studies) or as a method of outcome assessment (also in both RCTs and nonrandomized studies) because both these use cases are important to people with BD and depression, and both use cases have reported qualitative data on adverse events [6]. As we reviewed evidence of varying types, we are unable to make any definitive comments on the causality of the adverse events.

Methods

We used a methodology based on the Cochrane Handbook for Systematic Reviews of Interventions and completed a PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) checklist (Checklist 1). The study was preregistered with PROSPERO (CRD42023396473) [21].

Inclusion Criteria

We included studies if they met the following criteria: they involved self-monitoring, EMA, or repeated symptom assessment in people with BD or depression over a minimum period of 3 months, with symptom ratings conducted at least weekly. Each study was required to use a validated measure of mood or to validate the chosen measure against an established mood measure. Studies published in any language were eligible and could be either digital or nondigital, although we anticipated that the majority of studies would use digital technologies. We included RCTs or nonrandomized studies with 20 or more participants with BD or depression [22]. We chose a cutoff of 20 participants to include mood monitoring protocols that were closer to clinical implementation (eg, the National Institute for Health and Care Excellence frequently excludes studies of fewer than 20 participants in its reviews and guideline documents). Studies with fewer than 20 participants were also considered unlikely to have sufficient data on adverse events. We searched gray literature (eg, conference abstracts, dissertations, policy literature, and reports identified through ProQuest and Google

XSL•FO
RenderX

Scholar [for details, refer to the next subsection]) for unpublished studies that were eligible for inclusion.

Search Strategy and Selection Criteria

The complete search strategy is presented in Multimedia Appendix 1. We searched Ovid MEDLINE, Embase, PsycInfo, Scopus, IEEE Xplore, ProQuest SciTech Premium Collection, ProQuest Dissertations & Theses Global, and Google Scholar using the defined search terms. The initial search was conducted on March 3, 2023, and updated on October 28, 2024 [23]. All abstracts were appraised by two screeners, and any disagreements were discussed until consensus was reached, with adjudication by a third independent screener if required. The full text of potentially relevant papers was retrieved, and if unavailable, the corresponding author was contacted. To determine whether potentially relevant studies met the inclusion criteria, the full text was reviewed separately by two authors, again resolving discrepancies through discussion or, if necessary, consultation with a third author. Reference lists of included studies and relevant systematic reviews [13,14,24-31] were also screened to identify additional eligible studies. Key authors were contacted to inquire about any ongoing or unpublished studies that might meet the inclusion criteria.

Data Extraction

Two independent reviewers extracted data from studies meeting the inclusion criteria using identical data extraction forms. Any irregularities in the data extraction were discussed, and discrepancies were resolved through discussion. No deviation from the protocol registered with PROSPERO occurred. We defined an adverse event as any untoward or unintended medical occurrence in a participant, regardless of whether it was related to the intervention or investigation [32]. All adverse events were included in the results and assessed for relatedness to the mood monitoring protocol by two psychiatrists. Those deemed possibly related were then meta-analyzed. Because of confounding factors in the expected psychiatric deterioration in individuals with relapsing-remitting conditions, we were not able to make definitive inferences about adverse event causality.

Assessment of Study Bias

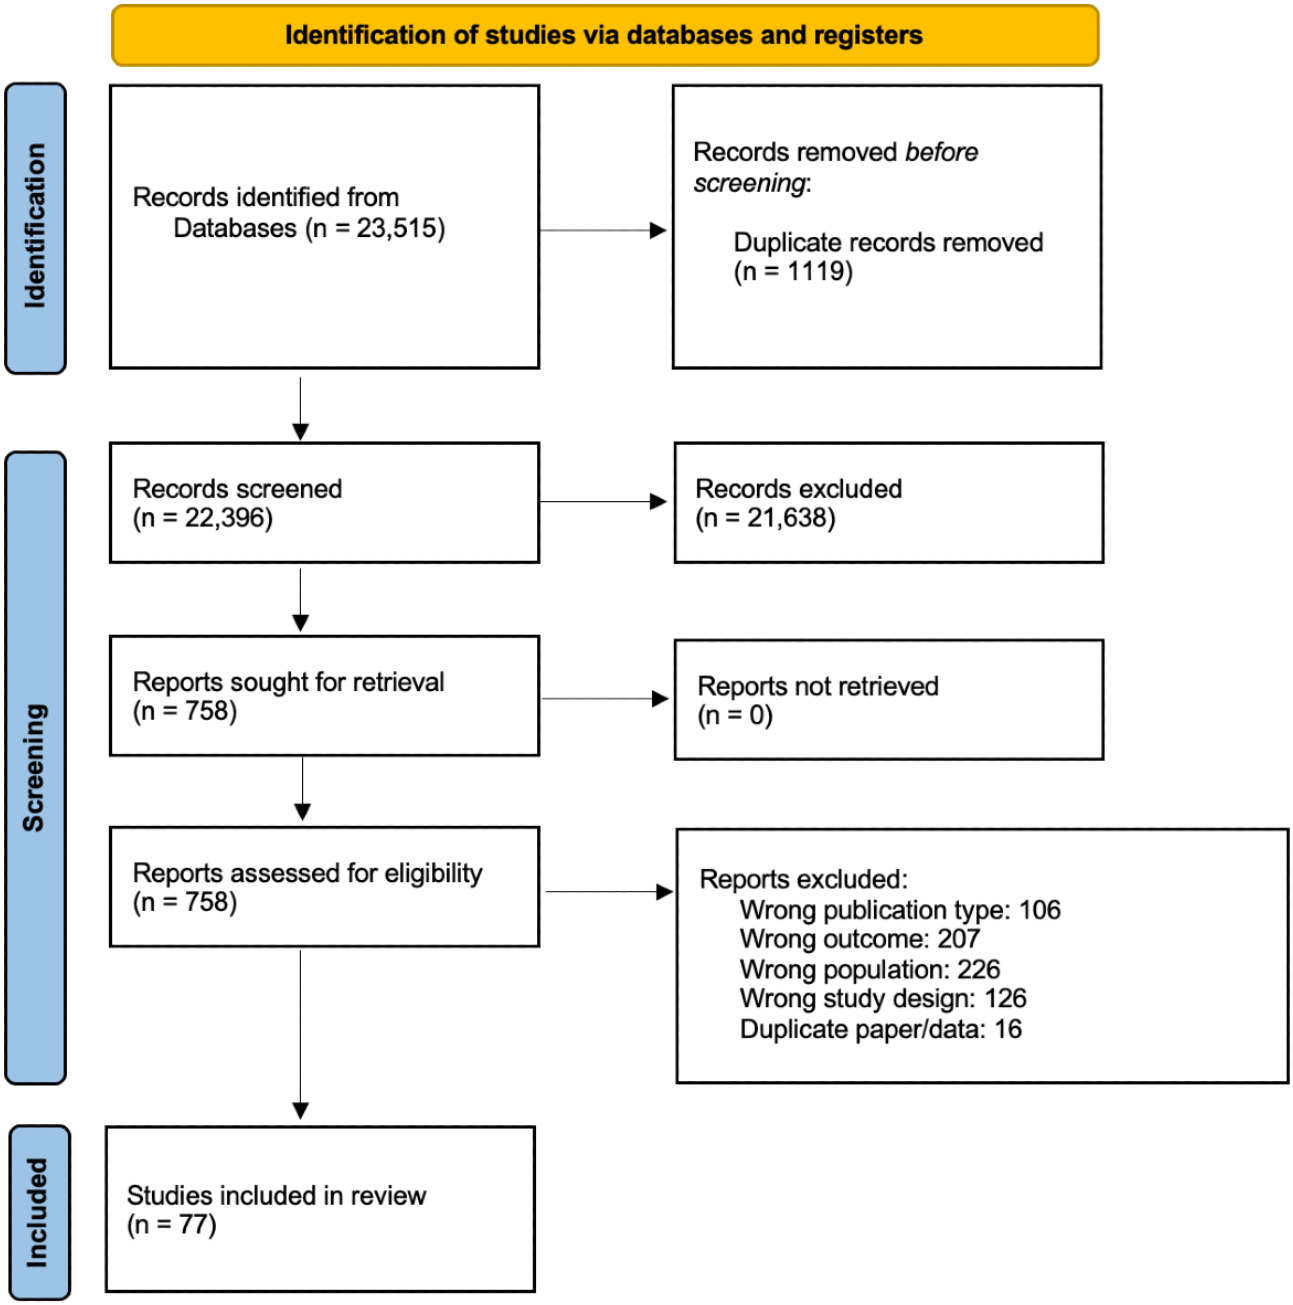
The Cochrane risk-of-bias tool (RoB 2) was used for RCTs [33], and the Cochrane risk of bias in nonrandomized studies of interventions tool (ROBINS-I) [34] was used for nonrandomized studies. Risk of bias was assessed by two independent reviewers, and any disagreements were resolved via discussion.

Synthesis of Results

For quantitative data, studies were grouped, where possible, according to the variable assessed (eg, adverse events such as self-harm or subjective worsening of mood), and data were pooled in a meta-analysis. We conducted a separate analysis for specific adverse events because we hypothesized that their prevalence would vary. The results of each primary study were pooled by means of an inverse variance–weighted approach with random or fixed effects models, informed by examination of between-study heterogeneity. Stata *metan* code was used to perform the analysis for proportion data. Comparisons with only 2 studies were excluded from any separate analysis.

For qualitative data, papers were read and reread by two independent reviewers. We assessed qualitative reporting of adverse events in the quantitative papers because we hypothesized that quantitative reporting might be limited [12]. Second-order constructs were extracted and managed using Microsoft Excel. Any disagreements were discussed until consensus was reached. Constructs were reviewed to assess how the themes juxtaposed and compared across studies. Reviewers independently reviewed the second-order constructs [35] and compiled third-order constructs [35,36] that summarized and encapsulated the various themes across the studies using NVivo 12 (Lumivero) [37]. These constructs were then refined through discussion between researchers until a shared understanding was reached.

The guidelines for meta-ethnography outlined by Noblit and Hare [38] were used to conduct the analysis. Noblit and Hare [38] proposed three ways to synthesize data: (1) reciprocal translation (where the findings of one study are understood in terms of findings expressed in other studies in the synthesis [39]) if the data are directly comparable; (2) refutational translation (which explains and explores inconsistencies, exceptions, and incongruities in the data between studies [40]) if the data are in opposition; and (3) an integrating approach that makes sense of the parts—a “line of argument” synthesis that uses both similarities and differences across the studies. Our assessment of the included studies showed consistent themes in terms of the adverse events reported in mood monitoring and ambulatory assessment protocols. Therefore, we used the “line of argument” approach to make sense of apparent contradictions in the data before integrating the emergent concepts into a framework of reported adverse events.



Results

Overview

The search identified 23,515 papers, of which 1119 (4.76%) were duplicates and removed. There were no studies reported in languages other than English that met the inclusion criteria. After title and abstract screening, 21,638 (96.61%) of the 22,396 papers were excluded, resulting in a total of 758 (3.5%) papers being reviewed in full. Of these 758 papers, 77 (10.2%) met the eligibility criteria. Of these 77 papers, 33 (43%) reported adverse events, usability issues, or feasibility issues and were included in the analyses. The PRISMA flow diagram is presented in Figure 1.

XSL•FO

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram showing the number of studies identified, screened, assessed for eligibility, and included in the final analysis.

The 77 included studies included 16,165 participants, and the 33 studies with usable data included 4949 participants. Tables S1 and S2 in Multimedia Appendix 1 present detailed characteristics of the studies and the mood monitoring protocols used, Table S3 in Multimedia Appendix 1 reports risk-of-bias assessments, and Table S4 in Multimedia Appendix 1 reports adverse event data. Tables 1-3 present facilitators, barriers, and suggested improvements, respectively, for mood monitoring protocols.

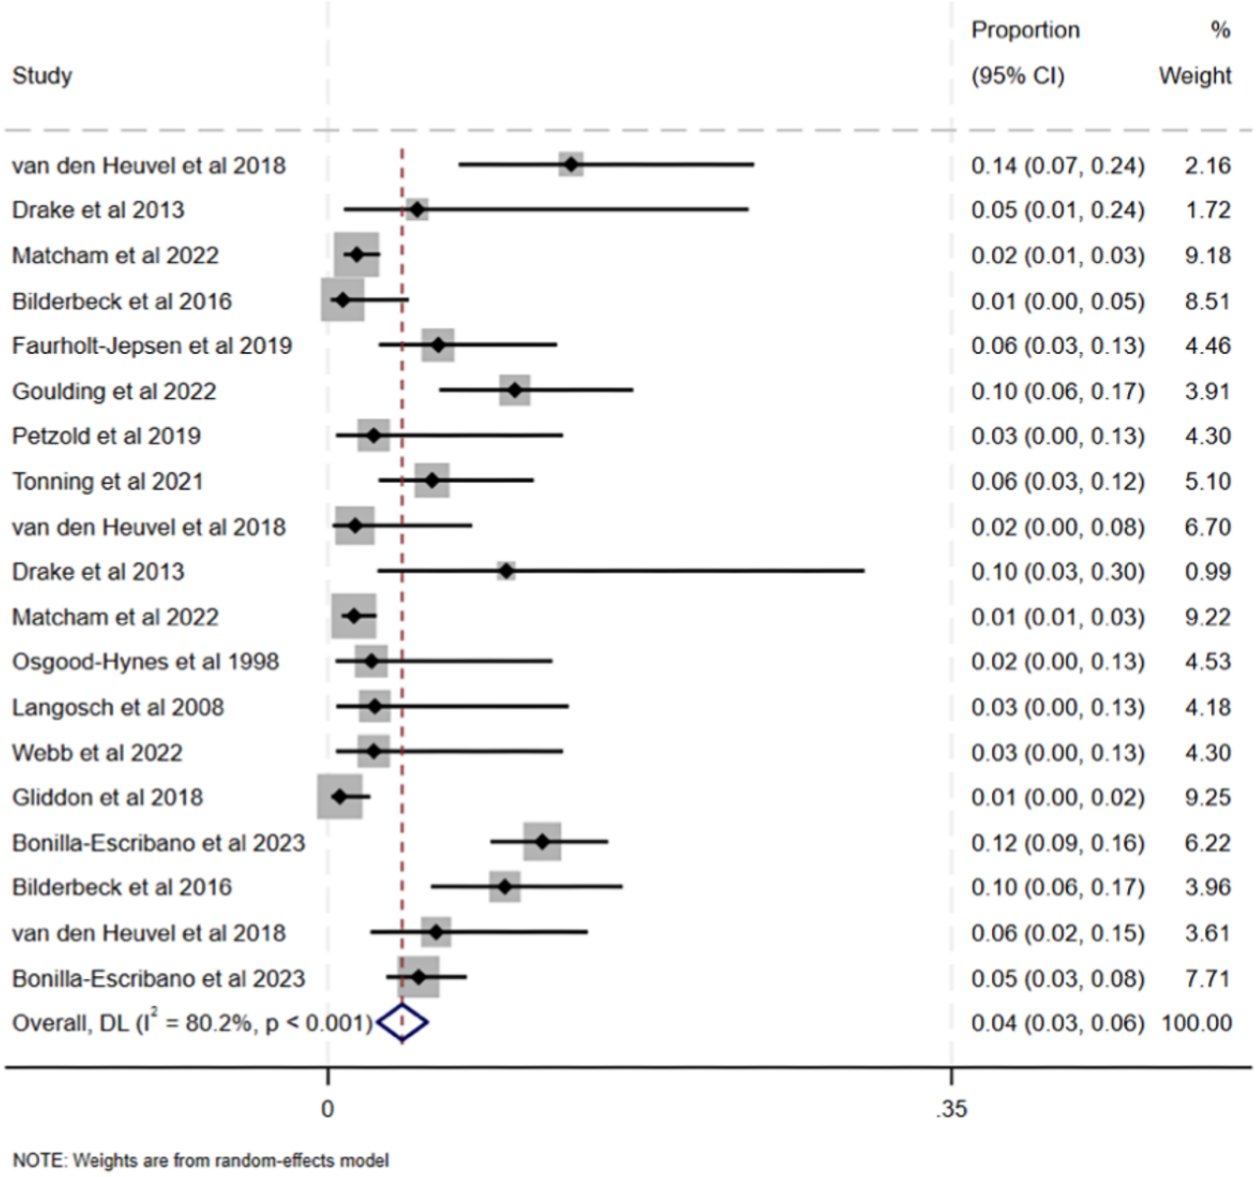
The 77 included studies used 54 different mood monitoring protocols, and these are reported in Tables S1 and S2 in Multimedia Appendix 1. Follow-up periods varied from 3 months [65] to 3 years [66]. All studies included participants with depression and BD; however, 3 (4%) of the 77 studies also included a mixed sample (individuals with other diagnoses were included) [55,67,68] (Tables S1 and S2 in Multimedia Appendix 1). All studies used adult samples, apart from the study by Webb et al [69], which used a sample of adolescents.

Of the 77 studies, 15 (19%) reported adverse events, and 20 (26%) reported acceptability or usability issues (Table S1 in Multimedia Appendix 1). In some situations, usability issues or barriers to use and adverse events overlapped (eg, worsening of mood and burden of mood monitoring). Only 3 (4%) of the 77 studies used validated outcome assessments to measure adverse events [70-72]. The studies that reported adverse events (15/77, 19%) [44,51,53,55,57,59,60,62-64,71,73-76] did so via attrition numbers, which do not capture the number of people who experienced adverse events but remained in the study. Of the 77 studies, 13 (17%) [54,57,60,62,63,68,72,77-81] explicitly reported whether a deterioration in mood had occurred.

Only 2 (3%) of the 77 studies [61,82] explicitly reported an absence of adverse events. A total of 25 adverse events that varied from mild to severe were reported in the included studies (15/77, 19%). These were classified according to relatedness to the mood monitoring protocol (Table S4 in Multimedia Appendix 1), and those that were possibly related and included 3 or more studies were meta-analyzed. The studies by Smit et al [64] (which reported worsening of mood in the context of antidepressant discontinuation) and Helmich et al [63] (which reported negative psychological symptoms in the context of receiving psychological therapy) were excluded from the meta-analysis due to these confounding factors in the relatedness of the adverse events and the ambulatory assessment. Furthermore, studies reporting relapse were not meta-analyzed because the rates for relapse (40% - 60%) were considered too high to be related to the mood monitoring.

Of the 77 studies, 15 (19%) reported severe adverse effects, some of which were thought to be possibly related to the intervention (Table S4 in Multimedia Appendix 1). Of the 77 studies, 15 (19%) reported hospitalization [42-44,54,55,57,59,60,62,70,80,81,83-85]. Some of the studies measured hospitalization but did not report this as an adverse event; in many studies of BD, relapse and hospitalization are seen as an unfortunate part of the disease process. Of the 77 studies, 3 (4%) [44,55,60] reported hospitalization as an adverse event, and these were included in the meta-analysis because they were deemed to be possibly related to mood monitoring.



Meta-Analysis

Total Prevalence of Adverse Events

Pooled prevalence of adverse events was 0.042 (95% CI 0.028-0.056; $P<.001$; Figures 2 and 3). Heterogeneity was high (Cochran $Q_{18}=91.00$; $P<.001$; $I^2=80.2\%$), demonstrating large between-study variability. Because of the pronounced heterogeneity, we used a random effects model to pool the data. The funnel plot for the total prevalence of adverse events demonstrated visual asymmetry, suggesting possible publication bias and small study effects in the meta-analytic estimate (Figure S1 in Multimedia Appendix 1). The Egger test demonstrated that there were small study effects (Figure S2 in Multimedia Appendix 1), suggesting possible publication bias.

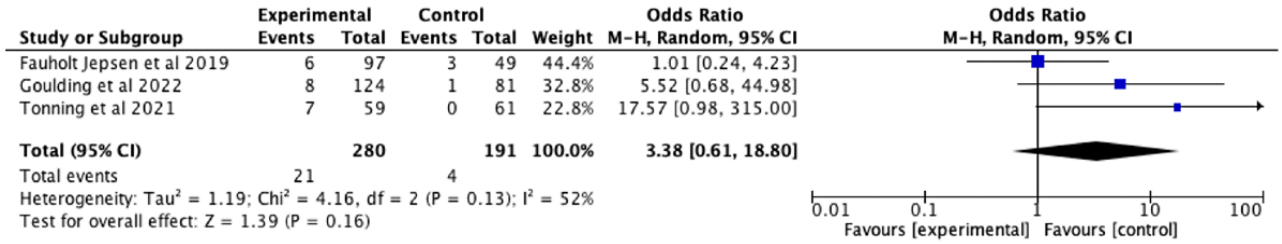
RenderX

Figure 2. Forest plot of prevalence of adverse events with percentage weighting [44,47,51,53,55,59,60,62,70,71,74,76,80].

XSL•FO
RenderX

Figure 3. Forest plot of prevalence of adverse events stratified by type of adverse event (negative psychological symptoms: too burdensome or stressful; negative psychological symptoms: subjective worsening of mood; self-harm; and hospitalization) [44,47,51,53-55,59,60,62,70,71,74,76].



Prevalence of Negative Psychological Symptoms: Too Burdensome or Stressful

Pooled prevalence of negative psychological symptoms: too burdensome or stressful was 0.04 (95% CI 0.02-0.07; *P*<.001). Heterogeneity was high (Cochran Q_7=26.31; *P*<.001; I^2= 73.4%), suggesting low-quality evidence that the prevalence of these negative psychological symptoms was related to mood monitoring.

We compared the difference in negative psychological symptoms: too burdensome or stressful in RCTs with an appropriate non–mood monitoring control group (Figure 4), which included 3 studies [57,59,62]. The pooled odds ratio was 3.38 (95% CI 0.61-18.80). Heterogeneity was moderate (τ^2=1.19; χ^{2}_{2}=4.2; *P*=.13; I^2=52%). There was no statistically significant difference between burdensome or stressful adverse events in mood monitoring controls and non–mood monitoring controls, but our analyses were limited by the paucity of data (*P*=.16).

XSL•FO
RenderX

Figure 4. Forest plot of odds ratios of negative psychological symptoms: too burdensome or stressful adverse events in randomized controlled trials comparing mood monitoring experimental arms versus non–mood monitoring control arms [54,59,62].

Prevalence of Negative Psychological Symptoms: Subjective Worsening of Mood

Pooled prevalence of negative psychological symptoms: subjective worsening of mood was 0.02 (95% CI 0.01-0.02; *P*=.001). Heterogeneity was very low (Cochran Q_3=1.77; *P*=.62; I^2= 0%), providing moderate evidence of a worsening of mood related to mood monitoring in 2% of the participants; however, as these data were from only 4 (5%) of the 77 nonrandomized studies reporting a rare outcome, the evidence is not robust enough.

Prevalence of Self-Harm

Pooled prevalence of self-harm was 0.05 (95% CI −0.02 to 0.10; *P*<.001). Heterogeneity was very high (Cochran Q_3=42.86; *P*<.001; I^2=93%), again suggesting low-quality evidence that the prevalence of self-harm was related to mood monitoring.

Prevalence of Hospitalization

Pooled prevalence of hospitalization was 0.06 (95% CI 0.04-0.09; *P*=.26). Heterogeneity was low (Cochran Q_2=2.70; *P*=.26; I^2=26.1%). Despite this nonsignificant relationship between mood monitoring and the risk of hospitalization, this remains a serious adverse event, and there should be improved monitoring of hospitalization that might be associated with mood monitoring.

Discussion

This systematic review assessed adverse events and examined acceptability and usability issues in mood monitoring and ambulatory assessment protocols. We investigated facilitators and barriers, as well as adverse effects, associated with mood monitoring among both people with depression and those with BD. Overall, the reporting of adverse events (15/77, 19%) and usability issues (20/77, 26%) was very poor, and we were unable to infer the causality of these adverse events. Furthermore, due to the severe underreporting of adverse events as well as heterogeneity and publication bias in the included studies, there was limited certainty in the prevalence, duration, and severity of these adverse events. The most frequent facilitators of mood monitoring were perceiving mood monitoring as helpful (9/24, 38%) and ease of use (10/24, 42%). The most common barriers to mood monitoring were that it was time consuming or that there were technical issues with the mood monitoring app (9/24, 38%). There were a range of suggestions for improvements, with the most common being a request for personalization of the app to the user's needs for mood monitoring. In terms of adverse events, evidence that approximately 2% (1/77) of people with depression or BD experience a lowering of mood with mood monitoring was the most robust. Evidence that mood monitoring might be burdensome to patients or lead to self-harm was of very low quality. There was no significant association between mood monitoring and hospitalization.

While many users found mood monitoring protocols to be therapeutic, our findings also demonstrate that a small number of users in these studies reported negative psychological effects. It is unclear whether this highlights a potential area for improvement or whether the relationship is noncausal. Our quantitative findings are in keeping with other reviews of adverse events in smartphone app interventions; for example, Linardon et al [9] found a deterioration rate of 6%. In our review, only a minority of the studies (17/77, 22%) explicitly reported adverse events, and only 12 (16%) of the 77 studies explicitly reported whether a deterioration in mood had occurred. Any adverse findings are important because mood monitoring measures are more commonly used in longitudinal studies. Negative experiences could obfuscate any positive effects if mood monitoring is used as an assessment measure in interventional studies.

While we cannot demonstrate here that mood monitoring causes a worsening of mood, this study identifies some plausible ways in which mood monitoring could potentially worsen mood or anxiety and potentially increase subjective stress. These include mood monitoring serving as an unwelcome reminder of mental illness, the burden of mood monitoring, the intervention being time consuming and repetitive, and technical problems that may frustrate users. Although these mechanisms remain speculative, other research suggests that rumination, perceived helplessness, and intrusive reminders may contribute to mood deterioration [6]. It was unclear whether these feelings of worsening mood were experienced by everyone or by only certain individuals, and not all studies reported negative psychological effects. However, some concerns were reported by participants in the majority of the studies (10/15, 67%; eg, increases in subjective stress). These adverse effects must be considered carefully when determining who may or may not benefit from these interventions moving forward. It may be necessary to incorporate additional therapeutic elements into the app to offset the negative effects or offer additional support to users.

By reviewing acceptability and usability issues of mood monitoring and ambulatory assessment protocols, we demonstrate the great potential to improve existing protocols to maximize acceptability, engagement, adherence, user experience, usability, and safety. The data on suggested

XSL•FO
RenderX

improvements were limited, with only 7 (9%) of the 77 studies reporting data, and included personalization (3/7, 43%) and additional human contact (2/7, 29%). Other research that has explored this in more detail concluded that users place high emphasis on personalization and customization and continue to greatly value human contact with their clinician—the tool is an aid to this contact, not a replacement for it [6]. Other research has suggested that personalization should be a core feature of any future protocol development to maximize successful implementation and uptake [6]. Qualitative research demonstrates that users desire an intuitive and easy-to-use passive data protocol that builds on their existing strengths, with high emphasis on personalization and customizability [6]. Such tools may allow users to self-manage their mood disorder in their own way while retaining control over their data. Reported types of personalization include data collection, data sharing, feedback provided, and methods of interaction with the protocol (eg, notifications or wearables) [6].

In terms of the limitations of the review, only a small proportion of studies provided data, and there was evidence of publication bias in reporting as well as high heterogeneity in some of the outcomes. Many studies were nonrandomized or observational with small sample sizes or few observation weeks. As some adverse events were rare, attribution to mood monitoring rather than another factor, such as concurrent treatment or natural history of the condition, requires caution, especially in relation to any inference of causality or precision in estimates of incidence. The review combined multiple heterogeneous studies, and while this is a common limitation of many systematic reviews, the heterogeneity in some analyses was substantial, decreasing certainty in the result of the analyses. We could not ascertain the causes of heterogeneity, but it may be due to the wide range of mood monitoring and assessment protocols used across the included studies. Given the limited number of high-quality RCTs comparing mood monitoring with appropriate controls, causal inferences could not be drawn. Moreover, as is typical when assessing adverse events, issues of attribution and relatedness limit causal interpretation [32].

The level of detail provided in these studies was limited, and it was difficult to establish whether the adverse effect was related to the intervention itself. Furthermore, many studies included a variety of features beyond mood monitoring, which made it challenging to isolate the specific negative effects of mood monitoring. There were limited data on the contextual factors that might influence participants' experiences of mood monitoring in depression. These factors include differences between digital and nondigital formats; wearable and nonwearable devices; active and passive data collection; EMA and non-EMA designs; interventions with therapeutic elements and those without; and human-, avatar-, and digitally supported interventions. Participant-related factors such as country income level, age, depression severity, ethnicity, gender, socioeconomic status, and disability were also underrepresented [6]. Nonetheless, this review focuses on actual intended use based on empirical data, often over prolonged periods of time, rather than focusing on hypothetical use derived from focus groups.

However, there are grounds to think that harm, safety, and usability are not given the priority expected for devices used in people with serious mental illness and that published reports should systematically report adverse events and usability to ensure that both these issues can be monitored and addressed. Future protocols should measure potential mood deterioration objectively to enable these quantitative data to be triangulated with qualitative data, allowing any potential causality to be inferred or refuted. Low rates of reporting negative effects are common across digital interventions and may be hindering the development of safer interventions [9]. It may be possible for major funders (eg, Wellcome Trust and UK Research and Innovation) and regulatory bodies to introduce the requirement for grant holders and developers of technology to use responsible innovation networks that explicitly ask research teams to consider negative adverse effects and their measurement, mitigation, and reporting (eg, internationally recognized standards such as Good Clinical Practice [86]). The data in this review show that previous studies have not considered these issues adequately.

Acknowledgments

This work was supported by a Wellcome Trust Fellowship to LAW. The authors would like to thank the University of Nottingham Library Service for assistance with formulating the search terms. RM was chief investigator on a grant from the UK National Institute for Health and Care Research (NIHR) Applied Research Collaboration East Midlands Mental Health and Well-Being Theme and an investigator on the Remote Assessment of Disease and Relapse–Central Nervous System study. RM has received other NIHR funding for research on interventions for depression and bipolar disorder as an NIHR Senior Investigator and is the lead for the Nottingham NIHR Biomedical Research Centre Mental Health and Technology Theme and the NIHR Mental Health HealthTech Research Centre Adult Mental Health Theme.

Authors' Contributions

LAW and RM were responsible for the original study design. LAW was responsible for the search and identification of relevant papers, data extraction, and risk-of-bias assessments. JM-C was responsible for data extraction. LAW, RM, JM-C, and BG were responsible for subsequent interpretation, editing, and rewriting of the report.

Conflicts of Interest

RM has received funding from Novartis to serve on a data management and ethics committee for two trials on the treatment of depression. All other authors declare no conflicts of interest.

Abstract

Background: Population aging has intensified the global burden of dementia, creating significant challenges for patients, caregivers, and health care systems. While traditional in-person dementia care faces barriers, digital health technologies offer promising solutions to enhance accessibility, efficiency, and patient-centered care. However, evidence on applicability, safety, and effectiveness in dementia care remains fragmented, underscoring systematic evaluation.

Objective: This study aims to assess the effectiveness, applicability, safety, and cost-efficiency of telemedicine technologies in dementia care, providing a comprehensive summary of evidence spanning clinical, psychological, socioeconomic, and operational impacts for persons living with dementia and their caregivers and assess alignment with the World Health Organization (WHO) Age-friendly Cities and Communities' Framework and Dementia Inclusive Society Framework.

Methods: An overview of systematic and scoping reviews was conducted following a search in 5 databases (MEDLINE, Embase, Scopus, Epistemonikos, and Cochrane Database of Systematic Reviews), with a gray literature search on February 20, 2024. Eligible studies reported predefined outcomes related to telemedicine interventions for integrated dementia care, including effects on mental health, quality of life, physical activity, hospitalization, financial costs, safety, social isolation, and motor function. Screening and data extraction were performed by 10 reviewers. The findings were synthesized using the Thematic Analysis in Meta-Evidence (TAME) methodology, combining thematic and lexical analyses with single-proportion meta-analysis for

XSL•FO
RenderX

comprehensive qualitative-quantitative synthesis. The methodological quality was assessed using the AMSTAR 2 (A Measurement Tool to Assess Systematic Reviews), with GRADE-CERQual (Confidence in the Evidence from Reviews of Qualitative Research) for outcomes' confidence in evidence.

Results: Ninety-one reviews provided evidence on the impact of telemedicine in dementia care. The most frequently reported outcomes were the effects of remote interventions on psychiatric and psychological well-being, particularly depression and anxiety (relative frequency of occurrence [RFO]=65%, 95% CI 54-75, moderate certainty of evidence). Fifty-seven studies highlighted the positive impact of telemedicine and telehealth on satisfaction and quality of life for persons living with dementia, caregivers, and health care providers (RFO=63%, 95% CI 52-73, moderate certainty of evidence). Remote technology-related interventions for reducing falls and managing behavioral symptoms were also frequently reported (RFO=33% 95% CI 23-44], moderate certainty of evidence). These interventions showed effectiveness in alleviating social isolation and loneliness (RFO=31%, 95% CI 22-41, moderate certainty of evidence). The methodological quality of the included reviews varied significantly, with the majority rated as low or critically low quality.

Conclusions: Telemedicine and telehealth have been demonstrated to be effective and valuable tools in dementia care, offering significant benefits across psychological well-being, quality of life, and social impacts for persons living with dementia and their caregivers. This supports the adoption and implementation of telemedicine in dementia care, aligning with the strategies outlined in the United Nations Decade of Healthy Ageing (2021 - 2030).

Introduction

The population aging has accelerated at an unprecedented pace in recent times [1]. Besides the economic, social, and political implications, aging also brings attention to the significant health challenges posed by progressive neurodegenerative disorders, commonly referred to as dementia. These disorders present substantial burdens for health and care providers, patients, families, caregivers, and policy makers [2,3].

Traditionally, dementia care has been delivered primarily through in-person consultations. However, providing such care has posed significant challenges, particularly in rural communities where access to specialized services is limited, and for an already overstretched and overwhelmed health and care workforce. To attend these appointments, patients and their caregivers often face numerous barriers, including logistical difficulties, time constraints, and financial burdens [4].

The advent of digital health technologies (DHTs) has revolutionized the landscape of dementia care. These innovations range from medication reminder systems to sophisticated machine learning algorithms (ie, artificial intelligence) designed to predict and prevent falls and other adverse events, offering new opportunities to enhance the quality and accessibility of care [5].

Our research group was among the first to analyze the applicability, safety, enablers, and facilitators of multiple DHTs in clinical practice [6-10]. Through a range of observational studies, randomized clinical trials, and evidence-based medicine research, we have demonstrated the significant impact of DHTs across multiple modalities, including in medical and health care practice [7,11], cardiology and cardiovascular care [12,13], diabetology and endocrinology [12], dermatology [14], gynecology, and obstetrics [15]. Building on this foundation, we undertook an extensive bibliometric analysis to synthesize existing evidence on DHTs specifically tailored for holistic and integral dementia care [16]. This analysis highlighted critical methodological limitations and revealed a significant knowledge gap in the collation and systematization of global findings related to the use of telemedicine and telehealth for dementia care. The identified knowledge gap underscores the need for further research initiatives to enhance the integration of these technologies into dementia care practices. It highlights the need for horizontal, collaborative, and transformative partnerships, avoiding duplication of efforts.

Expanding on this work, the remote delivery of health care services offers a promising approach for addressing needs across various medical specialties, including Neurology and Psychiatry [17-19]. Recognizing gaps identified in our initial bibliometric analysis, we present this second publication in a series of studies evaluating the impact of digital health technologies on dementia care, focusing on their effects on patients and caregivers [20].

This study critically examines existing systematic and scoping reviews to assess the applicability, safety, and effectiveness of telemedicine and telehealth services in improving multiple aspects of dementia care. These aspects include clinical outcomes (eg, cognitive function, behavioral symptoms, and quality of life), mental health (eg, the psychological and psychiatric well-being of patients and caregivers), process-related outcomes (eg, medication adherence, patient engagement, and health care use), and economic factors (eg, cost-effectiveness analyses). To note, our study resonates with large-scale health projects launched within the EU4Health program, that is, a direct grant to Member States Joint Action addressing Dementia and Health (JADE) aimed at prevention and early detection leveraging cutting-edge technology, which, combined, highlights the importance of improving dementia care frameworks and builds upon unprecedented person-centered assistance models [21]. In particular, on the one hand, clinical care pathways for patients living with dementia are designed to establish and foster high-quality evidence-based best practices (tailored upon 8 pilot initiatives within 5 European Union

XSL•FO
RenderX

countries); while on the other hand, person-centered new care models emphasize recognizing unmet needs in determined practices through the revision and analysis of at least 10 care frameworks for dementia and other neurocognitive abnormalities [21] in 6 European Union countries. In summary, these initiatives positively impact the development of applicable and valuable insights into the definition of telemedicine and telehealth-mediated interventions involved in dementia care, highlighting the need for scalable, data-based solutions to improve patient-centered assistance.

The findings of this study aim to provide valuable insights into the real-world effectiveness, applicability, safety, and cost-efficiency of telemedicine and telehealth technologies in dementia care. This study serves as a practical guide for practitioners, health authorities involved in decision-making, and patients and their caregivers, offering evidence-based perspectives on the role of telecommunication and remote health care services in dementia management.

Methods

Overview

This overview of systematic reviews is based on a large project registered with the International Prospective Register of Systematic Reviews (CRD42024511241) [22]. Given the study design, which is based on secondary data, no ethical review was required. The study adheres to the PRISMA 2020 (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) reporting guidelines [23]. All methods used in the research were pre-established before data collection, minimizing potential biases commonly associated with other evidence synthesis approaches.

Search Strategy and Selection Criteria

First, an experienced information librarian (LØ) systematically searched multiple databases for article retrieval. The search strategy was tailored in collaboration with specialists in epidemiology, evidence-based medicine, geriatrics and gerontology, neurology, psychiatry, psychology, and policy makers (Multimedia Appendix 1) [5,24-113]. In our overview, 5 leading databases were searched for eligible reviews (MEDLINE, Embase, Scopus, Epistemonikos, and Cochrane Database of Systematic Reviews). Furthermore, the first 300 hits on Google Scholar were screened, potentially identifying studies from the gray literature. The systematic search was performed on February 20, 2024. The inclusion criteria were primarily related to systematic or scoping reviews reporting relevant data on the applicability, effectiveness, and safety of telemedicine and telehealth services for the management of people living with dementia. Included reviews were deemed eligible with reported relevant data on people living with dementia (in any form of neurodegenerative disorders), including Alzheimer disease, vascular dementia, Lewy body dementia, and frontotemporal dementia, regardless of the international classification used (eg, *ICD-11* [*International Classification of Diseases, 11th Revision*], *ICD-10* [*International Statistical Classification of Diseases and Related Health Problems, Tenth Revision*], or *DSM-5* [*Diagnostic and Statistical Manual of Mental Disorders* {Fifth Edition}]). Although the diagnosis of dementia commonly occurs among the older population, we are aware of early presentation of the disease among younger individuals. Therefore, we considered eligible for inclusion primary records including young and older people living with dementia. We included reviews that reported relevant data on patient outcomes and evaluated the impact of these telemedicine and telehealth on the daily lives of formal or informal caregivers. We included systematic and scoping reviews from multiple countries, regardless of the publication language. Definitions for each type of review are available in previously published sources [114,115]. Narrative reviews were excluded from eligibility due to their higher susceptibility to bias [116].

After obtaining the records from the databases, duplicates were removed on EndNote (Clarivate Analytics), and the final list of studies was imported into Covidence (Veritas Health Innovation). Ten investigators on our team performed the independent and dual-stage screening process (IJBN, HMA, IW, CC, GD, AS, IK, VGB, BS, and AOM). Similarly, for papers deemed eligible for inclusion, the same authors performed data extraction independently and in duplicate. Any discrepancies were resolved through discussion facilitated via an online smartphone-based instant messaging platform. A complete list of included and excluded studies with reasons for exclusion after full-text review has been developed in Multimedia Appendix 1 [5,24-113].

Definition of Terminologies

We understand that telemedicine and telehealth are commonly used interchangeably. However, for practical differentiation, we used the World Health Organization's (WHO's) definitions [117,118] of telemedicine described as "the delivery of health-care services where distance is a critical factor, by all health-care professionals using information and communication technologies for the exchange of valid information for diagnosis, treatment and prevention of disease and injuries all in the interests of advancing the health of individuals and their communities—page 2" [117]. Notably, we emphasize that telemedicine is a component of telehealth, primarily applied to educational purposes, along with different applications wherein information and communication technologies are used to enhance health care services [117,119,120].

We used the previously published definition for systematic reviews, defined as "a research report which searched for primary research studies on a specific topic using an explicit search strategy, had a detailed description of the methods with explicit inclusion criteria provided, and provided a summary of the included studies either in narrative or quantitative format (such as a meta-analysis)"—page 3 [121]. We included Cochrane and non-Cochrane systematic reviews, with or without meta-analysis, that reported on the clinical, mental, managerial, or economic effects of telemedicine and telehealth services in dementia care. Scoping reviews were defined as evidence synthesis studies that "systematically identify and map the breadth of evidence available on a particular topic, field, concept, or issue, often irrespective of source (ie, primary research, reviews, and nonempirical evidence) within or across contexts"—page 1 [122]. Studies reporting relevant data on

XSL•FO
RenderX

different modalities of DHTs were included. However, when multiple types of digital intervention were described, only results specific to telemedicine and telehealth were extracted and accounted for in the final analysis.

Data Extraction and Management

Ten researchers (IJBN, HMA, IW, CC, GD, AS, IK, VGB, BS, and AOM) independently participated in data extraction using a prevalidated extraction Microsoft Excel (Microsoft Corporation) spreadsheet. Each study underwent data extraction by 2 reviewers and was re-evaluated by a third reviewer to verify the accuracy of selected data. We extracted key characteristics of each review, including the title and first author, year of publication, journal, review objective, main population studied, number of included primary studies, key reported outcomes relevant to this analysis, and the review category (systematic or scoping). Regarding review findings, we qualitatively analyzed telemedicine and telehealth's reported impact and role in the following areas: (1) psychiatric or psychological outcomes; (2) satisfaction and quality of life for patients, families, or health care providers; (3) metrics of habitual physical activity; (4) hospitalization rates; (5) financial aspects; (6) safety outcomes; (7) clinical improvement of underlying diseases beyond neurological or dementia-related disorders; (8) social isolation and loneliness; (9) motor progression in clinical and research contexts; and (10) prevention of falls and management of behavioral and psychological symptoms. The explanation of how findings were collated and the processes is briefly explained under the "Data Analysis and Synthesis" section.

In addition, we assessed the reviews to identify the influence of telemedicine and telehealth on at least one of the 10 domains of WHO Age-friendly Cities and Communities' Framework [123] adapted to Dementia Inclusive Society [124], including housing, social participation, respect and social inclusion, civic participation and employment, communication and information, community support and health services, outdoor spaces and buildings, transportation, safety, and caregiver support, alongside medical management [123]. This mapping was conducted by 2 independent researchers and validated by an expert on age-friendly environments at the WHO Regional Office for Europe. The WHO Age-Friendly Cities and Communities' Framework is a key component of the United Nations Decade of Healthy Ageing (2021‐2030) program, aligning with the Sustainable Development Goals [125] and encompassing a series of actionable activities. Finally, we extracted all necessary information to evaluate the overall quality of the included systematic reviews.

Assessment of the Methodological Quality of Included Reviews and Certainty of the Evidence in Included Reviews

We independently evaluated the methodological quality of the included systematic reviews based on the AMSTAR 2 (A Measurement Tool to Assess Systematic Reviews) measurement approach [126]. The tool consists of 16 domains, 7 of which are prioritized due to their critical impact on a review's validity, transparency, and replicability [126]. While we chose not to report a final summary score, we accounted for the implications and effects of inadequate ratings for each evaluated domain in our final analysis [126]. Systematic reviews were classified as having "high," "moderate," "low," or "critically low" quality. The certainty of evidence for the main findings of the reviews was assessed using the GRADE-CERQual ("Confidence in the Evidence from Reviews of Qualitative Research") methodology [127]. This evaluation considered 5 key factors influencing the evidence: methodological limitations, coherence, data adequacy, relevance, and publication bias. The confidence in each qualitative primary review finding was rated as "high," "moderate," "low," or "very low."

Data Analysis and Synthesis

Given the included studies' methodological heterogeneity, we used qualitative and quantitative approaches to summarize the findings, adhering to established methodological guidance for conducting mixed methods systematic reviews [128]. Our research group recently published the Thematic Analysis in Meta-Evidence (TAME) Visualization Methodology, specifically designed for reporting results from studies predominantly based on qualitative evidence, using thematic and lexical analysis principles. The TAME methodology combines content analysis with single-proportion meta-analysis, enabling the calculation of the overall proportion of studies reporting a particular finding. This integrated approach enhances the interpretation and visualization of mixed methods evidence, providing a comprehensive understanding of the data. Final estimates were expressed as the relative frequency of occurrence (RFO) and 95% CI. Our study used single-proportion meta-analysis to graphically and numerically present the results. This method facilitates the conversion of qualitative data into quantifiable outcomes, enabling a clear and straightforward evaluation of qualitative findings through mathematical representation. R (version 4.4.0; R Core Team) was the software used for statistical analysis.

Ethical Considerations

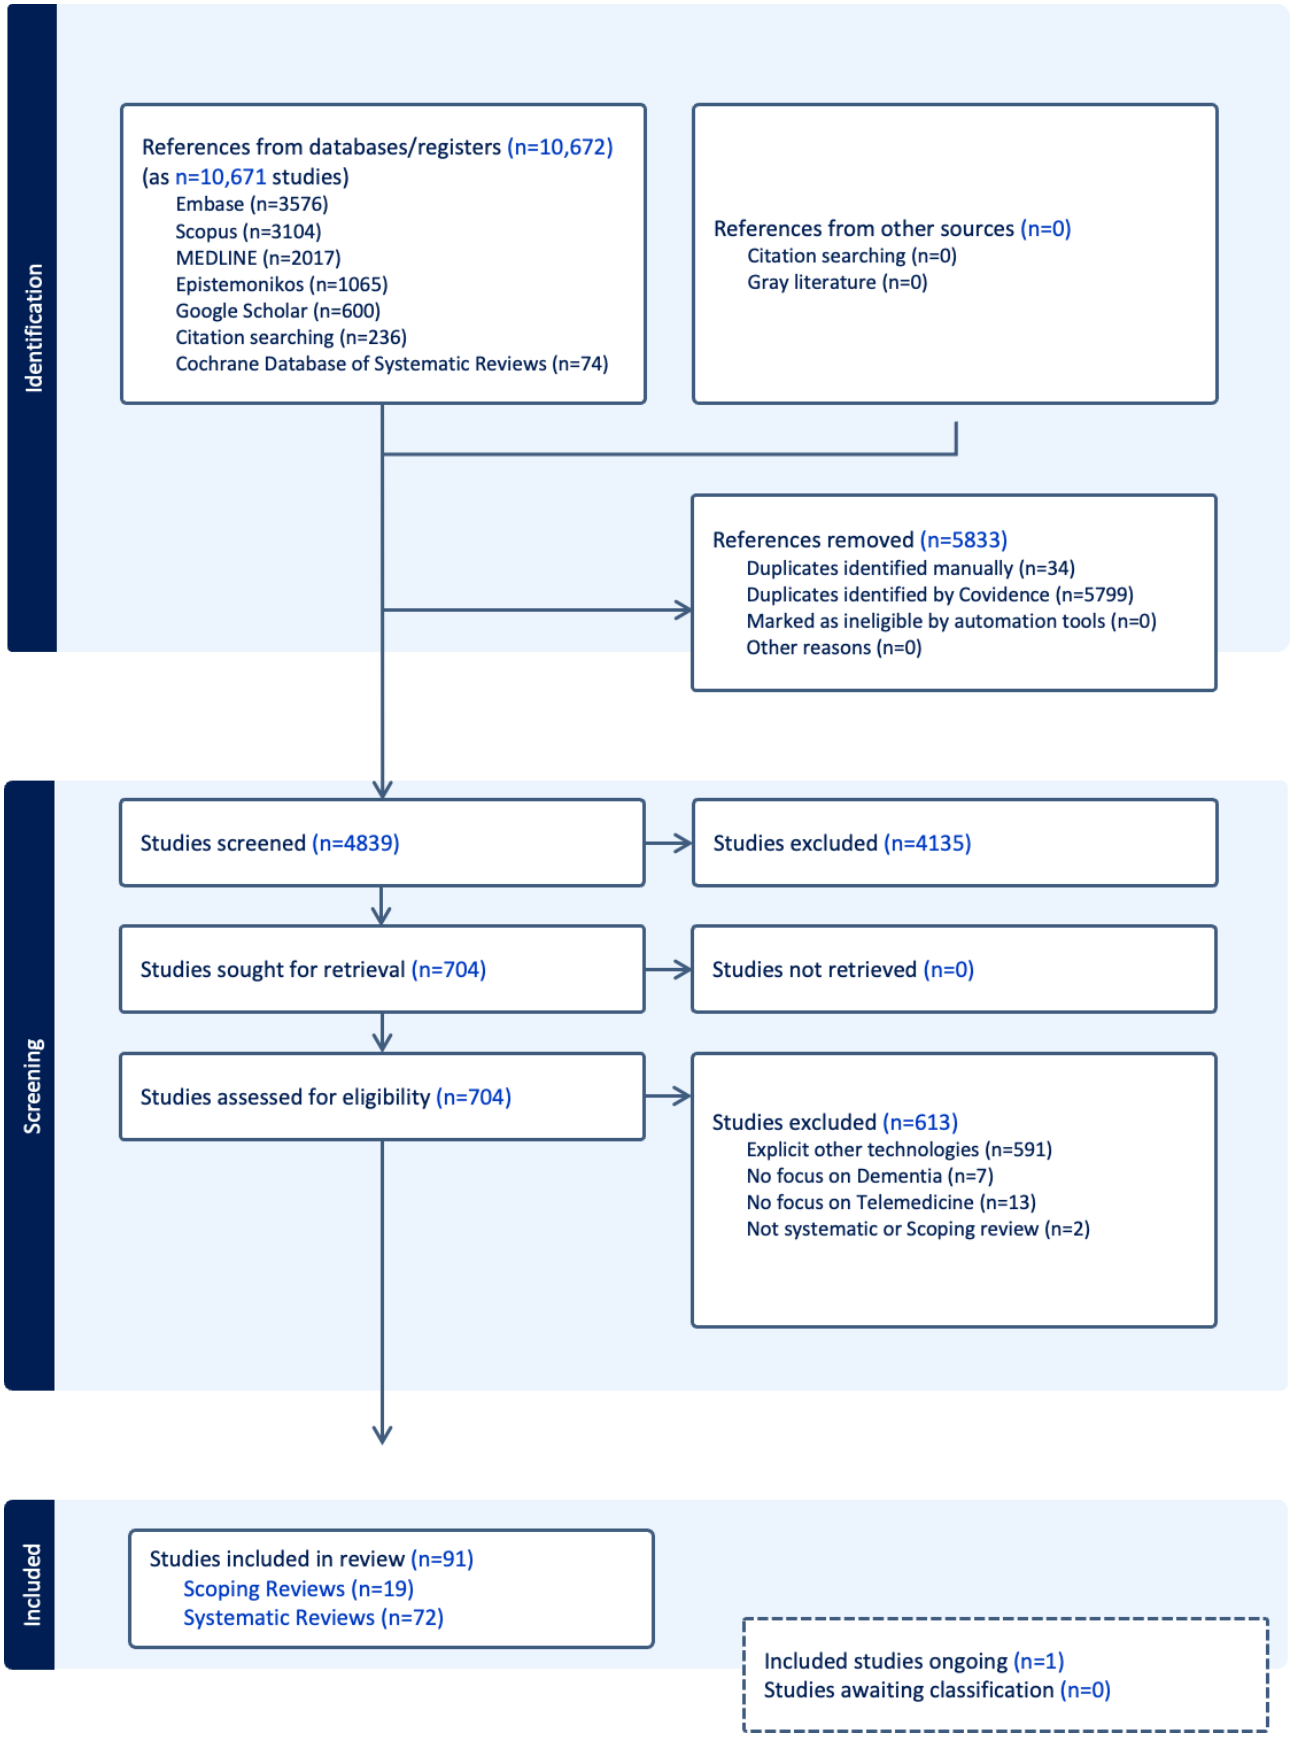
This study was exempt from ethical approval as it did not involve original human data collection.

Results

Search Results and Characteristics of Included Studies

In our bibliometric analysis, we shortlisted 704 studies within the broader category of DHTs applicable to dementia care [20]. After prioritizing systematic and scoping reviews focusing on specific modalities of telemedicine-related digital intervention, 91 reviews [5,24-113] were included in our final analysis (Figure 1). The ipsilateral main objectives and participants of the included reviews, published between 2008 and 2024, are summarized in Multimedia Appendix 2 [5,24-113]. The number of publications remained relatively stable from 2008 to 2015, with one to 3 reviews published annually. However, a notable growth phase began in 2016, accelerating further during the COVID-19 pandemic, significantly increasing research activity in this field. This surge was evidenced in the publications of 13 reviews in 2021 [26,44,47,60,82,84,87,88,94,95,99-101] and 18 in 2023 [35,37,39,48,50,53,62,66,75,76,92,93,97,98,102,104,109,111].

XSL•FO
RenderX



Most reviews were published in the *Aging & Mental Health* (n=6), *International Journal of Geriatric Psychiatry* (n=5), and *Cochrane Database of Systematic Reviews* and *Journal of Medical Internet Research* (n=4). Several of the included reviews highlighted findings related to remote cognitive assessments and populations in remote or resource-limited settings, reflecting the importance of accessibility in dementia care. Among the 91 included reviews [5,24-113], the majority were systematic reviews (n=72), while 19 [33,35,37,39,43,48,59,63,66,68,70,81,84,91,93,98,109-111] were classified as scoping reviews. Although we did not assess the percentage of overlapping primary studies across the included reviews, the total number of primary studies encompassed within these reviews amounted to 2929 records, reflecting a substantial body of evidence analyzed in the present overview of reviews.

The included reviews predominantly evaluated telemedicine and telehealth technologies' effectiveness, feasibility, and acceptability in dementia care. Many included reviews (28/91, 30%) also assessed remote cognitive assessments, primarily using telephone- and video-based tools, focusing on mild cognitive impairment and dementia. Likewise, several studies (49/91, 53%) explored the impact of psychoeducational, psychotherapeutic, and social support online interventions to support caregivers' mental health and well-being. Also, some reviews highlighted the potential of telemedicine and telehealth services to enhance clinical outcomes, ensure caregiver support, facilitate safety outcomes, and decrease loneliness for people living with dementia.

Outcome-specific RFO estimates ranged from 2% (95% CI 0 - 8, related to the impact of telemedicine on motor progression in both clinical and research contexts) to 65% (95% CI 54 - 75, related to the reported impact of telemedicine on psychiatric or psychological outcome), as shown in Figure 2. Below, we summarize findings for the top 5 most prevalent domains, with additional findings for 5 other domains provided in Table 1.

Table . Summary of review findings and confidence in the evidence for the use of telemedicine and telehealth services for multifaceted dementia care.

GRADE-CERQual components	RFO[a] % [95% CI]	Methodological limitations[b]	Coherence	Adequacy of data	Relevance[c]	Overall assessment[d]
Reported impact of telemedicine on psychiatric or psychological-related outcome	65% [54 - 75]	Moderate concerns	Moderate concerns[e]	Moderate concerns[f]	No or very minor concerns[c]	Moderate confidence
Reported impact of telemedicine on patients, family, or health care providers' satisfaction or quality of life	63% [52 - 73]	Moderate concerns	No or very minor concerns[g]	Moderate concerns[h]	No or very minor concerns[c]	Moderate confidence
Reported impact of telemedicine on habitual physical activity metrics	19% [11 - 28]	Moderate concerns	Moderate concerns[i]	Moderate concerns[j]	No or very minor concerns[c]	Moderate confidence
Reported impact of telemedicine on hospitalization	8% [3 - 15]	Moderate concerns	Serious concerns[k]	Serious concerns[l]	Moderate concerns[m]	Very low confidence
Reported impact of telemedicine on financial-related effect	30% [21 - 40]	Moderate concerns	Moderate concerns[n]	Moderate concerns[j]	No or very minor concerns[c]	Moderate confidence
Reported impact of telemedicine on safety-related outcomes	23% [15 - 33]	Moderate concerns	No or very minor concerns[g]	Moderate concerns[j]	No or very minor concerns[c]	Moderate confidence
Reported impact of telemedicine on clinical improvement of underlying diseases (besides the ones related to neurological or dementia disorders)	26% [18 - 37]	Moderate concerns	Moderate concerns[o]	Moderate concerns[j]	No or very minor concerns[p]	Moderate confidence
Reported impact of telemedicine on social isolation and loneliness	31·0% [22·0 - 41·0]	Moderate concerns	Moderate concerns[i]	Moderate concerns[j]	No or very minor concerns[c]	Moderate confidence
Reported impact of telemedicine on impacting motor progression in both a clinical and research capacity	2% [0 - 8]	Moderate concerns	Serious concerns[k]	Serious concerns[l]	No or very minor concerns[c]	Very low confidence
Reported impact of telemedicine on preventing falls and managing behavioral and psychological symptoms	33% [23 - 44]	Moderate concerns	Moderate concerns[i]	No or very minor concerns[h]	No or very minor concerns[c]	Moderate confidence

[a]RFO: relative frequency of occurrence.

[b]We downgraded one level of confidence in the evidence based on the methodological quality of included systematic reviews and not based on the methodological limitations of primarily included studies. The rationale is that the AMSTAR 2 tool has 7 strict critical domains, which, if they occur at least once, decrease overall confidence by 2 levels. Nevertheless, since several experts have already suggested that the reporting of many items in the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement is suboptimal, we believe that this lack of reporting or evaluation might be associated with a “mass effect,” where researchers simply follow an inadequate pattern. Therefore, we decreased one level in the certainty of evidence instead of 2 levels on reviews’ methodological limitations.

XSL•FO
RenderX

[c]Based on the alignment of most studies reporting this outcome in the reality of telemedicine and telehealth interventions for dementia care, we considered this domain to have minor concerns evidencing not significant reduction of confidence in the relevance of collated results and with a well-coverage of needed analyses.

[d]Although most of our included reviews were classified as "very low methodological quality" using the AMSTAR 2 tool, we believe that the reported data are significant enough not to decrease the confidence level primarily based on the methodological quality.

[e]We downgraded one level for coherence because of inconsistent findings across included reviews, ambiguous or differential measurement of outcomes, and due to competing theories or formats reported (within the modality of telemedicine and telehealth, we observed competing theoretical explanations on different degrees of effectiveness according to the intervention type).

[f]The evaluated data are overall rich in details for caregivers' findings and emotional well-being. However, inconsistent data volume decreased the confidence in some reported findings, specifically, those associated with psychiatric outcomes.

[g]Collated results on this outcome demonstrated elevated systematic coherence, with consistent evidence of convenience, reduction of travel burden, and remarkable positive feedback from patients and their caregivers. Likewise, caregiver self-efficacy and emotional well-being outcomes demonstrated generally elevated coherence. With regard to safety outcomes, we judged this outcome as having minor concerns because safety outcomes and benefits are consistently reported within studies (particularly related to fall prevention, monitoring, and reducing physical harm).

[h]Synthesized evidence related to satisfaction with telemedicine interventions for dementia care is adequate and sufficiently robust across included reviews, though the impact on quality of life is mostly heterogeneous. Related to the impact of telemedicine on preventing falls and managing behavioral and psychological symptoms, the obtained data were deemed adequate, with a variety of interventions covering both falls and behavioral symptoms.

[i]Included reviews contained relevant evidence related to the enhancement of physical activity, adherence to exercise programs following the intervention for patients living with dementia. However, findings are not consistent across all studies. As far as the potential of telemedicine to reduce social isolation and loneliness, we judged it as moderate evidence because, overall, qualitative evidence collated is consistent, but quantitative outcomes are mixed, with some showing no improvement. Related to the impact of telemedicine in preventing falls and managing behavioral and psychological symptoms of dementia, multiple positive findings were observed across included reviews, though with some inconsistent results across studies.

[j]Judged as moderate concerns due to lack of detailed report or uneven reporting across themes approached within included studies.

[k]Findings for hospitalization outcomes are overall scattered and inconsistent, with some minor isolated positive reports.

[l]We downgraded this domain due to limited detailed data within included reviews; besides, whenever available, there was no significant impact on hospitalization. Regarding the impact of telemedicine on motor progression in either clinical or research settings, we downgraded the evidence because of limited evidence, with most studies reporting no data.

[m]We observed the reporting of some relevant findings across included reviews; however, they were primarily focused on emergency department metrics and readmission rates, which hinder and limit direct relevance.

[n]We observed that the obtained findings related to the financial impact of telemedicine are generally consistent, but with some variability in reporting of long-term savings and cost parameters.

[o]We systematically observed that merged results generally align but with relevant inconsistencies in clinical outcomes and variability in effectiveness across the different interventions delivered.

[p]As we considered cognitive clinical outcomes in a separate domain, we are judging this domain as nonserious concerns because included reviews systematically reported relevant improvements in chronic disease management.

Impact of Telemedicine and Telehealth on Psychiatric and Psychological Outcomes

Globally, the report of the impact of telemedicine and telehealth on both psychiatric and psychological outcomes was the most frequent among the 10 included dementia-inclusive domains (RFO=65%, 95% CI 54 - 75; weight: 9.9%). Included reviews predominantly demonstrated the positive impact of these technologies in dementia care, either by the reduction of depression and anxiety symptoms among included patients (particularly as a result of telephone- or video-based cognitive behavioral therapy and psychoeducation), enhancement of cognitive and mental health outcomes (expressed by improved cognitive function [evidenced by increased Montreal Cognitive Assessment and Quality of Life–Alzheimer Disease {QOL-AD} scores]), and decrease of informal or formal caregiver burden and stress attributed to the delivery of dementia care. Similarly, several reviews highlighted the enhanced social support and self-efficacy associated with the use of telemedicine and telehealth, which ultimately provided emotional and social benefits while helping caregivers manage stress more effectively. However, despite these positive outcomes, some reviews reported mixed or limited effectiveness in addressing psychiatric and psychological outcomes. Notably, studies that found no significant difference between telemedicine or telehealth interventions and standard care often concluded that the interventions were not inferior to traditional approaches. For instance, one meta-analysis observed inconsistent benefits regarding caregiver workload and depression. It reported no significant effect on caregiver burden (standardized mean difference=0.05; 95% CI –0.20 to 0.30) across multiple studies, highlighting variability in effectiveness.

In addition, some reviews identified challenges associated with telemedicine and telehealth services. Fatigue and frustration were commonly reported as adverse effects of online assessments, particularly among users (patients or caregivers) unfamiliar with the technologies used. These findings underscore the need to address usability and accessibility to optimize the impact of telemedicine on dementia care.

Impact of Telemedicine and Telehealth on Satisfaction and Quality of Life for Patients, Families, or Health Care Providers

Fifty-seven studies (RFO=63%, 95% CI 52 - 73; weight=9.8%) reported on the impact of telemedicine and telehealth on satisfaction or quality of life among patients, families, and both formal and informal health care providers. Overall, the majority of studies indicated a positive impact, particularly associated with interventions such as videoconferencing, telephone-based support, and telepsychiatry services, which were linked to high satisfaction rates among end users.

XSL•FO
RenderX

In studies that explicitly measured satisfaction, reported rates ranged from 80% to 90%, highlighting the broad acceptance of these remote care approaches [101,108]. Telemedicine and telehealth were frequently described as convenient and accessible, with benefits such as reduced travel-related burden and enhanced user support. Furthermore, most studies observed improved quality of life for both patients and caregivers, often through increased self-efficacy in managing work- or task-related responsibilities and by alleviating stress associated with traditional in-person care delivery.

In addition, we observed that some technologies (ie, online cognitive rehabilitation systems and remote activity monitoring platforms) facilitated patients' empowerment (by promoting their independence associated with care) and improved their engagement in care. Online assistance groups and peer-support frameworks were also reported to encourage and facilitate social interaction among users, reduce caregiver distress, and enhance users' emotional well-being. Regarding the negative and mixed impacts of telemedicine and telehealth services on users' satisfaction and quality of life, only a few studies (9/91, 9.8%) reported nonsignificant improvement on these outcomes. For instance, one systematic review and meta-analysis of internet-based interventions revealed mixed findings, with some studies showing minimal gains in quality of life and others reporting no significant differences compared to standard care [72]. Some studies also reported adverse effects derived from the use of telemedicine and telehealth, particularly related to user satisfaction, such as user-related anxiety reported by caregivers, discomfort during the use of video consultations, and lack of physical contact [25,37]. Likewise, some reviews suggested the limited impact of telemedicine and telehealth in reducing caregiver work-related burden [35]. This conclusion was supported by findings from multiple meta-analyses, which reported no significant improvements in caregiver burden.

Impact of Telemedicine and Telehealth on Fall Prevention and Management of Behavioral and Psychological Symptoms

We extracted relevant data from reviews (30/91, 33%) to evaluate the impact of telemedicine and telehealth on preventing falls and managing behavioral and psychological symptoms, ranking it as the third most prevalent domain (RFO=33%, 95% CI 23% - 44%; weight=9.9%). The pooled estimates were supported by multiple reviews highlighting the effectiveness of remote assistive technologies and teleassistance platforms in reducing falls with metrics indicating a general fall reduction of 28% to 31% and a decrease in indoor falls ranging from 32.7% to 63.8%. Furthermore, we observed that telemedicine technologies demonstrated notable effectiveness in managing behavioral and psychological symptoms. Reviews reported improvements in overall well-being, reductions in disruptive behaviors, and effectiveness in addressing agitation, hallucinations, and sleep disturbances, further emphasizing the potential of telemedicine to enhance dementia care in these areas. We observed that some studies demonstrated that remote interventions promoted a better caregiver response and a decrease in negative-derived reaction to improved caregiver responses and reductions in negative caregiver reactions to deviant behaviors. Variability in the reported magnitude of effect for this outcome was relatively limited, with only a small number of reviews indicating no significant improvements in the occurrence of disruptive behaviors or reductions in falls among people living with dementia who received remote interventions.

Impact of Telemedicine and Telehealth on Social Isolation and Loneliness

Remote support technologies, particularly video conferencing systems and online peer assistive platforms, emerged as a promising alternative for reducing social isolation and loneliness among people living with dementia. These technologies ranked as the fourth most frequently reported outcome (RFO=31%, 95% CI 22% - 41%; weight=9.9%). The identified technologies facilitated sustained social engagement by fostering meaningful interactions between patients and their caregivers. By enabling patients to engage in community activities, participate in peer support networks, and share their lived experiences in safe, supportive environments, these technologies played a critical role in strengthening social connectedness. This, in turn, contributed to improved emotional well-being and reduced feelings of isolation among individuals living with dementia and their caregivers. For instance, one review found that approximately 86% of enrolled individuals in virtual cognitive stimulation therapy reported improved engagement in social tasks, with 67% of caregivers observing a notable reduction in loneliness through peer interactions. The qualitative evidence consistently highlighted the emotional benefits of telemedicine and telehealth technologies in dementia care. Users frequently reported reduced feelings of loneliness, improved relationship quality, and a strong sense of solidarity fostered by online communities. While these emotional advantages were evident across included reviews, the quantitative outcomes remained less definitive. For instance, one review found that video conference-based interventions improved metrics related to perceived social support but did not demonstrate statistically significant changes in support domain scores. This disparity underscores the need for further research to quantitatively validate the emotional benefits reported by users.

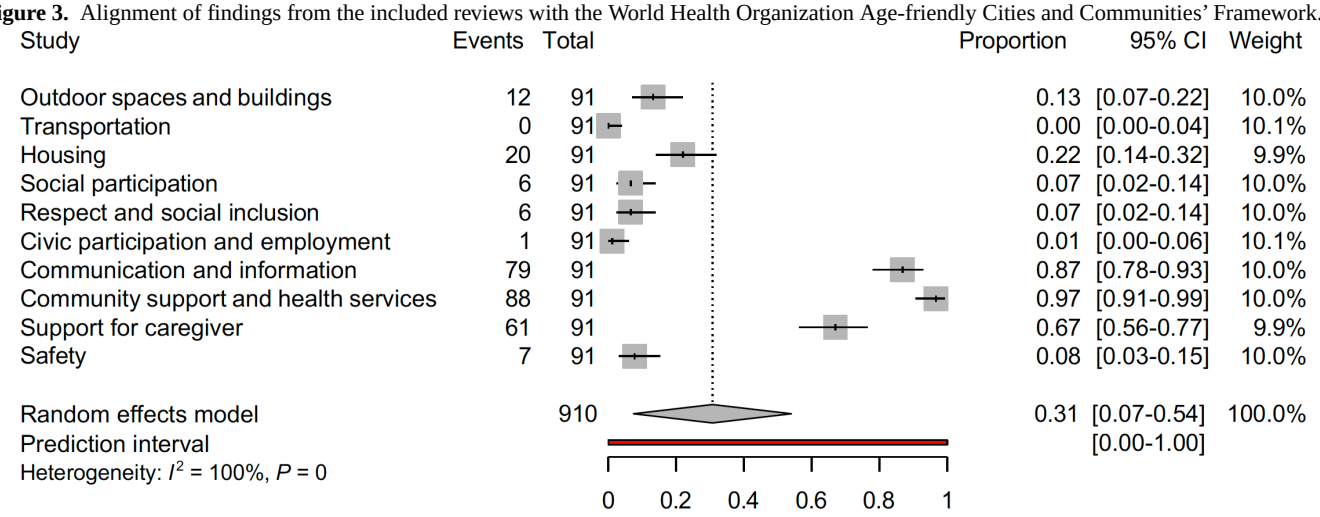
Overall Findings Aligned With the WHO's Dementia Inclusive Society Framework

Our meta-analysis, presented in Figure 3, illustrates the alignment of findings from the included reviews with the WHO Age-friendly Cities and Communities' Framework and its derivative Dementia Inclusive Society Framework. The analyses reveal that the domains with the highest pooled estimates are "community support and health services," "communication and information," and "caregiver support" (RFO=97%, 95% CI 91% - 99%, 87%, 95% CI 78% - 93%, and 87%, 95% CI 78% - 93%, respectively). In contrast, domains, such as "transportation" and "civic participation and employment," were the least represented, with RFO of 0% (95% CI 0% - 4%) and 1% (95% CI 0% - 6%), respectively. Figure 4, an upset plot illustrating domain co-occurrence, highlights key patterns in how telemedicine interventions are applied in dementia care as well as in the daily routine of people living with dementia. The analysis emphasizes a predominant focus on "Community

XSL•FO
RenderX

support and health services" and "Communication and information," which often intersect. This intersection underscores telemedicine's critical role in connecting patients and caregivers to essential health services and informational resources, effectively addressing fundamental care needs remotely. Less frequently observed domains, such as "Social participation" and "Respect and social inclusion," also intersect with other domains, pointing to the untapped potential of telemedicine to foster social connectedness and reduce isolation. These findings suggest that while telemedicine is already proving essential in many areas, its capacity to promote broader social integration remains underexplored and warrants further investigation. Likewise, people living in rural communities can benefit from using telemedicine, connecting them with medical professionals to maintain a level of connectivity [129,130].

Figure 3. Alignment of findings from the included reviews with the World Health Organization Age-friendly Cities and Communities' Framework.



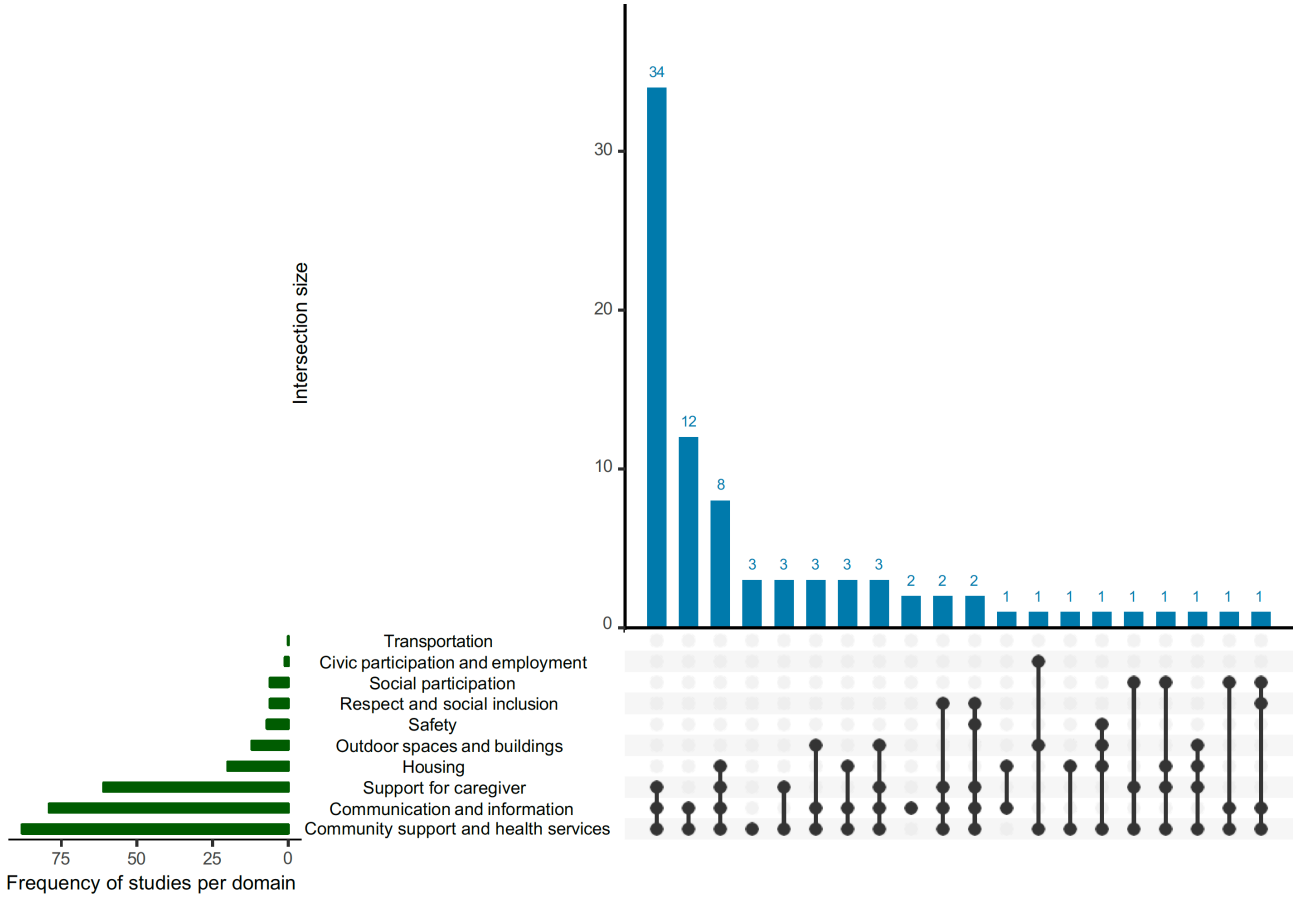


Figure 4. Domain co-occurrence in the Dementia Inclusive Society Framework for telemedicine interventions. The left bar chart (green) shows the frequency of studies addressing each domain, while the upper bar chart (blue) depicts the number of studies covering specific combinations of domains (intersection size). Black dots in the matrix indicate the domains included in each combination, with connected dots representing multiple-domain overlaps.

XSL•FO
RenderX

Methodological Quality of Included Systematic Reviews

The AMSTAR 2 evaluation of included systematic reviews is summarized in Multimedia Appendix 3 [5,24-113]. All 4 Cochrane reviews were rated as high quality [46,47,58,88]. However, most non-Cochrane reviews were classified as "critically low quality" due to several major and minor methodological shortcomings. These included the absence of published protocol or failure to report protocol deviations, incomplete or noncomprehensive search strategies, omission of the final list of excluded studies, inadequate assessment of the risk of bias in individual studies and their implications, improper use of meta-analytical approaches, and lack of publication bias analysis. These issues highlight significant methodological gaps in many of the included non-Cochrane reviews.

Certainty of Evidence and Qualitative Synthesis

Most of the included reviews used either qualitative methods alone or a mixed methods approach for evidence synthesis, integrating qualitative and quantitative data using our thematic, content, and lexical-based methodology. Many reviews provided detailed analyses of the overall impact of telemedicine and telehealth services on both individuals living with dementia and their caregivers (formal or nonformal). Table 1 presents the summary of qualitative findings and associated confidence assessments.

Several themes emerged as systematically homogeneous across the included reviews, with the direction of effect clearly leaning toward either positive or negative outcomes. Quality appraisals were conducted exclusively for outcomes related to the reported impact of telemedicine across these areas. Overall, our evaluation demonstrated promising results for the 10 primary outcomes, although the findings were somewhat heterogeneous across standardized domains. This variability underscores the need for further research to refine and standardize the evidence base supporting the integration of telemedicine in dementia care.

Discussion

Principal Findings

Our review included 91 systematic and scoping reviews examining the applications of telemedicine and telehealth in dementia care [5,24-113]. While the findings were promising, evidence on the effectiveness of remote health interventions across clinical, psychological, and socioeconomic outcomes was often mixed or inconclusive. The findings suggested that telemedicine and telehealth interventions have the potential to improve psychiatric and psychological symptoms, alleviate caregiver burden and emotional stress for both formal and informal caregivers, and enhance the quality of life for patients and other end users. Evidence also pointed to the potential of telehealth to reduce social isolation, aid in fall prevention, and effectively address behavioral symptoms, although the consistency of these effects across reviews varied. Although less frequently addressed, some reviews indicated possible financial benefits associated with telemedicine and telehealth services in dementia care. However, significant methodological limitations in the included reviews, including variability in outcomes of interest and heterogeneity among primary studies, introduced uncertainty related to the restricted generalizability and robustness of our results. These limitations underscore the need for further high-quality research to support more definitive and reliable recommendations.

We observed that the use of telemedicine and telehealth interventions revealed significant psychiatric and psychological benefits for both patients and caregivers (moderate certainty of evidence). Our systematic synthesis demonstrated that these modalities of DHTs contribute to statistical and clinical reduction of depression, anxiety, and caregiver workload burden. In addition, some submodalities of remote services (ie, remote cognitive-behavioral therapy) and psychoeducational exercises have demonstrated an increase in mental health outcomes, with potential improvement in cognitive function and mood stability. Telemedicine and telehealth services benefit not only people diagnosed with dementia but also their caregivers and support networks. Our study highlights that many included reviews reported reduced stress levels and improved coping mechanisms, largely due to the convenience and accessibility of mental health–related resources provided through these technologies. Importantly, our findings do not categorically establish whether DHTs should be implemented as a supplement to traditional in-person care tools or as a replacement strategy.

Our findings align closely with the WHO's Mental Health Action Plan 2013 - 2030, which promotes enhancing access to mental health services based on high-quality scientific evidence and decreasing care inequities worldwide [131]. Recently, the WHO has emphasized the importance of tailored, population-specific health care strategies to address diverse needs in dementia care settings. While our findings indicated positive outcomes associated with telemedicine and telehealth interventions, caution is warranted before generalizing these results, as the evidence stems from heterogeneous settings. To advance the field, future studies should prioritize future customization in their design to address the unique needs of patients and caregivers more effectively.

In 2007, the WHO introduced the people-centered health care framework, advocating a critical shift from health care systems focused on diseases and institutions to systems designed around the needs of individuals—treating everyone as integral components of society [132]. For health care systems to be truly universal and accessible to all, including underserved, socially vulnerable, and marginalized populations, this renewed perspective must prioritize integration and person-centered care, ensuring that no one is left behind [130,133-136].

Our findings align with these global trends in medical research, demonstrating that telemedicine and telehealth interventions effectively deliver health care services to diverse groups, including patients, family members, and caregivers (moderate confidence level). These interventions also benefit individuals in resource-limited settings and isolated geographical areas [137-140]. Specifically, 57 reviews [24,27,31,32,35,38,41,42,44,46,47,48,52,53,56,58,60,62,64,66,68,69,71,72,78,80,82,83,86,88,89,91,93-111,113] (RFO=63%, 95% CI 52 - 73) reported positive impacts on

XSL•FO
RenderX

satisfaction and quality of life among patients, families, and health care providers. This personalized, microregional approach to care highlights telemedicine's potential—particularly in dementia-related conditions—to enhance care convenience and actively engage patients and caregivers in health management, adhering to the principles of patient-centered care [141].

However, challenges remain in settings where the lack of physical presence in remote interventions slightly decreases user experience, particularly for certain conditions and among individuals unfamiliar with digital platforms [136,140]. In such scenarios, the feasibility, effectiveness, safety, and systematic implementation of telemedicine interventions require further evaluation. Given that an integrated, people-centered approach relies on core principles of equity in access, quality, responsiveness, participation, efficiency, and resilience, we emphasize the urgent need for adaptive telemedicine solutions. These approaches should not only address the diverse characteristics of users but also foster the cocreation of systems tailored to their unique life circumstances [136,142]. This includes developing hybrid care models that combine online and in-person care modalities, when feasible and appropriate, to optimize health care delivery and outcomes.

Social isolation and loneliness have been commonly classified as the century's most damaging and prevalent human condition ever reported [143,144]. Accurately estimating the prevalence of loneliness and social isolation remains challenging due to limited and variable data. However, existing literature suggests that loneliness may affect up to 47.8% of adults aged 65 years and older [145]. Therefore, properly addressing these 2 events has potentially emerged as major areas where digital health (particularly telemedicine and telehealth solutions) contribute positively [139]. In our review, the impact of telemedicine and telehealth on social isolation and loneliness was reported in 28 reviews [25-27,31,32,36-38,41,45,48,49,53,65-67,91,93-95,98-100,104,106,109-111] (RFO=31%, 95% CI 22 - 41; weight: 9.9% moderate certainty of evidence). Remote supporting technologies, such as videoconferencing systems and online peer assistive platforms, have proven to be promising tools in reducing social isolation and loneliness among people living with dementia. These technologies also offer structured opportunities for social engagement, effectively alleviating associated symptoms, particularly in older adults. Notably, our findings also support the United Nations Decade of Healthy Ageing (2021 - 2030) by demonstrating that telemedicine interventions, such as virtual cognitive stimulation therapy, can significantly enhance social engagement and reduce feelings of loneliness. One study reported that 86% of participants experienced improved social connection and decreased sensations of loneliness. In addition, 67% of health caregivers noted a notable improvement in their social relationships with family members and the community following the adoption of telemedicine services. Despite these positive qualitative outcomes, slight inconsistencies in the quantitative synthesis for loneliness reduction and social participation among individuals living with dementia remain. These limitations highlight the need for further research to better quantify the effectiveness of telemedicine and telehealth in fostering social support and community engagement in dementia care. By addressing these gaps through robust and well-designed studies, the global understanding of telemedicine's impact can be strengthened, supporting the WHO's missions to create socially inclusive environments for aging populations, particularly through the integration of digital transformation initiatives [137-140].

The cost-effectiveness of telemedicine has been analyzed in multiple primary studies for a diverse array of medical conditions and specialties [146-149]. For instance, according to a study published in 2023 by Patel and colleagues [150], where the estimated cost savings of using telehealth among patients with cancer was evaluated, it was found that the estimated mean (SD) total cost savings ranged from US $147.4 (US $120.1) at US $0.56/mile (US $0.348/km) to US $186.1 (US $156.9) at US $0.82/mile (US $0.510/km). Likewise, in a study performed in a cost and effectiveness study of outpatients pulmonary care center in a rural area in Wisconsin (United States), the authors reported that telemedicine was found to be more cost-effective (US $335 per patient per year) compared to routine care (US $585 per patient per year) and on-site care (US $1166 per patient per year) [151]. When a sensitivity analysis was carried out, it revealed that the cost-effectiveness of telemedicine was sensitive to changes in the values for the number of patients, probability of successful telemedicine consultation, telemedicine equipment cost, utility of telemedicine, and percentage effort assigned to the on-site pulmonary physician [151]. Our data also suggested that telemedicine's economic impact was substantial (with moderate certainty of evidence) due to its relative potential to decrease health care costs and increase accessibility. Another critical factor to consider in the cost-effectiveness model is the reduction in the need for in-person visits, along with the associated travel expenses [152,153]. This benefit is especially significant in resource-limited regions where in-person dementia care services are often inaccessible or precarious. Finally, telemedicine holds significant potential to deliver high-quality services and ensure the continuous provision of care. Together, these capabilities contribute to advancing the WHO's goals of promoting equitable and universal access to health care. It is worthwhile mentioning that despite demonstrating cost benefits related to the use of remote interventions in dementia care, the development of robust cost-effectiveness studies and frameworks is still required, providing relevant insights for health care policy makers involved in advocating sustainable health care strategies across multiple regions in the globe [152-155].

Although we extracted and processed all barriers and facilitators mentioned in the included reviews, we chose to present them narratively due to the extensive body of literature that has emerged in these domains over recent years. Overall, the adoption of telemedicine and telehealth in dementia care is mediated by multiple components. Our findings suggested important barriers to the access and use of remote intervention for both patients and caregivers, including the need for in-person interactions, privacy and security concerns, technological challenges (eg, high-speed internet and device accessibility), and digital literacy gaps, which are particularly more challenging for older groups. In addition, geographic and accessibility limitations play a significant role in the hall of barriers,

XSL•FO
RenderX

essentially in rural areas, complicating the delivery of telemedicine solutions due to multiple factors (ie, lack of infrastructure, limited connectivity, and lack of required technical support and professional training) [139,156]. On the other hand, our summary of facilitators that foster telemedicine uptake includes a wide range of modulators, such as enhanced health care accessibility, the convenience of remote care, and potential cost savings. Moreover, some reviews emphasized that training and educational activities prior to the large-scale and realistic implementation of interventions, availability of continuous technical support, and willingness to use the technologies are critical for effective use of these interventions.

Our overview of both scoping and systematic reviews included a considerable number of reviews, assessing the impact of telemedicine and telehealth solutions based on a complex and comprehensive number of relevant domains in dementia care. As is standard practice in our group, we adhered to established methodological requirements, including registering a protocol prior to project initiation, conducting a comprehensive literature search, providing justification for excluding shortlisted studies, using appropriate synthesis methods, and addressing potential biases that could influence the results. In addition, we used the AMSTAR 2 tool and GRADE-CERQual methodology to ensure the generation of high-quality evidence, emphasizing reliability, academic rigor, and methodological robustness. However, it is equally important to acknowledge and discuss the limitations of our study. First, our overview included patients with a diverse subtype of dementia, including Alzheimer disease, vascular dementia, Lewy body dementia, and frontotemporal dementia, which limited our work in terms of heterogeneity. This may obscure definitive conclusions and recommendations derived from our study. Furthermore, inconsistencies and variability in the quality of reporting across the included reviews introduced a degree of uncertainty in several outcomes assessed during the quality evaluation phase. This ultimately led to the downgrading of the certainty of evidence for all 10 primary outcomes. Despite these limitations, our overview offers an innovative perspective on the potential of telemedicine in dementia care. It identifies actionable strengths and critical knowledge gaps, serving as a foundation for generating higher-quality evidence in the fields of neurology, psychiatry, geriatrics, and gerontology, as well as telemedicine and telehealth.

Conclusion

In conclusion, the results of this review underscore the transformative potential of telemedicine and telehealth in addressing the complex challenges of dementia care. Our comprehensive analysis revealed predominantly positive outcomes from the use of remote interventions across psychological, clinical, social, and economic outcomes. These findings are crucial for enhancing equality, accessibility, and sustainability in dementia care across diverse social and health care contexts. However, while the results are promising, they also emphasize the urgent need to address the heterogeneity in methodological quality and reporting across systematic and scoping reviews. The premises supported by this research are both viable and impactful, with the potential to be widely applicable. To fully achieve their potential as an integrated approach that overcomes multiple barriers, telemedicine and telehealth must be envisioned and implemented.

Acknowledgments

The authors wish to thank Anneliese Arno (Evidence for Policy & Practice Centre, University College London, London, United Kingdom, and School of Public Health and Preventive Medicine, Monash University, Melbourne, Australia) for granting complimentary access to Covidence (Veritas Health Innovation, Melbourne, Australia). We would like to thank the Healthier Together initiative as the strategic framework for support to Member States, and the financial support provided under the EU4Health program for the implementation of actions such as the Joint Action JADE Health. In addition, this work was supported by the European Commission under the project "Supporting Member States in strengthening health information systems and boosting health data governance." The author NSG is grateful for the research productivity grant provided by the National Council for Scientific and Technological Development of Brazil (Conselho Nacional de Desenvolvimento Científico e Tecnológico), process 309183/2025-1. The corresponding author (DNO) and the Project Manager (IJBN) affirm that the manuscript is an honest, accurate, and transparent account of the study being reported. Additionally, no important aspects of the study have been omitted, and any discrepancies from the study as registered have been explained. To disseminate our results and enhance the social and scientific impact of our research, we plan on writing several social media posts outlining the main conclusions of our paper. Additionally, we plan to present our results in 2025 at the Global Digital Health Summit (India) and at the Alzheimer's Association International Conference (Canada).

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

IJBN, YY, and DNO contributed to the study conceptualization and the development of the review protocol. LØ conducted the data search. IJBN, HMA, IW, AS, VGB, IK, CC, BS, and GD performed the title, abstract, and full-text screening. The same group (IJBN, HMA, IW, AS, VGB, IK, CC, BS, and GD) also carried out the data extraction. IJBN and NSG conducted the statistical analyses. IJBN, YY, RFD, JVH, LL, CR, HRM, NAM, and DNO made substantial contributions to the interpretation

XSL•FO
RenderX

of the results. IJBN wrote the first draft of the manuscript. All authors edited or substantively reviewed the publication. All authors had full access to all the data in the study, and IJBN, YY, and DNO directly accessed and verified the underlying data reported in the manuscript. All authors approved the final version of the publication. All authors had final responsibility for the decision to submit the manuscript and agreed to be accountable for all aspects of the work, ensuring that any questions related to the accuracy or integrity of any part of the work are appropriately investigated and resolved.

Abstract

Background: Youth mental health issues have been recognized as a pressing crisis in the United States in recent years. Effective, evidence-based mental health research and interventions require access to integrated datasets that consolidate diverse and fragmented data sources. However, researchers face challenges due to the lack of centralized, publicly available datasets, limiting the potential for comprehensive analysis and data-driven decision-making.

Objective: This paper introduces a curated directory of publicly available datasets focused on youth mental health (less than 18 years old). The directory is designed to serve as critical infrastructure to enhance research, inform policymaking, and support the application of artificial intelligence and machine learning in youth mental health research.

Methods: Unlike a systematic review, this paper offers a brief overview of open data resources, addressing the challenges of fragmented health data in youth mental health research. We conducted a structured search using 3 approaches: targeted searches on reputable health organization websites (eg, National Institutes of Health [NIH] and Centers for Disease Control and Prevention [CDC]), librarian consultation to identify hard-to-find datasets, and expert knowledge from prior research. Identified datasets were curated with key details, including name, description, components, format, access information, and study type, with a focus on freely available resources.

Results: A curated list of publicly available datasets on youth mental health and school policies was compiled. While not exhaustive, it highlights key resources relevant to youth mental health research. Our findings identify major national survey series conducted by organizations such as the NIH, CDC, Substance Abuse and Mental Health Services Administration (SAMHSA), and the U.S. Census Bureau, which focus on youth mental health and substance use. In addition, we include data on state and school health policies, offering varying scopes and granularities. Valuable health data repositories such as ICPSR, Data.gov, Healthdata.gov, Data.CDC.gov, OpenFDA, and Data.CMS.gov host a wide range of research data, including surveys, longitudinal studies, and individual research projects.

Conclusions: Publicly accessible health data are essential for improving youth mental health outcomes. Compiling and centralizing these resources streamlines access, enhances research impact, and informs interventions and policies. By improving data integration and accessibility, it encourages interdisciplinary collaboration and supports evidence-based interventions.

(JMIR Ment Health 2025;12:e73852) doi:10.2196/73852

KEYWORDS

youth mental health; publicly available datasets; data accessibility; data integration; artificial intelligence; evidence-based research

Introduction

Many mental health conditions develop during youth and adolescence, making it a global public concern [1-3]. The number of young people experiencing mental health issues continues to rise. According to the Centers for Disease Control and Prevention (CDC), the percentage of high school students reporting feelings of sadness and hopelessness increased

XSL•FO
RenderX

significantly over the past decade, rising from 28% in 2011 to 40% in 2023 [4]. This marked increase highlights a growing mental health crisis among adolescents, emphasizing the urgent need for prevention and early intervention. Adolescence is a period of significant psychological, emotional, and social development, making it a critical window for addressing mental health concerns [5]. When left unaddressed, these issues can lead to long-term worse consequences, including impaired educational attainment, strained relationships, and adverse health outcomes in adulthood, far beyond adolescence. In 2021, the U.S. Office of the Surgeon General released an advisory titled "Protecting Youth Mental Health," emphasizing the urgent need to address the mental health challenges faced by young people [6].

Young individuals with substance use disorders are at an elevated risk of developing co-occurring mental health challenges, including suicidal behaviors, which can exacerbate lifelong difficulties, contribute to social issues, and result in poorer treatment outcomes [7,8]. Preventable mental health issues, such as adolescent suicide [9,10] and substance use [11,12], significantly contribute to youth disease, disability, and mortality, highlighting the importance of proactive measures in urgent need to save lives and improve the well-being of young people. Suicide, one of the leading causes of death among young people, is often preventable through the timely identification of warning signs, access to supportive networks, and evidence-based interventions [10]. Similarly, substance use disorders, which frequently emerge during adolescence, can be reduced through early preventive strategies that focus on education, community support, and behavioral health services [12]. Investing in preventive mental health care during adolescence yields far-reaching benefits [13], not only for affected individuals at the time, but also for them later in life, their families, communities, and societies. Effective prevention programs can enhance resilience, reduce stigma, and promote mental well-being, ultimately fostering healthier and more productive generations overall.

A significant gap persists between the mental health needs of children and adolescents in the United States and the availability of services to meet those needs [14]. Most young people with mental health conditions do not seek or receive treatment [15]. Barriers include limited awareness of available services, inaccessibility, insurance coverage issues, insufficient coordinated care, a shortage of specialized providers, unstable living conditions, concerns about confidentiality, and fear of stigmatization [15,16]. Schools have been identified as critical settings for screening, preventing, and treating youth mental health issues, as students spend the majority of their daily time in these environments [5,17]. To address this critical issue, it is essential to strengthen youth-focused mental health services, integrate mental health education into school curricula, and equip educators, parents, and peers with tools to recognize and respond to early signs of distress [5]. By prioritizing prevention and early treatment, we can disrupt the cycle of untreated mental health issues and cultivate supportive environments where young people can thrive.

In alignment with these efforts, evidence-based medicine continues to drive advancements in mental health care [18]. Evidence-based approaches are crucial for addressing youth mental health challenges [19]. To ensure high-quality, impactful research and promote its translation into clinical practice, service delivery, and policy, the National Institute of Mental Health (NIMH) developed its strategic plan for research aiming at achieving these goals [20]. This plan addresses emerging challenges and opportunities by leveraging scientific advances to improve mental health outcomes. Among its 4 goals, Goal 2—"Examine Mental Illness Trajectories Across the Lifespan"—closely aligns with the collection and analysis of mental health data using diverse datasets.

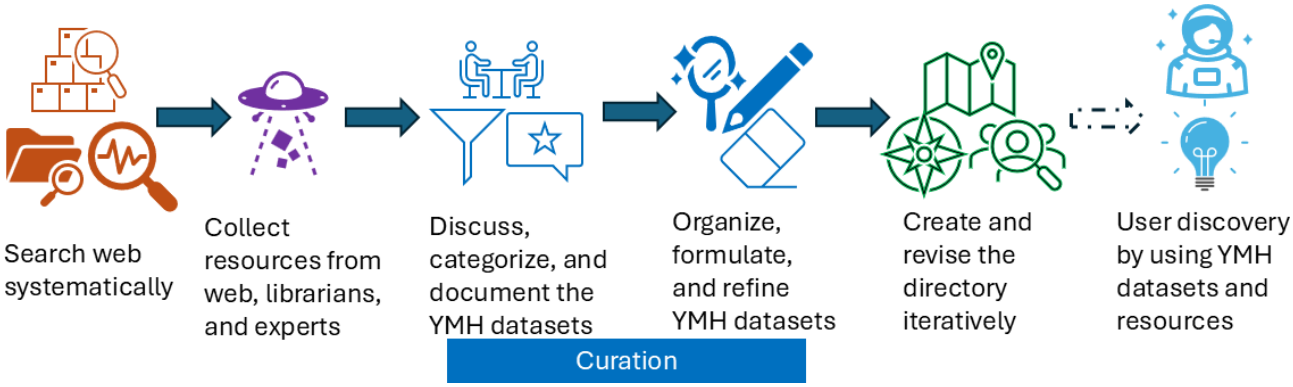
Mental health conditions are multifaceted [21], influenced by a combination of biological factors (eg, brain trauma and genetics), psychological factors (eg, stress and traumatic events), and environmental, social, and economic determinants. Understanding these complexities demands the collection and integration of diverse datasets to capture the full spectrum of influences on mental health, especially for youth. By assembling data that capture biological, psychological, social, and environmental factors, researchers can reveal a more comprehensive picture of mental health conditions, discover patterns, identify at-risk populations, and design targeted interventions that address the unique needs of young people. Notable existing data sources include national surveys such as the Youth Risk Behavior Surveillance System (YRBSS) [22], the National Survey on Drug Use and Health (NSDUH) [23], and the National Survey of Children's Health (NSCH) [24], large-scale longitudinal studies such as the Adolescent Brain and Cognitive Development (ABCD) study [25], and targeted clinical trials [26] exploring the efficacy of early interventions and prevention strategies.

The growing volume of biomedical data generated by these studies provides a solid foundation for data mining and knowledge discovery to extract meaningful insights across diverse data types [27-30]. The new emerging artificial intelligence (AI) techniques [28], such as machine learning (ML), natural language processing, and especially generative AI [29], are increasingly used to analyze large-scale datasets, identify early indicators of mental health issues, and develop predictive models for conditions such as depression, anxiety, suicide, and substance use disorders. For example, AI is being used to process real-time data from wearable devices [31], social media activities [32], and electronic health records [28] to gain insights into behavioral patterns and risk factors among adolescents. In the mental health domain, AI has been increasingly applied to develop high-quality predictive models and perform advanced data analyses. For example, deep learning techniques have been used with structural magnetic resonance imaging data from large-scale studies such as the ABCD to predict biological sex and identify gender-related variations in brain structure [33]. In addition, AI-driven analyses have been used to assess the effectiveness of telehealth interventions using datasets such as the NSDUH and other Substance Abuse and Mental Health Services Administration (SAMHSA) resources [34].

One significant challenge in data science and AI is the lack of accessible health care data. Electronic health record data are often restricted due to privacy and security regulations, such as

XSL•FO
RenderX

Health Insurance Portability and Accountability Act (HIPAA). This limitation highlights the critical role publicly available datasets play in enabling big data analysis and advancing research. These datasets are particularly vital in advancing youth mental health research, where access to comprehensive data is crucial for revealing meaningful insights and discovering new interventions.



With the National Institutes of Health (NIH) data sharing policy, an increasing amount of research data is now available for secondary data reuse, enabling a broader range of studies to build upon existing findings. Datasets such as the YRBSS, NSDUH, NSCH, and ABCD study provide researchers with open access to comprehensive data on behavioral, social, and biological factors that influence mental health. Effectively integrating these datasets will be crucial in deepening our understanding of mental health and developing innovative solutions for prevention and treatment. By leveraging these resources, researchers can collaborate across institutions, validate findings, and accelerate the discovery of new insights. Furthermore, publicly available data facilitate the development of AI-powered tools to identify trends, predict risks, and personalize mental health interventions. This approach can lead to scalable, equitable solutions to address the growing mental health needs of young people worldwide.

This paper aims to review existing publicly available datasets related to youth mental health and provide a detailed directory as a reference tool for researchers interested in integrating diverse datasets for advanced data analysis or AI-assisted discovery across different aspects of youth mental health. By highlighting the scope and potential of these datasets, this paper seeks to guide future research efforts in leveraging diverse data sources to better understand and address the complex challenges facing youth mental health.

Methods

In this brief review, we used a multifaceted approach to identify publicly available datasets relevant to youth mental health. As the study does not involve human participants or identifiable personal information, ethics approval was not required, consistent with the guidance from the U.S. Department of Health and Human Services Office for Human Research Protections (45 CFR 46). Figure 1 presents the overall workflow, which includes conducting a structured web search, consulting with librarians, and incorporating knowledge shared by domain experts. The search results were then curated through organizing, formulating, and refining the identified datasets. The resulting directory has the potential to support discovery and evidence-based research in youth mental health.

Figure 1. Overall workflow of curating the youth mental health data directory (dashed arrow indicates anticipated usage of the directory). YMH: youth mental health.

The structured search included 3 main approaches: (1) targeted search: we conducted focused searches of reputable websites of health organizations, institutions, and government agencies (eg, NIH and CDC). Our search focused primarily on U.S.-based resources; (2) librarian consultation: we collaborated with professional librarians specializing in health and social sciences to identify and verify datasets not readily found in publicly available search engines; and (3) expert knowledge: leveraging our team's expertise and prior familiarity with youth mental health research, we included datasets we had previously worked with or identified as significant in the field.

For our targeted search, we began with a literature review on PubMed using Medical Subject Headings (MeSH) terms. We conducted 2 separate searches: the first focused on mental health and the second on substance use.

- Mental health search: ("Datasets as Topic"[MeSH]) AND ("Mental Health"[MeSH]) OR ("Behavioral Medicine"[MeSH])
  Filters: Child (birth-18 years), Child (6 - 12 years), Adolescent (13 - 18 years)
- Substance use search: ("Behavioral Medicine"[Majr]) OR ("Mental Health"[Majr]) AND ("Substance-Related Disorders"[Majr])
  Filters: Child (birth-18 years), Child (6 - 12 years), Adolescent (13 - 18 years)

The inclusion criteria were as follows: (1) the article was peer reviewed and written in English; (2) the full text was available; (3) the research was conducted using publicly available datasets, including studies using multiple datasets; and (4) the primary focus was on mental health or substance use. We also included datasets focused on school health policies and systems that, while not containing individual-level mental health data, provide essential contextual information relevant to youth mental health research. These datasets support investigations of structural and environmental influences on mental health outcomes and were

XSL•FO
RenderX

included to encourage more integrative and upstream approaches in the field.

The search returned 197 papers for mental health and 294 papers for substance use. All papers were manually reviewed by the first author (HM), who extracted the datasets mentioned in the articles. The results were validated by the second author (XJ). After identifying the datasets, we visited the corresponding websites directly to obtain more detailed information about each dataset. We also consulted our university librarians and one of the authors (CES), an expert in youth mental health, to identify and add additional relevant datasets.

Next, we curated and categorized the identified datasets, providing a detailed and consistent description of each, including the following elements:

1. Dataset name: the title of the dataset and the organizations responsible for its creation.
2. Description: the primary research goals and questions the dataset is designed to address.
3. Components: key variables and types of data collected, such as biological, psychological, social, or economic data.
4. Downloadable site: direct URL link to download the dataset, with an emphasis on datasets that are freely available and do not require restrictive licensing or complex application processes.
5. Data format: information about the format of the data (eg, CSV, SAS, SPSS, and so on).
6. Data categories: the type of study or data collection method, such as national surveys, administrative records, or longitudinal cohort studies.
7. Access requirements: public-use data are openly accessible without restrictions. Restricted-use data typically require a Data Use Agreement (DUA), an approved proposal, and access through a secure data center or administrative process. These requirements are often necessary to access sensitive variables such as detailed geographic information or personally identifiable data.

Results

A list of publicly available datasets addressing youth mental health and school policies was compiled in Table 1. While this is not a comprehensive list of all available datasets, it includes key resources that are relevant to youth mental health. The CDC initiates, conducts, and supports many national surveys to understand youth mental health, including the YRBSS, School Health Profiles (SHP), School Health Policies and Practices Study (SHPPS), National Health Interview Survey (NHIS), and the National Youth Tobacco Survey (NYTS). Another important agency is the SAMHSA [35] which collects data related to substance use and mental health services, including NSDUH, National Substance Use and Mental Health Services Survey (N-SUMHSS), Mental Health Client-Level Data (MH-CLD), and Treatment Episode Data Set (TEDS). The U.S. Census Bureau also conducts an annual household survey, the NSCH, which provides national- and state-level data on the health and health care needs of children aged 0 - 17 years, as well as their families and communities. The NIMH Data Archive is a valuable resource for mental health data, including studies focusing on youth mental health. One such study is the ABCD study, which tracks over 11,000 children starting at ages 9 - 10 to examine how factors such as substance use and genetics influence brain development. Another is the Treatment for Adolescents with Depression Study (TADS), along with its follow-up, Substance Use and Other Outcomes Following Treatment for Adolescent Depression (SOFTAD), evaluates treatments for adolescent depression and their long-term effects on substance use and other outcomes. In addition, the Agency for Healthcare Research and Quality (AHRQ) conducts the annual Medical Expenditure Panel Survey (MEPS) to collect data on health care use, costs, insurance coverage, and health status from individuals, families, medical providers, and employers across the United States. The National Data Archive on Child Abuse and Neglect (NDACAN) curates a wide range of datasets related to child maltreatment, including administrative records, survey results, and state- and local-level reports. These datasets provide valuable insights into the prevalence, characteristics, and outcomes of child abuse and neglect, as well as the effectiveness of related systems and services.

Table . Overview of publicly available datasets addressing youth mental health and school policies.

Name	Administered by	Description	Components	Reference	File format	Category	Access requirements
Youth Risk Behavior Surveillance System (YRBSS)	CDC[a] Division of Adolescent and School Health (DASH)	Since 1991, the YRBSS has been administered during the spring of odd-numbered years to students in grades 9 - 12 enrolled in U.S. public and private schools.	Focuses on youth health behaviors and conditions, including sexual activity, injury and violence, bullying, diet, physical activity, obesity, mental health, suicide-related behaviors, and substance use.	[36]	Access and ASCII	Cross-sectional and nationally representative survey	Public-use data
School Health Profiles (SHP)	CDC DASH	Since 1996, the survey has been conducted every even-numbered year to assess school health policies and practices in states, large urban school districts, and U.S. territories.	Covers topics such as health education, physical education and activity, tobacco use prevention, nutrition services, school health policies, family and community involvement, school-based health services, and professional development.	[37]	ASCII, SAS, or Excel	Cross-sectional survey	Restricted-use data
School Health Policies and Practices Study (SHPPS)	CDC	Since 1994, the survey has been conducted every 6 years at the state, district, school, and classroom levels for grades K–12.	Covers 8 components of school health at the state and district levels: health education, physical education and activity, health services, mental health and social services, nutrition services, safe school environment, staff health promotion, and family and community involvement.	[38]	ASCII, Access, SAS, SPSS	Cross-sectional and nationally representative survey	Public-use data

XSL•FO
RenderX

Name	Administered by	Description	Components	Reference	File format	Category	Access requirements
National Health Interview Survey (NHIS)	CDC through the National Center for Health Statistics (NCHS)	Since 1957, the survey has been conducted annually on the civilian noninstitutionalized population, selecting one adult (Sample Adult) and one child (Sample Child) randomly from each family.	Includes annual core topics such as chronic conditions, functioning and disability, insurance, health care access and use, health behaviors, and demographics; rotating core topics include health care use, mental health assessments, chronic pain, preventive services, industry and occupation, and injuries.	[39]	ASCII, CSV, SAS, SPSS, STATA	Cross-sectional and nationally representative survey	Public-use data and restricted-use data
National Youth Tobacco Survey (NYTS)	CDC	Since 1999, the NYTS has been conducted annually as a voluntary, school-based, self-administered survey targeting U.S. middle and high school students.	Measures tobacco-related items, including demographics, youth access, and exposure to secondhand smoke.	[40]	SAS, Access, and Excel	Cross-sectional and nationally representative survey	Public-use data
National Survey of Children's Health (NSCH)	Health Resources and Services Administration's (HRSA) Maternal and Child Health Bureau (MCHB) and U.S. Census Bureau	Conducted annually as a household survey, it is the largest national- and state-level survey on the health and health care needs of children aged 0 - 17 years, their families, and their communities.	Covers family health and activities; health conditions and functional difficulties; insurance status, type, and adequacy; health care use and access; impact of child's health on the family; medical home; parental health and neighborhood perceptions; physical and mental health; preventive and specialty care; school readiness; and transition to adult care.	[41]	SAS, STATA	Cross-sectional and nationally representative survey	Public-use data

XSL•FO
RenderX

Name	Administered by	Description	Components	Reference	File format	Category	Access requirements
National Survey on Drug Use and Health (NSDUH)	Substance Abuse and Mental Health Services Administration (SAMHSA)	Since 1971, the survey has been conducted annually and provides representative data of persons aged 12 years and older in the civilian noninstitutionalized population of the United States	Includes topics on the use of tobacco, alcohol, and drugs; substance use disorders; mental health issues; and receipt of substance use and mental health treatment	[42]	SAS, SPSS, Stata, Delimited, R	Cross-sectional and nationally representative survey	Public-use data and restricted-use data
National Substance Use and Mental Health Services Survey (N-SUMHSS)	SAMHSA	Annual survey of all active substance use and mental health facilities across the United States	Provides number, location, and characteristics of public and private-owned mental health and substance use facilities in the United States	[43]	SAS, SPSS, Stata, Delimited, R	Cross-sectional and nationally representative survey	Public-use data and restricted-use data
Mental Health Client-Level Data (MH-CLD)	SAMHSA	Since 2011, MH-CLD captures patients treated in facilities that are either operated by or receive block grant funding through a state mental health agency.	Collects demographic and mental health characteristics data on approximately 5 to 6 million patients receiving care in outpatient, hospital inpatient, and residential services each year	[44]	SAS, SPSS, Stata, Delimited, R	Administrative records data	Public-use data and restricted-use data
Treatment Episode Data Set (TEDS)	SAMHSA	TEDS is a national data system of annual admissions to and discharges from substance use treatment facilities that are licensed or certified by Single State Agencies to provide substance use treatment services.	Contains demographic, substance use, mental health, clinical, legal, and socioeconomic characteristics of all admissions and discharges aged 12 years and older who are receiving publicly funded substance use treatment services.	[45]	SAS, SPSS, Stata, Delimited, R	Administrative records data	Public-use data and restricted-use data

Adolescent Brain Cognitive Development Study (ABCD)	NIMH[b] Data Archive	It is a prospective cohort study that enrolled 11,876 children aged 9 to 11 years, recruited from 21 study sites in the baseline year (2016 - 2018). This study will follow participants until they are approximately 19 - 20 years old.	Collects data on brain development, physical health, behavioral patterns, and mental health, including neuroimaging, substance use, cognitive assessments, and psychosocial factors. It also gathers genetic and epigenetic data to explore how environmental and genetic influences affect adolescent development over time.	[46]		Longitudinal cohort study	Restricted-use data
Treatment for Adolescents with Depression Study (TADS) and Substance Use and Other Outcomes Following Treatment for Adolescent Depression (SOFTAD)	NIMH Data Archive	TADS included 439 participants ages 12 to 17 years from various geographic regions in the United States who were diagnosed with major depression. The SOFTAD study recruited 196 of these 439 adolescents and followed them for an additional 3.5 years to explore whether successful treatment of depression reduces the risk of developing substance use disorders and other outcomes.	Examines the short- and long-term effectiveness of the antidepressant medication fluoxetine (Prozac), cognitive behavioral therapy alone, and their combination for treating depression in adolescents.	[47]	SAS, SPSS, CSV	Randomized longitudinal clinical trial	Restricted-use data
Medical Expenditure Panel Survey (MEPS)	Agency for Healthcare Research and Quality (AHRQ)	Started in 1996, it is an annual survey of families, individuals, medical providers (doctors, hospitals, pharmacies, etc), and employers across the United States. It includes 2 main components: Household Component and Insurance Component.	Collects data on the specific health services that Americans use, how frequently they use them, the cost of these services, and how they are paid for, as well as data on the cost, scope, and breadth of health insurance held by and available to U.S. workers.	[48]	SAS, Stata, R, ASCII	Cross-sectional and nationally representative survey	Public-use data and restricted-use data

National Data Archive on Child Abuse and Neglect (NDACAN)	U.S. Department of Health and Human Services	Since 1988, NDACAN promotes scholarly exchange among researchers in the child maltreatment field. The archive provides access to national-, state-, and local-level data.	Provides access to national-, state-, and local-level data primarily aimed at tracking the volume and nature of child maltreatment reports each year in the United States, and supports research to inform policies and practices that improve child welfare and protect children.	[49]	SAS, SPSS, and STATA	A data repository containing cross-sectional, nationally representative, and Administrative/clinical data	Restricted-use data
NKI Rockland Sample (NKI-RS)	NIH[c] and the New York State Office of Mental Health	Approximately 1500 individuals aged 6 to 85 years were recruited from the Rockland County community in New York.	Provides a rich neuroimaging and phenotypic resource to characterize lifespan normative brain-behavior relationships. Includes psychiatric diagnostics, medical, behavioral, and cognitive phenotyping; multimodal brain imaging (resting fMRI[d], diffusion MRI[e], morphometric MRI, arterial spin labeling); genetics; and actigraphy.	[50] [51]	BIDS and CSV	Longitudinal study	Public-use data and restricted-use data
Healthy Brain Network (HBN)	Child Mind Institute	HBN creates a Biobank from a community sample of 10,000 children and adolescents (ages 5 - 21 years) residing in the New York City area	Collects a wide array of data, including neuroimaging (MRI), genetics, behavioral assessments, and clinical data to improve understanding of brain health and mental illness across age groups.	[52] [53]	BIDS and CSV	Cross-sectional study with biobanking and some longitudinal follow-up.	Restricted-use data

[a]CDC: Centers for Disease Control and Prevention.

[b]NIMH: National Institute of Mental Health.

[c]NIH: National Institutes of Health.

[d]fMRI: functional magnetic resonance imaging.

[e]MRI: magnetic resonance imaging.

Like the ABCD study, there are 2 other local neuroimaging studies: the NKI Rockland Sample (NKI-RS) [54] and the Healthy Brain Network (HBN) [55]. The NKI-RS focuses on understanding brain function and structure across a wide range of conditions, while HBN aims to improve the diagnosis and treatment of mental health and learning disorders by identifying biological markers, such as brainwave signals and imaging data. Both studies provide valuable neuroimaging data to advance

XSL•FO

research in mental health and cognitive development. Image data from both studies are stored on Amazon Web Services (AWS) S3, providing accessible and scalable storage for large datasets.

The Inter-university Consortium for Political and Social Research (ICPSR) [56], based at the University of Michigan, is one of the world's largest archives of social science data. It offers extensive datasets for research and education across social, behavioral, and health sciences. These datasets include both publicly available and restricted-access data from single studies, U.S. national surveys, and international studies and surveys. A search for "youth mental health" or "youth substance use" or "adolescent mental health" or "adolescent substance use" on ICPSR returns 362 studies. Table 2 shows 10 randomly selected public-use youth mental health datasets from the ICPSR. For example, Monitoring the Future: A Continuing Study of American Youth, funded by National Institute on Drug Abuse, is a study of the behaviors, attitudes, and values of Americans from adolescence through adulthood. To date, 133 data files are hosted at ICPSR.

Other central repositories for open data from the U.S. government include Data.gov, which are presented in Table 3. The Department of Health and Human Services (HHS) publishes datasets as part of its Open Data program. The primary resource for public access to health-related data is Healthdata.gov, with additional specialized sites available for specific topics, including Data.CDC.gov, OpenFDA, and Data.CMS.gov. Figure 2 summarizes the results.

National Longitudinal Study of Adolescent to Adult Health (Add Health), 1994 - 2018	Adolescents in grades 7 through 12 were enrolled during the 1994 - 1995 school year and were followed into young adulthood through 4 in-home interviews. The most recent interview was conducted in 2008, when participants were between 24 and 32 years old.	Collects data on social, economic, psychological, and physical well-being, alongside contextual information about family, neighborhood, community, school, friendships, peer groups, and romantic relationships.	[57]	SAS, SPSS, STATA, R, ASCII, Delimited	Longitudinal cohort study
Family cumulative risk and mental health in Chinese adolescents	This study examines the developmental cascades among family cumulative risk, life satisfaction, and symptoms of anxiety and depression in Chinese adolescents.	Covers family cumulative risk and mental health	[58]	SPSS	Observational study
Resilience and Mental Health among Juveniles	The first study involved 201 juveniles, the second involved 253 juveniles.	Study 1 analyzes the relationship between resilience and overall mental health of juveniles admitted to youth education centers. Study 2 examines how resilience directly and indirectly affects juveniles' mental health.	[59]	SPSS	Observational study
Adolescent Depression	This dataset focuses on self-compassion, self-efficacy, and trait resilience as mediators between insecure attachment (specifically attachment anxiety and attachment avoidance) and depression.	Collects anxiety and depression	[60]	SPSS	Observational study
Health Behavior in School-Aged Children (HBSC), 2009 - 2010	Since 1982, the WHO[a] Regional Office for Europe has sponsored the HBSC study, surveying the health behaviors of young people every 4 years in over 40 countries. The data available here are from the results of the U.S. survey conducted during the 2009 - 2010 school year.	Includes questions on substance use (tobacco, alcohol, marijuana), family composition, physical health, health behaviors (eating habits, dieting, physical activity, body image), health issues, and bullying. Also collects school administrator data on programs, policies, and health course content.	[61]	SAS, SPSS, STATA, R, ASCII, Delimited	Cross-sectional and nationally representative survey

National Youth Survey (NYS) Series	NYS is a longitudinal study of delinquency among American youth during the period 1976 through 1980. For this series, parents and youth were interviewed about events and behavior of the preceding year to gain a better understanding of both conventional and deviant types of behavior by youths.	Includes data on demographics, socioeconomic status, family disruptions, neighborhood issues, parental expectations, labeling, family and peer influences, attitudes toward deviance, parental discipline, community engagement, substance use, victimization, pregnancy, depression, outpatient services, domestic violence, and sexual activity.	[62]	SAS, SPSS, STATA, ASCII, Delimited	Longitudinal cohort study
National Survey of Children: Wave I, 1976, Wave II, 1981, and Wave III, 1987 (ICPSR 8670)	The survey aims to assess the physical, social, and psychological well-being of American children, create a national profile of their living conditions, analyze the relationship between these conditions and child development, and examine the effects of marital disruption on children and family	Provides information on the child's well-being, family, family disruption experiences, behavior, physical health, and mental health.	[63]	ASCII	Longitudinal cohort study
Child Abuse, Neglect, and Violent Criminal Behavior in a Midwest Metropolitan Area of the United States, 1967 - 1988 (ICPSR 9480)	The study examines the link between childhood abuse or neglect and later criminal behavior, focusing on whether early victimization leads to criminal offending in adolescence or adulthood, and its association with juvenile and adult arrests, particularly for violent offenses.	Part 1: Demographics (age, race, sex, birthdate). Part 2: Abuse/neglect details (type, duration, removal, placement, survival). Part 3: Family information (household, disruptions, reporters) and perpetrator data (relation, age, race, sex). Part 4: Adult arrest charges (occasion, counts, year, location, offense). Part 5: Juvenile arrest charges (year, number of arrests, offense). Parts 1 - 3 focus on individuals under age 11; Part 4 covers adult charges; Part 5 covers juvenile charges.	[64]	SAS, SPSS, STATA, ASCII	Prospective cohort study

Monitoring the Future: A Continuing Study of American Youth (12th-Grade Survey), 2020 (ICPSR 38156)	This survey of 12th-grade students examines changes in values, behaviors, and lifestyle orientations of American youth. Students complete one of 6 randomly assigned questionnaires, each with unique topical questions but all including core questions on demographics and drug use.	Covers use of substances such as tobacco, alcohol, marijuana, prescription drugs, LSD, cocaine, ecstasy, heroin, and more. Also includes attitudes toward religion, women's roles, educational goals, self-esteem, drug education, and exposure to violence and crime.	[65]	SAS, SPSS, STATA, R, ASCII, Delimited	Cross-sectional and nationally representative survey with a longitudinal subsample
Youth, Education, and Society Supplement: School Health Policies and Practices Survey (YES), 2006 - 2014 (ICPSR 36350)	YES surveyed secondary schools in the Monitoring the Future study and a larger supplementary sample, conducting annual surveys of school administrators from 2006 - 2007 to 2013 - 2014 school year.	Includes school characteristics, nutrition and physical education policies, lunch programs, and vending machines, stores, and snack bars.	[66]	SAS, SPSS, STATA, ASCII	Cross-sectional and nationally representative survey

Figure 2. The summary view of the youth mental health data directory. ICPSR: Inter-university Consortium for Political and Social Research; YMH: youth mental health.

In addition to the raw data collected, researchers often identify, code, and summarize publicly available research reports and publications within a particular domain (eg, children and adolescent psychotherapy), categorizing them as researcher assertions rather than data assertions [72]. Such literature data, similar to systematic literature reviews, represent another critical form of publicly accessible information. Despite their descriptive nature, they can be used for meta-analyses, understanding the current state of the field, identifying potential research gaps, and conducting other aggregate evidence-based analyses. Common and reliable sources for identifying data or studies include PubMed, Cochrane Library, PsycINFO, Embase, ClinicalTrials.gov, and NIH RePORT for research portfolios.

Discussion

Summary of Results

Our findings highlight several major national survey series, conducted by organizations such as the CDC, SAMHSA, and the U.S. Census Bureau, that focus on youth and adolescent mental health and substance use. For instance, the YRBSS monitors behaviors that may negatively impact the health of high school students. The NSCH provides extensive data on various aspects of children's lives, including physical and mental health, health care access and quality, and their family, neighborhood, school, and social environments. Similarly, the NSDUH offers estimates of substance use and mental illness at the national, state, and local levels, helping to identify prevalence across different groups, track trends over time, and assess treatment needs.

We also collect data on state and school health policies, which provide data with different scopes and granularities. Since youth spend the majority of their daily time at school, these policies play a crucial role in their mental health. The CDC's Division of Adolescent and School Health (DASH) has developed an action guide to promote mental health and well-being in schools [73]. It also collects data on youth and school health policies and practices through initiatives such as the SHP. Similarly, the CDC has conducted the SHPPS to provide additional insights. These 2 datasets, SHP and SHPPS, are primarily focused on school policy and practice, rather than on individual student data or a sample of student data. However, they are important for researchers who want to study the impact of policy on student mental health, which is why we have also included them in our directory.

The World Health Organization (WHO) conducts a similar survey, the Global School-based Student Health Survey (GSHS), to help countries measure and assess behavioral risk and protective factors among young people aged 13 to 17, related to the leading causes of morbidity and mortality among children and adults worldwide.

The ABCD study, NKI-RS, and HBN are 3 influential neuroimaging studies that are contributing valuable insights into brain development and mental health. A key aspect of their success is the use of advanced storage solutions such as AWS S3, which enables them to handle large and complex datasets efficiently. By using AWS S3, these studies improve data management and provide easier access to large-scale neuroimaging data, advancing mental health research and supporting personalized, data-driven treatment approaches.

ICPSR, Data.gov, Healthdata.gov, Data.CDC.gov, OpenFDA, and Data.CMS.gov are valuable health data repositories that host a wide range of research data, including surveys, longitudinal studies, and individual research projects. These platforms provide extensive datasets that are crucial for public health research, policy analysis, and decision-making. They offer access to data on various health topics, such as disease prevalence, health care use, medication usage, and health behaviors, allowing researchers, policymakers, and practitioners to make informed decisions and conduct comprehensive analyses to improve public health outcomes.

Evaluation of the Strengths and Limitations of Datasets in This Directory

To support researchers in selecting the most appropriate data sources, we summarize key strengths and limitations of publicly available datasets included in this directory. These evaluations highlight the robustness of mental health measures, longitudinal design, and coverage of specific subpopulations. Several datasets, such as NHIS, NYTS, NSCH, YRBSS, and NSDUH, are cross-sectional in design. While they provide nationally representative snapshots of mental health indicators, behaviors, and service use, their cross-sectional nature limits the ability to examine developmental trajectories or long-term outcomes. The YRBSS, in particular, focuses on high school students and includes mental health-relevant items such as depressive symptoms, suicidal ideation, and risk behaviors, but it does not provide clinical diagnosis or longitudinal follow-up. In contrast, datasets such as the ABCD study and MEPS offer longitudinal data, allowing researchers to track changes in mental health, cognitive development, and service use over time. The ABCD study is especially notable for its multimodal design, incorporating neuroimaging, genetics, and detailed behavioral and psychosocial assessments, making it a rich resource for studying the developmental pathways of mental health and substance use. Some datasets, for example, MH-CLD and TEDS, provide detailed clinical information on service encounters but may lack comprehensive symptom-level or diagnostic data, particularly for youth. In addition, access to certain datasets, such as those housed in the NDACAN or clinical trials such as TADS and SOFTAD, may require additional steps for approval and involve samples that are not broadly generalizable.

Importance of Publicly Available Data for Youth Mental Health Research

Adolescence is a pivotal stage of development where mental health challenges, such as anxiety, depression, and trauma-related disorders, often emerge. However, these challenges remain under-researched due to limited access to comprehensive, high-quality datasets. Furthermore, considering youths are at the early stage of one's life, effective management and treatment of mental health conditions will have profound impacts on the rest of their lives, which distinguishes the crucial period and critical nature of studying youth mental health.

Access to publicly available data enables researchers to identify trends and patterns in mental health conditions, risk factors, and service use among diverse populations of youth. Such data also allow for the evaluation of the impact of school health policies on mental health outcomes, shedding light on how these policies can support students' well-being and promote mental health education. By uncovering key insights into the prevalence and effects of mental health challenges, these data guide future research and inform intervention strategies. Furthermore, they provide a foundation for developing evidence-based interventions tailored to the unique needs and characteristics of different youth groups, promoting more effective and targeted outcomes.

Publicly available data also help to address health disparities by providing a means to explore differences in mental health outcomes based on factors such as socioeconomic status, race, and geographic location. This, in turn, can inform more equitable solutions and ensure that mental health services reach those who need them most. Furthermore, open access to data fosters cross-disciplinary collaboration, bringing together experts from various fields such as psychology, public health, and education to tackle complex mental health issues from multiple angles.

Moreover, publicly available datasets empower community organizations, schools, families, and mental health providers by providing actionable insights that help shape programs, allocate resources more effectively, and create supportive environments for youth.

Significance of Curating a List of Publicly Available Data and Resources for Youth Mental Health Research

With the growing number of studies, datasets, and reports being published across various platforms—each designed to address specific aspects of health and often collecting data independently without integration—the volume of fragmented data is increasing. This highlights the urgent need to create a centralized list of health data repositories to streamline access, reduce redundancy, and enhance their overall utility, thereby accelerating advancements in youth mental health research.

Compiling a list of available data also encourages data reuse, allowing researchers to explore secondary research questions and make the most of existing datasets. While there are similar efforts, such as ICPSR, its scope is broader and not specifically focused on youth mental health. In contrast, our directory focuses exclusively on youth mental health, helping users save time by eliminating the need to search for datasets individually. Moreover, ICPSR does not provide a comprehensive list of youth mental health datasets, omitting key resources such as the NYTS and MH-CLD.

In addition, a centralized health data repository helps policymakers by providing easy access to relevant data, empowering them to make informed, data-driven decisions to improve youth mental health outcomes. Furthermore, such a resource supports interdisciplinary collaboration by enabling researchers from diverse fields—such as public health, psychology, pediatrics, education, and social work—to access and use datasets relevant to their work. This collaborative potential can accelerate innovation, inform policy, and drive the development of targeted interventions to address complex health challenges such as youth mental health effectively.

Benefits of Linked Datasets

The list of publicly available data and resources not only promotes secondary data analysis but also provides a foundation for more advanced linked data analysis. By integrating datasets from different sources, such as school health policies and youth mental health outcomes, researchers can gain deeper insights into the relationships between various factors influencing youth well-being. For example, Foti et al [74] investigated how state and local agencies use the YRBSS and SHP in various ways to monitor and address issues related to adolescent and school health. Gould et al [75] used 2 national surveys to assess the impact of the BP Deepwater Horizon oil rig explosion on mental health, substance use disorders, chronic health conditions, and use among local residents. The first survey was the NSDUH

XSL•FO
RenderX

Gulf Coast Oversample (GCO), part of the 2011 NSDUH, and the second was the CDC's Gulf States Population Survey (GSPS). Linked data allowed researchers to conduct more comprehensive analyses that can inform more effective interventions and policies, both locally and globally.

However, several challenges exist in linking youth mental health datasets. First, the number of well-known and widely available datasets in this field is limited. This paper aims to introduce existing datasets by compiling them from multiple sources into a centralized directory. Second, the lack of standardized frameworks hinders the integration of youth mental health data. Data collected and archived by various organizations and studies result in inconsistencies in terminology, variations in data structures, and differences in how key concepts—such as mental health outcomes, demographic information, and treatment interventions—are represented across datasets. One widely recognized solution to this challenge is the use of ontologies, which have been successfully applied in the medical field. Ontologies provide a structured framework to harmonize these core concepts, facilitating more efficient data sharing, comparison, and integration [76]. While some ontologies exist in the behavioral and mental health domain, such as the Behavior Change Intervention Ontology (BCIO) [76], Addiction Ontology [77], Mental Disease Ontology [78], Mental Health Management Ontology [79], and Social Determinants of Health Ontology (SDoHO) [80], they remain insufficient and lack detailed coverage specific to youth mental health. The absence of comprehensive standardization creates significant barriers to effective data integration and analysis, further underscoring the urgent need for ontologies in the behavioral sciences [81].

Limitations

While the availability of publicly accessible health data is invaluable for advancing research on youth mental health, there are several limitations that must be addressed. First, our list is not comprehensive, but it serves as a starting point for researchers to discover and access relevant health data repositories. Second, there are inconsistencies across datasets. Datasets across different platforms may use varying definitions, classifications, and measurement tools for mental health conditions, making it difficult to compare or combine data from multiple sources. This lack of standardization can introduce biases and complicate analyses. Third, many publicly available datasets are cross-sectional, capturing a snapshot of youth mental health at a particular point in time. However, understanding mental health requires a longitudinal approach, tracking changes over time. The lack of long-term data restricts the ability to assess causal relationships or predict future mental health outcomes. Finally, some datasets may not adequately represent certain geographic regions or demographic groups, particularly marginalized communities. This lack of representation can hinder the understanding of mental health disparities and limit the applicability of research findings to diverse populations.

Future Work

Despite these limitations, several avenues for future work can improve the utility and impact of publicly available data for youth mental health research. This paper represents an initial step in creating a dedicated directory for publicly available youth mental health data resources. In the future, we aim to develop a Youth Mental Health Ontology (YMHO) based on the datasets in this directory, harmonizing the data with established standards (eg, Observational Medical Outcomes Partnership [OMOP] Common Data Model [CDM] [82]) and YMHO itself. By compiling the high-quality datasets, based on defined criteria, to advance the understanding of youth mental health.

There is a need for standardized definitions, measures, and data collection methods across datasets to facilitate data sharing and integration. Such standardization would allow researchers to more effectively compare and combine data from different sources, leading to more robust findings.

Continued advances in ML and AI are expected to drive breakthroughs across a wide range of research fields, including mental health, in the coming years. However, these advancements depend on large volumes of well-curated, FAIR (Findable, Accessible, Interoperable, and Reusable) data. Effective and automatic curation processes, as shown in the central part of Figure 1, are crucial for data integration and harmonization, encompassing the characterization, annotation, management, and preservation of digital datasets. Here are several existing automatic curation examples. PubTator [83] is an AI-empowered annotation tool, a key component of automatic curation; some efforts focus on automatic population of ontology (Ontorat [84]) or streaming some parts of the workflow (ROBOT [85]) as well as other efforts [86,87]; other efforts focus on automatically identifying candidate key phrases to facilitate ontology construction and maintenance [88-91]. In addition, automatic curation could include information extraction, key component recognition, data integration, and so on. These processes will further improve the efficiency and accessibility of these valuable resources and also meet the needs of a large number of curated data for ML and AI to apply.

Building collaborative platforms that integrate multiple data sources and encourage interdisciplinary collaboration will promote innovative solutions to youth mental health issues. These platforms could also facilitate real-time data sharing, allowing for quicker responses to emerging mental health trends and crises.

Conclusions

The availability of publicly accessible health data is a cornerstone for improving youth mental health outcomes. Compiling an extensive list of such data and resources not only streamlines access but also enhances the impact of research, interventions, and policies for youth mental health. This initiative is vital for fostering collaboration, addressing disparities, and advancing the collective goal of healthier, more resilient adolescents.

Abstract

Background: In recent years, policymakers worldwide have been increasingly concerned with promoting public mental well-being. While digitally supported well-being interventions seem effective in general nonclinical populations, their cost-effectiveness remains unclear.

Objective: This study aims to systematically synthesize evidence on the cost-effectiveness of digitally supported mental well-being interventions targeting the general population or adults with subclinical mental health symptoms.

Methods: PubMed, Embase, Scopus, and Web of Science were systematically searched for health economic or cost-minimization studies. Eligibility criteria included interventions in the general population or adults showing risk factors or subclinical mental health symptoms, with at least 1 digital component. Study quality was comprehensively assessed using the Consensus Health Economic Criteria list.

Results: Of 3455 records identified after duplicate removal, 12 studies were included: 3 studies evaluated universal prevention, 3 investigated selective prevention, and 6 covered indicated prevention. Six studies applied a societal perspective. Incremental cost-utility ratios were reported in 6 of the included studies and varied from dominant to €18,710 (US $ 23,185) per quality-adjusted life year. In general, digitally supported well-being interventions in nonclinical adults, and particularly indicated prevention strategies, seemed to generate improved health outcomes at lower costs from a societal perspective. The quality appraisal highlighted several shortcomings of the available literature.

Conclusions: Overall, the use of digital tools for mental well-being prevention and promotion in nonclinical adult populations has the potential to be cost-effective. Nevertheless, to adequately guide policymaking, more evidence is still needed. Future studies should ensure valid argumentation for the applied time horizon and perspective, alongside rigorous sensitivity analyses in accordance with best practices to improve cost-effectiveness evidence. Furthermore, assessment methods more sensitive to changes in well-being such as the EQ Health and Well-being instrument could be considered.

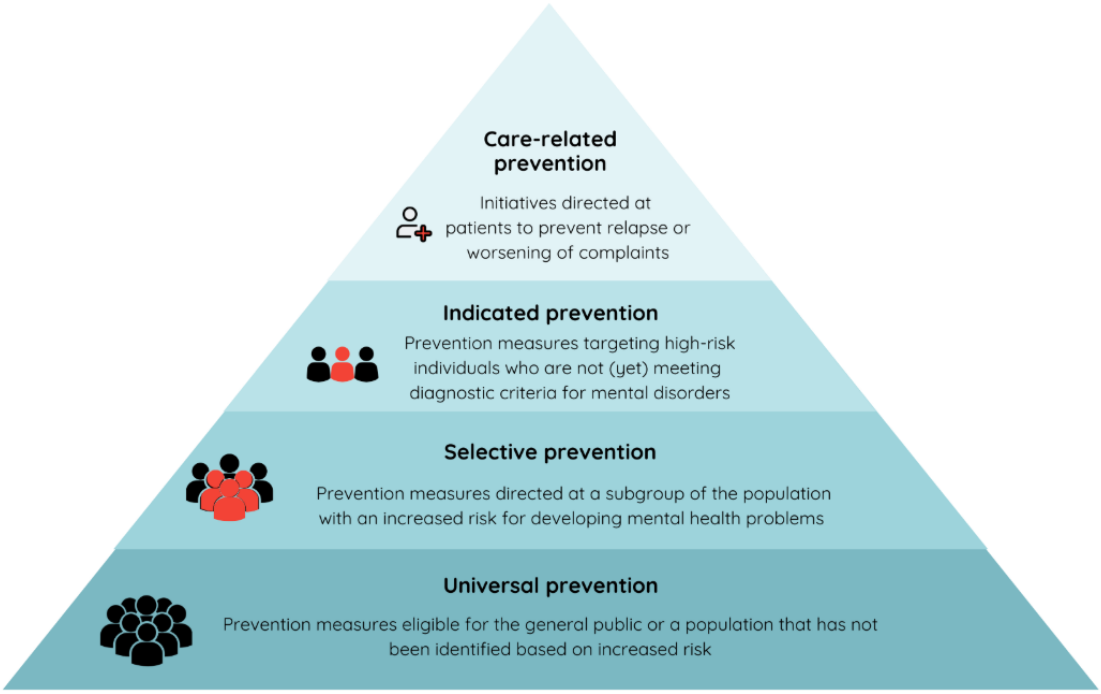
Introduction

Over the past decades, policymakers have increasingly recognized that societal welfare goes beyond economic success and includes the mental well-being of citizens as well [1-3]. Mental well-being is commonly conceptualized in terms of three core components: (1) subjective well-being, including life satisfaction, frequent positive emotions, and infrequent negative emotions; (2) positive psychological functioning and self-actualization; and (3) optimal social functioning [4]. The growing interest in public well-being is underpinned by evidence linking mental well-being to a wide range of beneficial outcomes such as greater health and longevity, enhanced productivity, and stronger social relationships [5,6]. Given these far-reaching positive effects, promoting public well-being has become a priority on political agendas worldwide, as reflected in the objectives of the World Health Organization (WHO) and the Council of the European Union (EU Council) [7,8]. The WHO's Mental Health Action Plan (2013 - 2030) prioritizes promotion of mental well-being, prevention of mental ill health, and access to appropriate care, whereas the EU Council advocates for investments in people's overall well-being as a means to enhance societal resilience and support sustainable economic growth.



The promotion of public well-being could be facilitated with digital tools such as smart devices, mobile apps, and websites, considering their potential for accessibility and scalability.

Recently, a meta-analysis indeed found support for the effectiveness of fully automated digital interventions in improving the mental well-being of the general population [9]. Moreover, digital well-being interventions are frequently regarded as a cost-effective strategy [9]. Nevertheless, scientific evidence to support this claim is still limited. A recent systematic review concluded that web-based interventions for mental disorders are likely to be cost-effective compared with care as usual [10]. In addition, evidence suggests that mental health prevention and promotion strategies are cost-effective [11]. However, ambiguity remains about the value for money of digitally supported well-being prevention and promotion for the general public.

Mental well-being prevention and promotion strategies can be categorized based on their target population. In particular, a distinction can be made between universal, selective, indicated, and care-related prevention (Figure 1) [12,13]. Universal prevention is suitable for the whole population and is directed at the general public, which has not been selected based on specific characteristics or risk factors. In the case of selective prevention, the intervention targets populations with an elevated risk of developing mental health problems. An intervention strategy addressed to individuals identified as high risk, while not meeting diagnostic criteria for mental disorders, is described as indicated prevention. Finally, care-related prevention is directed at patients to reduce the likelihood of relapse and the worsening of complaints and is considered a fundamental part of treatment itself [12,13]. As the focus of this review is on general adult populations, populations at risk, and high-risk adults with up to subclinical symptoms, cost-effectiveness evidence of universal, selective, and indicated prevention strategies with a digital component will be included.

Figure 1. Classification of prevention strategies.

In sum, this study aims to systematically review health economic evaluations and cost-minimization analyses of digitally supported mental well-being interventions intended to prevent mental ill-being and promote mental well-being in the general population, populations with an increased risk, or high-risk adults with up to subclinical symptoms. Since health economic evaluations provide information on both the costs and effects of alternative courses of action, they are of great value to decision makers facing budget constraints. As such, our results will be of interest to policymakers worldwide as they provide information on the value for money of digitally supported well-being prevention strategies. This knowledge is crucial in outlining the optimal strategy for preventing mental health problems and promoting the well-being of citizens.

Methods

The protocol (PROSPERO: CRD42024516673) and reporting of this systematic review follow the 2020 PRISMA (Preferred Reporting Items for Systematic reviews and Meta-Analyses) guidelines [14] (the PRISMA checklist is provided in Checklist 1).

Search Strategy

A systematic search was performed in 4 different databases (PubMed, Embase, Web of Science, and Scopus) on February 13, 2024. Email alerts were activated on all databases to receive updates on relevant papers after this date. These email alerts were systematically screened by SC until December 2024. The search strategy included search concepts related to mental well-being, digital interventions, and economic evaluations. The complete search strategy can be consulted in Multimedia Appendix 1.

XSL•FO
RenderX

Study Selection

The inclusion and exclusion criteria are shown in Textbox 1. The criteria were defined a priori and in line with the population, intervention, comparator, and outcome framework. The aim was to include health economic evaluations or cost-minimization studies on digitally supported mental well-being interventions in nonclinical adult samples, populations at risk, or high-risk adults with subclinical symptoms. Universal, selective, and indicated prevention strategies were thus included. Based on these eligibility criteria, titles and abstracts were screened with Rayyan [15] by 2 independent researchers (SC and FVDW). In a second step, the full texts were screened by 2 reviewers (SC and FVDW) using the same eligibility criteria. Discrepancies were discussed with a third reviewer (LA). To identify potentially missed papers, the reference lists of the included papers were checked.

Textbox 1. Eligibility criteria for study inclusion.

Inclusion criteria:

- Population: Adults (aged 18 years or older); nonclinical population or at risk for mental issues (up to subclinical symptoms).
- Intervention: Any type of digital well-being intervention including, but not restricted to, digital apps, text messaging, and online website interventions or mixed interventions with both digital and nondigital components.
- Comparator: No intervention, non–digital intervention, same intervention but different frequency.
- Outcomes: Economic outcomes (eg, cost-effectiveness and cost-utility analysis) or cost-minimization outcomes (whereby effects are assumed equivalent across interventions).
- Study design: Model-based or within-trial health economic evaluations.
- Language: English.
- Publication type: Peer-reviewed papers reporting findings of eligible study designs.

Exclusion criteria:

- Population: Children, adolescents, animals, and patient populations.
- Intervention: Interventions with no digital component.
- Comparator: Not applicable.
- Outcomes: Outcomes related to effectiveness, intervention costs, or health resource use costs only.
- Study design: Pre/post, reports, systematic reviews, meta-analyses, observational, cross-sectional, case studies, case series, case-control.
- Language: Non-English publications.
- Publication type: Conference abstracts, protocols, commentaries, animal studies, retracted papers, book chapters, and unpublished literature.

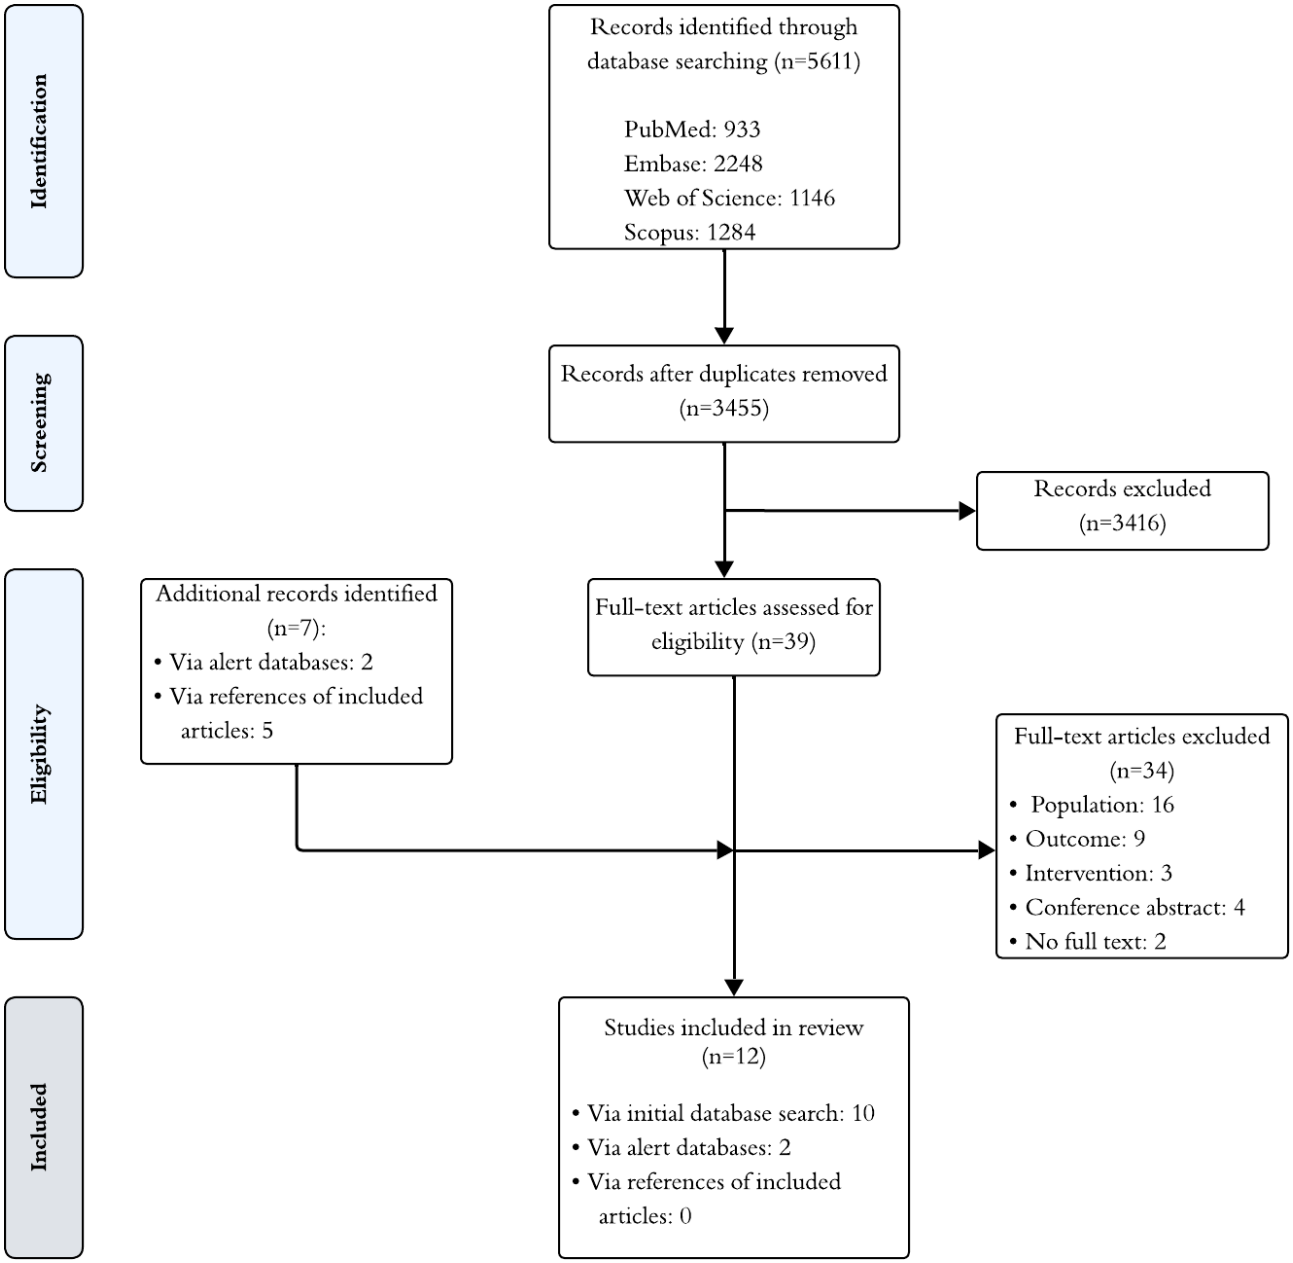
Synthesis of Results

After study selection, the following data from the included studies were extracted: (1) General study characteristics: first author, publication year, country, participant characteristics, type of intervention(s), and comparator. (2) Methods: study perspective, time horizon, type of economic evaluation, and sensitivity analyses. (3) Results: costs, effects, incremental costs, incremental effects, incremental cost-effectiveness ratio (ICER) or incremental cost-utility ratio (ICUR), and author conclusions.

To facilitate comparison across studies, costs and ICERs or ICURs were converted with a web-based calculator to Euro (reference year: 2024 and reference country: Belgium) [16].

Quality Appraisal

Based on the Consensus Health Economic Criteria list, which is applicable to both trial-based and model-based economic evaluations [17], the quality of the included studies was comprehensively assessed. In line with Werbrouck [18] and Willems et al [19], the Consensus Health Economic Criteria list was slightly adapted. In particular, “not applicable” was considered a valid option when judging discounting (item 14) since discounting applies only to those studies with a time horizon longer than 1 year.



Results

Study Selection

An overview of study identification, screening, and inclusion is displayed in the PRISMA flowchart (Figure 2). From 5611 studies identified (3455 after duplicate removal), 12 studies were included in this review after verifying eligibility. Multimedia Appendix 2 [20-53] provides an overview of excluded studies during full-text screening with reasons. Study characteristics and health economic outcomes can be consulted in Table 1. Multimedia Appendix 3 [54-65] provides the full assessment of the studies.

Study Characteristics

All but 1 study were conducted in Europe [54-58,60-65]. The remaining study took place in Australia [59]. The studies were published between 2013 and 2024. The majority of studies applied within-trial analyses with a time horizon between 24 weeks and 14 months [54-58,60,62-65]. Six within-trial economic evaluations applied a societal perspective, which includes all health care–related costs regardless of who is paying, as well as costs related to productivity losses [54,56,58,62-64]. Two studies adopted a Markov model to evaluate cost-effectiveness in the long run, with a time horizon of either 5 years [61] or 11 years [59]. One of them applied a health care provider perspective [61], while the other used a partial societal perspective, which did not account for direct nonmedical costs (ie, costs outside the health care sector but directly related to disease) [59]. In both Markov models, all input parameters were literature-driven.

Interventions

Half of the included studies evaluated an indicated prevention strategy (ie, focus on individuals with an identified elevated risk but not meeting diagnostic criteria) [54-56,59,60,63]. Selective prevention (ie, directed at populations with an increased risk) was assessed in 3 studies [57,62,64], and 3 studies concerned universal prevention strategies (ie, directed at the general public, not selected based on risk factors) [58,61,65].

The value for money of web-based interventions was investigated in 10 studies [54-56,58-63], 1 study evaluated email guidance [65], and the other examined smartphone apps [57]. Most interventions encompassed psychoeducation and exercises [54-56,58-60,62-65]. One study investigated the cost-effectiveness of mindfulness apps [57]. Moreover, 4 studies combined web-based interventions with optional text messages for guidance and support [54-56,58]. Only 1 study examined hybrid prevention (ie, combination of digital and nondigital interventions) [61]. To evaluate value for money, interventions were compared with care as usual [61], enhanced care as usual [54], no intervention [59,64,65], or wait-list control (WLC) [55-58,62,63].

Well-Being Outcomes

In 7 of the included studies, (incremental) cost per quality-adjusted life year (QALY) was the primary health economic outcome [54,56,58-60,62,63]. Some studies included specific well-being–related outcomes, such as life satisfaction [57], flourishing mental health [65], or treatment response in terms of stress [55,56,58], anxiety [65], or depression [65]. Furthermore, 3 studies documented the return on investment (ROI) [58,59,61].

Quality Appraisal

The quality appraisal of the included studies is shown in Table 2. Only 2 studies justified the chosen time horizon [59,63]. In the study by Monteiro et al [63], the applied time horizon

XSL•FO
RenderX

mirrored the follow-up period of the trial on which health economic evaluation is based, whereas Le et al [59] opted for an 11-year time horizon. These authors argued that a long time horizon is necessary to fully evaluate the impact of preventative strategies. In addition, approximately half of the included studies failed to provide sufficient justification for choosing a perspective other than the societal one [55,57,60,61,65]. Finally, only 6 studies combined probabilistic sensitivity analyses with another type of sensitivity analysis (eg, threshold analysis or one-way sensitivity analysis) on top of the point estimate results and provided adequate argumentation for the applied variable ranges [54,59,62-65].

Cost-Effectiveness of Digitally Supported Well-Being Interventions

Overall, the results of the included studies indicate that digitally supported interventions have the potential to cost-effectively promote and support well-being in adults. In particular, for the 6 studies reporting QALYs, all but 1 study found a dominant ICUR, meaning that digital well-being promotion in adults produces better health outcomes while reducing costs [56,58,59,62,63]. In the remaining study, an ICUR of €18,710 (US $23,185) per QALY was found [54].

Universal prevention strategies with a digital component were found to be cost-effective [65], cost-saving [61], or even dominant (ie, producing better health outcomes at lower costs) [58] (Figure 3). In particular, the ICER in the study by Schotanus-Dijkstra et al [65] equaled €1664 (US $2062) per extra person with flourishing mental health. Lokkerbol et al [61], on the other hand, found an ICUR of €15,764 (US $19,534) per averted disability-adjusted life year or €15,650 (US $19,392) per averted disability-adjusted life year when lowered treatment costs were assumed. The results of these studies appeared to be robust under sensitivity analyses. Nevertheless, only in one of these studies were the evaluations conducted from a full societal perspective instead of a limited perspective [58]. Thus, these cost-effectiveness results should be further confirmed from a societal perspective, providing a broader picture of costs and consequences.

Figure 3. Cost-effectiveness results per prevention type.

Among the 3 studies evaluating selective prevention strategies, the results were inconclusive (Figure 3). In the study by Monteiro et al [62], web-based cognitive behavioral therapy for women with low risk for postpartum depression appeared to be dominant compared with WLC. Fitzhugh et al [57] also reported favorable results for selective prevention. These authors concluded that mindfulness meditation delivered via smartphone apps is a cost-effective way to promote life satisfaction among police officers. However, the validity of this positive conclusion is limited as it is based on the average cost-effectiveness ratio (ie, the intervention costs divided by the effects of that particular intervention), whereby cost and effects are not compared with an alternative strategy. In a study among nurses, Noben et al [64] evaluated web-based mental health promotion, which was found to be not only less costly but also less effective. Their ICER equaled €5400 (US $6691) per treatment response in terms of improved work functioning. This finding could be

XSL•FO
RenderX

related to a lack of integration of the e-mental health tools in the workplace, resulting in reduced effectiveness [64].

Indicated prevention using digitally supported tools appeared to be cost-effective [54], dominant (ie, better health outcomes at lower costs) [55,56,59,63], or cost-saving [60] (Figure 3). However, the cost-saving result in the study by Lintvedt et al [60] should be interpreted with caution since the authors failed to compare the intervention with an alternative, and no sensitivity analyses were performed. Web-based indicated prevention was compared with either WLC [55,56,63] or no intervention [59]. Only Buntrock and colleagues [54] used an active comparator to determine the cost-effectiveness of a guided web-based self-help intervention. This intervention was compared with "enhanced usual care," which consisted of additional web-based psychoeducation. From a societal perspective, these authors found an ICUR of €18,710 (US $23,185) per QALY.

Despite the lack of comprehensive sensitivity and subgroup analyses in most studies, some cost-effectiveness drivers could be identified. Several studies highlighted costs as key drivers of cost-effectiveness [55,56,61-63,65]. Additionally, 2 studies noted that cost-effectiveness results improved when using more sensitive measures for assessing QALY gains [54,56]. In particular, in both studies, interventions had a higher probability of being dominant when QALYs were measured with the Short Form 6 Dimensions (SF-6D). This measurement tool is more sensitive to changes in mild conditions than the EQ-5D. Furthermore, the modeling assumptions had an impact on the cost-effectiveness findings of Le et al [59]. In particular, the transition probabilities and the assumed duration of intervention effects affected the ROI. However, it is unclear whether these observed changes are statistically significant.

Discussion

Principal Findings

Notwithstanding the rapidly growing market for digitally supported mental well-being tools for the general public, their value for money remains unclear [9]. Nevertheless, information on the "best buy" is essential for policymakers as they are faced with the challenge of maximizing citizen well-being while financial resources are scarce [66]. Therefore, this systematic review aimed to summarize the current evidence on the cost-effectiveness of digitally supported interventions to prevent mental ill-being and promote well-being in nonclinical adults. In particular, universal (ie, for the general public), selective (ie, for at-risk populations), and indicated (ie, for individuals with identified vulnerabilities, not meeting diagnostic criteria) prevention strategies with a digital component were included in this review. Alongside offering guidance to policymakers, the results of our review will inform researchers about existing evidence gaps and methodological shortcomings when planning and conducting future health economic evaluations.

Overall, digitally supported interventions appear to cost-effectively promote well-being among nonclinical adult populations. Half of the included studies investigated the cost-effectiveness of digitally supported indicated prevention strategies [54-56,59,60,63], with many reporting dominant results. In particular, these interventions produced better health outcomes at lower costs than WLC [55,56,63] and no intervention [59]. On the other hand, the nondominant, yet cost-effective findings reported by Buntrock et al [54] for web-based indicated prevention could be attributed to their active comparator, which included web-based psychoeducation. Next, digitally supported selective prevention was covered in only 3 studies, and their results were inconclusive. However, due to the limited number of studies, firm conclusions about their cost-effectiveness cannot be drawn. Likewise, evidence on universal prevention strategies with a digital component is sparse. While the available evidence suggests cost-effectiveness, additional research is needed to validate these findings. Finally, whether the mode of delivery (ie, web-based, app, or email) is related to different cost-effectiveness results is hard to evaluate since only 1 study evaluated smartphone apps [57] and 1 study investigated an email-guided intervention [65]. As such, based on the current state of the evidence, identifying a single most cost-effective type of digital prevention strategy for well-being remains challenging, underscoring the need for cautious interpretation and future research.

Despite growing recognition of the importance of public mental well-being, public investments in mental health remain limited, particularly for prevention and promotion. On average, governments across the globe allocate 2.1% of health expenditure to mental health, and in the majority of countries, less than 20% of this share is devoted to the promotion of mental well-being and prevention of mental illness [67]. As such, this review offers timely insights that can inform sustainable public mental health strategies. According to our results, digitally supported tools for well-being promotion in nonclinical adults are generally cost-effective. However, it is important to note that more cost-effectiveness evidence is still needed on digitally supported well-being interventions to adequately guide policymaking. Therefore, we urge policymakers to invest in research on effective and cost-effective well-being promotion and to make decisions informed by such research.

Based on the findings of this review, several recommendations for future research can be formulated as well. First, as mentioned before, cost-effectiveness evidence on digitally supported well-being promotion and prevention remains limited. Health economic evaluations should become standard practice when conducting interventional research. Additionally, to improve assumptions made and reduce uncertainty regarding long-term intervention effects, trials should encompass longer follow-up periods. Second, when planning future economic evaluations, researchers are advised to carefully consider outcome measurement. According to 2 studies, cost-effectiveness results improved when using more sensitive measures for assessing QALYs [54,56]. In the general population or people with subclinical symptoms, the EQ-5D might suffer from ceiling effects, potentially leading to an underestimation of effectiveness and cost-effectiveness results [68]. Additionally, only 1 of 5 EQ-5D items measures mental health. To address these limitations of the EQ-5D, future research could consider assessment methods more sensitive to changes in well-being, such as the EQ Health and Well-being (EQ-HWB) instrument,

XSL•FO
RenderX

which was specifically designed for use in health economic evaluations and captures both health and well-being [69]. Likewise, the WELLBY (well-being year) approach could offer a more comprehensive assessment of consequences in economic evaluations for well-being promotion initiatives [66]. Compared with the QALY, the WELLBY has a broader outlook and defines quality of life in terms of subjective well-being or how people feel about their lives. As a single-item measure, the WELLBY can easily complement existing preference-based measures of health, such as the EQ-5D, in health economic evaluations. Third, the ICUR or ICER should be interpreted in light of a willingness-to-pay (WTP) threshold. Two of the included studies [57,60] did not report a WTP threshold, while a range of different thresholds was applied in the remaining studies. For prevention, WTP thresholds are indeed less well-established, and there are valid arguments for both higher and lower thresholds compared with those for treatment [70]. Additionally, future research should investigate the WTP threshold for well-being outcomes (eg, EQ-HWB, WELLBY, depression-free years, etc). Given the limited consensus on WTP thresholds for well-being and preventive measures, researchers are encouraged to report their results in light of a WTP threshold accompanied by valid argumentation for the applied threshold. The WHO recommends a threshold of 1-3 times the gross domestic product per capita [71]. However, in light of opportunity costs, a more conservative threshold of 50% of the gross domestic product per capita has been proposed as well [72,73]. Fourth, there is abundant room for further progress in determining cost-effectiveness drivers. For instance, it is unfortunate that none of the studies explored the impact of dropout and adherence on cost-effectiveness results. This should be addressed in future economic evaluations since digital interventions are likely to suffer from reduced adherence [74].

Furthermore, our quality appraisal highlighted several shortcomings of the available literature, which should be addressed in future research. First, in most studies, justification for the applied time horizon was lacking. Future studies are thus advised to choose a time horizon that captures relevant long-term costs and effects and to articulate the rationale behind their choice clearly. Second, the study's perspective determines which costs are considered in the economic evaluation and thus affects cost-effectiveness results. Since different stakeholders are involved in and affected by health promotion and prevention, it is recommended to apply a full societal perspective or even multiple perspectives [75]. In any case, transparency about the perspective used and the underlying rationale is key. Third, sensitivity and subgroup analyses were insufficiently conducted in several studies, limiting the robustness of the results and our understanding of cost-effectiveness drivers. To deal with data uncertainty and underlying assumptions in health economic evaluations, future studies should adopt best methodological practices, such as conducting sensitivity analyses and subgroup analyses according to current standards [17]. For instance, when conducting sensitivity analyses, clear justification for the applied variable ranges should be provided.

Strengths and Limitations

A major strength is that this review provided a comprehensive overview of the value for money of digitally supported well-being promotion for adults, with a particular focus on universal, selective, and indicated prevention, to conclude with clear recommendations for both policymakers and researchers. Nevertheless, some limitations should be addressed. First, although evidence on the effectiveness of digital tools for well-being promotion and prevention is growing, the number of cost-effectiveness studies remains low, particularly for universal and selective prevention. As such, it was impossible to thoroughly compare different prevention strategies (ie, universal, selective, and indicated) in terms of cost-effectiveness to properly guide policymaking. Second, because of methodological variation, comparison across the different studies should be done with caution. Third, due to the limited number of health economic evaluations and cost-minimization studies, publication bias could not be comprehensively assessed. It is indeed possible that cost-effective results are favored. Therefore, as health economic evidence accumulates, this should be further explored.

Conclusions

This systematic review summarizes the current cost-effectiveness evidence for digitally supported well-being promotion for adults. In particular, universal, selective, and indicated prevention strategies are included. Overall, such interventions appear to be cost-effective, with several studies showing dominance. As such, digital tools could offer a financially sustainable approach to promoting public mental well-being. Nevertheless, the evidence available remains low. Future studies are needed to address evidence gaps as well as existing methodological shortcomings by choosing an appropriate time horizon that encompasses all relevant costs and consequences, improving transparency, and conducting sufficient sensitivity analyses to account for data uncertainty. Furthermore, assessment methods more sensitive to changes in well-being, such as the EQ-HWB or WELLBY approach, could be considered.

Abstract

Background: Online counseling chat services are increasingly used by young people worldwide. A growing body of literature supports the use and effectiveness of these services for adolescent mental health. However, there is also a need to provide an overview of the main existing resources to identify unmet needs and gaps in the field.

Objective: This study aims to provide an overview of existing online counseling chat services targeting individuals aged 12‐30 years in 4 European countries (Belgium, Finland, Hungary, and Spain), and to identify potential needs and gaps by comparing the collected data with recognized quality standard criteria that define the best practices in the field of counseling.

Methods: A web search was conducted in the 4 participating countries using the same keywords to identify the main chat services. The final selection of chat services was made using a stratified purposive sampling method. A common data extraction database was developed to record information from these websites. Finally, the extracted information was compared against the fulfillment of 7 selected criteria from the Child Helpline International Quality Standards Framework. Additionally, certain chat characteristics were compared with the number of Child Helpline Quality Standard criteria fulfilled.

Results: The search identified a total of 66 service providers offering 71 different chat services. Nongovernmental organizations accounted for more than half of the total service providers42 of 66 (64%). Additional helplines, such as hotlines, were also available through 54 of 66 (82%) service providers. Artificial intelligence tools were incorporated into 6 of 66 (9%) chat services. Differences were observed between countries; for example, the use of volunteers as counselors was predominant in Hungary and Belgium. Topic-specific chat services were common in Belgium and Spain, whereas in Finland and Hungary, chat services generally welcomed a wide range of topics for young people to discuss. Comparisons with Child Helpline International's recommendations revealed some gaps—for example, only 9 of 71 (13%) chat services operated 24 hours a day, and only 10 of 71 (14%) offered interactions in minority groups or foreign languages. Additionally, the use of free social media platforms for chat services was prevalent in some countries, which could compromise users' privacy. Being part of the Child Helpline International consortium was marginally associated with meeting a higher number of standard criteria (β coefficient 1.55; P=.08).

Conclusions: This study provides a comprehensive overview of existing online chat counseling services in 4 European countries. Our findings suggest that some existing chat services for young people could be improved in areas such as accessibility, data security, and the inclusion of vulnerable groups.

KEYWORDS

online chat; text-messaging; helpline; youth; mental health; Europe

Introduction

The mental health of adolescents and young people is a global concern. Recent data indicate that 59% of Europeans aged 15‐24 years reported experiencing some form of emotional or psychological issue in the past year [1]. According to some reports, factors such as repeated economic crises, unemployment, the normalization of economic precarity, climate

XSL•FO
RenderX

change, fears of conflict, and the COVID-19 pandemic have affected the mental health of young European people "somewhat" or "a lot" [2]. While most European countries provide universal health care coverage, formal entitlement does not always guarantee actual access to care. Various obstacles, such as long waiting times, bureaucratic procedures, and geographical barriers, can hinder access to mental health services [3]. Consequently, an increasing number of young individuals are turning to online platforms for support with their psychosocial challenges [4].

Compared with previous generations, online mental health support may be particularly appealing to youth [5]. Some studies suggest that young people may feel less judged in virtual environments [6], experience greater self-sufficiency [7], and enjoy increased control and autonomy [8], enabling them to seek help without disclosing their needs to parents, peers, or others [9].

Among the various digital support services available, real-time online counseling chat services (OCCSs) have unique characteristics that distinguish them from other forms of teletherapy or digital assistance. One notable feature is the "online disinhibition effect," where users are more likely to disclose personal information due to reduced behavioral inhibitions in the online environment. This effect is driven by factors such as dissociative anonymity, invisibility, and authority minimization, among others [10]. Furthermore, users can engage in chat conversations from virtually anywhere and discuss sensitive topics without the need for a private setting. This flexibility allows them to control the pace and rhythm of the interaction [11,12]. In addition, research by Cohen et al [11] suggested that young people often prefer text-based communication over verbal exchanges (such as phone calls), which they may find intimidating. Existing literature on OCCSs has focused on analyzing the usefulness of these services in terms of effectiveness [13], predicting users' satisfaction [14], identifying peak contact hours [15], profiling repeated users [16], and reporting relevant insights from the experiences of both counselors and users [17,18]. However, to our knowledge, no study has identified or explored the characteristics of existing OCCSs across different countries.

Child Helpline International is a global organization dedicated to strengthening child protection systems worldwide to improve the quality of responses to children and young people in need of protection, support, and guidance, and to advocate for their rights [19]. According to data published by Child Helpline International, online chat counseling services are currently the second most popular form of helpline among adolescents and children, after telephone calls [4]. The organization has also issued recommendations to ensure the quality of helplines for children and youth, including OCCSs [20].

Gathering relevant information about existing services and identifying potential gaps is a crucial first step in developing high-quality services that can meet the growing demand for mental health support [21].

Therefore, this study aimed to (1) identify primary service providers offering OCCSs that support the mental health and well-being of young people aged 12-30 in 4 European countries; (2) collect relevant information about these services using published data available on their websites; (3) identify potential unmet needs by comparing the available information with a selected set of quality criteria established by Child Helpline International; and (4) examine whether certain characteristics of service providers are associated with meeting a greater number of quality criteria. We hypothesize that organizations affiliated with the Child Helpline International network are more likely to meet a higher number of quality criteria than those that are not part of the consortium, and that more recently established chat services may also comply with a greater number of these criteria.

Methods

Procedure

This study is part of the Crisis Help and Assistance for Youth during Challenging Times (CH@T-YOUTH) project, launched under the ERASMUS+ framework as a Cooperation Partnership in youth and co-funded by the European Union (from September 1, 2023, to January 31, 2026). The primary aim of the project is to generate knowledge about OCCSs that support youth mental well-being. In addition, the project seeks to facilitate the exchange of knowledge among service providers and youth workers, and to promote ethical reflection aimed at enhancing the quality of both emerging and existing nonprofit OCCSs across Europe.

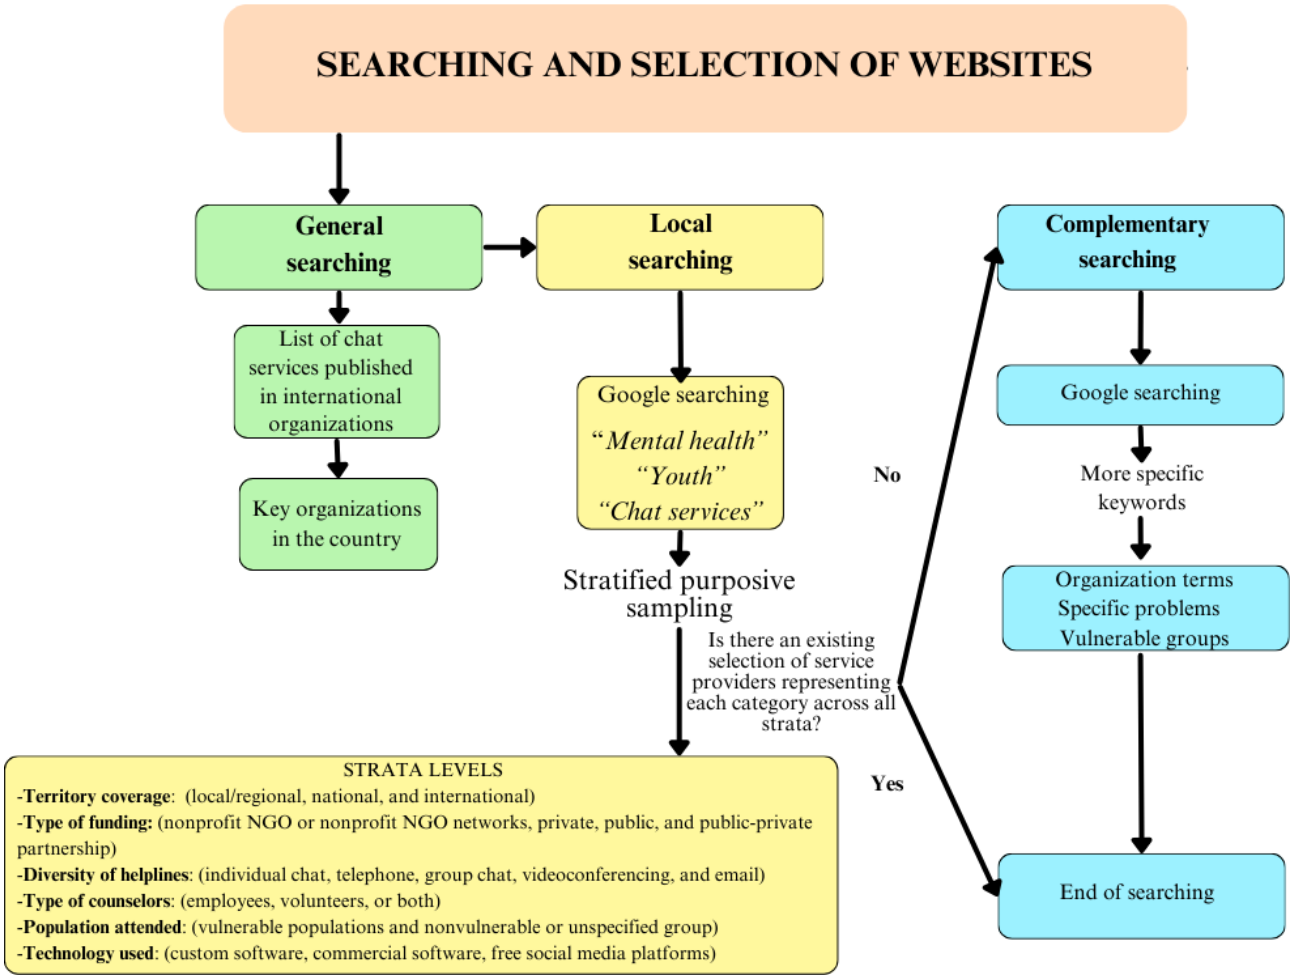
The initial phase of the study aimed to deepen the understanding of OCCSs for youth across 4 participating countries, namely, Belgium, Finland, Hungary, and Spain, representing diverse geographical regions within Europe. The first step, as referred to in this article, was to identify existing services and extract data on their characteristics, focusing only on publicly available information from websites, to assess the level of information accessible to users. To achieve this, a common, step-by-step methodology was applied. This methodology, used in previous studies [22], guided the compilation of a comprehensive country-wise catalog of the main chat service providers in the 4 participating countries.

Service Inclusion and Exclusion Criteria

The inclusion criteria focused on organizations providing OCCSs to individuals aged 12-30, or to organizations where the majority of clients fell within this age range. Eligible services were required to target either the general youth population or specific vulnerable groups (such as Ukrainian refugees, minorities, or the LGBTIQ+ [Lesbian, Gay, Bisexual, Transgender, Intersex, Queer/Questioning, and others] community), with mental health and well-being as a primary or secondary outcome.

Online chat services that were not free of charge, or that functioned solely as referral services—providing users with relevant contact points without offering ongoing support—were excluded from this study. Organizations that solely offered other forms of text-based helplines, such as asynchronous messaging, email contact points, or chat services without real-time human interaction (ie, limited to artificial intelligence) were also excluded. However, organizations that provided additional

XSL•FO
RenderX



services or helplines were included if their chat services met the specified inclusion criteria.

Search Strategy

A web search study was conducted from March to May 2024. The process of searching and selecting websites is summarized in Figure 1. First, the websites of Child Helpline International, the International Association for the Prevention of Suicide, HelpGuide, Mental Health Europe, the Red Cross, and SOS Children's Villages were consulted to identify key organizations in the target countries. In addition, an internet search was conducted using the Google web browser. Common keywords such as "mental health," "chat online," and "youth" were translated into local languages—Dutch, Finnish, Swedish, Hungarian, Spanish, Catalan, Basque, and Galician—to identify OCCS providers. In the case of Finland, keywords were also used in English. The internet search was not constrained by Google's algorithms, as our goal was to replicate the type of search a typical user might perform when seeking help. The selection of service providers was guided by a stratified purposive sampling strategy, aimed at capturing major variations among the identified services, rather than identifying a common core, although common themes may still emerge during analysis [23]. The different strata levels that guided the selection of chat providers are shown in Figure 1. The mapping process was considered complete once all categories within the strata were filled, if possible, at least once.

If any of the levels was not covered, a complementary internet search was conducted using addition terms related to service providers (eg, foundation, association, organization), minority populations (eg, LGBTIQ+, refugee, immigrant) and key mental health issues (eg, anxiety, depression, eating disorders, loneliness, bullying; Figure 1).

Figure 1. The process of searching and selecting websites. NGO: nongovernmental organization.

Data Extraction

To facilitate data collection from the websites, a common online database using Webropol (Webropol Oy) was developed and completed by researchers from each participating country (IHL, ED, MR, and VU). The database included information on the following variables: year the organization was founded (*before the 1990s, 1990 - 2000, 2001 - 2010, 2011 - 2024);* type of funding (*nonprofit nongovernmental organization [NGO] or nonprofit NGO networks, private, public, and public-private partnership*); diversity of helplines offered (*individual chat, telephone, group chat, videoconferencing, and email*); type of counselors used (*employees, volunteers, or both*), number of counselors (*<50, 50 - 250, and >250*); number of users served annually, based on the latest report; and availability of annual reports detailing the organization's activities (*yes, or no information/not available*). In addition, the websites of all service providers were thoroughly explored for details about their chat services. The data collection captured the following information: the year the chat service was established (*before*

XSL•FO
RenderX

2010; 2011 - 2018, pre–COVID-19; 2019 - 2021, COVID-19 period; and 2022 - 2024, post–COVID-19 period); coverage of the chat (*local/regional, national, or international*); age groups covered in the chat (*<18, >18, specific age range including minors and adults, everyone, or no information*); languages used in the chat (*official languages recognized by the government, minority or foreign languages, both official and minority/foreign languages, or English-only chat services*); technology employed in the chat (*custom software, commercial software, free social media platforms, or others*); chat availability (*24/7, specific hours 7 days a week, specific hours and days, other, or no information*); target populations (*youth with addiction issues, LGBTIQ+ community, individuals who experienced abuse or neglect, pregnant women, individuals who experienced gender or domestic violence, other vulnerable groups, or nonvulnerable/unspecified group)*; and specific issues addressed (*all topics, specific mental health problems, violence, addiction, other specific psychosocial issues, sexuality gender, 2 of the specific topics, or not reported*). In cases where websites provided incomplete information, no further contact was established, to reflect the level of information publicly available to users.

Comparison With the Child Helpline International's Core Quality Standard Framework

The data collected were compared with the Child Helpline International's Core Quality Standards (CQS) framework [20]. The CQS framework was developed as a valuable reflection tool and reference point for quality management in child helplines. According to this framework, high-quality child helplines should be rights-based; advocate for children; facilitate meaningful participation of children and young people; be reliable; ensure safety and not cause harm; be accessible; child-centered; accountable; responsible; and effective in emergencies. The comparison focused on the following 3 CQS criteria: (1) *Advocating for children* (ie, the child helpline amplifies the voice of children by collecting, collating, and sharing data about children's contacts); (2) *Safety—do not harm* (the child helpline should safely collect, record, and protect children's information using a secure platform); and (3) *Accessibility* (the child helpline should be accessible, operate nationally and 24/7, and provide a safe, inclusive service to recognized marginalized groups such as minority language speakers, LGBTIQ+, refugees, or those in other vulnerable situations). Marginalized groups were defined as those facing additional barriers in accessing mental health services, including people using minority or foreign languages in the country. These groups were categorized based on the collected data and existing literature on vulnerable populations [20,24-26]. The fulfillment of the remaining CQS criteria could not be assessed using the publicly available data published on the websites. Finally, a total composite score ranging from 0 to 7 was created, reflecting the number of CQS criteria met by each service provider.

Analyses

The characteristics of OCCS and their providers were described using frequencies and percentages, both overall and by country. The main findings were descriptively compared with the selected criteria from the CQS framework. This comparison allowed for the identification of potential gaps and provided an opportunity to evaluate the ecological validity of specific criteria. Finally, to assess whether certain characteristics of chat services were associated with meeting a higher number of the selected Child Helpline International quality criteria, a linear regression analysis was conducted. The analysis included the year the chat service was established and whether the service belonged to the Child Helpline International consortium (Yes/No) as independent variables.

Results

Characteristics of Service Providers

The main characteristics of the 66 service providers were examined (Table 1).

Not reported/not available	48 (73)	15 (65)	16 (80)	7 (78)	10 (71)

The number of service providers ranged from 23 in Belgium to 9 in Hungary. Half of the providers identified were established before the 1990s. Nonprofit NGOs were the predominant type of service provider in most countries. Most organizations (54/66, 82%) also offered additional helplines beyond online chat services, with telephone support being the most common. The combination of telephone, email, and individual chat was particularly popular (accounting for 23/66, 35%, services). In addition, 6 out of 66 (9%) providers incorporated some form of artificial intelligence into their chat services. In Finland and Spain, counselors were typically a mix of both employees and volunteers, whereas services with mostly volunteers were characteristic in Hungary and Belgium. Of the 66 service providers, 48 (73%) did not report the number of counselors available in their organization.

Characteristics of Chat Services

Table 2 shows the main characteristics of online chat counseling services.

Not reported	2 (3)	1 (4)	0 (0)	1 (11)	0 (0)
Average users who attended the chat (last reported year)					
Median (range)	1181 (19 - 33,151)	2356 (38 - 8281)	2332 (91 - 33,151)	194	899 (19 - 3500)
Not reported	49 (69)	14 (61)	14 (67)	8 (89)	13 (72)

Some service providers offered multiple chat helplines, which explains the discrepancy between the number of service providers and the total number of chat helplines. While 27 of 71 (38%) organizations did not report when their OCCSs began, available data indicate an increase in the number of chat services over the past 2 years, particularly in Finland and Spain (Table 2). Some chat services (26/71, 37%) targeted both minors and adults within a defined age range, followed by services open to everyone (22/71, 31%) and those aimed specifically at minors (10/71, 14%) or adults (6/71, 8%); 32 of the 71 (45%) OCCSs were open to any topic or issue related to well-being, while the remaining services focused on specific areas such as violence or addiction. The number of users served in the last reported year ranged from 19 to 33,151.

Comparison With the Child Helpline International's Child Helpline International's CQS Framework

The comparison of the collected data with the Child Helpline International's CQS framework is presented in Table 3.

The results in Table 3 show that 40 of 71 (56%) service providers reported publishing data on their activity annually. Regarding the sharing of data on children's contacts, only 22 of 71 (31%) OCCSs publicly reported the number of users.

In terms of accessibility, only 9 of 71 (13%) chat services were available 24/7, and almost half of the OCCSs were available less than 7 days a week and only during certain hours (Table 3). Regarding coverage, 30 of 71 (42%) OCCSs had national coverage, while 36 of 71 (51%) operated at the local or regional

XSL•FO
RenderX

level. In terms of accessibility for marginalized or minority/vulnerable groups, 28 of 71 (39%) chat services specifically targeted these populations, primarily youth with addiction issues, followed by the LGBTIQ+ community, individuals who experienced abuse and neglect, pregnant women, and individuals who experienced gender-based violence (Table 3). Results also showed that only 10 of 71 (14%) OCCSs provided services in minority or foreign languages.

Another important point is that helplines should be safe. For example, it is not recommended to use platforms that do not protect users' data. In general, the most commonly used technology in OCCSs was commercial and custom software developed by external companies. However, in countries such as Spain, most OCCSs (14/18, 78%) used social media.

The results show the relationship between the number of Child Helpline Quality Standard criteria met and certain chat service characteristics. Being part of the Child Helpline consortium was marginally associated with meeting a higher number of standard criteria (β coefficient=1.55; *P*=.08). However, the year the chat service was established was not significantly related to the number of criteria met (β coefficient=3.66; *P*=.94).

[a]Local/regional coverage means the service is mainly intended for users in a specific city, municipality, or region. National coverage refers to services accessible across the entire country. International coverage includes services that are accessible to users beyond one national context, sometimes across multiple countries.

[b]LGBTIQ+: Lesbian, Gay, Bisexual, Transgender, Intersex, Queer/Questioning, and others.

Discussion

Principal Findings

This study aimed to identify and collect relevant information about the main OCCSs in Belgium, Finland, Hungary, and Spain. A total of 66 service providers, comprising 71 different OCCSs, were identified and evaluated against Child Helpline International's quality standards. Most services were NGOs with extensive helpline experience before the implementation of OCCSs. Key areas for further improvement were time accessibility, data security, and the coverage of certain vulnerable groups. Service providers that were part of the Child Helpline International consortium were marginally more likely to meet a higher number of quality standard criteria.

Our findings show that the number of chat services increased during and after the COVID-19 pandemic. This suggests that helpline providers have diversified their outreach methods, with chat services becoming an integral part of helpline offerings in the 4 countries studied. However, hotlines remained the most commonly provided form of support. This finding aligns with data reported by Child Helpline International [4].

Regarding the types of assistants attending the chat, our results showed that services were primarily staffed by paid personnel, followed by volunteers, and then a combination of both. Some studies have argued that lay volunteers may better relate to the experiences of callers [27]. However, the quality of support provided by volunteers and paid counselors has been found to be comparable [27]. By contrast, the lack of financial compensation for volunteers may contribute to higher intentions to leave, particularly in response to stressful situations [28].

Our study also identified potential gaps by comparing the publicly available information on web sources with the CQS framework provided by Child Helpline International [20]. While the framework advocates for 24/7 availability, it acknowledges that, when resources are limited, queries should at least be answered during consistent and reliable operating hours. Our findings showed that the majority of the existing OCCSs were available for fewer than 7 days a week and operated only during specific hours. Most organizations were NGOs; hiring staff is expensive, and finding volunteers to ensure 24/7 coverage is a challenge. In addition, previous studies have suggested that one-third of user contacts occur after 8 PM [29]. Therefore, if a 24/7 service is not feasible, identifying and covering peak hours based on young people's schedules may be a more realistic approach in the context of limited resources. Our study also found that the few OCCSs operating 24/7 were mostly government-funded or operated through public-private partnerships, and typically staffed by paid professionals or a combination of staff and volunteers. Literature has shown that night shifts are among the tasks most strongly associated with elevated distress levels and the intention to resign among helpline volunteers [28]. Although concrete evidence is lacking, it is reasonable to assume that night shifts in 24/7 services are primarily covered by paid personnel. In resource-limited settings, an alternative approach to optimizing resource allocation and availability can be seen in Finland, where different service providers have collaborated to analyze peak usage times and adjust their operating hours accordingly [30].

Another critical point is that existing OCCSs should improve accessibility for minorities and vulnerable groups by studying and addressing help-seeking barriers specific to these populations [20]. One example is that some service providers offered dedicated chat services, apart from the general ones, tailored to the needs of these groups. Regarding specific vulnerable populations, the LGBTIQ+ community was represented in all countries, with at least one chat service aimed at them. This is a positive finding, as the LGBTIQ+ collective often perceives general-population helplines as inappropriate or unsupportive and typically prefers specialized services where they feel better understood [31]. Individuals with substance use issues were also broadly covered. Youth in particular often face stigma and shame when seeking help for substance use problems [32]. Specialized anonymous service tailored to their needs may therefore facilitate better access to care. However, other marginalized groups, such as migrant and refugee populations, were underserved, with only 1 chat service specifically tailored to them. This represents an important gap, as chat services could be particularly beneficial for these populations, who often face

XSL•FO
RenderX

significant barriers to accessing traditional face-to-face health care services [6]. For example, concerns about deportation may prevent individuals, especially those with irregular status, from seeking assistance [33].

In addition, according to Child Helpline International, helpline services should be accessible to users who speak minority languages within the country. Our data indicated that only 10 of 71 (14%) OCCSs offered services in minority or foreign languages. Cooperation between European countries could enhance the coverage of OCCSs for vulnerable populations, such as migrants, refugees, and minorities. Some initiatives have already been established to support Ukrainian refugees, illustrating the potential of collaborative efforts to improve accessibility [34,35]. To conclude our discussion on accessibility, one rationale for service providers operating multiple chat helplines may be to enhance access to counseling services for marginalized groups. This approach aligns with Child Helpline International's standards, which advocate tailoring OCCSs to meet the diverse needs of different populations.

Regarding the visibility of OCCSs, Child Helpline International recommends a national-level service [20]. However, in our study, half of the service providers had local or regional coverage, while the remainder were supported by national and international institutions. In the context of Europe—with its linguistic, cultural, and administrative diversity—local and regional services may be particularly well suited to respond to the specific needs of their target populations. For example, a local service may be more attuned to the social or cultural features of a specific area. Working together to establish networks among local and regional services could further improve visibility and help address the specific needs of users [30].

The Child Helpline International guidelines also emphasize the importance of ensuring privacy and security in OCCS conversations [20]. Low adherence to ethical standards regarding online privacy in counseling was previously reported by Chester and Glass [36], who found that 42% of online counselors did not use any encryption to protect user confidentiality. Our study showed that in some countries, such as Spain, free social media software was one of the platforms most commonly used by chat service providers. While such platforms may enhance accessibility for users, they can also compromise privacy. To ensure security in an ever-changing digital environment, it is essential to continuously evaluate ethical, technical, and usability considerations—and to learn from the practices of other OCCSs.

Another area for improvement is the systematic collection and publication of activity data, which can enhance visibility, inform policy design, and support funding allocation. Child Helpline International has specifically advocated for clear criteria in the analysis and reporting of contact trends [20]. Although more than half of the service providers published data regularly, most did not report information on the number of cases handled. This may stem from the absence of a long-term strategy and a reluctance to have their performance evaluated by third parties [37], particularly among smaller NGOs, where funding is often uncertain. Improving systematic data collection and ensuring transparency about the characteristics of OCCSs could significantly enhance visibility and help attract additional resources, including funding. This is particularly important because, while some countries have government-funded organizations, most service providers are NGOs that rely primarily on external donations.

Regarding the factors associated with meeting a greater number of Child Helpline International's recommendations, the year the chat service was created was not significantly related. Only membership in Child Helpline International showed a marginal association with meeting a higher number of criteria. It is possible that having sufficient funding and resources is more closely linked to meeting the standards set by Child Helpline International. Smaller, local, and regional service providers, which accounted for half of our chat services, often lacked the resources to meet these requirements comfortably. However, we could not test this with the data collected. Further studies are needed to examine this relationship. Collaboration among service providers, knowledge exchange, and additional research are essential to move from ideal practices to practical, implementable solutions, particularly for NGOs with limited resources.

Limitations

This study provides valuable insights into the characteristics of OCCSs and their service providers across 4 European countries, while also identifying existing gaps. However, several limitations should be acknowledged. The study was limited to 4 European countries (Belgium, Finland, Hungary, and Spain), which may have led to the omission of certain types of services present in other regions. Nevertheless, the selected countries represent different parts of Europe and encompass all major welfare system types within the European Union. Additionally, while the web search aimed to replicate a typical user's behavior, Google's algorithms were not controlled, meaning that implicit personalization may have introduced bias. Another limitation is that data collection relied exclusively on publicly available information from web sources. As a result, certain quality standard criteria established by Child Helpline International could not be assessed, such as the existence of standard operating procedures to guide staff or whether service providers had access to adequate funding. In cases where comparisons were possible, data were often incomplete; for example, only a small number of service providers reported the number of users served via chat, which limited the conclusions that could be drawn about service impact. Therefore, future studies should consider gathering this information through additional methods, such as surveys or interviews with professionals in the field and young service users. Moreover, due to time and resource constraints, as well as the limited prior research on this topic, the methodology focused on a selection of OCCSs. However, the representativeness of this selection could not be guaranteed. Using a stratified purposeful sampling strategy, the study included countries with varying numbers of associations and heterogeneous services, alongside countries with fewer associations that exhibited similar profiles. This approach resulted in differing saturation points. Furthermore, the Google search in Belgium was conducted solely in Dutch, which is only one of the country's 3 official languages. Consequently, some

XSL•FO
RenderX

significant chat service providers may have been overlooked. Despite these limitations, this study presents a replicable methodology that can be used to expand and deepen the existing knowledge in this area.

Conclusions

This study provides the first comprehensive overview of the main characteristics of helpline providers and their OCCSs operating across a range of European countries. Our findings suggest that OCCSs for young people should improve transparency by sharing data on users' contacts and address existing gaps in user privacy and accessibility, particularly for vulnerable and minority groups. Exploring existing resources and identifying potentially unmet needs are essential steps toward facilitating information exchange. Ultimately, these efforts can help address ethical and technical considerations and support the development of consensus-based practices for delivering high-quality services.

Acknowledgments

This work was co-funded by the European Union ERASMUS+ program (partner agreement number 2023-1-FI01-KA220-YOU-000153237, CHAT YOUTH). Abstract

Background: Digital addiction, affecting a significant portion of the population, particularly young people, is linked to psychological issues and social problems, making its prevention and management a crucial public health issue.

Objective: This umbrella review aimed to comprehensively analyze the factors influencing digital addiction by re-evaluating the methodologies and evidence quality of existing meta-analyses.

Methods: Databases including PubMed, Web of Science, the Cochrane Library, and Embase were systematically searched for reviews and meta-analyses related to factors associated with digital addiction up to September 24, 2024. The methodological quality of the identified studies was assessed using the modified "A Measurement Tool to Assess Systematic Reviews 2" (AMSTAR 2) tool, while the Grading of Recommendations Assessment, Development, and Evaluation (GRADE) tool was used to evaluate the quality of the evidence presented in the literature.

Results: A total of 18 articles were included in the review, with AMSTAR 2 assessments revealing 6 moderate-quality, 4 low-quality, and 8 very low-quality studies. In total, 29 significant factors associated with digital addiction were identified. Notably, 4 studies achieved both moderate AMSTAR 2 and GRADE ratings, indicating that positive parent-child relationship (r=−0.15, 95% CI−0.18 to −0.11; P<.05) effectively mitigate the risks of digital addiction. Conversely, urban residence (odds ratio [OR] 2.32, 95% CI 1.19-4.53; P<.001), adverse childhood experiences (r=0.21, 95% CI 0.18-0.24; P<.001), and social anxiety (r=0.34, 95% CI 0.19-0.48; P<.001) were identified as factors that may increase the risk of developing digital addiction.

Conclusions: This study found that social factors such as urban residence were associated with an increased risk of digital addiction, whereas social support served as a protective factor against this risk. Nonetheless, the methodologies used in analyzing the factors related to digital addiction require further refinement.

Introduction

Digital addiction is characterized by a detrimental dependence on digital media and high-tech devices, including social networking, smartphone, and internet addictions [1,2]. Although digital addiction is not officially classified as a diagnosable disorder, some psychologists argue that it bears similarities to substance use disorders [3]. It is estimated that smartphone addiction affected 26.99% of individuals, social media addiction 17.42%, and internet addiction 14.22%, with notably higher rates among young people [2,4]. A cross-sectional study involving 31,659 university students from 2015 to 2018 revealed prevalence rates of 37.93% (12,009/31,659) for mild, 6.33% (2003/31,659) for moderate, and 0.20% (63/31,659) for severe internet addiction [5]. Digital addiction contributes to psychological issues, including attention deficits, depression, and anxiety, while also exacerbating social isolation, sleep disorders, and diminishing academic and occupational performance [6]. Consequently, the effective prevention and

XSL•FO
RenderX

management of digital addiction has emerged as a critical public health concern [7].

Studies have sought to identify modifiable risk and protective factors associated with digital addiction, categorizing them into three main domains, namely individual, digital media, and environment [7-11]. The emphasis has primarily been on individual and social determinants, which encompass intrapersonal and interpersonal factors, including gender differences, psychological traits, and health behaviors, as well as broader social influences. Despite the existence of numerous systematic reviews and meta-analyses addressing factors linked to digital addiction, these investigations often focus on specific individual factors without providing updated, comprehensive insights. It is notable that 1 study identified 34 modifiable factors such as intrapersonal factors (eg, time spent playing and psychological conditioning), interpersonal factors, and social factors and concluded that intrapersonal factors were more likely to have a greater impact on internet gaming disorder [8]. However, this study's focus on internet gaming disorder represents only 1 facet of the broader spectrum of digital addiction.

Umbrella review is an emerging evidence synthesis method that evaluates multiple meta-analyses on related topics to derive more comprehensive conclusions. Unlike traditional meta-analyses, umbrella reviews assess the methodological quality and risk of bias across various studies, enhancing the ability to detect inconsistencies and differences in findings [12]. This approach offers a broader understanding of the credibility and robustness of the evidence, helping to identify potential heterogeneity and diversity among studies.

This study aimed to further promote the integration of different research findings by conducting a comprehensive analysis of existing influences on digital addiction through umbrella analyses, while also evaluating the methodology and quality of existing meta-analyses and systematic reviews.

Methods

Study Design

This umbrella review was conducted in accordance with the registered protocol (Open Science Framework Registry) and the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 statement [13]. Our study protocol has been registered with PROSPERO (registration number CRD42024594911).

Literature Search Strategy

This study followed the umbrella review process established by Aromataris et al [12], searched databases such as PubMed, Web of Science, the Cochrane Library, and Embase, and selected systematic reviews and meta-analyses on the influencing factors of digital addiction included in the databases up to September 24, 2024. The keywords used included digital addiction, digital overuse, internet addiction, internet-based addiction, problematic internet use, gaming disorder, social media addiction, influencing factors, risk factors, causative factors, contributing factors, meta-analysis, and systematic review, etc, and the search was conducted using a combination of subject words and free words. Taking the PubMed database as an example, the search strategy was shown in Multimedia Appendix 1. We also hand-searched the references of eligible included studies and google scholar to identify further relevant articles.

Inclusion and Exclusion Criteria

We included studies on the influencing factors of digital addiction if they met the following inclusion criteria: (1) study type was systematic reviews and meta-analyses; (2) studies that focused on the various determinants of any type of digital addiction across different populations; (3) studies that reported the overall effect size, including but not limited to pooled Pearson correlation coefficients or Spearman rank correlation coefficients (r), standardized mean difference, and odds ratio (OR) along with their 95% CIs or credible intervals.

Meta-analyses focusing exclusively on a single influencing factor were selected, prioritizing the most recent study with the largest number of included studies when duplicates were present [14]. When multiple systematic reviews addressed the same influencing factor, only the most recent review with the largest number of individual studies providing study-level estimates was included to prevent sample duplication. No language or date restrictions were applied. Articles lacking study-level effect sizes and 95% CIs for systematic reviews, or those based on animal models, were excluded. In addition, we excluded conference abstracts, editorials, narrative reviews, and systematic review protocols.

Literature Screening and Data Extraction

This study was conducted by 2 researchers who screened the literature and extracted data according to the inclusion and exclusion criteria. In case of disagreement, consulting a third researcher (ZFF) assisted in making the decision. Duplicate literatures were eliminated through the title and abstract, and the full texts were carefully read to extract information such as the first author, publication time, number of studies included and sample size, exposure factors, main outcome indicators, meta-analysis effect model, effect size and its 95% CI. When the same meta-analysis contained multiple health outcome indicators, each outcome indicator was extracted separately.

Literature Quality Assessment

In this study, the modified version of the systematic review methodology quality assessment tool (AMSTAR 2 [A Measurement Tool to Assess Systematic Reviews 2]) was used to assess the methodological quality of systematic studies [15]. AMSTAR 2 evaluated the methodological quality and credibility of the study from 16 items in 3 dimensions (including 7 key items and 9 non–key items) such as research design and registration, literature search and selection, quality assessment of the study, and data extraction. It demonstrated good inter-rater consistency, practicality, and a wide range of applications. Referencing the interpretation by Zeng et al [16], it was considered that ≤1 non–key item not met was high-quality research, ≥2 non–key items not met was medium-quality research, 1 key item not met was low-quality research, and ≥2 key items not met was extremely low-quality research.

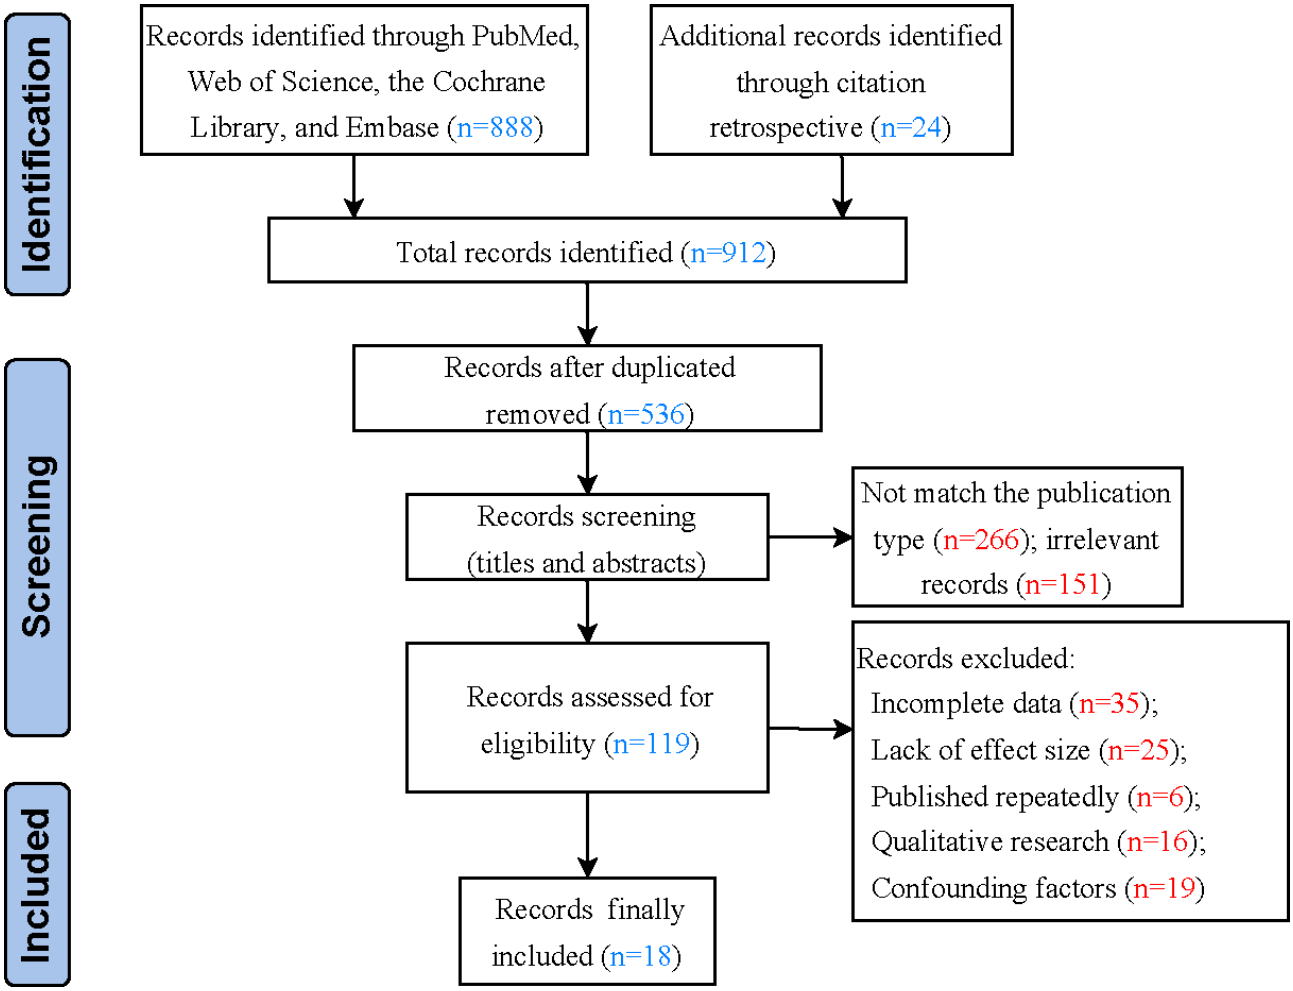
XSL•FO
RenderX

The Grading of Recommendations Assessment, Development, and Evaluation (GRADE) tool was used to evaluate the evidence quality level of the literature [17]. The GRADE grading system evaluated the outcome indicators based on 5 downgrade factors such as limitations, heterogeneity, indirectness, imprecision, and publication bias. This study stipulated that no downgrade factors were high-quality evidence, the existence of 1 downgrade factor was medium-quality evidence, the existence of 2 downgrade factors was low-quality evidence, and downgrade factors ≥3 were extremely low-quality evidence [18,19]. While the GRADE system typically assigns an initial "very low" quality rating to evidence derived from observational studies due to inherent limitations such as potential confounding and bias, it allows for upgrading or downgrading based on additional factors such as the magnitude of effect, dose-response relationships, and the presence of plausible confounding factors. In this umbrella review, we applied the GRADE framework to evaluate the quality of evidence across meta-analyses, which often include a mix of observational and other study designs. This approach enables a more nuanced assessment of the evidence, considering factors such as risk of bias, inconsistency, indirectness, imprecision, and publication bias. By doing so, we aimed to provide a comprehensive evaluation of the credibility and robustness of the findings related to digital addiction.

Data Analysis

This study conducted a methodological assessment using AMSTAR 2 and evaluated the quality of evidence with GRADE, aiming to identify high-quality and significant results from the most up-to-date and comprehensive available evidence. Significant heterogeneity was defined as present when the I^2>50% or the P<.1 [20]. A meta-analysis was considered to have a small sample size if there were fewer than 1000 participants in the meta-analysis [21,22]. Notably, a significant publication bias was inferred if the largest weighted effect size in the meta-analysis was subordinate to the overall effect size, indicating a significant small study effect (SSE) [21,23]. Publication bias was quantitatively assessed using the Egger test [24] and the Begg test [25], with a P value <.05 [26] indicating the presence of statistically significant bias.

Results



Literature Screening Results and Basic Characteristics

Through a database search and additional manual search, a total of 912 relevant articles were initially identified. After removing duplicates, 536 articles remained. Following a review of titles and abstracts, 387 articles were excluded (266 due to mismatched study types and 151 for being irrelevant). After full-text screening and reviewing in Multimedia Appendix 1, 101 articles were further excluded due to incomplete data or lack of effect size. As illustrated in Figure 1, the final selection process resulted in the inclusion of 18 articles that met the inclusion criteria.

The included meta-analyses were published between 2020 and 2024, reporting on 24 potential influencing factors related to digital addiction, with personality traits further subdivided into 8 categories. The sample sizes of the studies ranged from 300 to 159,425 participants. The included literature mainly used the New Castle-Ottawa scale (NOS) and the Joanna Briggs Institute (JBI) systematic review checklist to assess research quality. A total 6 studies did not specify the methods used for quality evaluation or risk of bias assessment. The basic characteristics of the included literatures are seen in Table 1.

Methodological Quality Evaluation

Through evaluation with the AMSTAR-2 tool, all included meta-analyses exhibited some methodological deficiencies. Specifically, 6 were of moderate quality, 4 of low quality, and 8 of very low quality, with none classified as high quality. For key items, the compliance rates were as follows: item #2 (whether the review reported that its methods were established a priori and explained any major changes to the protocol), item #4 (whether a comprehensive literature search was conducted), item #7 (whether a list of excluded studies and reasons for exclusion were provided), and item #9 (whether a satisfactory technique for assessing the risk of bias in individual studies was used) all had a compliance rate of 83.33% (15/18); the compliance rate for item #11 (whether appropriate methods were used to combine results) was 72.22% (13/18); item #13 (whether bias was explained) had a compliance rate of 33.33% (6/18); and item #15 (whether the authors properly investigated and discussed the potential impact of publication bias) was 55.56% (10/18). The results of the methodological quality evaluation are presented in Table 2.

[s]PY: partially complaint.

Evidence Quality Grading

Based on the GRADE evaluation system, of the 24 outcome indicators, 1 study provided high-quality evidence, 5 provided moderate-quality evidence, 11 were of low quality, and 7 were of very low quality. The detailed results of the evidence quality assessment are presented in Table 3.

XSL•FO

[a]Risk of bias: bias occurs when the results of a study do not represent the truth because of inherent limitations in design or conduct of a study

[b]Inconsistency: this refers to unexplained variability among the results of the included studies.

[c]Indirectness: it refers to the extent to which the people, interventions, and outcome measures are similar to those of interest.

[d]Imprecision: the authors have the option of decreasing their level of certainty one or two levels if the confidence intervals are wide.

[e]Publication Bias: this occurs when the dissemination of research findings is influenced by the nature and direction of results.

[f]Y: compliant.

[g]NY: not compliant.

Influencing Factors for Digital Addiction

Intrapersonal Factors

As shown in Table 4 and Figure 2, most of the included studies were highly significant. In this study, Ding et al [32] discovered that individuals with higher levels of self-esteem (r=−0.25, 95% CI−0.29 to −0.22; P<.001) and self-control (r=−0.48, 95% CI−0.53 to −0.42; P<.001) are more prone to digital addiction. Similarly, Zewde et al [39] found that men are at a higher risk of digital addiction compared with women (OR 1.92, 95% CI 1.43-2.75; P<.001). Furthermore, Zhuang et al [8] reported that individuals with a higher grade point average (r=−0.15, 95% CI −0.25 to −0.16; P<.05) are less likely to be threatened by digital addiction. These findings were rated as moderate evidence in terms of methodological quality with AMSTAR 2 tool.

[a]ES: effect size.

[b]NS: not significant.

[c]OR: odds ratio.

Figure 2. Forest plot of factors associated with digital addiction. AMSTAR 2: a measurement tool to assess systematic reviews version 2; ES: effect size; g: Hedge's g; GRADE: Grading of Recommendations Assessment, Development, and Evaluation; NS: not significant; OR: odds ratio; *: classified as moderate with AMSTAR 2 or GRADE; **: classified as high with AMSTAR 2 or GRADE.

On the other hand, the quality assessment conducted using the GRADE tool revealed that Chung's analyses, which identified a protective impact of the discount probability against digital addiction (r=−0.32, 95% CI −0.85 to −0.20; P<.47), was graded as high-quality evidence [28]. However, the statistical results were not significant. In addition, Rajesh et al [36] found that different personality traits have varying impacts on digital addiction was also rated as moderate evidence quality. Specifically, they suggested that individuals with openness (r=−0.05, 95% CI −0.08 to −0.01; P<.05), agreeableness (r=−0.07, 95% CI −0.10 to −0.04; P<.05), and conscientiousness (r=−0.15, 95% CI −0.18 to −0.11; P<.001) were protected against the addictive potential of digital media. Conversely, those experiencing loneliness (r=0.23, 95% CI 0.19-0.27;

XSL•FO
RenderX

P<.001), depression (*r*=0.18, 95% CI 0.13-0.23; *P*<.05), impulsivity (*r*=0.25, 95% CI 0.18-0.32; *P*<.001), and shyness (*r*=0.20, 95% CI 0.14-0.25; *P*<.001) are at a greater risk of developing digital addiction. Although no publication bias was found in the above analyses, it is important to emphasize that none of the analyses addressing intrapersonal factors achieved moderate or high ratings in terms of methodology and quality of evidence.

Interpersonal Factors

Of the 5 analyses examining interpersonal factors associated with digital addiction, only 1 study by Zhuang et al [8] met the criteria for moderate methodological and evidence quality with AMSTAR 2 tool. This study focused on parent-child relationship and showed that the stronger the parent-child relationship (*r*=−0.15, 95% CI −0.18 to −0.11, *P*<.05), the lower the probability of digital addiction. No risk of publication bias was identified in this analysis (Table 4 and Figure 2).

Social Factors

The findings revealed that urban residence (OR 2.32, 95% CI 1.19 - 4.53; *P*<.001) by Zewde et al [39], exposure to adverse childhood experiences (*r*=0.21, 95% CI 0.18 - 0.24; *P*<.001) by Hao et al [42], and the presence of social anxiety (*r*=0.34, 95% CI 0.19 - 0.48; *P*<.001) by Wu et al [43] were significant predictors of digital addiction. Notably, all 3 analyses were accorded moderate ratings in the evaluation of methodological and the quality of evidence rating with AMSTAR 2 and GRADE tools, and no evidence of publication bias was identified in the analyses. Furthermore, Wan et al [37] suggesting that individuals with stronger social support networks (*r*=−0.17, 95% CI −0.21 to −0.13, *P*<.001) exhibited a reduced likelihood of developing digital addiction. However, this particular analysis did not achieve a similar assessment in the quality of evidence, although it was recognized for its moderate methodological quality (Table 4 and Figure 2).

Discussion

Principal Findings

This umbrella review identified a range of intra-personal, interpersonal, and social factors influencing digital addiction. In a comprehensive examination of the aforementioned factors, several studies were noted for their methodological assessment. The studies conducted by Ding et al [32] on self-esteem and self-control, by Zewde et al [39] on male gender, and by Wan et al [37] on social support, all achieved moderate rankings for methodological rigor. However, the evidence for these factors was considered circumstantial or questionable in accuracy, resulting in a classification of low quality. On the other hand, study by Zhuang et al [8] concluded that a strong parent-child relationship significantly mitigated digital addiction, while study by Zewde et al [39] identified urban living as a risk factor. In addition, study by Hao et al [42] on childhood adverse experiences, and study by Wu et al [43] on social anxiety, findings from both of these studies received ratings of moderate methodological quality.

Intrapersonal factors significantly influence digital addiction, with our study evaluating 21 such factors, of which only 3 received moderate ratings on the AMSTAR 2 and 8 on the GRADE scale, all focusing on the associations between personality traits and digital addiction. Despite some methodological limitations, our findings were consistent with finding by Geng et al [44], indicating that self-control inversely associated with digital addiction, suggesting that individuals with lower self-regulation are more prone to emotional and impulsive behaviors, thereby fostering harmful digital usage patterns. In addition, specific personality traits can serve as protective factors against digital addiction [44,45]. As previous research has indicated, self-esteem, which is a reflection of an individual's sense of perceived value, is associated with higher self-efficacy and self-control, ultimately reducing addiction risk [46]. Traits such as self-consciousness, characterized by self-discipline and organizational skills, tend to promote caution in digital interactions, favoring real-life experiences [47]. Furthermore, individuals exhibiting higher levels of agreeableness and openness are less likely to encounter risks associated with digital addiction [36,47]. Conversely, traits such as narcissism, characterized by self-centeredness and lack of empathy, may drive individuals to seek internet-based validation, increasing addiction susceptibility [48]. Consistent with previous research [49-53], impulsivity is a notable risk factor for digital addiction, as highly impulsive individuals often struggle to resist internet-based temptations. Shyness may prompt individuals to engage more in digital socialization to avoid in-person interactions, potentially heightening addiction risk [54]. Thus, our results suggest that while positive personality traits may buffer against digital addiction, negative traits can increase vulnerability. At present, cognitive behavioral therapy and psychosocial interventions are recognized as efficacious strategies for mitigating the symptoms of internet addiction. Cognitive behavioral therapy has been shown to substitute impulsive behaviors with more reasoned actions and improve self-control [55], thereby contributing to the prevention and management of digital addition [56]. Psychosocial interventions have been effective in addressing internet addiction and enhancing self-esteem. By focusing on the psychological and social dimensions of the individual, these approaches promote the development of a positive personality and can be effective in curbing digital addition behaviors [57,58]. Furthermore, gender differences are crucial, as males are more likely to develop digital addictions, likely due to their preference for strategy, role-playing, and action genres, which are inherently more addictive [59].

Among the 4 interpersonal factors associated with digital addiction, 1 study was rated as moderate on both the AMSTAR 2 and GRADE scales, indicating that it provided reasonably convincing evidence through robust methodology [8]. This finding is consistent with previous research, which has demonstrated that enhanced parent-child relationships can effectively reduce the risk of digital addiction among adolescents [60,61]. Research suggests that there is a link between excessive parental screen time and problematic screen behaviors in their offspring. Excessive use of digital devices by parents reduces interaction with their children; this, along with their children's emulation of their parents' screen-using habits, contributes to the development of screen-using behaviors in adolescents. This pattern of behavior has the potential to evolve into digital

XSL•FO
RenderX

addiction [62,63]. Therefore, providing guidance on the use of digital devices, especially for parents of young children, may become a viable intervention strategy to counteract the emergence of digital addiction in children.

Six of the included studies explored examined the influence of social factors on digital addiction, with 4 rated as moderate quality based on AMSTAR 2 criteria. However, only 3 of these studies received a moderate rating from GRADE. Evidence indicates that urbanization uniquely affects addiction; urban residents often face environmental pollution and discomfort associated with city life, which can heighten psychological stress and contribute to digital addiction [64]. In addition, a lack of social support emerges as a critical risk factor for internet addiction. Insufficient social connections can lead to unhappiness, prompting individuals to seek emotional fulfillment through social media, potentially worsening addiction issues [65,66]. Late childhood, a pivotal period for social and emotional development, shows a marked negative association between internet engagement and various well-being dimensions. This correlation suggests that the rising levels of unhappiness and anxiety in children are closely linked to increased internet use. Furthermore, adverse childhood experiences related to home environments and parental pressures significantly influence children's development, leading to increased time spent on digital media [[67,68]]. In addition to the previously mentioned parental digital guidance, group counseling has also been reported to play a significant role in enhancing the self-control abilities of school-aged children with internet addiction [69]. However, when parents are also involved in group counseling, research has proven that it requires parents to have previously successfully dealt with challenges such as social anxiety, social isolation, and social skill deficits, or else group counseling will be much less effective [69].

Intrapersonal factors influencing digital addiction have been extensively studied, predominantly focusing on personality traits. However, most meta-analyses seem to suffer from methodological flaws, and even those without serious issues often reveal publication bias in original studies, thereby diminishing the quality of the evidence [32,39]. Therefore, it raises concerns about the risk of publication bias, where positive results are more readily published, potentially obscuring the true nature of the cause-and-effect relationship [70]. In contrast, fewer studies examining interpersonal and social factors demonstrate better methodological rigor and evidence quality. These factors often exert their influence on digital addiction indirectly by affecting psychological traits or personality characteristics. For example, Malak et al [71] used structural modeling to show that social support mediates the relationship between anxiety and stress, contributing to internet-based gaming disorders, a form of digital addiction [66]. Thus, it is misleading to solely consider interpersonal and social factors when exploring correlates of digital addiction. Instead, this indicates the need for further research to elucidate the complex interplay between these domains.

Limitations

While this umbrella review evaluated numerous factors associated with digital addiction, several limitations persist. First, the focus on published meta-analyses may lead to the omission of factors that are less studied or have not garnered significant attention [72]. Second, the broad scope of the review complicates the generalization of results due to the diversity of research findings included. Finally, many systematic reviews analyzed similar exposure factors and were conducted within a relatively short timeframe, resulting in potential overlap among initial studies. To mitigate this, we prioritized the inclusion of the most recent meta-analyses with the highest number of studies and aimed to exclude those exhibiting considerable overlap with original studies.

Conclusion

In conclusion, a range of intrapersonal, interpersonal, and social factors significantly influences an individual's susceptibility to digital addiction. A rigorous evaluation using the AMSTAR and GRADE frameworks identified negative parent-child relationships, urban residence, adverse childhood experiences, and social anxiety as credible risk factors. These findings are essential for informing effective public health strategies aimed at preventing digital addiction. However, further refinement of the methodologies used to analyze these factors is necessary to enhance the robustness of future research.

Acknowledgments

This study was supported by the National Natural Science Foundation of China (No 82473613) and Guangdong Basic and Applied Basic Research Foundation (No 2023A1515030155). The funding sponsors had no role in the design of the study, the collection, analyses, or interpretation of data, the writing of the manuscript, and the decision to publish the results.

Abstract

Background: Given the increasing prevalence of mental health problems among adolescents, early intervention and appropriate management are needed to decrease mortality and morbidity. Artificial intelligence's (AI) potential contributions, although significant in the field of medicine, have not been adequately studied in the context of adolescents' mental health.

Objective: This review aimed to identify AI interventions that have been tested, implemented, or both, for use in adolescents' mental health care.

Methods: We used the Arksey and O'Malley framework, further refined by Levac et al, along with the Joanna Briggs Institute methodology, to guide this scoping review. We searched 5 electronic databases from the inception date through July 2024 (inclusive). Four independent reviewers screened the titles and abstracts, read the full texts, and extracted data using a validated data extraction form. Disagreements were resolved by consensus, and if this was not possible, the opinion of a fifth reviewer was sought. We evaluated the risk of bias (ROB) for prognosis and diagnosis-related studies using the Prediction Model Risk of Bias Assessment Tool. We followed the PRISMA-ScR (Preferred Reporting Items for Systematic reviews and Meta-Analyses extension for Scoping Reviews) checklist for reporting.

Results: Of the papers screened, 88 papers relevant to our eligibility criteria were identified. Among the included papers, AI was most commonly used for diagnosis (n=78), followed by monitoring and evaluation (n=19), treatment (n=10), and prognosis (n=6). As some studies addressed multiple applications, categories are not mutually exclusive. For diagnosis, studies primarily addressed suicidal behaviors (n=11) and autism spectrum disorder (n=7). Machine learning was the most frequently reported AI method across all application areas. The overall ROB for diagnostic and prognostic models was predominantly unclear (58%), while 20% of studies had a high ROB and 22% were assessed as low risk.

Conclusions: In our review, we found that AI is being applied across various areas of adolescent mental health care, spanning diagnosis, treatment planning, symptom monitoring, and prognosis. Interestingly, most studies to date have concentrated heavily on diagnostic tools, leaving other important aspects of care relatively underexplored. This presents a key opportunity for future research to broaden the scope of AI applications beyond diagnosis. Moreover, future studies should emphasize the meaningful and active involvement of end users in the design, development, and validation of AI interventions, alongside improved transparency in reporting AI models, data handling, and analytical processes to build trust and support safe clinical implementation.

Introduction

Mental Health Among Adolescents

According to the World Health Organization, adolescence is defined as the age interval between 10 and 19 years [1]. It is a pivotal time of life when vulnerability to mental health issues increases [2] as it encompasses critical years for mental, social, and emotional growth [3]. It is a period when questioning of one's identity is common, along with the gradual assertion of independence [4]. This may be accompanied by rebellion against parents, while self-expression within the world at large begins. During adolescence, there are important hormonal shifts, and the brain undergoes significant developmental changes in neural pathways and behavioral patterns that will remain throughout adulthood, impacting mental health [5]. Certain mental illnesses that begin in adolescence continue into adulthood, causing long-term morbidity and a significant burden on society [5,6].

Globally, it is estimated that while 1 in 7 adolescents experience mental health problems, these remain largely unrecognized and untreated [7]. A meta-analysis of 29 studies involving 80,879 youth during the COVID-19 pandemic revealed that depressive and anxiety symptoms among children and adolescents had doubled compared with prepandemic estimates, highlighting the impact of external stressors on this vulnerable population [8]. Reviews have further emphasized that this mental health burden is compounded by increased screen time and social media use, with complex bidirectional relationships identified between digital media exposure and psychological well-being [9,10]. Suicide is the fourth most significant cause of death among older adolescents (15 - 19 y) [7], accounting for 9.1% of all mortalities in this age range [11]. In 2016, the worldwide incidence of excessive episodic drinking among adolescents aged 15 to 19 years was 13.6%, with males being the most vulnerable [12]. Mental health problems that begin early tend to continue throughout adulthood [13]. Therefore, there are serious consequences from such illnesses during adolescence and later in life [14]. This supports the need for early intervention and appropriate management of adolescents' mental health problems [13,15].

Role of Artificial Intelligence in Adolescents' Mental Health Care

Artificial intelligence (AI) is a branch of computer science and engineering dedicated to developing systems that can perform tasks typically requiring human intelligence, such as learning, reasoning, and decision-making [16,17]. AI has been proven to have the ability to deliver significant benefits in a variety of sectors and levels of health care [18], including administrative planning [19], resource management [20], prevention [21], screening [22], diagnostics [23], and treatment [24,25]. Adolescents as a collective are deeply engaged with utilizing technology, particularly social media, and perceive it as a mainly positive experience [17]. However, recent reviews have revealed a nuanced relationship between technological engagement and mental health outcomes [9]. While social media can provide valuable social support and connection, excessive use has been associated with an increased risk of anxiety, depression, and other mental health challenges [26]. In light of this complex relationship, technology is increasingly seen as a possible avenue for developing targeted solutions to health problems [19].

Comprehensive reviews of AI-enabled mental health interventions have demonstrated promising results, particularly in the form of chatbots and digital health platforms that can provide immediate support and increased access to mental health resources [9]. These digital interventions have shown promise in delivering mental health care, offering new pathways for treatment and support, with reviews highlighting their potential to overcome barriers to traditional care access [10]. Furthermore, advanced machine learning (ML) approaches have demonstrated significant potential in predicting suicide risk through social media patterns, offering new possibilities for early intervention and prevention strategies [27].

At the patient-level, Voss et al [28] have demonstrated how a socialization intervention for autistic adolescents that combined wearable AI-assisted Google Glass helped them reflect on their moods and emotions, resulting in better socializing skills [28]. Similarly, McGinnis et al [29] developed a digital phenotype for adolescents' internalizing psychopathology using wearable sensors, finding that tasks inducing positivity, anxiety, and fear could identify depressive, anxious, and trauma-related disorders with 75% accuracy [29]. Chang et al [30] assessed methylphenidate's efficacy in attention deficit hyperactivity disorder (ADHD) treatment through neuroimaging markers, using a pattern recognition method to analyze volumetric differences in structural magnetic resonance imaging [30]. Their study employed support vector machine classification to distinguish between varying volumetric measures [30]. In a related study, Li et al [31] used ML techniques to examine gray matter volume correlations in adolescents with ADHD, successfully differentiating between ADHD and non-ADHD structural magnetic resonance imaging samples.

At the health care professionals' (HCP) level, AI technologies are proving instrumental in supporting HCPs who work with underprivileged adolescents. These tools facilitate earlier intervention, enhance engagement with therapeutic services, and raise awareness of mental health conditions, such as through the deployment of therapeutic chatbots [32,33]. These technological interventions are particularly valuable given the findings of recent reviews demonstrating the effectiveness of digital mental health interventions in reaching underserved populations [9,10]. At the system level, AI has the potential to address data shortage, particularly in non-integrated health care settings, by aiding in data collection through patient tracking and surveillance during screening procedures [34]. The integration of AI-powered tools has shown promise in standardizing mental health assessments and improving the accuracy of early detection systems, particularly when combined with traditional clinical approaches [14]. Recognizing both the potential of AI and the existing gaps in the literature, we conducted a systematic scoping review to synthesize current evidence on AI applications in adolescent mental health. Our goal is to provide a foundational understanding that may inspire future research and innovation in this rapidly evolving field.

XSL•FO

Methods

Study Design

We used the Arksey and O'Malley framework [35], further refined by Levac et al [36], along with the Joanna Briggs Institute methodology [37], to guide this scoping review. This framework includes the following steps: (1) defining the review topic, objective, and research questions; (2) identifying relevant publications; (3) choosing studies that matched our eligibility criteria; (4) extracting and charting data from included studies; (5) aggregating, summarizing, and reporting the findings; and (6) discussing the findings with relevant stakeholders including HCPs and AI researchers/experts.

The protocol of the study is registered and accessible on the Open Science Framework website [38] . We used the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analysis-Scoping Reviews) reporting guideline for reporting the study [39] (Checklist 1). We used the PROBAST (Prediction Model Risk of Bias Assessment Tool) to examine the risk of bias (ROB) in eligible studies. This tool evaluates the ROB and usability of diagnostic and prognostic predictions from studies that used AI models [40]. PROBAST is classified into 4 domains: participants, predictors, outcomes, and analysis, while ROB may be judged as low, high, or unclear [40]. By using PROBAST, we aimed to critically evaluate and provide insights into the potential biases associated with the relevant included studies.

Eligibility Criteria

Overview

We used the Population, Intervention, Comparison, Outcomes, Setting, and Study (PICOS) design components to develop our search approach for peer-reviewed papers in English [41].

Population

We included studies addressing (1) individuals between 10 and 19 years of age and (2) HCPs who provide care to adolescents with mental health problems, such as nurses, social workers, dietitians, public health practitioners, family physicians, community-based workers, clinical psychologists, pediatricians, psychiatrists, and pediatric psychiatrists.

Intervention

This study includes any AI system, in accordance with McCarthy's definition [42]. We included studies that "tested" or "implemented" or "tested and implemented" AI methods, such as computer heuristics, expert systems, fuzzy logic, knowledge representation, automated reasoning, data mining, and ML. We excluded studies related to robot-assisted care and studies using simulated data to replicate real-world situations [43].

Comparators/Control

There was no restriction under this design component.

Outcome

Our outcome of interest related to: (1) adolescents; (2) HCPs; and (3) health care system.

Setting and Study Design

We included studies in any health care setting, and all designs and publication types except reviews, opinion pieces, conference papers and abstracts, editorials, commentaries, news, and letters.

Information Sources and Search Strategy

An experienced information specialist (GG) developed and executed comprehensive literature searches. The systematic literature search was conducted in an iterative manner across 5 electronic bibliographic databases: MEDLINE (Ovid), EMBASE (Ovid), Web of Science Core Collection, Compendex, and INSPEC. Initially, we included studies published until February 2020. Subsequently, given the rapid developments in the field of AI applications in adolescent mental health care, we extended our search through July 2024 (inclusive). This approach resulted in nearly tripling our included studies, ensuring our review reflected the current state of technological advancements in this domain. Retrieved records were managed with EndNote X9.3.3 (Clarivate) and imported into review software (ie, DistillerSR, Evidence Partners, Ottawa, ON) to facilitate the selection process (Multimedia Appendix 1).

Selection Process

Four independent reviewers (PG, LP, GS, and RG) screened the titles and abstracts of the initially identified records. The same 4 reviewers then independently assessed the full texts of studies selected in Level 1 screening for eligibility. In cases where disagreements arose, the reviewers first discussed their differences to attempt a resolution through consensus. If a consensus could not be reached, a fifth reviewer (SAR) was consulted to make the final decision. Studies that met the eligibility criteria were then included for full data extraction.

Data Collection

A data extraction form, informed by aspects of the Cochrane Effective Practice and Organization of Care (EPOC) review group data collection checklist [44], was created and completed with team members' input. We extracted study characteristics (eg, country of research, aim of study), population characteristics (eg, adolescents' gender, age, and race), intervention characteristics (eg, various AI methods used, performance measures of AI interventions), and outcome characteristics (eg, AI application on the continuum of adolescents' mental health care).

Assessment of Risk of Bias

Three reviewers independently (GS, RG, and PG) assessed the included studies using the PROBAST criteria to determine the ROB in each eligible study for PROBAST evaluation [40]. Fourth reviewer (SAR) validated the assessments.

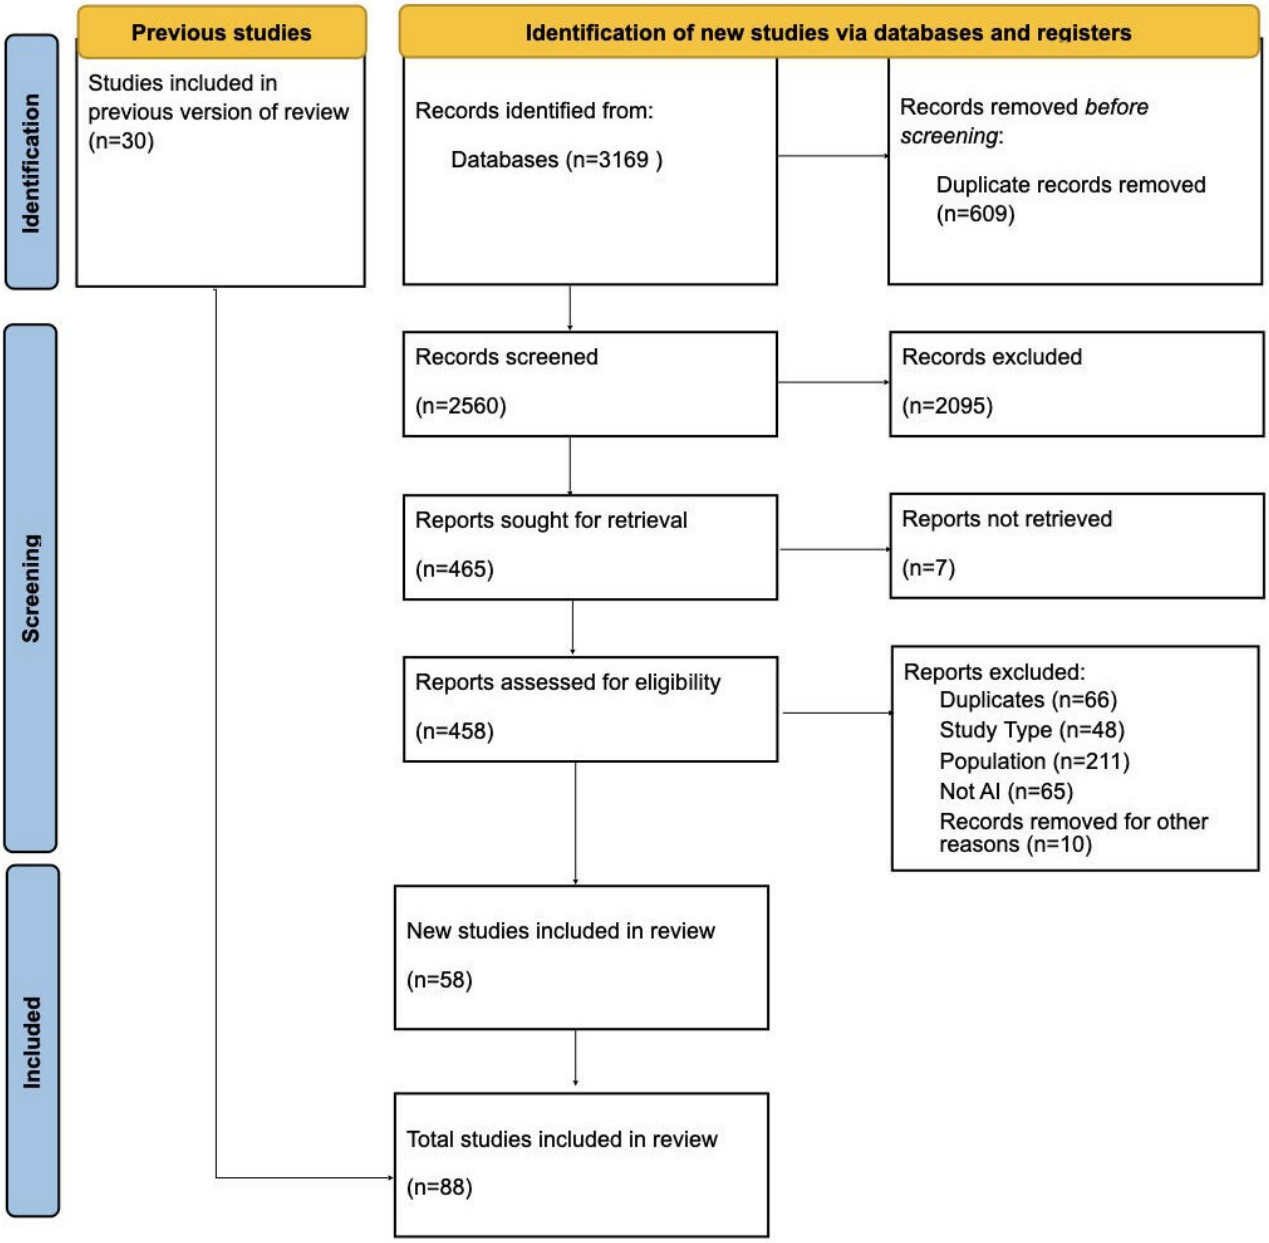
Synthesis

The techniques used to build preliminary synthesis comprised textual descriptions of the studies, grouping, clustering, and tabulation [45]. We used a narrative technique to synthesize the data after extracting it from the relevant studies. We particularly detailed the characteristics of AI interventions, the nature and conditions of adolescents' mental health, and whether or not end users were engaged in the development or validation process

XSL•FO
RenderX

of these interventions. For data synthesis, we used Distiller software and Microsoft Excel.

Consultation



Throughout the review, we kept all study team members up to date and solicited their comments about the quality and accuracy of the ongoing data-gathering process. Furthermore, we had the opportunity to present our preliminary findings to a diverse group of participants (primary care researchers, AI-health care researcher, and family physician) at 2 virtual symposiums, FMF 2021 [46], and AAAI 2021 Spring Symposium Series on Applied AI in Healthcare: Safety, Community, and the Environment [47]. We carefully considered and integrated the received feedback into our review, enhancing its overall quality and robustness.

Results

Overview

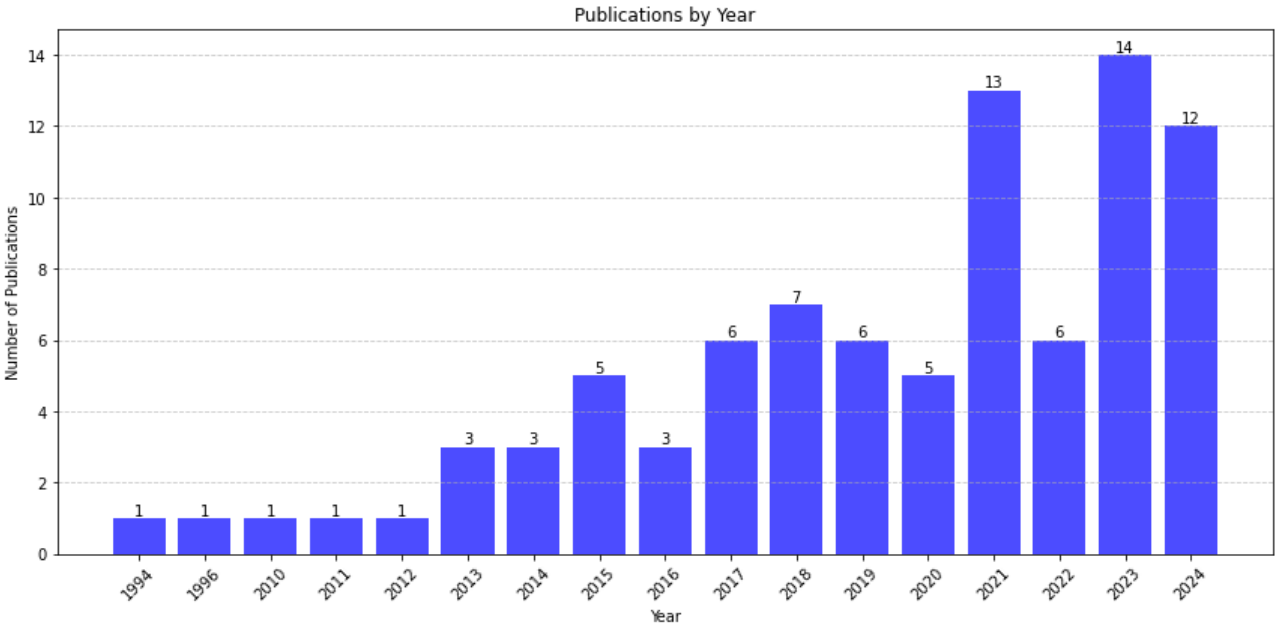
Through searching the identified bibliographic databases, we obtained 4213 papers. After deduplication, we obtained 3364 papers. Finally, 88 papers were included after 2 rounds of screenings for data charting and analysis (Figure 1).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of the selection procedure. AI: artificial intelligence.

Study Characteristics and Aims

Overview

The 88 papers included in this review aimed to test and implement an AI model in mental health care for adolescents.



Countries and Publication Dates

Considering the 88 included papers, despite a plateau trend from 1994 to 2012, the number of studies published annually on adolescents' mental health using AI has progressively increased until 2018, when a decrease was observed. This trend continued

XSL•FO
RenderX

with the start of the COVID-19 pandemic in early 2020. However, an increase in studies was observed after February 2020. Figure 2 depicts the timeline of AI-based papers (n=88). Four countries contributed the highest number of publications: the United States (n=26), China (n=18), the United Kingdom (n=5), and South Korea (n=5).

Figure 2. Frequency and timeline of artificial intelligence research studies by year of publication.

Population Characteristics

Adolescents

Of the 88 papers, 68 stated their sample size. Among those 68 papers, 42 reported the sex distribution. The race/ethnicity of the participants was reported in 34 of the 88 papers (Table 1).

Table . Adolescents' variables reported (N=88).

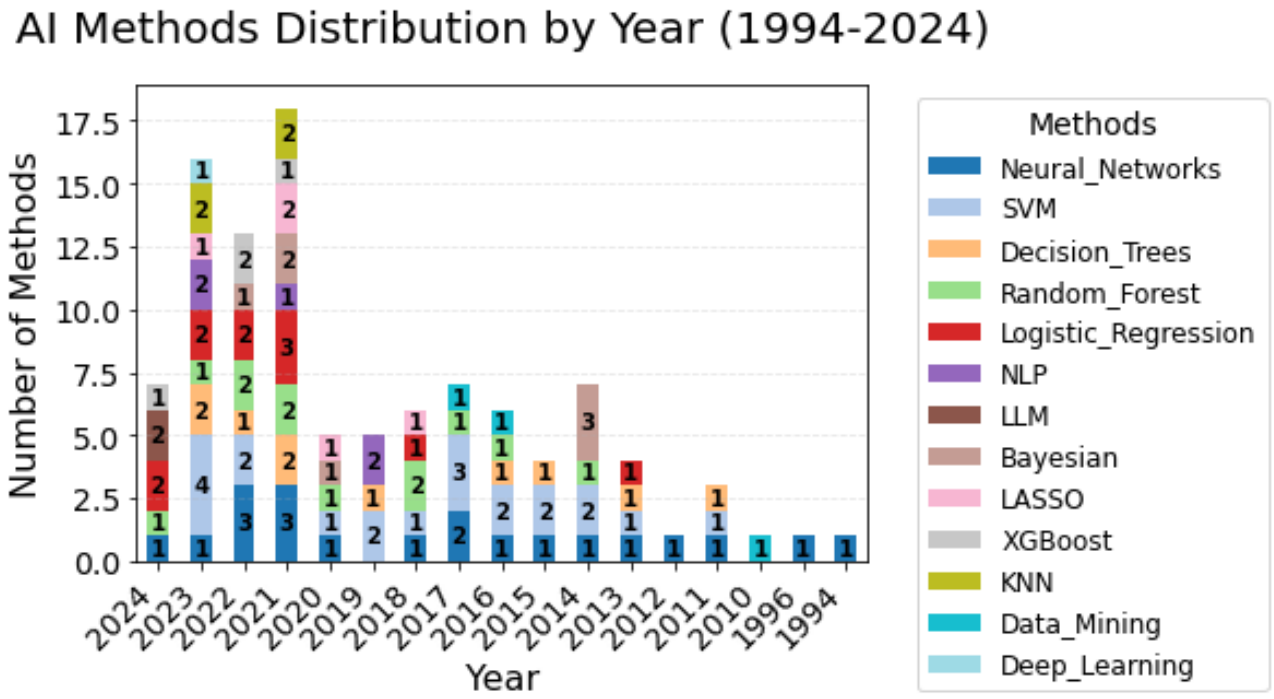
Reported variables	Values, n (%)
Sex	44 (50)
Sample size	68 (77)
Race/ethnicities[a]	34 (38.6)
Other sociodemographic[b]	50 (56.8)

[a]Race/ethnicities: Caucasian/White, Japanese, Chinese, Indian, Malay, Black, Oriental, African American, Asian-American, Hispanic, Native American/Alaskan, Asian, and Mixed.

[b]Other sociodemographic: parental marital status, parental educational level achieved, socioeconomic aspects (eg, parental and household income), place of residence, criminal records, maternal history of depression, neighborhood level of deprivation, adolescents' traumatic events, and their level of education.

Health Care Professionals

No studies provided information regarding the total number, sex, gender, age, and race/ethnicity of the HCPs. Their only role was described as collaborators who assisted researchers in assigning eligible adolescents to a study or confirming the adolescents' mental health disorders before using the AI systems. Adolescent psychiatrists, child psychiatrists, mental health professionals, pediatric-psychiatric clinicians, and adolescent forensic psychiatrists were among the HCPs involved in the mentioned process.



Intervention

AI Methods

Out of 88 included papers, 86 papers (97.7 %) reported on the testing and usage of off-the-shelf AI models. Such models were readily/instantly accessible or relevant to the specific context with slight modifications, but may have also been applicable to a wide range of other contexts or issues [48]. A total of 21 papers (23%) used support vector machine (Figure 3) as the most used AI method. Details of the AI methods are provided in the Multimedia Appendix 2.

XSL•FO
RenderX

Figure 3. Distribution of AI methods in research studies over the years. AI: artificial intelligence; KNN: k-nearest neighbours; LLM: large language model; NLP: natural language processing; SVM: support vector machine.

Performance of AI systems

Out of 88 included papers, 11 papers (13%) did not report the model performance. Of all the methods used, fuzzy sets, data mining methods, and random tree classifiers were the ones with the highest performance accuracy within the available data sets for the defined task (accuracy: 90% - 100%). Among the included studies, 34 papers (38%) reported the performance of AI methods using "accuracy" as the sole evaluation metric. More details on the included papers' AI methods and performance measures are provided in the Multimedia Appendix 2.

Mental Health Disorders

Studies focused predominantly on mood disorders and depression (16 out of 88 studies, 18.2%), with depression being the most frequently studied condition (9 out of 88 studies, 10.2%). Suicide- and self-harm-related conditions were the second most studied area (15 studies, 17%), including investigations of suicide attempts, risk, and behavior (11 out of 88 studies, 12.5%) and nonsuicidal self-injury (2 out of 88 studies, 2.3%). Neurodevelopmental disorders were examined in 11 studies (12.5%), with autism spectrum disorder being notably prevalent (8 out of 88 studies, 9.1%). Stress and psychological conditions were investigated in 10 studies (11.4%), with psychological stress/pressure being the most common (5 out of 88 studies, 5.7%). General mental health conditions were explored in 9 studies (10.2%). Substance use disorders were investigated in 7 studies (8%), including alcohol-related disorders (3 out of 88 studies, 3.4%) and cannabis use disorders (2 out of 88 studies, 2.3%). The remaining studies (20 out of 88 studies, 22.7%) covered diverse conditions, including eating disorders, school violence, psychosis, and various behavioral conditions. The details about the mental health disorders can be found in Multimedia Appendix 3.

AI Applications on the Continuum of Adolescents' Mental Health Care

The included papers reported on the use of AI in adolescent mental health care for the following applications: (1) 78 (89%) papers focused on the use of AI for the facilitation and improvement of the diagnostic processes, such as more accurate diagnosis, enhanced disease pathogenesis knowledge, and identification of associated disease risk factors; (2) 10 (11%) papers used AI for improving treatment by boosting treatment accuracy and implementing more targeted interventions; (3) 19 (21%) papers reported on the application of AI to improve monitoring and evaluation; and (4) 6 (6%) papers used AI for improving prognosis, for example, by discovering new disease biomarkers. More details can be found in Multimedia Appendix 3.

Legal Information and Data Privacy

The legal information on data privacy and security using AI was not reported in any of the included papers.

AI Delivery Mechanism

AI delivery mechanism refers to how the AI interventions were administered, for example, a smartphone app, computer software, and website. Among the included papers, 45 (50%) papers reported using different delivery mechanisms, including computer software (n=14), smartwatch (n=1), microblog (n=9), and virtual reality network interface (n=20).

Data Type Used to Develop AI Interventions

Data type refers to the operational data acquired from patients as a result of their participation in the studies with the intent of utilizing intelligent models for a very specific process of tagging

XSL•FO
RenderX

phrases, qualities, characteristics, and images [49]. The data type reported in all of the included papers is provided in Table 2.

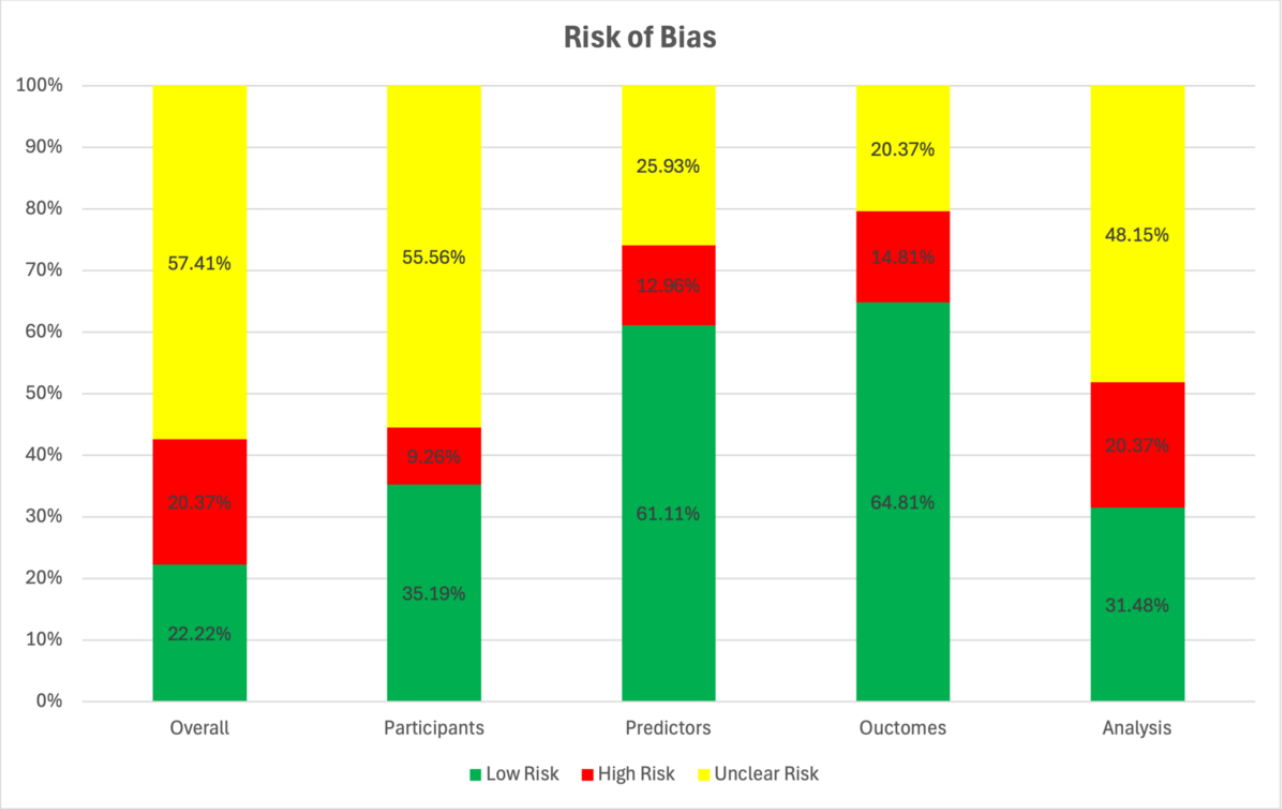


Table . Types of data used to develop artificial intelligence interventions (N=88).

Type of data	Values, n (%)
Clinical data	41 (47)
Image and computer vision data	21 (23)
Text data	26 (30)

Risk of Bias

We identified the papers that were eligible to be evaluated using PROBAST. About 60% (53) of our included papers qualified to be analyzed using that tool. Among those, 10 (20%) papers were at high ROB according to our assessment with PROBAST (Figure 4), 31 (58%) papers were at "unclear risk" and 12 (22%) papers were at "low risk." Details for each domain are provided in Figure 4. The detailed ROB table is available in Multimedia Appendix 4.

Figure 4. Risk of bias graph: assessing the risk of bias in 5 categories, namely overall, participants, predictors, analysis, and outcome (presented as percentages).

Discussion

Principal Findings

This review encompassed 88 studies examining the application of AI interventions in adolescent mental health care. These studies were critically evaluated, yielding the following key observations.

AI Models, Performance, and Risk of Bias

ML was the most commonly used AI method in adolescents' mental health care. Of all the methods reported, fuzzy sets, data mining, and random tree classifiers were the ones with the highest performance accuracy within the available data sets for the defined task (Accuracy: 90% - 100%). Most of the included papers (86/88, 97 %) reported on the testing and use of an off-the-shelf AI model. The findings indicate that off-the-shelf models cannot be used directly in all clinical and mental applications, given that models with extensive training data sets fail to reflect the complexities of clinical mental cohorts [50]. Studies have shown that even models trained on extensive datasets can fail to reflect real-world clinical complexities, particularly due to issues like small or nonrepresentative datasets, lack of robust validation, and insufficient adaptation to individual or cohort-specific differences [51]. Obtaining representative training data is fundamental to data-driven AI models' performance in clinical settings. Otherwise, the data might be misinterpreted because of a lack of relevant information [52]. Furthermore, we observed a lack of standardized evaluation metrics, with 38% (34/88) of studies relying solely on accuracy. While accuracy is useful, it does not

XSL•FO
RenderX

account for class imbalances or other key performance aspects such as sensitivity, specificity, and F_1-score, which are critical in health care applications.

Additionally, our PROBAST assessment found that the majority (31/53, 58%) of our included studies had overall "unclear risk". While some aspects of these studies may have been well-conducted and transparent, there was insufficient information to confidently assess the ROB in at least one of the 4 PROBAST domains (Participants, Predictors, Outcome, Analysis). Therefore, there may be potential biases or methodological issues that could affect the validity or reliability of the results, but these are not clearly documented or described. We encourage future studies to have more detailed reporting and transparency in research methodology to ensure that studies can be accurately evaluated and their findings confidently applied in practice.

In our review, we also observed that there was no mention of adherence to a particular reporting framework or guideline in any of the included papers. Studies that report on the usage of AI methods in general and in the context of physical and mental health care should follow validated frameworks or guidelines in reporting their findings [53]. Transparent reporting of AI models' data and methodologies can facilitate identification of the possible biases and promote an accurate assessment of the efficacy, reproducibility, and reuse of AI and ML methods in future research [53].

Mental Health Applications of AI in the Continuum of Care and Practice

We discovered AI interventions in adolescents' mental health care in four major domains: (1) facilitating diagnostic processes such as identifying mental health related diagnostic imaging and biomarkers; (2) monitoring and evaluation such as improving follow-up visits; (3) treatment such as improving treatment accuracy; and (4) prognosis such as assisting with identifying prognostic-related biomarkers. Our findings were consistent with the previous literature on the use of AI in assisting mental health diagnosis, prognosis, treatment, and monitoring and evaluation [54]. Previous studies showed that AI interventions might enhance mental health treatments in several ways, including predicting treatment response [55], possibly avoiding or substituting impotent medication experiments [56], and invasive, costly brain stimulation therapies or time-consuming psychotherapies [56]. As for monitoring and evaluating mental health problems, AI was shown to remotely monitor and detect subjective and objective markers of psychotic recurrence [57]. Predicting whether adolescents may develop mental health problems is essential for accurate and early intervention to avoid major unfavorable consequences in the future. Additionally, studies have shown that applying AI methods to panel data, that is, data collected in a series of repeated observations of the same subjects over some extended time frame to measure the change, might help improve the accuracy of prognoses for mental health patients [58]. For instance, by combining imaging, electronic medical records, genetic, and speech data to predict depression patterns [59], risk of suicide [27], and future substance abuse among adolescents [60]. While our results showed that AI was used for the 4 main elements of diagnosis, prognosis, treatment, and monitoring and evaluation purposes in adolescents' mental health care, most articles were concerned with the diagnosis only, and many fewer used AI in other applications. This gap needs to be addressed in future studies.

End Users' Involvement

Our analysis highlighted that "end users" have been slightly or inadequately involved in AI interventions' development, validation, and testing in adolescents' mental health care. This limited engagement with HCPs and patients during the intervention's design process raises concerns about the suitability of AI interventions to meet their specific needs in clinical practice [61]. Involving end users in designing and developing such interventions can help produce better applications and significantly boost the likelihood of adoption. Our findings were in line with earlier research on the need to keep stakeholders in the loop when developing, testing, and validating AI interventions to screen for bias [61,62]. The failure to incorporate human elements into previous technological paradigm changes resulted in poor usage and major accidental mistakes [63]. To maximize the effectiveness and usability of AI in adolescent mental health care, it is essential to use a user-centered design approach that emphasizes the importance of involving end users throughout the entire process, including the design, development, and validation stages. Similarly, engaging diverse stakeholders throughout the AI lifecycle is important for creating effective and equitable solutions. Integrating equity, diversity, and inclusion (EDI) principles—using frameworks such as EDAI [64]—can help ensure AI systems are designed and validated with the needs and perspectives of all end users in mind, reducing bias and improving usability. Future research should prioritize EDI-oriented, user-centered approaches for adolescent mental health AI interventions.

Biological Sex and Gender-Related Concerns

Sex and gender interplay in the emergence of diseases [65] such as depression [66], coping mechanisms [67], and influencing various factors such as diagnosis, prognosis, symptomatology expression, and therapeutic efficacy [68]. This interaction helps provide more accurate and customized recommendations tailored to each unique patient [69]. Our results indicated that the distinction between biological sex and gender-related characteristics was not reported, and few projects explicitly accounted for this when presenting demographic data. Additionally, these findings revealed that the sex distribution was specified in nearly three-fourths of the included studies, but only for adolescents and not for HCPs. None of the papers examined gender-related indicators for either patients or HCPs. These findings mirrored related research that highlighted the importance of sex and gender differences being reported explicitly as a potential source of mental and clinical heterogenicity among adolescents. This approach helps reduce health disparities and identifies the role of interindividual variances when incorporating them with AI [70-72].

XSL•FO
RenderX

Geographic Distributions and Ethno-Racial Information

According to our results, most AI research in adolescent mental health was conducted in North American and East Asian contexts. Our findings also show that the race/ethnicity of patient participants was reported in less than a third of the included papers, with no discussion of the races/ethnicities of participating HCPs. Furthermore, for those papers that included patient ethnicity, we discovered that the obtained data were primarily associated with Caucasian/White populations, raising concerns about the dataset's representativeness, and potential biases. Similarly, research [73] evaluating the models' performance in predicting suicide, underlined the relevance of how ethno-racial unrepresentative datasets would impact the forthcoming AI models' prediction results. This would lead to less benefit and more risks for patients who are Black, American Indian/Alaska Native, or whose ethno-racial demographic is unknown, compared with White, Hispanic, and Asian patients [73].

AI interventions could make predictions that discriminate against marginalized and vulnerable patient populations, leading to unsatisfactory patient outcomes due to the imbalanced health care datasets used to develop them [74,75]. Given the clear ethnic and racial differences in health care datasets (eg, disease biomarkers, prevalence, and outcomes), the inclusion of this information is likely to improve the accuracy of AI for all populations of the study [76]. By ignoring ethno-racial distinctions in the AI models, we are creating tools that do not consider diverse groups of adolescents, resulting in less effective, biased, and poor performance, particularly for minority groups with different ethnic/racial backgrounds [64]. Therefore, we propose that future research properly consider and report ethno-racial differences in AI algorithms for adolescent mental health care using frameworks such as EDAI [64].

Limitations

We have added a new understanding of AI use in adolescent mental health care, but we also note some limitations in our research. First, since only English papers were considered, there may be publication bias, as studies published in other languages may yield different findings. Second, our search strategy may not have collected all relevant studies because we used the World Health Organization's definition of adolescent to determine our inclusion criteria, and the definition of adolescent can still vary by country and charter. While terminologies like "adolescent," "youth," and "young people" are commonly used interchangeably [77,78] and may have distinct definitions in different settings/locations, this study focused mainly on the second decade (10-19 years) of life. Third, limitations in the search methodology may have resulted in the omission of certain pertinent publications, such as gray literature (eg, simulated data and robotics) and lower-level evidentiary records, including opinion pieces, editorials, comments, news, letters, and conference abstracts without full-text articles. These sources were excluded to ensure the inclusion of peer-reviewed, high-quality evidence and to minimize the risk of incorporating incomplete or nonrigorous findings. While gray literature and conference papers can provide insights into emerging AI implementations, they often lack the methodological transparency and validation required for robust analysis [79].

Conclusions

This review provides information on the AI interventions that have been tested and implemented for use in adolescents' mental health care. Overall, we found AI supporting adolescents' mental health care across the included papers. In our included papers, AI has been used for various purposes in adolescent mental health care, including facilitating and enhancing diagnostic processes by enabling more accurate diagnosis, increasing our understanding of disease pathogenesis, and identifying associated risk factors. Additionally, AI has contributed to improving treatment outcomes by enhancing treatment accuracy and enabling the implementation of targeted interventions. It has also been used for enhancing monitoring and evaluation processes while aiding in prognosis by identifying novel disease biomarkers. While our results showed that AI was used for the 4 main elements of diagnosis, prognosis, treatment, and monitoring and evaluation purposes in adolescents' mental health care, most papers were concerned with the diagnosis only, and many fewer used AI in other areas. This gap needs to be addressed in future studies. Moreover, future studies are encouraged to work on the meaningful and active involvement of end users in designing, developing, and validating AI interventions, ensuring inclusivity and diversity, and better reporting of AI models, data collection, and analysis processes. Last, as the integration of AI into health care, particularly in the context of adolescent mental health, is still emerging, it is essential to invest in education and capacity-building for HCPs, patients, and AI developers.

Acknowledgments

SAR is Canada Research Chair (Tier II) in AI and Advanced Digital Primary Health Care, received salary support from a Research Scholar Junior 1 Career Development Award from the Fonds de Recherche du Québec-Santé (FRQS) during a portion of this study, and her research program is supported by the Natural Sciences Research Council (NSERC) Discovery (grant 2020-05246). This study was partially supported by these funding sources.

Data Availability

Datasets used or analyzed during this study are available from the corresponding author upon reasonable request.

Abstract

Background: The global shortage of mental health professionals, exacerbated by increasing mental health needs post COVID-19, has stimulated growing interest in leveraging large language models to address these challenges.

Objectives: This systematic review aims to evaluate the current capabilities of generative artificial intelligence (GenAI) models in the context of mental health applications.

Methods: A comprehensive search across 5 databases yielded 1046 references, of which 8 studies met the inclusion criteria. The included studies were original research with experimental designs (eg, Turing tests, sociocognitive tasks, trials, or qualitative methods); a focus on GenAI models; and explicit measurement of sociocognitive abilities (eg, empathy and emotional awareness), mental health outcomes, and user experience (eg, perceived trust and empathy).

Results: The studies, published between 2023 and 2024, primarily evaluated models such as ChatGPT-3.5 and 4.0, Bard, and Claude in tasks such as psychoeducation, diagnosis, emotional awareness, and clinical interventions. Most studies used zero-shot prompting and human evaluators to assess the AI responses, using standardized rating scales or qualitative analysis. However, these methods were often insufficient to fully capture the complexity of GenAI capabilities. The reliance on single-shot prompting techniques, limited comparisons, and task-based assessments isolated from a context may oversimplify GenAI's abilities and overlook the nuances of human–artificial intelligence interaction, especially in clinical applications that require contextual reasoning and cultural sensitivity. The findings suggest that while GenAI models demonstrate strengths in psychoeducation and emotional awareness, their diagnostic accuracy, cultural competence, and ability to engage users emotionally remain limited. Users frequently reported concerns about trustworthiness, accuracy, and the lack of emotional engagement.

Conclusions: Future research could use more sophisticated evaluation methods, such as few-shot and chain-of-thought prompting to fully uncover GenAI's potential. Longitudinal studies and broader comparisons with human benchmarks are needed to explore the effects of GenAI-integrated mental health care.

KEYWORDS

LLM; mental health; clinical skills; digital mental health intervention; evaluation; large language model; generative artificial intelligence

Introduction

Artificial intelligence (AI) is a branch of computer science that emulates human intelligence using computational technologies to perform tasks that require an understanding of natural language, deep learning, adaptation, problem-solving, and decision-making [1]. AI applications in health care have surged in recent years, and the field has seen a variety of use cases, such as applying computer vision in diagnosing breast cancer from imaging and using predictive modeling to predict suicide risk [2-4]. With the advances of large language models (LLMs) such as ChatGPT by OpenAI in 2022, there has been a significant shift toward models that excel in natural language understanding and generation [5]. LLMs such as ChatGPT have quickly gained widespread adoption due to their remarkable versatility. Their ability to understand and generate contextually

XSL•FO
RenderX

relevant responses make LLMs highly effective in nuanced language comprehension, achieving higher levels of conversational depth. Indeed, LLMs excel at a wide range of tasks, including generating human-like text, summarizing complex information, translating languages, answering questions, and assisting with creative writing [6,7].

The mental health burden globally, and in the United States, has increased significantly post the COVID-19 pandemic, exceeding the capacities of the slow growth of mental health professionals [8]. Health professional shortage areas for mental health are defined as areas with a population-to-provider ratio of at least 30,000 to 1. According to the Behavioral Health Workforce 2023, as of December 2023, 169 million people living in the United States live in a mental health professional shortage area [9]. To fill the enlarging service gap, the interest and exploration of generative artificial intelligence (GenAI) applications in mental health have been growing over the past few years. LLMs such as ChatGPT, Claude, and Bard hold great promise in mitigating this stark situation to reduce clinicians' burden and increase clinician efficiency through LLM-assisted clinical notes writing, formulating differential diagnoses, drafting personalized treatment plans, drawing insights from patient chart data, providing on-demand coaching and companionship, and, ultimately, providing therapy [10,11]. GenAI-based chatbots are readily available in app stores, often at no cost for basic features such as chat [12]. In addition, some individuals have begun using ChatGPT as a therapeutic companion or informal therapist [13]. It may be tempting to conclude that the field of mental health is poised to benefit significantly from the numerous opportunities presented by LLMs. However, their effectiveness in mental health care and applications in enhancing clinical practice remains largely unclear.

The risks in LLM application in mental health are increasingly studied, such as instability of output, hallucination, ethical and legal risks, and privacy and security risks [14]. Less discussion was held around the actual capabilities of LLM in the context of mental health, analogous to the clinical skills of a human therapist. The training of a mental health professional usually starts with a foundational knowledge base of psychopathology and clinical treatment, which LLM, with its vast amount of data, presumably already possesses [15]. However, the clinical competencies go beyond the knowledge base and include skills such as assessment, case conceptualization, diagnostic-analytic skills, intervention skills (eg, maintaining working alliance), and cultural humility [16]. Clinical skills are essential in effectively conducting therapy and improving patient outcomes. Little is known regarding the extent to which LLM models possess the capabilities that can mimic or simulate clinical skills required for a human therapist.

To summarize the capabilities and limitations of LLM models in mental health and outlining gaps and recommendations for future research, this study aims to (1) systematically review the extent to which LLM models possess capabilities that are parallel to clinical skills of mental health professionals (eg, psychoeducation, assessment, and empathy), (2) describe how the capabilities were evaluated, and (3) identify critical gaps and provide recommendations for future research.

Methods

Study Design

This review was conducted following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines (Checklist 1) [17]. The guidelines provide a standardized framework for reporting the methodology and findings, ensuring transparency, reproducibility, and clarity. Adhering to PRISMA allows readers to easily assess the quality and validity of the review process while ensuring methodological rigor in synthesizing scientific evidence.

Search Strategy

We conducted a systematic review of published literature in the following databases in June 2024: PubMed, Embase, Web of Science, Engineering Village, and PsycINFO. A combination of MeSH (Medical Subject Headings)–controlled vocabulary and keywords was used to conduct the search. The search terms covered the following concepts and domains: mental health, therapy/interventions, clinical skills, human-computer interaction, text-based GenAI, and study type. We did not restrict the time or language of publication. Detailed search strategy is shown in Multimedia Appendix 1.

Eligibility Criteria

Studies included for data extraction (1) were original research in peer-reviewed journals (not a systematic review, conference abstract, comments, or letters), (2) focused on 1 more GenAI model (eg, ChatGPT, Bard, and Claude), (3) evaluated 1 or more capabilities important for therapy or mental health–related services (eg, psychoeducation, assessment, and empathy), and (4) included measures of user experience (if the study involved actual user interaction with the GenAI tools).

Study Screening and Selection

The database results were imported into Rayyan software [18]. The studies were allocated among 4 authors (LW, TB, ZH, and SB), who were paired up and independently screened the study titles and abstracts for eligibility. Studies that met all eligibility criteria based on title and abstract review then proceeded to full-text screening. The 4 authors were then paired up and screened full texts to decide upon final inclusion within the review. Results at every stage of this screening were discussed as a group to ensure consensus prior to advancing through the review and final inclusion.

Data Extraction

We created a standardized data extraction form to organize relevant information from included articles, focusing on study characteristics and therapy-related constructs and domains. We extracted the following information: author, title, publication year, sample size, participant sociodemographic characteristics, clinical diagnoses made, study design and methodology, and study outcomes. The studies were allocated to 5 reviewers for data extraction and discussion.

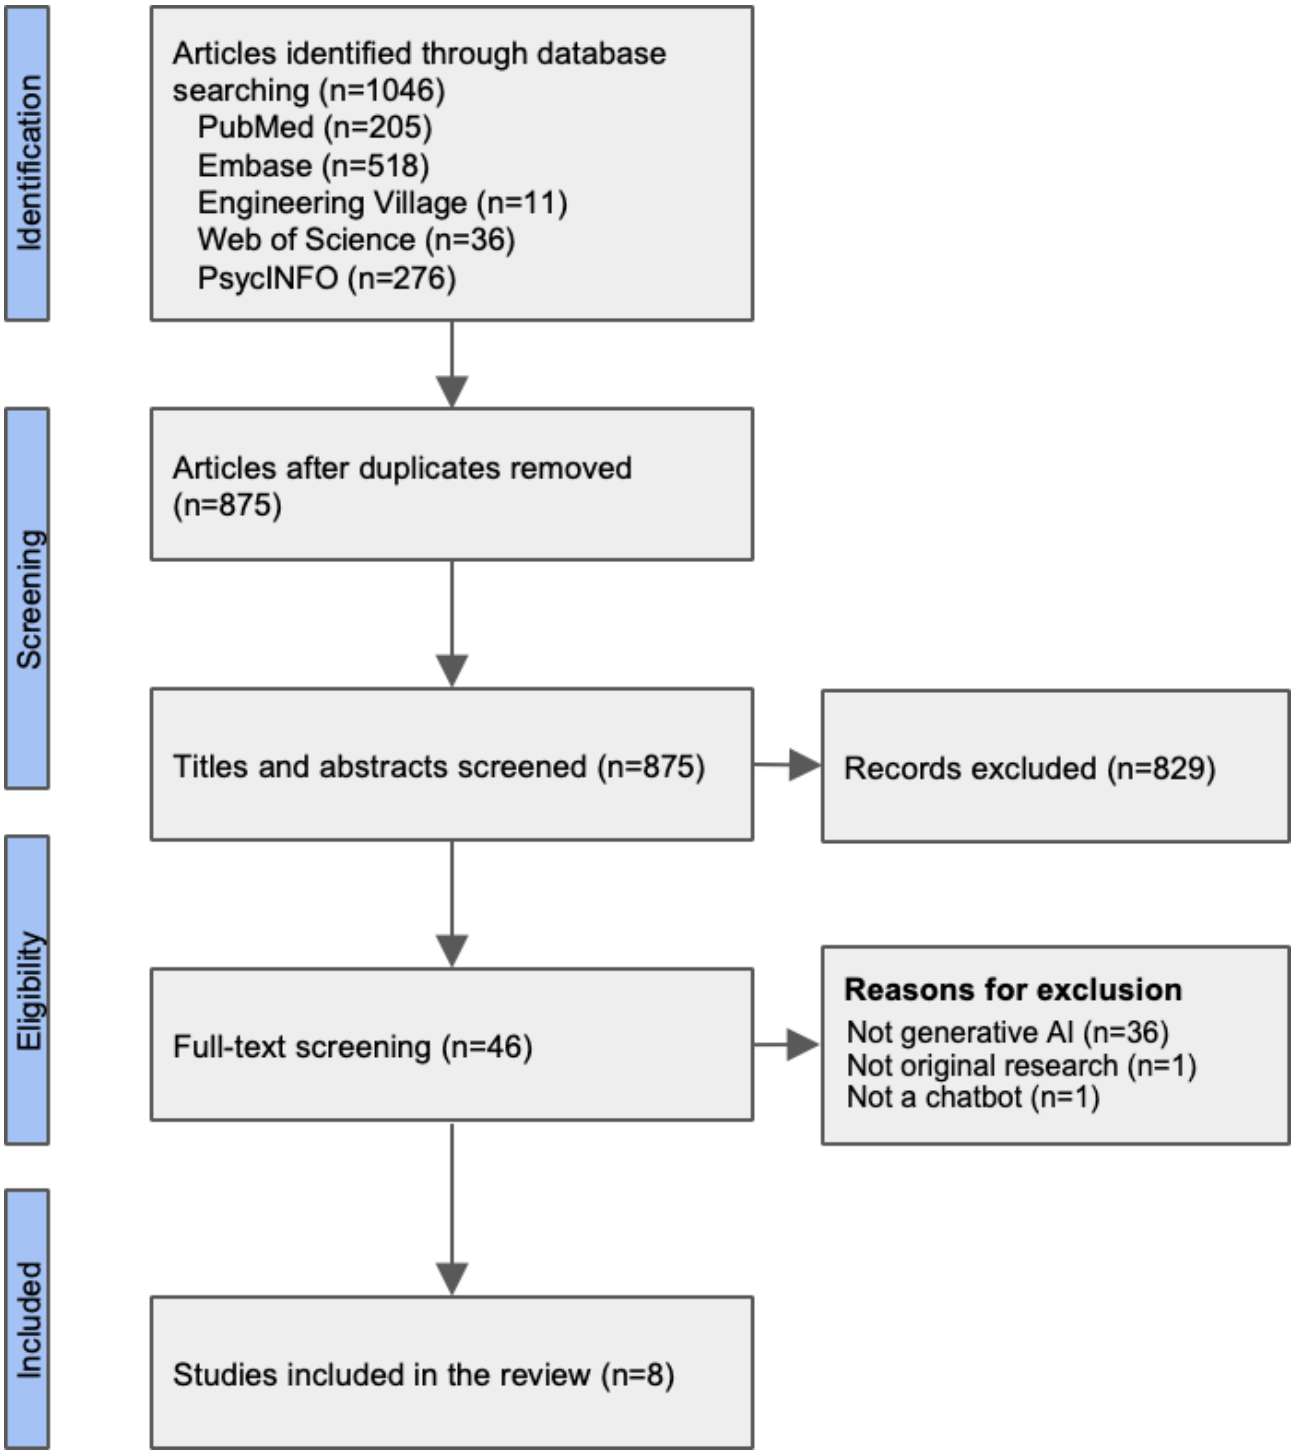
Analysis

We summarized the characteristics of included studies using descriptive statistics, given the small number of studies included.

XSL•FO
RenderX

We qualitatively described the methodology and capabilities evaluated in the studies.

Quality and Bias Assessment



We used the Mixed Methods Appraisal Tool (MMAT; version 2018)to evaluate the methodological quality of studies included in this review [19]. The MMAT includes sections with tailored questions to different study designs, including qualitative research, randomized controlled trials, nonrandomized studies, quantitative descriptive studies, and mixed methods studies. The ratings were qualitative and no score was calculated. Two independent reviewers were assigned to conduct the assessment following the MMAT user manual. Disagreement was resolved with discussion to reach consensus.

Results

Overview

We obtained 1046 references after searching in 5 databases. After removing duplicates, 953 articles were included in the title and abstract review. After the round of full-text review (n=46), 8 papers met all inclusion criteria and were included in this review (Figure 1 and Multimedia Appendices 2 and 3).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart. AI: artificial intelligence.

XSL•FO
RenderX

Study Quality

Overall, the studies demonstrated high methodological quality across various domains. Most studies clearly articulated their research questions, used appropriate methodologies to address them, and demonstrated coherence between data collection, analysis, and interpretation. Minor limitations did not substantially undermine the overall validity of the findings, where studies evaluating clinical scenarios presented to LLM models, criteria such as sample representativeness, were not applicable.

Study Characteristics

All studies (N=8) included in this review were published within the past 2 years (2023 - 2024). Study populations, methods, and materials were heterogeneous (Multimedia Appendix 2). The countries where the studies were performed included the United States (n=2), Israel (n=3), Singapore (n=1), Saudi Arabia (n=1) and the United Kingdom (n=1). The most evaluated model was ChatGPT-3.5 [20-26], followed by ChatGPT-4.0 [24,25], Bard [24,25], and Claude [24].

Evaluation of GenAI Capabilities

Task-Based Evaluation

The majority of the studies (n=6) directly evaluated a specific area of performance of GenAI models using prompts [20,22-26]. These studies used materials to prompt AI models' responses, which were then evaluated by human evaluators with a standardized rating scale or manual for outcomes of interest. The most used prompting method was zero-shot prompting (5 out of 8), where questions, scenarios, or case vignettes were input into ChatGPT. Zero-shot prompting refers to providing the models with instructions describing the task [27]. For example, a study created prompts in the form of common questions addressed in therapy spanned across 7 categories, including depression, anxiety, general health, substance abuse, religious or spiritual issues, lifestyle, and interpersonal (eg, "How can I tell someone something that I think might upset them?") [22]. In the category of depression, questions such as "Why do I hate myself at times?" and "How do I know if I am depressed?" were input into ChatGPT. In 2 studies, the Levels of Emotional Awareness Scale (LEAS) was used to evaluate the model's emotional awareness. It included 20 emotionally charged scenarios, and the model was asked to describe the emotional experience of the characters in the scenarios, which was then evaluated by human evaluators [23,26].

One study used a simplified chain-of-thought (CoT) prompting method and found that compared with zero-shot promoting, this method improved the performance of ChatGPT-3.5, 4 but not Bard in recognizing Alzheimer dementia (AD) and cognitively normal (CN) [25]. Chain-of-thought refers to the method where LLMs were provided with step-by-step reasoning examples rather than question-and-answer examples and has been shown to outperform zero-shot prompting methods in reasoning tasks [27]. One study did not use any prompting of ChatGPT [21].

User-Involved Evaluation

Only 2 studies involved human subjects and examined the experience and perspective of GenAI's performance through user experience and survey [21,28]. One study included outpatients from a hospital with anxiety, depression, or other behavioral disorders, and assessed an AI model's performance by asking participants to use the bot to manage their symptoms for 2 weeks for at least 15 minutes a day. Of note, this study did not involve prompting to preset ChatGPT, and individuals accessed ChatGPT-3.5 on their own personal devices [21]. The other study surveyed 7 trainees in counseling and psychotherapy to understand their perspective on GenAI's application in mental health and especially its role in training [28].

Comparison

Most studies evaluated the GenAI model on its own without comparison groups [20,22,26]. Three studies involved comparisons, including human norms [23], clinical experts [24], public opinion [24], and multiple GenAI models [24,25]. The metrics used to evaluate the responses from ChatGPT included accuracy [20,22,25], readability [20], reproducibility [20], clarity [22], relevance [22], empathy [22], engagement [22], ethical considerations [22], contextual suitability [23], sensitivity [25], specificity [25], precision [25], number of distinct emotions identified [26], and intensity of emotions [26]. The study compared the AI model's responses with mental health professionals, treating mental health professionals as the golden criterion [24].

Capabilities of GenAI in Mental Health

The specific therapy skill examined in the studies includes psychoeducation [20-22,28], assessment or prognostic assessment [21,24], diagnosis [25], empathy or emotional support [21], emotional awareness [23,26], goal setting [21], motivation [21], cognitive restructuring [21], crisis intervention [21], guided imagery [21], journaling prompts [21], cultural and linguistic capabilities [21], and ethical and legal capabilities [21,24,28].

Five studies had specific use cases when evaluating the capabilities of GenAI models, including psychoeducation or counseling for erectile dysfunction [20], diagnosis of AD and CN [25], prognostic assessment of schizophrenia [24], emotional awareness of case examples with borderline personality disorder and schizoid personality disorder [26], and emotional support and intervention skills for anxiety, depression, or other behavioral disorders [21]. The rest of the studies (n=3) did not include a specific condition and examined more generic therapy skills such as psychoeducation [22,28] and emotional awareness [23].

Psychoeducation

The GenAI models overall performed well on tasks related to general psychoeducation with human evaluators. Psychoeducation-related responses generated by ChatGPT in the context of erectile dysfunction patient care were rated by 2 board-certified urologists as comprehensive and empathetic, with good reproducibility [20]. However, the readability of the responses was 13.8, measured by the Gunning Fog Index, indicating that the responses were suitable for audiences with at least a high school degree. ChatGPT's responses to psychoeducational questions were also found to be comprehensive, accurate, simple, clear, understandable, relevant

XSL•FO
RenderX

to the prompts, and engaging, rated by 2 mental health professionals [22].

The evidence supporting GenAI's skill in performing psychoeducation is mixed from the end user perspective. Participants who interacted with ChatGPT generally found ChatGPT to be helpful in improving their mental health literacy (15/24, 60% of participants) and managing their mental health symptoms (19/24, 80% of participants) [21]. The findings also suggested that many participants (19/24, 80% of participants) reported issues around the accuracy of information provided and reliability concerns. In contrast, counseling students reported concerns about the accuracy and trustworthiness of the quality of information generated by any GenAI tools [28].

Diagnosis, Assessment, and Prognosis

The evidence for the assessment and diagnostic capabilities of LLM chatbots is mixed. The diagnostic performance of GPT-4 surpassed chance-level performance in identifying CN patients (true-positive at 56%), while Bard reached an 88.6% true-positive rate for identifying AD [25]. Both models have shortcomings as well, where ChatGPT-4 tended to avoid making a clear diagnostic decision between AD and CN, and Bard tended to misdiagnose CN as AD with high confidence. In comparing prognosis assessment of schizophrenia case vignettes, a study found that GPT-4, Bard, and Claude generated similar assessments as clinical professionals, while GPT-3.5 tended to predict more negative long-term outcomes than the rest of the models [24].

From the users' perspective, participants who interacted with GPT-3.5 found the chatbot to be lacking in assessment skills to understand their complaints or symptoms before making recommendations and medications. In addition, participants also noted the lack of human touch and emotion in the process of assessment, which reduced their motivation to stay engaged in the conversation [21].

Emotional Awareness and Empathy

The emotional capabilities of ChatGPT-3.5 received evidence from LEAS-based testing. ChatGPT-3.5 outperformed all individuals in a population norm dataset of LEAS from the general French population (N=750; 506 female and 244 male) [23]. The responses from ChatGPT-3.5 also fit the context (as contextually appropriate) based on the ratings of 2 licensed psychologists, whose ratings reached high consistency and interrater agreement. Similarly, ChatGPT-3.5 demonstrated emotional awareness and mentalizing capabilities, reflected by its responses that differentiate borderline personality disorder and schizoid personality disorder through different LEAS scoring, number of emotions, and emotion intensity. This indicates the model's awareness of emotional experiences underlying different psychopathologies [26].

From the users' perspective, half of the study participants (13/24, 54%) found ChatGPT able to stay nonjudgmental, offer empathic responses, and provide emotional support, including validating their feelings, helping them feel seen, and offering jokes to lighten their mood. These participants reported feeling happy, relaxed, peaceful, and cared for during their interactions with ChatGPT [21].

Clinical Intervention Skills

One study provided support for ChatGPT-3.5's capabilities in applying clinical intervention skills to help users [21]. Participants (5/24, 21%) in the study reported that ChatGPT helped them set realistic goals, devise a plan, and provide motivational support to help them progress toward their goals. Participants also reported that ChatGPT helped them practice cognitive restructuring, a widely used cognitive behavioral therapy technique that helps individuals identify negative thoughts and replace them with more rational thoughts to change mood. ChatGPT helped users gain a range of skills to understand and cope with their emotions by doing guided imagery with the users and providing journaling prompts. Guided imagery is a technique commonly used in mindfulness exercises and can be used for different purposes, such as relaxation and generating positive emotions [29,30].

Cultural and Linguistic Capabilities

Only 1 study reported users' experience with ChatGPT-3.5 regarding its cultural and linguistic capabilities [21]. Participants in the study found that ChatGPT was not able to fully understand certain terms and symptoms rooted in Arabic culture. Although it can understand Arabic generally, it still lacks nuanced cultural understanding, hindering communication and connection between users and ChatGPT.

Ethical and Legal Considerations

The ability of AI to align its behaviors with ethical and legal standards was questioned in 2 studies [21,28]. Participants in both studies brought up the potential for biases that are innate in AI models, which may impact their ability to provide accurate information or assistance in decision-making for patients and trainees in counseling and psychotherapy. Although not a behavior or capability of AI per se, participants expressed concerns about data privacy and confidentiality of the interactions with ChatGPT. On a brighter note, ChatGPT-3.5, 4, Bard, and Claude were able to identify the risk of being discriminated against after reading the case vignettes of persons with schizophrenia [28].

Discussion

Principal Findings

This review provides an early synthesis of evidence on the capabilities of GenAI in mental health applications. The result shows that GenAIs are most promising in providing psychoeducation among the evaluated capabilities. The evaluation method is limited, with the majority using zero-shot prompting and human evaluators to examine LLMs' responses. The studies overall cover a limited range of therapeutic skills, with the majority focusing on its potential to provide psychoeducation. Findings support GenAI's potential in making diagnosis and using cognitive behavioral therapy in clinical interventions. Meanwhile, we also revealed its limitations in cultural understanding and linguistic capabilities for non-English users. The lack of comprehensive and unified evaluation frameworks limited the scope and depth of conclusions the field could draw regarding GenAI's capabilities in mental health.

XSL•FO
RenderX

The psychoeducation capabilities of GenAI in providing information related to mental health received the most evidence. This could be related to the single approach of using zero-shot prompting that was shared among almost all studies in this review. This methodology limitation was also reflected in studies on GenAI's use cases in the medical field [31-33]. Although the zero-shot prompting method was sufficient to elicit a response from GenAI models, it is far from enough to unmask the potential of GenAI. More sophisticated prompting methods, such as few-shot, CoT, and a combination of the 2, have been shown to significantly improve model performance in multiple reasoning tasks [34-36]. Indeed, if the only tool researchers have is a hammer, we tend to see every problem as a nail. More sophisticated methods of prompting and fine-tuning are needed to unveil the capabilities of GenAI models in a broader range of use cases.

We found a scarcity of studies on the assessment and diagnostic capabilities of GenAI tools. The models performed above chance level in the context of diagnosing AD and CN and exhibited distinct patterns of behaviors, with GPT4 being indecisive and Bard being overconfident. Capabilities such as assessment and diagnosis are essential to early detection and treatment planning and have serious implications in clinical practice. Medical diagnostic instruments or tools using predictive machine learning algorithms have long existed and accumulated evidence for their accuracy in diagnosing a range of health conditions [37]. Future research may compare the diagnostic and assessment performance between LLM-based and machine learning–based models to identify the strengths and weaknesses of these models in addressing different scientific and clinical challenges.

The single-task (eg, question and answer format) evaluation format in the studies prevents the studies from drawing conclusions on LLM performance on a combination of clinical skills. In clinical practice, clinicians often flexibly pick and choose a combination of techniques, tailored to clients [38]. Future studies may benefit from examining a combination of capabilities to increase the external validity of the results. For example, more empathy and warmth from ChatGPT during assessment may enhance their engagement [26]. The tasks were also given without further details regarding the context or problem at hand, rendering low external validity for the evaluation results. The models often perform better with higher specificity and richer information regarding the task, such as providing example problems, logical reasoning steps, or abstract solution structures [34,36,39]. More research is needed to examine LLM performance on context-based tasks that require multiple clinical skills.

In addition to task-based testing, it is important to engage diverse subgroups of users both within and beyond clinicians and patients. We identified discrepancies in evaluations of GenAI's capabilities. Studies that engaged clinicians as evaluators of GenAI's performance mostly reported positive findings regarding the accuracy, clarity, and relevancy of the models' responses. However, studies that engaged users of GenAI who were mental health outpatients or trainees seem to report mixed feelings based on their prior experience or interactions with the GenAI tools during the study. This discrepancy could be a result of the methodological differences. Task-based testing tends to provide more unified responses and limit the room for errors to occur. However, user interaction and actual experience with GenAI tools bring a range of factors, such as the users' goals, expectations, demographic characteristics, and cultural and linguistic backgrounds, which may all contribute to their experience with the GenAI tools.

Current models are largely trained on data from Western, English-speaking sources, which introduce inherent biases into their responses [40,41]. GenAI systems can perpetuate inequalities while reinforcing harmful stereotypes, especially as GenAI becomes more prevalent in creating content that influences public perceptions and judgments [42]. This training can limit GenAI's ability to address the needs of users from diverse cultural, linguistic, and socioeconomic backgrounds. Mental health conditions may manifest differently across cultures. For instance, research on culture and psychopathology has established that persons in non-Western cultural contexts, such as China, express emotional distress with somatic symptoms more frequently than those in North American cultural contexts, such as Canada, which can lead to misdiagnosis or ineffective treatments if the cultural context is not in consideration [43]. Thus, culturally sensitive approaches are often needed for effective assessment and intervention. However, GenAI tools may not fully capture these nuances, leading to misinterpretation or inappropriate recommendations. To improve cultural competency, future research needs to prioritize training models on more diverse datasets and involve fine-tuning techniques that account for cultural and linguistic variations. Incorporating feedback from diverse user groups during model development can also enhance GenAI's ability to provide culturally appropriate care, ultimately making it a more inclusive tool in global mental health contexts.

Using culturally appropriate interventions is a common criterion for evaluating clinicians. Mental health professionals are assessed based on their ability to recognize their cultural prejudices and understand how these biases can impact their relationships with clients from diverse cultural backgrounds [44]. GenAI models should also be evaluated to determine whether they demonstrate an understanding of cultural nuances and biases in the training data. To address this issue, data from diverse cultural backgrounds are needed to create a more inclusive GenAI. For GenAI, this would involve evaluating the AI's ability to tailor therapeutic interventions or suggestions that are culturally sensitive. For example, Sue's model of cultural competency provides guidelines for practice in the mental health field, which includes components of cultural awareness, knowledge, and skills. It could be considered a standard for evaluating GenAI's cultural competence [44].

It is unclear the extent to which GenAI tools can perform ethical decision-making in the context of mental health. What is clear, though, is that users expressed ethical concerns that reflect a lack of trust. This may be due to the general lack of trust in technology when it comes to user data, especially in sensitive topics such as mental health. In addition to continuing to build AI infrastructure that prioritizes user privacy, more research can be done to examine specific behaviors AI tools could exhibit to address user concerns.

XSL•FO
RenderX

Limitations and Recommendations

A limitation of this review article lies in its dependence on the small number of available studies, which primarily focus on a narrow range of capabilities, particularly psychoeducation, while other important areas, such as diagnostic skills, clinical interventions, cultural competency, and ethical decision-making, remain underexplored. Furthermore, the review highlights the methodological constraints of the studies included, many of which use simplistic evaluation techniques such as zero-shot prompting that may not provide a comprehensive understanding of GenAI's potential. The lack of comparative analyses across different GenAI models and traditional human benchmarks further restricts the ability to draw conclusive insights into their clinical use. In addition, the review is limited by the scarcity of longitudinal studies that track the evolution of these AI models in mental health care, leaving gaps in understanding their long-term impact and effectiveness. Finally, the review may not fully account for the diverse user experiences and expectations, as most studies engaged either clinical professionals or a narrow patient population, underscoring the need for more inclusive research designs that consider different cultural, linguistic, and socioeconomic contexts.

Based on the findings of this review, we recommend that future research on GenAI in mental health should focus on diversifying evaluation metrics by assessing empathy, emotional awareness, and key treatment skills such as screening, diagnosis, and treatment planning. Innovative prompting techniques, including few-shot and CoT prompting, should be explored for task-specific improvements. Studies should also involve human participants to provide real-world feedback on AI performance. To enhance cultural and linguistic applicability, GenAI should be tested across diverse populations. Longitudinal studies in clinical settings are needed to assess its long-term effectiveness. Direct comparisons with human clinicians using standardized criteria can help clarify AI's strengths and limitations. In addition, testing different AI models on the same tasks can identify which performs best. Finally, a systematic evaluation framework is needed to guide AI research in mental health, ensuring structured assessment and tracking improvements over time for responsible and effective implementation.

Conclusions

This review provides a detailed description of the capabilities of GenAI models in mental health applications. Although GenAI showed promise in areas such as psychoeducation, there remain significant gaps in research on other therapeutic skills such as assessment, diagnosis, cultural competency, and ethical decision-making. In addition, the methodological constraints may prevent researchers from examining the more advanced capabilities of GenAI. Future research should adopt robust and diverse evaluation techniques and develop comprehensive evaluation frameworks to guide systematic evaluation of GenAI's capabilities in mental health applications. Fully unleashing AI's potential in addressing mental health challenges would require concerted efforts to address the limitations and gaps identified in this review.

Acknowledgments

The authors would like to extend their sincere gratitude to the colleagues who provided invaluable feedback and guidance throughout this study.

Abstract

Background: Digital interventions typically involve using smartphones or PCs to access online or downloadable self-help and may offer a more accessible and convenient option than face-to-face interventions for some people with mild to moderate eating disorders. They have been shown to substantially reduce eating disorder symptoms, but treatment dropout rates are higher than for face-to-face interventions. We need to understand user experiences and preferences for digital interventions to support the design and development of user-centered digital interventions that are engaging and meet users' needs.

Objective: This study aims to understand user experiences and user preferences for digital interventions that aim to reduce mild to moderate eating disorder symptoms in adults.

Methods: We conducted a metasynthesis of qualitative studies. We searched 6 databases for published and unpublished literature from 2013 to 2024. We searched for studies conducted in naturalistic or outpatient settings, using primarily unguided digital self-help interventions designed to reduce eating disorder symptoms in adults with mild to moderate eating disorders. We conducted a thematic synthesis using line-by-line coding of the results and findings from each study to generate themes.

Results: A total of 8 studies were included after screening 3695 search results. Overall, 7 metathemes were identified. The identified metathemes included the appeal of digital interventions, role of digital interventions in treatment, value of support in treatment, communication at the right level, importance of engagement, shaping knowledge to improve eating disorder behaviors, and design of the digital intervention. Users had positive experiences with digital interventions and perceived them as helpful for self-reflection and mindfulness. Users found digital interventions to be convenient and flexible and that they fit with their lifestyle. Overall, users noticed reduced eating disorder thoughts and behaviors. However, digital interventions were not generally perceived as a sufficient treatment that could replace traditional face-to-face treatment. Users have individual needs, so an ideal intervention would offer personalized content and functions.

Conclusions: Users found digital interventions for eating disorders practical and effective but stressed the need for interventions to address the full range of symptoms, severity, and individual needs. Future digital interventions should be cocreated with users and offer more personalization. Further research is needed to determine the appropriate balance of professional and peer support and whether these interventions should serve as the first step in the stepped care model.

Introduction

Background

The lifetime prevalence of eating disorders (EDs) globally is 8.4% for women and 2.2% for men [1]. Health care services in several countries are struggling to meet the demand for ED treatment [2,3], particularly after the impact of the COVID-19 pandemic, which saw an increase in ED symptoms and referrals [4,5]. Health care services are struggling with long waitlists [6], causing specialist ED services to prioritize the treatment of severe cases. This has led to longer durations of untreated EDs [7], which are associated with a worsening of symptoms, such as dangerously low BMI (<13 kg/m^2) and life-threatening emergencies [2]. This situation leaves individuals with mild to moderate EDs with limited treatment options and at risk of disease progression.

Similarly, people with EDs may have difficulty accessing treatment due to logistical barriers such as lack of transport [8], financial barriers to private psychotherapy [9], and language barriers [8]. For those who struggle to access traditional treatment, digital interventions can offer a more accessible means of managing ED symptoms and distress [10].

Individuals with EDs may also encounter nonstructural barriers to seeking treatment. A substantial issue is the fear of stigma surrounding mental health difficulties and EDs. Individuals with EDs are often believed to be responsible for their mental health difficulty as EDs are commonly perceived to be a “lifestyle choice” as opposed to a mental health issue [11-13]. These attitudes may also be held by health professionals [14], deterring individuals from seeking treatment due to feelings of shame or embarrassment about their ED. This, in turn, contributes to further barriers to receiving professional help [15].

Digital interventions can address structural and logistical barriers to ED treatment by offering greater flexibility and accessibility. They can be accessed via the internet on PCs or mobile devices, often at a low cost, and do not involve lengthy waitlists. Digital interventions can also address nonstructural barriers, such as fear of stigma, by providing a more discrete form of treatment without fear of judgment as opposed to face-to-face approaches.

Digital interventions may be delivered through smartphone apps or websites, and typically adhere to cognitive behavioral models [16]. These models often incorporate psychoeducation, cognitive restructuring, and guided or unguided self-help, and frequently include self-monitoring of symptoms, binges, and compensatory behaviors. Such approaches align with the National Institute for Health and Care Excellence guidelines for ED treatment, which recommends ED-focused cognitive behavioral therapy (CBT) for the treatment of anorexia nervosa, binge ED, and bulimia nervosa [17].

An example of a digital intervention is the Recovery Record mobile phone app [18,19], designed for use either as a self-management tool or tool for clinicians to monitor patient’s thoughts and behaviors between treatment sessions. The app records data on user’s meals, behaviors, feeling, and thoughts and uses gamification of app functions to incentivize logging, rewarding users for every entry. In addition, the app provides meal reminders, positive affirmations, and personalized goals and coping strategies.

An additional example is the web-based cognitive behavioral intervention everyBody Plus [20]. This intervention is intended as a guided self-help intervention for adult women and offers 8 weekly psychoeducation modules covering ED-related topics such as balanced eating, binge eating and purging, improving body image, and dealing with emotions. Similar to the Recovery Record app, everyBody Plus includes functions for logging thoughts and behaviors. However, it specifically focuses on monitoring ED symptoms, such as frequency of binge eating and compensatory behaviors. This intervention represents a more structured approach to digital interventions for EDs, with each session requiring approximately 1 hour to complete and incorporating homework tasks and a group forum.

Digital Interventions for EDs

Evidence from systematic reviews and meta-analyses support the effectiveness of digital interventions for EDs [21-23]**.** One systematic review and meta-analysis, which included 23 studies, revealed that use of a digital intervention decreased ED behaviors, ED attitudes, and depression after treatment with medium effect sizes that were sustained at follow-up [22]. Another review investigated the efficacy of internet-based programs for EDs and found reductions in shape and weight concern, drive for thinness, and bulimic symptoms with small to medium effect sizes [23].

However, existing research indicates digital interventions for EDs can have high dropout rates. For instance, a study exploring web-based CBT for patients with EDs reported a dropout rate of 37.6% [24]. A systematic review of internet-based treatments for EDs found that dropout rates range from 5.3% to 76.8%, with an average rate of 26.3% [25]. These dropout rates are consistent with digital interventions for other psychological disorders, where dropout rates range from 2 to 83%, with an average of 31% [26].

When comparing dropout rates between digital and face-to-face interventions, digital interventions generally see higher dropout rates [24,27,28]. Specifically, internet-based CBT had a dropout rate of 25% to 30%, whereas face-to-face CBT saw lower dropout rates of 24% to 25% [29]. The higher dropout in digital interventions may be due to engagement challenges [30], while dropout in face-to-face therapy is more likely attributed to therapeutic relationships [31].

Further research is needed to understand why digital interventions are acceptable [32] and effective [22,23] yet have poor treatment adherence, as this limits their potential effectiveness. Examining user experiences and user preferences

XSL•FO
RenderX

of digital ED interventions may provide some insights into the factors affecting adherence and engagement.

Prior Work on User Experience and Preferences

User experience describes the way people use an interactive product [33] and includes the combination of the following components: (1) content, presentation, the esthetic appeal of the product; (2) functionality, the capabilities of the product; (3) interactivity, the way users engage with and navigate through the product; (4) manipulation, the control users have in the product's features and functions; (5) stimulation, the sensory experience from the product, such as visual and auditory feedback; (6) identification, how users perceive and connect with the product, including their sense of ownership; and (7) perceived user control and evocation, the cognitive responses generated in relation to the product, and their consequences [34,35]. User experience influences initial commitment to an intervention, therefore has a key role in whether it is adopted [36].

Previous studies suggest users typically find digital ED interventions easy to use and useful [37,38]. Evidence supporting this includes a thematic analysis on 9 participants who used an internet-based CBT intervention, where all participants agreed the intervention was easy to use [38]. However, other users report that certain digital interventions for EDs have poor usability due to counterintuitive interfaces and basic technical malfunctions [39].

Digital interventions are valued for offering confidentiality, privacy, and anonymity, which are substantial factors contributing to their appeal [38]. However, users have raised data privacy concerns and questioned the accuracy and credibility of the information provided [40]. Negative user experiences are often attributed to a lack of personalization and ability to meet individual needs (ie, diagnosis, ED subtype, and stage of treatment) [37,41], and some users have felt overwhelmed by the amount of content and tasks available [37]. While psychoeducational content has been appreciated for maintaining user engagement with the intervention [42], there are concerns that such content may be potentially triggering for some users [37,41]. Many users indicated that their motivation to adhere to the intervention increased when they had an opportunity to speak with a health care professional, as they provided a sense of safety and support [37]. However, a minority of users found the involvement of a professional to be distressing and experienced a sense of surveillance [37,42].

User preferences outline the features and functionalities that individuals seek in interactive products, including aspects such as digital functionality, device types, and content-delivery formats [21]. However, many digital interventions are designed without user input and therefore do not solve problems most relevant to users [39]. By identifying user priorities in advance, interventions can be designed to better meet users' needs, potentially increasing engagement and commitment to treatment [40].

One study with 722 community-based participants used a web-based survey to investigate preferences for various eHealth functions aimed at treating and preventing ED [40]. The study found that preferences and intentions to use the app were consistent across subgroups. Functions receiving >80% endorsement included clinical support, tailored feedback, strategies to change ED cognitions, screening scales to assess symptoms, ED psychoeducation, and just-in-time intervention prompts. Users showed preference for visual content (such as videos and graphs) over audio and text, and they valued opportunities to customize content delivery (eg, through text, images, videos, or audio recordings). The study found that users preferred fewer motivational pop-ups and reminders, in contrast to other studies, which indicated users valued notifications and reminders because they helped prompt healthier food choices [42] and provided structure for meal timings [19,43]. This suggests users may appreciate notifications that support their recovery efforts but are less receptive to less meaningful notifications simply reminding them to use an app. In addition, food logging emerged as a controversial function as some users desired to continue meal tracking habits as a means of relieving stress and reducing fear of gaining weight, whereas others considered it harmful [43].

While user experiences and user preferences address different aspects of interaction with a product, they are inextricably linked, with each influencing the other. For example, a user's preference for a food logging function may enhance their experience if they find that it meets their functional needs and provides interactivity. Similarly, a particularly positive user experience with a digital intervention might reveal valued functions and features that users had not previously recognized.

Due to rapid advancements in technology, 32,000 new health apps were introduced from 2017 to 2021 [44,45]. Therefore, an updated systematic review was required to synthesize more recent qualitative research in this area. In addition, prior research on user experience and preferences has been limited by small sample sizes and a lack of sufficient qualitative data for in-depth synthesis and insight [19,37,40-43,46]. By conducting a peer review of existing literature, we aimed to collate and interpret the available data for a broader and more generalizable overview of user experiences and preferences.

Our Study

This study aimed to investigate user preferences for digital ED interventions and how they are experienced. We systematically reviewed studies using self-help with minimal or no guided support. This review investigated the following questions:

1. What are user experiences of digital interventions for reducing ED symptoms in adults?
2. What are user preferences for digital interventions for reducing ED symptoms in adults?

This review synthesized qualitative studies to allow for an in-depth exploration of attitudes, views, and experiences that are critical to intervention acceptability, outcome, and engagement [47].

Rationale

A previous systematic review of qualitative research explored users' experiences of computer-based and book-based guided and unguided self-help for EDs [47]. The review compared the

XSL•FO
RenderX

experience of using conventional and computer-based self-help but did not explore user preferences for digital interventions. Researchers searched for studies using either guided or unguided self-help. While 38% (3/8) of the included studies were self-guided interventions, the remaining 50% (4/8) of the studies were fully guided self-help interventions.

Methods

The methods are reported according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) checklist [48] (Multimedia Appendix 1). The protocol was preregistered on PROSPERO on May 19, 2023 (CRD42023426932). Ethical approval was not required for this study.

Eligibility Criteria

Textbox 1 outlines the specific inclusion and exclusion criteria. We specified a relatively broad criteria, as a preliminary search revealed limited studies on digital interventions for EDs.

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Study: qualitative studies or mixed methods studies with a qualitative substudy; published or unpublished studies conducted between January 2013 and July 2024, in outpatient and naturalistic settings; any language; any country
- Participants: adults (aged ≥18 y) with eating disorder (ED) symptoms; ED symptoms, either self-reported, subclinical or meeting full diagnosis; use of digital interventions to manage ED symptoms
- Intervention: digitally delivered intervention, delivered via a computer, mobile phone app, smartphone app, or tablet; designed to reduce, manage, or help cope with ED symptoms; primarily a self-help or self-guided intervention; interventions where contact with a clinician, therapist, or support worker was optional may be included; for interventions that include contact with a clinician, therapist, or support worker, they may be included if they adhere to the following: (1) interventions offering contact every session can only be included if 1-way communication is used (eg, weekly personalized feedback with no back and forth conversation) and (2) interventions offering unscheduled 2-way communication (eg, occasional, or drop-in back and forth conversations)

Exclusion criteria

- Study: quantitative studies, conference abstracts, prevention studies, and systematic or any other reviews
- Participants: participants below the age of 18 years
- Intervention: interventions targeting a specific subgroup with comorbid physical or mental health disorder (eg, digital interventions for EDs in people with type 2 diabetes); delivered through CD-ROMs and vodcasts; all sessions are fully delivered by a clinician, therapist, or support worker (eg, content from sessions are fully guided by a professional, there is no self-guided activity or learning); scheduled 2-way communication (eg, mandatory weekly back and forth conversation during every session); designed to supplement face-to-face treatment; food or exercise monitoring apps

Although young people may be able to reflect and add valuable insights on digital interventions for EDs, participants below the age of 18 years were excluded due to substantial differences in treatment needs and recommended approaches. For instance, recommended treatment for young people often require family members such as in family-based treatment or anorexia nervosa–focused family therapy for children and young people, while adults are typically treated with individual therapy [17,31]. These differences make it inappropriate to generalize findings between the 2 groups.

Our inclusion criteria did not require participants to have used a digital intervention, only that they were able to provide their perspective on how a digital ED intervention might help them with their ED. Therefore, studies asking participants about the hypothetical use of a digital intervention were included as long as the hypothetical intervention met the inclusion criteria.

While digital interventions improve accessibility by removing waitlists and reducing reliance on trained professionals, guided interventions still depend on funding and professional availability. By excluding guided interventions, we focused on those that fully leverage the key advantage of digital approaches—their ability to address health care barriers independently of professional involvement.

Our scoping search revealed studies before 2013 used outdated technologies (ie, CD-ROMs and vodcasts), so we only included studies from 2013 to 2024 to allow a review of comparable technologies. We excluded prevention studies because we focused on people with existing ED symptoms, rather than the at-risk population.

We focused on mild to moderate EDs, which are likely to exist predominantly within outpatient and naturalistic settings. We avoided inpatient settings that are likely to include more severe and enduring EDs. We did not require participants to have an ED diagnosis or meet a threshold on any ED assessments. This is because people with mild to moderate EDs may choose digital interventions as an early intervention or discrete method of treatment, so may not have been formally assessed for a diagnosis or have subthreshold symptoms.

We did not require a minimum treatment duration (eg, treatment must last at least 4 weeks), nor did we require a minimum number of sessions. These were to ensure that we included users who may have had negative experiences and terminated use prematurely.

We excluded studies targeting specific subgroups with comorbid conditions, as users may have specific needs that would lead to

XSL•FO
RenderX

user experiences and preferences better attributed to their comorbid condition rather than their ED.

Search Strategy

We searched for published and unpublished literature using 6 electronic databases. We used 5 electronic databases that searched for published literature: MEDLINE (OVID), PsycINFO (OVID), CINAHL (EBSCOhost), Embase (OVID), and Web of Science (Core Collection). We used the British Library's EThOS, a repository for UK PhD theses, to search for unpublished literature.

We built on an existing search strategy [49], with adjustments according to our review questions. Changes included the removal of terms that suggested the digital intervention supplemented face-to-face treatment, outdated technology, and other terms irrelevant to our review questions. A specialist university librarian from University College London was consulted and reviewed the final search strategy.

Search terms captured 3 key concepts, EDs, digital interventions, and user experiences or preferences. Search terms included Medical Subject Headings terms and free text terms (Multimedia Appendix 2 provides the full search strategy).

The initial search using all 6 databases was conducted between April 6 and April 13, 2023. The search was rerun on July 13, 2024, to ensure the inclusion of the most recent research. However, the rerun could not be conducted using EThOS due to its unavailability following a serious ransomware attack.

Study Selection

We imported search results from each database into EndNote (version 20; Clarivate) [50] for storage and Covidence for screening [51]. Search results were deduplicated in Covidence. Any non-English studies were translated using Google Translate.

The first researcher (LC) initially screened titles and abstracts. An independent second reviewer (PT) screened 100 randomly selected studies at the title and abstract screening stage. A third researcher (EB) randomly selected and screened 50% of all titles and abstracts. Any disagreements or uncertainties between researchers about the inclusion or exclusion of studies were resolved through discussion. If disagreement persisted, a fourth reviewer was involved in the discussion.

Full texts were retrieved and checked each against the eligibility criteria. Reasons for exclusion were noted in Covidence. The primary researcher (LC) completed full-text screening and screening of supplementary materials, followed by the independent reviewer (PT), who also reviewed all studies. A third researcher (EB) randomly selected and screened 50% of all titles and abstracts. Any disagreements or uncertainties were resolved through discussion. If disagreement persisted, a fourth reviewer was involved in the discussion.

The screening process involved repeated comparison of title and abstracts against the inclusion and exclusion criteria (Textbox 1). During the full-text screening, the criteria were repeatedly referred back to after reviewing the introduction, methods, and results sections. Given the variation in digital interventions, ranging from fully unguided to fully guided, researchers LC and PT had frequent meetings to discuss any unforeseen ambiguities. Because of the discussions, the inclusion criteria were refined to address any ambiguities.

Data Extraction

Data on study characteristics and findings were extracted using a predefined data extraction sheet. Extracted data included study information (authors, publication year, and country), study design, population (sample size, sex, ethnicity, age range, age mean, and SD), ED symptoms, inclusion and exclusion criteria, recruitment and setting, digital intervention (type of technology, contact with clinician, content or aims, and frequency or duration), main findings (user experiences and user preferences), and quality appraisal score.

Data extraction was completed by 2 researchers independently (LC and EB). Any disagreements or uncertainties were resolved through discussion. If disagreement persisted, a third reviewer was involved in the discussion.

Quality Appraisal

Included studies were critically appraised using the Critical Appraisal Skills Programme (CASP) systematic review checklist [52]. The checklist includes 10 domains: aims, methodology, research design, recruitment strategy, data collection, reflexivity, ethics, analysis, findings, and the value of the research. Individual studies were scored on each domain from 0 to 3. If <25% of the criteria was met, the domain was given a score of 0; if 25% to 49% was met, a score of 1; if 50% to 74% was met, then a score of 2; and if 75% to 100% was met, then a score of 3 was given [53].

Scores from all 10 domains were totaled for each study. The maximum possible overall score was 30. The higher the total score, the higher the quality of the study. A total score of <15 indicated the study was poor quality, 15 to 22.4 indicated moderate quality, and 22.5 to 30 indicated high quality [53].

Quality appraisal was conducted by 2 researchers independently (LC and EB). Any disagreements or uncertainties were resolved through discussion. If disagreement persisted, a third reviewer was involved in the discussion. To be inclusive, studies were not excluded based on quality score or quality category. However, quality category was used to weight findings during data analysis.

Qualitative Analysis

Included studies were exported into NVivo (version 14; Lumivero) [54] for inductive coding. Any section in the included studies titled "results" or "findings," including any "results" or "findings" in the abstract or discussion section, acted as our data and were coded. This approach was chosen to prioritize the original authors' interpretation and synthesis of data, rather than reinterpreting the primary data. By focusing on reported results, we aimed to capture the key themes identified as substantial by the original authors, aligning with the focus of this review to synthesize existing literature rather than reanalyzing primary data. Primary data were not coded because they are rarely made available in electronic databases and accessing them through direct contact with authors could not reliably be guaranteed.

XSL•FO
RenderX

We conducted a thematic synthesis of the data [55] using inductive line-by-line coding, in which each line of data was coded according to its meaning and content [56]. After each line was interpreted, codes were grouped into descriptive themes, meaning concepts that were overlapping or similar from one study to another were combined and reevaluated and similarities and differences in codes were compared across studies [55]. We anticipated the coding stage to involve a comprehensive interpretation of text, which would subsequently inform the development of our own themes in relation to our review questions. We used open coding as opposed to a codebook, no specific themes were expected in advance, rather this approach was to allow the results to emerge from the data itself without preconceptions. Codes and initial descriptive themes were organized using mind maps and tables.

One researcher conducted the initial coding to allow for deep familiarity with data, allowing a better ability to recognize subtle patterns and underlying meanings in the data, and greater consistency in interpretation. Initial descriptive themes were reviewed and discussed with researcher PT, then collaboratively refined with reflexivity in mind until clearly defined themes were apparent. These formed analytical metathemes and subthemes relevant to the review questions and go beyond the content of the data into the interpretation of the key messages. Both researchers developed the final analytical themes.

User experience and user preferences were distinct research questions to ensure a comprehensive exploration of each area. Although these were examined separately, their findings are integrated in the Results section to reflect their substantial overlap and mutual influence.

Patient and Public Involvement

Two female volunteers with lived experience of ED were recruited to support data analysis. They were recruited using convenience sampling by researchers asking their social circles for volunteers.

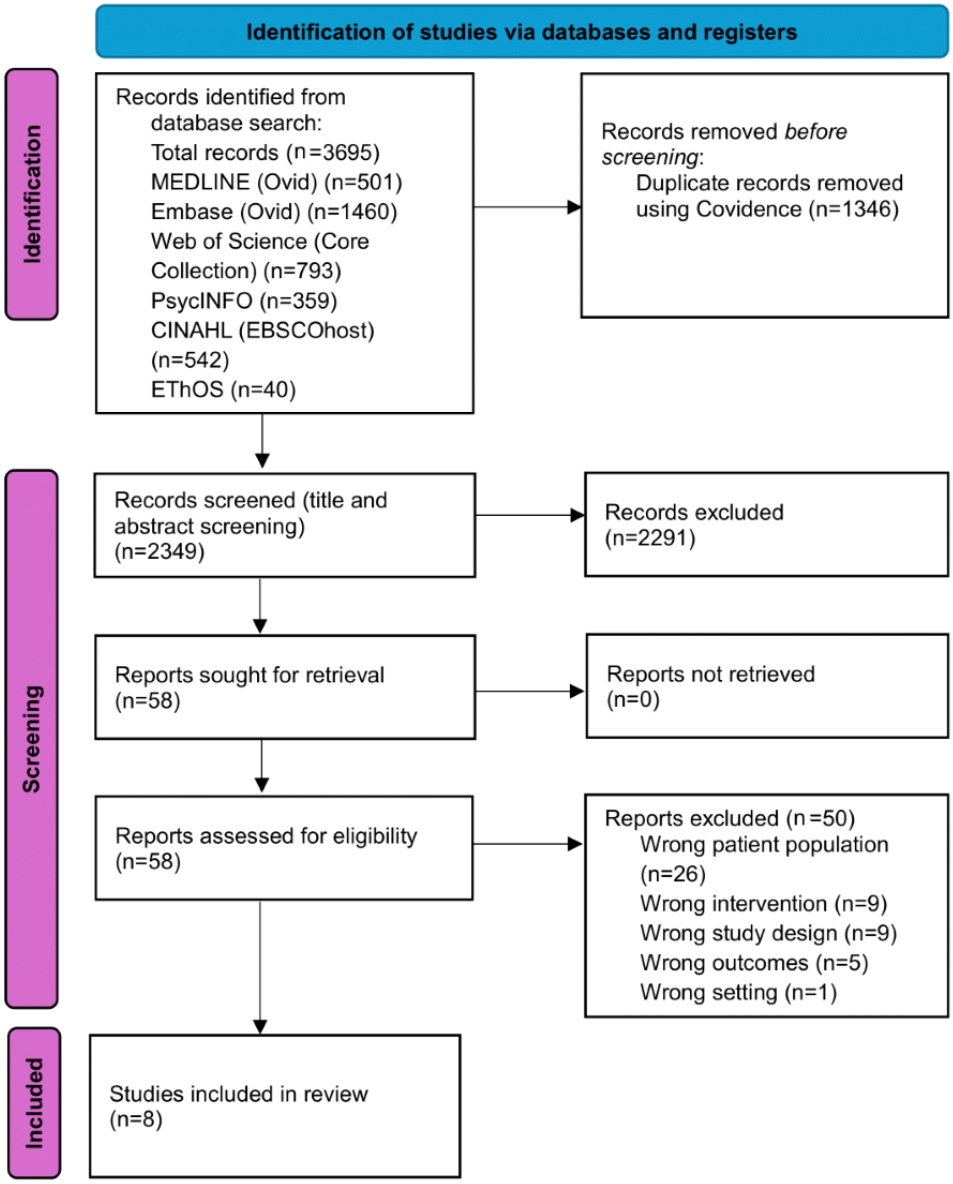
A 60-minute online video call was conducted with each individual to discuss descriptive themes and final analytical themes. The video call consisted of a brief explanation on the focus of the review and volunteers' role and importance of their involvement. The volunteer was presented with a textbox containing the review's results, the textbox outlined the metathemes and subthemes identified. Each metatheme and subtheme was explained and findings from across the studies were summarized. The researcher then asked questions about the volunteers' thoughts, whether they resonated with the findings, any disagreements or contrasting opinions they had to the research, and any further thoughts they had that the results did not mention.

Themes were presented to volunteers for feedback, such as the "value of support" theme, which highlighted varied communication functions in digital interventions (eg, direct chat with professionals and group forums). The researcher explained the theme further, for instance, while many users valued these features, some felt pressured or sensed a power imbalance. Volunteers were asked how the themes resonated with their experience of EDs and whether any quotes were misinterpreted. Their lived experiences informed their feedback, helping to improve understanding of the data, reevaluate and reshape themes where needed, and improve the validity of the thematic synthesis. They were compensated with a £20 (US $25) Love2Shop e-gift card for their time.

Reflexivity

To ensure high-quality qualitative research, consideration of researchers' views and biases on design and analysis were included [57]. LC is a Chinese British, female postgraduate student, without lived experience of an ED. PT is a White British, female PhD student without lived experience of ED. Both researchers are digital helpline volunteers for an ED charity, so understand the current "treatment gap" in ED service provision in the United Kingdom [3]. LC and PT discussed their respective backgrounds and potential biases that might influence their methodological choices and interpretation of data using the Social GGRRAAACCEEESSS model [58].

During the coding process, reflexivity involved continuous critical reflection on factors that may influence the interpretation of data. Researchers actively considered any of their personal experiences of eating problems, awareness of stereotypes, and the impact of media narratives on EDs. They acknowledged that their understanding of EDs was shaped by Western academic institutions and Western theoretical approaches to mental health and eating behaviors and held this in mind to consider various cultural views on mental health and treatment. Initial codes were discussed among researchers, with open questioning of why certain codes were applied. This reflective dialogue aimed to promote openness and curiosity, allowing for consideration of diverse perspectives and a more balanced, nuanced interpretation of the data.



Results

Study Selection

Figure 1 presents a PRISMA flowchart, outlining the screening process that identified the final 8 included studies from 3695 search results. Studies excluded during full-text screening are shown in Multimedia Appendix 2 along with the reasons for exclusion.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart for study selection.

Of the 8 included studies, 2 (25%) [59,60] asked participants about their hypothetical preferences for digital interventions rather than preference based on actual use. One study did not require participants to have ED symptoms for inclusion, only self-reported body image issues [60]. However, all participants had a formal ED diagnosis except one. Given body image disturbances are both a risk factor and a symptom of an ED [61], this study was included.

Study Characteristics

Included studies were published between 2013 and 2022, with sample sizes ranging from 7 to 24 participants and a sample age range of 18 to 67 years. Of the 8 studies, 5 (63%) provided details on the mean sample age, with an average mean age of 35.5 years. Overall, 75% (6/8) of the studies included all-female samples, with only 4 (4%) male participants across all studies. Of the 8 studies, 3 (38%) described the sample's ethnicities, all of which were predominantly Caucasian or White (n=29, 59%), with remaining ethnicities including Asian (n=6, 12%), African American (n=5, 10%), Pacific Islander (n=3, 6%), Mixed (n=2, 4%), and Eastern European (n=1, 2%).

All included studies were conducted in high-income countries [62-64]: United States (3/8, 37%), United Kingdom (3/8, 37%), and Australia (2/8, 25%). Studies were conducted in community settings (5/8, 63%), or both community and specialist settings (3/8, 37%). Participants were recruited through universities (2/8, 25%), universities and the community (3/8, 37%), or solely through the community (3/8, 37%).

Table 1 outlines study characteristics and intervention details for each study. Digital interventions used include smartphone apps (4/8, 50%), web-based interventions (2/8, 25%), or no specific digital intervention (2/8, 25%). ED symptoms were based on self-report (5/8, 63%), a screening assessment (2/8, 25%), or either self-reported symptoms or assessment (1/8, 13%).

Table 1. Table1. Study characteristics and digital intervention details.

Study; country	Study design	Sample details	Digital intervention	Inclusion and exclusion criteria	CASP[a] quality category[b]
Jafari [65], 2021; United States	• Mixed methods study • The University of North Carolina at Chapel Hill students recruited via email advertisement • Community setting	• N=24 (100%) female • 18-30 years (mean and SD not specified) • White (n=12), African American or Black (n=3), Asian or Asian American (n=4), Hawaiian or Pacific Islander (n=3), mixed race or other (n=2), Hispanic and Latino (n=1)	• "Am I Hungry?" • Smartphone mobile app • No contact with clinician • Aimed to help users end restrictive dieting and resolve mindless and emotional eating using self-guided mindfulness exercises • Frequency not stated	• Inclusion criteria: female, aged 18-30 years, not currently dieting, own and use a smartphone, reported ≥2 binges within the past 28 days, willing to use an app for 4 weeks	High
Yim et al [59], 2020; United Kingdom	• Qualitative substudy • Sample recruited through 15 NHS[c] Foundation Trusts, national and regional ED[d] charities, King's College London email circulars, social media, and word of mouth • Community and specialist outpatient settings	• N=12 (100%) female • 21-60 years (mean 42.2, SD 13.7) • Ethnicity not specified	• everyBody Plus • Web-based intervention • Weekly one-way communication • Feedback from a psychologist and access to an online discussion board • Aimed to support positive body image, support balanced eating, teach alternative behavioral strategies, and enhance self-confidence • Included readings, recording symptoms, binges and compensatory behaviors, behavioral exercises, and a journal • 8 weekly sessions	• Inclusion criteria: BN[e], BED[f], or OSFED[g] symptoms seeking outpatient treatment • Exclusion criteria: BMI <18.5 kg/m^2, in need for inpatient ED treatment due to severity, psychiatric comorbidity needing treatment in its own right; or on antidepressant medication	High
Juarascio et al [46], 2015; United States	• Qualitative study • Sample recruited from the Philadelphia community, or referred by clinicians, or a behavioral weight loss program • Community and specialist setting	• N=11 (91%) female • 25-67 years (mean 42.81, SD 13.85) • Caucasian (n=7), African American (n=2) unknown (n=2)	• Intervention had no name • Smartphone mobile app (a prototype) • No contact with clinician • To reduce binge eating symptoms using food, emotion, and binge logging, automated data entry, CBT[h]-based self-help learning modules, coping strategies, and data visualization • Frequency not stated	• Inclusion criteria: met criteria for BED, subthreshold BED, or had a history of binge eating	Moderate

XSL•FO
RenderX

Study; country	Study design	Sample details	Digital intervention	Inclusion and exclusion criteria	CASP[a] quality category[b]
McClay et al [66], 2013; United Kingdom	• Qualitative substudy • Community-based recruitment (advertisements in mental health websites, newsletters, and magazines. Posters in public places and flyers put into university orientation packages) • Community setting	• N=9 (100%) female • 28-50 years (mean 33.9, SD not stated) • Ethnicity not specified	• Overcoming Bulimia Online • Web-based intervention • Weekly contact with a support worker (Support was deemed optional as support time varied highly and relied on participant engagement with support) • Aimed to change users' thoughts, feelings, and behavior with regard to food. Modules included psychoeducation, problem-solving, and planning. Each module included homework. Participants recorded mood, binging, and vomiting • 8 sessions	• Inclusion criteria [67]: aged ≥16 years, resident in the United Kingdom, BMI ≥18.5, met BN or EDNOS[i] criteria, established using the Eating Disorders Examination [68] • Exclusion criteria: currently participating in any other treatment-based ED research, self-reported drug or alcohol addiction, take street drugs daily or weekly, and no regular access to broadband with speakers or headphones	High
Linardon et al [69], 2022; Australia	• Mixed methods study • Advertisement distributed on the author's open-access psychoeducational website for EDs [70] • Community setting	• N=14 (79%) female • 19-47 years (mean 32.71, SD 8.26) • Caucasian (n=10) Asian (n=2), Eastern European (n=1), Hispanic (n=1)	• Break Binge Eating App • Smartphone mobile • No contact with clinician • Included psychoeducation, self-monitoring, learning healthier coping strategies. and body image • Frequency not stated	• Inclusion criteria: self-reported at ≥1 objective binge eating episode in past 28 days	Moderate
Yim et al [71], 2021; United Kingdom	• Qualitative study • Recruited sample with posters, clinicians' referrals, and university circular emails at South London and Maudsley ED Outpatient clinic and King's College London • Community and outpatient setting	• N=15 (100%) female • Age not specified • Ethnicity not specified	• No specific digital intervention referred to • Not applicable • No contact with clinician • Participants interviewed on ED needs and barriers and facilitators for online self-help programs • 4×30–60-minute sessions	• Inclusion criteria [20]: female participants aged ≥18 years. Self-identified as experiencing BN, BED, or a related subthreshold binge and purge ED • Exclusion criteria [20]: BMI <18.5 kg/m2, patients in need for inpatient eating disorder treatment due to the severity of the disorder, patients with substantial psychiatric comorbidity needing treatment in its own right, patients on antidepressant medication who have not been on a stable dose for at least 4 weeks, and patients not eligible for treatment coverage by health insurances or NHS due to low symptoms severity	Moderate
Jarman et al [60], 2022; Australia	• Qualitative • Recruited from a larger project (Web-Based Interventions to Reduce Eating Disorders [WIRED]) via posts on the project's social media accountsCommunity setting	• N=7 (100%) female • 21-33 years (mean 25.83, SD=5.34) • Ethnicity not specified	• No specific digital intervention used • Not applicable • No contact with clinician • Participants interviewed on their needs and preferences for app-based eating disorder interventions • Participants discussed user experiences and preferences hypothetically • Frequency not stated	• Inclusion criteria: self-identified lived experience of ED or substantial body image issues	High

XSL•FO
RenderX

Study; country	Study design	Sample details	Digital intervention	Inclusion and exclusion criteria	CASP[a] quality category[b]
Nitsch et al [72], 2016; United States	• Engagement and iterative usability study • Web-based and print advertisements in the San Francisco Bay Area and on the campus of a large private university • Community setting	• N=9 (100%) female • 18-25 years(mean and SD not specified) • Ethnicity not specified	• Student Bodies-Eating Disorders • Web-based program and mobile app • Unscheduled contact with a personal coach, plus an online, asynchronous guided discussion group [73] • Aimed to reduce disordered eating behaviors, improve body image, and support the development of coping skills • 40 ×10-minute daily sessions.	• Inclusion criteria: a positive response to ≥2 out of 5 on the SCOFF[j] questionnaire[k] [74] • Exclusion: lack of English language fluency, hearing impairments, and involvement in any depression or anxiety intervention research study	Moderate

[a]CASP: Critical Appraisal Skills Programme.

[b]CASP scores indicate study quality, with a score <15 indicating poor quality, 15 to 22.4 indicating moderate quality, and 22.5 to 30 indicating high quality.

[c]NHS: National Health Service.

[d]ED: eating disorder.

[e]BN: bulimia nervosa.

[f]BED: binge eating disorder.

[g]OSFED: other specified feeding or eating disorder.

[h]CBT: cognitive behavioral therapy.

[i]EDNOS: eating disorder not otherwise specified.

[j]SCOFF: Sick, Control, One Stone, Fat, Food.

[k]The SCOFF questionnaire is a widely used and validated screening tool for eating disorder symptoms.

Digital interventions involved no contact with a clinician or support worker (3/8, 37%) or minimal contact with a clinician (3/8, 37%). Digital interventions with minimal contact with a clinician encapsulate those which fall within the spectrum from guided to unguided, but still meet our inclusion and criteria. The study by Yim et al [59] was included due to the one-way nature of contact, the study by McClay et al [72] was included as the support was deemed optional due to reported high variability in support time due to reliance on the participant engaging with support, and the study by Nitsch et al [72] was included as contact was unscheduled and contact through discussion group was optional (Table 1 provides further details on contact with professionals).

Quality Appraisal

Studies were rated high quality (4/8, 50%) or moderate quality (4/8, 50%) based on the CASP systematic review checklist [52]. The CASP quality scores ranged from 18 to 25, with a mean of 22.1. The most common reason for low quality was a lack of reflexivity, where 50% (4/8) of the studies scored 0.

Table 2 outlines CASP scores for each study and their score for each domain. Domains are labeled 1 to 10 (1=clear aims, 2=appropriate qualitative methodology, 3=appropriate research design, 4=appropriate recruitment, 5=appropriate data collection, 6=considered reflexivity, 7=considered ethical issues, 8=rigor data analysis, 9=clear findings, and 10=value of research).

XSL•FO
RenderX

Table 2. Evaluation of the quality using the Critical Appraisal Skills Programme (CASP) systematic review checklist [52].

Study	CASP quality assessment score for each domain										
	Domain										CASP score[a]
	1	2	3	4	5	6	7	8	9	10	
Jarman et al [60], 2022	3	3	3	3	3	0	2	2	3	3	25
Juarascio et al [46], 2015	3	3	3	3	1	0	1	1	3	3	21
Linardon et al [69], 2022	3	3	0	1	2	2	1	1	2	3	18
McClay et al [66], 2013	3	3	3	3	3	0	2	3	3	3	26
Nitsch et al [72], 2016	3	3	3	0	2	2	1	3	2	2	21
Jafari [65], 2021	3	3	3	1	2	0	3	2	3	3	23
Yim et al [59], 2020	3	3	3	1	2	3	1	3	3	3	25
Yim et al [71], 2021	3	3	0	2	1	2	3	1	2	1	18

[a]The maximum overall score is 30. A total score <15 indicates the study is poor quality, 15 to 22.4 indicates moderate quality, and 22.5 to 30 indicates high quality. A score of 0 represents <25% of the criteria met, 1 being 25% to 49%, 2 being 50% to 74%, and 3 being 75% to 100%.

Qualitative Analysis

Overview

The main findings of each study are outlined in Multimedia Appendix 3 [46,59,60,65,66,69,71,72].

A total of 7 metathemes and 13 subthemes were identified, as outlined in Table 3. Quotes provided are from the studies, as opposed to the studies' participants.

Table 3. Metathemes and subthemes.

Metathemes	Subthemes
Appeal of digital interventions	• Accessibility • Anonymity • Flexibility
Role of digital interventions in treatment	• Stepping stone for therapy • Alternative treatment
Value of support in treatment	• Support from a professional • Peer support
Communication at the right level	—[a]
Importance of engagement	—
Shaping knowledge to improve eating-disorder behaviors	• Increased self-awareness and reflection • Improvements in eating-disorder behaviors
Design of the digital intervention	• Functions • Media format • User interface • Customization

[a]No subthemes.

Theme 1: Appeal of Digital Interventions

Users across studies were initially drawn to using digital interventions because they were accessible [46,59,60,65,66,69,71] and allowed for anonymity [46,59,66,71,72].

Accessibility

Users were drawn to digital interventions as an accessible means of getting treatment. The intervention did not have long waitlists, unlike the traditional face-to-face interventions, and was low cost compared to other treatment options such as private psychotherapy [65,66,72].

Users found them accessible because they already owned a device to use the intervention on and no travel was required [60,72]:

> *[Digital interventions are] accessible for everyone because technology is omnipresent.* [72]

Digital interventions were also seen as accessible for those who were non-native English speakers as they provided features such

XSL•FO
RenderX

as transcripts and audio recordings [69]. In addition, many users expressed optimism about digital interventions, recognizing their ability to address barriers they had personally encountered or were aware of in traditional treatment options [46,59,66,71].

Flexibility

Users identified flexibility to be a substantially appealing aspect of digital interventions. They perceived digital interventions as highly flexible and practical to use. This was attributed to the normalization of phone use across various situations and ease of access to the intervention through their mobile phone. Most users thought the intervention was compatible with their lifestyle and everyday routine [46,59,60,66,69,72]:

> *A key advantage...is the flexibility and freedom for the user to engage at any time.* [60]

Anonymity

Digital interventions were appealing because they offered a discrete method of help and the lack of face-to-face contact with a clinician made participants feel more comfortable [46,59,66,71,72]:

> *Self-help approach seemed like a desirable alternative to traditional face-to-face treatment, primarily because of the private, convenient, flexible, and anonymous nature.* [66]

Anonymity was appealing because some participants expressed shame and embarrassment about their ED symptoms or subtype, so preferred to keep treatment discrete from others [66,72]. Some participants saw technology and the internet as protection as it allowed them to remain anonymous. This made accessing treatment less daunting because they felt less vulnerable and more autonomous over their treatment [71,72].

Theme 2: The Role of Digital Interventions in Treatment

Across studies users saw digital interventions as less intensive and less effective compared to face-to-face treatment [59,60,69,71].

Stepping Stone for Therapy

Many users saw digital interventions as a means of early intervention or a prior step to getting traditional treatment—psychotherapy [59,60,65,69]. Therefore, users did not see digital interventions as a sufficient treatment to be used independently, but instead as a complementary tool to be used before or alongside psychotherapy:

> *Most regarded self-help as a prelude to getting "proper" treatment ("one tool in the toolbox"), rather than an alternative to traditional treatments.* [71]

Alternative Treatment

Many users had tried several treatment options for their ED, many of which were unsuccessful in helping them recover [46,65,66]. Some felt they had exhausted all their options for treatment and were failed by the health care system, therefore saw digital interventions as a tool users would seek out of desperation [59,66]:

> *Participants...had tried other approaches without success...and were open to learning a novel approach.* [65]

Theme 3: Value of Support

The digital interventions used in studies had varied levels of communication functions; some had direct contact with a psychologist, personal coach, or support worker [59,66,72]; some offered a community chat forum [59,72], and others did not offer either [46,60,65,69,71]. Nevertheless, users highly valued support from a professional [66,69,71] and peers [59,60,65,66,71].

Support From a Professional

Support from a professional helped users feel supported without being judged and kept them motivated by making them feel accountable [59,66]:

> *The support worker was a valued element...it was good to have someone there to help with their progress through the package without judgment: "...she has made a huge huge difference"* [66]

However, a minority felt pressured by the professional and disengaged as a result [50]. Users felt a reduced power imbalance with the professional compared to previous experiences with face-to-face therapy. However, this was at the cost of a reduced therapeutic alliance [71,72]. Due to this, some users still preferred face-to-face contact [72].

Peer Support

In the 2 studies that provided access to a discussion group [71,72], users highly valued peer support. One study [65] offered an intervention with neither support from peers nor a clinician, yet participants desired a discussion board to share mutual experiences and interact with others. One study, in which participants did not use an intervention but discussed their preferences hypothetically, found users valued peer support more than support from a professional [60]. Users thought that support from both peers and clinicians would increase motivation to use the intervention. Peer support could help users feel understood and reduce isolation and loneliness:

> *Being able to talk to people who are going through the same thing...is really important, because sometimes you just have questions that no one can answer even if they are a doctor or a therapist.* [60]

Similarly, a study that offered a discussion group [72] found increased motivation to continue treatment, as users thought having the option to communicate with other users reduced loneliness and increased their sense of connection and belonging. However, many were concerned with the potential harm of contact with others with an ED, as some users may share harmful thoughts or encourage each other's ED:

> *Most participants (3/4, 75%) also acknowledged that this may be unhelpful or even dangerous if used inappropriately.* [60]

XSL•FO
RenderX

Theme 4: Communication at the Right Level

Many users suggested the intervention's language had a key role in acceptability and motivation to continue use [46,60,72]. If they perceived insensitive language, they felt highly demotivated to continue using it [60,72].

Users disliked clinical language (eg, "binge eating episode"), acronyms (eg, "BED" and "CBT"), and formal language that made the intervention feel more serious and less enjoyable [46,60]. Users preferred informal and caring language, as this appeared more approachable and created a more pleasant experience [60]. However, there was an emphasis on a careful balance between professional and informal language [46]:

> *Wording and language used was an important issue as it was found to trigger negative emotions.* [46]

Theme 5: Importance of Engagement

Users highlighted facilitators that helped them initiate use and continue engagement. During initial use, users expressed the intervention's interactivity and highly engaging content, and functions that kept them returning [65,69]. One user suggested a way to ensure engagement was to include frequent updates with new content and features. Users across studies explained that they were more likely to continue using if they were inputting data, specifically logging calories, moods, or binges [46,59,65,69]. If the intervention had predictable functions or familiar content, they were more likely to disengage and terminate use prematurely [46]:

> *User: "I would keep using the app if it continued to update. There has to be new features and new things about it."* [46]

Theme 6: Shaping Knowledge to Improve ED Behaviors

Increased Self-Awareness and Reflection

Some users reported that the intervention resulted in positive changes in their ability and frequency of self-awareness, self-realization, and self-reflection. One study suggested that the intervention helped most users by promoting new knowledge and understanding of their ED [59].

Four studies reported that the majority of users noticed increased capability and frequency of self-reflection and self-awareness regarding their eating behaviors and beliefs about eating [46,59,65,72]. Users identified these positive impacts and attributed them to the intervention:

> *Participants described the overall positive impact of "holding off on an immediate desire" and learning to reflect on one's feelings and actions.* [65]

Improvements In ED Behaviors

The majority of users from two studies were able to use their new skills and understanding of ED and apply them when they were about to eat [65,66]. In one study [65], most participants noticed that they were more mindful before and during eating. This led to more scheduled and mindful eating behaviors (ie, less eating when not hungry). These improved eating behaviors were attributed to the intervention:

> *Many participants described taking a pause to reflect before or during eating, which led to less snacking, less eating out of boredom, eating smaller quantities of food, and less night eating.* [65]

Theme 7: Design of the Digital Intervention

Users expressed several preferences relating to functions, media and format, and user interface. Within all studies except one, users heavily emphasized the importance of personalization and customization [46,59,60,65,69,71,72].

Functions

Users across studies found food logging functions to be controversial. Some desired the function as they felt it would aid self-awareness and found it convenient to be able to track multiple domains (eg, food, emotions, and binges) in one app [46,59,65,69]:

> *Nice if there was an area or section of it where you could log your food. Like what you're eating so you could look back on it and see what you're eating and how your habits are changing.* [65]

However, some users had previously been dependent on food logging, in the form of calorie counting, to feel a sense of control. These users shared the potential harm of a food logging function [65].

Some users highlighted that questionnaires and quizzes were perceived as insensitive as they felt they made light of a serious concern [65]. They preferred functions that aimed to manage negative emotions over functions and content that were more light-hearted and game-like.

Media Format

Those who used an intervention with text-heavy content found reading long texts to be a negative experience [65,72]. Those who experienced a greater variety of audio, images, and text content appreciated it, suggesting variation of media formats is preferred [46,69]. This extended to the format of data input, as users desired an option to input audio files and photos, particularly when logging moods or binges [60]:

> *Participants liked that there was a mixture of audio, images, and text-based content delivery formats, which is consistent with a recent quantitative study finding that people who would use e-health for ED symptoms stated a preference for such blended content delivery formats.* [69]

User Interface

Users had mixed preferences regarding design and appearance. Some preferred very simple and clear designs with minimal distractions [60,69,72], while others preferred more color and visually engaging material [69]:

> *Those that rated the visual design positively appreciated the simplicity of the layout...Several participants did not find the visual layout to be appealing, and suggested...more user-friendly images to better capture the attention of users.* [69]

XSL•FO
RenderX

Most users had positive experiences with navigating the interventions. This could have been improved by additional navigation functions (eg, a home button) and a more personalized user journey (eg, bookmarks and recent history) [59,65,72]. Many participants, in one study, explained this would reduce cognitive demand making it easier to maintain engagement and complete sessions.

Most users did not have technical difficulties, but for the few that did, this negatively impacted their experience. Technical difficulties made the intervention appear unreliable, reducing the motivation to continue use [65,66,72].

Customization to the Individual

Users highlighted that people with EDs have unique triggers, symptoms, and levels of understanding of their ED, which can heavily differ across individuals [46,59,65,66]. Users preferred more opportunities to customize the intervention's functions and complexity of psychoeducation to meet their personal needs [59,65]. For example, users wanted to control the option to see more additional images if they had language needs or were non–native English speakers. Some users also wanted to have an option to turn on food logging functions, such as diaries of their daily food intake and calories, to feel a greater sense of control. Others wanted to turn off food-logging functions as they were perceived to be harmful and have the potential to trigger ED behaviors (eg, restriction or purging). Allowing users to customize functions and content would increase the relevance of content and increase motivation and commitment to use [60,65]:

> *The intervention was not a one size fits all and how the perceived usefulness and relevance were often dependent on participants' demographic and clinical characteristics.* [59]

Discussion

Principal Findings

Most users across studies reported positive experiences of using digital interventions for their EDs. Digital interventions allowed for an accessible, flexible, and anonymous approach to treatment, which was appealing to users. They found them convenient, flexible, and easily integrated into their lifestyles. Digital interventions improved their understanding of EDs and increased self-reflection on their beliefs about eating and eating behaviors. This aided mindfulness during urges to binge, and when eating. Nevertheless, most users still perceived digital interventions for ED to be an early intervention or as a "last resort" after several unsuccessful treatment attempts. Some negative experiences were reported, which were attributed to technical difficulties, excessive text, feeling pressured by the support from a professional, and clinical, formal language. These highlight specific areas for improvement.

In terms of user preferences, there were mixed opinions on functions and user interface, highlighting the importance of customization. Food logging appeared to be the most controversial function. Some users found it convenient to be able to log moods and behaviors in one place, as they would otherwise have a separate food logging app, whereas others expressed concern about its potential harm and perpetuate their overconcern with food and weight. Opinions on user interface were also mixed as some preferred simple designs, while others preferred color and visually engaging material. The mix of opinions suggests digital interventions should have options for users to turn off functions they perceive as unhelpful and to customize the user interface (eg, color schemes, use of images, or potentially having a 2 user-interface options such as "simple" and "detailed"). In fact, most users expressed the importance of customization based on individual users having unique triggers, symptoms, and levels of understanding of their ED.

Most users expressed that the language and tone of content should feel approachable and be understandable to people with limited knowledge of ED (eg, no clinical terms or acronyms). Most found support from a professional and peers to be valuable, with users prioritizing peer support due to prevalent feelings of loneliness in their ED experience. However, a minority disagreed and perceived professional support in digital interventions to instill a power imbalance and a sense of pressure on users. Some users were also concerned about the potential harm of peer support, such as negative interactions or unhelpful information exchange.

Most users emphasized the importance of an intervention that met their language, lifestyle, and engagement needs, while recognizing their variation in ED symptoms and severity. An ideal intervention would allow users to tailor content, functions, appearance, navigation (eg, bookmarks and recent history), and format of content (eg, videos, text, and audio) to meet their own needs.

Comparison With Prior Work

Our findings were generally consistent with prior work on digital interventions for EDs, yet provided some new insights.

Users' perceptions on the benefits of professional and peer support were in line with a prior review suggesting that support from a professional was a source of motivation in self-help, which led to more satisfaction [47]. Similarly, support from peers or a professional was perceived to be an important motivator in encouraging engagement and adherence, consistent with previous literature.

Our findings were consistent with previous work on digital interventions for other mental health disorders. One review of 208 studies on digital interventions for mental health (depression, anxiety, and ED) and related issues (stress, mood, and anxiety) identified factors affecting user engagement [75]. Users were more likely to continue use if the content had perceived relevance, and if they had the option to personalize content, consistent with this study.

Another study on digital interventions for severe mental health problems (including bipolar and schizophrenia) suggested users found that digital interventions aided reflection and change, and preferred highly interactive interventions [76], consistent with our findings. Interestingly, data privacy concerns were more salient in the existing 2019 review and concerns were related to companies and clinicians accessing their data, whereas users in our review were more concerned with privacy from their

XSL•FO
RenderX

friends and family [59,66] and less concerned about third-party companies [46].

We identified novel insights on user experiences, such as broader perceptions of digital interventions being an early intervention or "last resort" that were not mentioned in previous literature, as well as, user preferences, specifically what preferences were important for user engagement. New content and functions were important in maintaining engagement, so future interventions were recommended to occasionally update content and functions. We also found language used in digital interventions to be more important than previously suggested [21,47], as language had a key role in acceptability and motivation to continue use. Language was also an important factor in user experience, with language deemed insensitive or too formal substantially affecting users' experiences negatively, which provided a novel insight. Further, the support from professionals elicited feelings of accountability, which was either motivating or disengaging for users—an insight not found in previous studies [21,47].

Implications

This review supplements the literature on digital self-help interventions for EDs by exploring unguided self-help and by offering a qualitative exploration of the reasons behind low adherence. Previous reviews combined guided and unguided interventions, limiting their ability to draw firm conclusions about one or the other [47]. In addition, prior randomized controlled trials lacked the contextual understanding needed to explain low adherence due to their quantitative nature. Our qualitative review provides context as to why some people may not be engaging with digital interventions, and why there is low adherence [21].

Our findings can inform the design of digital interventions to better address the diverse needs and preferences of users with EDs. Key areas identified as important to most users include support from clinicians and peers, variation of media, and ways to ensure engagement, for instance, frequent updates and content for all knowledge levels.

The perceptions of digital interventions being an early intervention or "last resort" may suggest the need for flexible, adaptive approaches that can cater to users at different stages of their ED. For individuals viewing digital interventions as an early intervention, the design may prioritize easy accessibility, self-monitoring tools, and psychoeducation. For users who regard digital interventions as a "last resort," it is important to include relevant emergency contact information and design elements that build trust and hope. These users may be skeptical about mental health interventions due to negative experiences with health care and mental health interventions. To address this, interventions may combine unguided and guided care, offering support and encouragement throughout the process while rebuilding users' confidence in mental health support.

The findings from this review can help inform the design and development of digital interventions that address the existing "treatment gaps" for individuals with EDs. Digital interventions can be particularly beneficial for those with mild to moderate EDs who are attempting to access health care services but met with lengthy waitlists due to prioritization of severe EDs. Digital intervention can serve as the initial step in the stepped care model [77] to provide immediate access to mental health resources, psychological content, and supportive tools to help manage symptoms and distress.

Strengths

Our methodology was inclusive because we searched published and unpublished studies from any country and published in any language. Our search strategy was developed with a librarian's advice and expertise. This ensured that our search strategy was comprehensive and highly specific to our review questions. Two independent researchers completed screening, data extraction, and quality assessments, increasing this review's reliability. Data extraction and quality appraisal were conducted independently by 2 researchers, reducing errors of inaccuracy [78].

Reflexivity was used to identify and understand researcher biases and their potential impact on our interpretation of the results. Our research team lacked lived experience of EDs, therefore, we addressed this by using patient and public involvement to identify misinterpretations or gaps in our analysis. We recruited 2 people with lived experience of ED and used their feedback to iteratively develop themes. This improved the validity of our analysis.

Limitations

We aimed to be inclusive as we predicted limited relevant studies; however, this led to broad inclusion criteria and heterogeneity of study designs among included studies. Of the 8 included studies, 5 (63%) used study methods or interventions that were notably distinct. Of these, 2 (40%) did not require the use of a digital intervention [60,71], 1 (20%) used an intervention with a personal coach [72], 1 (20%) involved weekly communication and a online discussion board [44], and 1 (20%) study included weekly sessions with a support worker [66]. We included studies without a digital intervention [60,71] because we prioritized inclusivity, and they provided valuable insights on digital interventions more broadly and relative attitudes. However, because users were not speaking from experience, their preferences may be less accurate and may change after using an intervention, making our results less reliable. We included 3 studies that met our inclusion criteria for unguided interventions but still included some form of support, which may limit our review's ability to make generalizations specifically about fully unguided interventions.

Our review lacked ethnic and demographic diversity. Our compiled group of users primarily consisted of White female university students from Western countries. Only 38% (3/8) of the studies reported sample ethnicity, of which most users were White [46,65,69]. Six studies used all-female samples [59,60,65,66,71,72]; all studies were conducted in high-income countries; and 63% (5/8) of the studies recruited from university populations [59,65,66,71,72]. This limits the generalizability of our findings to the broader ED population, where cultural contexts may have important influences on user experiences and preferences. Further research is required with participants from underrepresented groups (eg, men, older adults,

XSL•FO
RenderX

nonuniversity students, ethnic minorities, non-Western countries, and economically deprived groups).

Future Work

More research is needed to understand the role of digital interventions in care pathways. Future studies should explore their potential as the initial step in the stepped care model [77] and whether they can replace or complement face-to-face treatment. In addition, research should focus on making digital interventions adaptable to different stages of recovery, identifying which populations benefit most, and understanding user experiences across demographics.

Our findings emphasize the importance of support, whether from professionals or peers. Future work should compare user experiences of peer support versus professional support to determine what users find meaningful. It should also explore the right balance of support, as too much can create pressure and too little can reduce motivation, particularly across varying levels of ED severity.

Future interventions should empower users with more agency in logging functionality. For example, users could log meals with varying detail levels, scan barcodes, or select images. They could also log related information such as moods or recovery goal alignment using diverse formats such as emojis, free-text, images, or voice notes, enhancing convenience and personal expression.

Another potential pathway to increasing personalization may be through the use of artificial intelligence. One approach to this is by designing digital interventions to be “just-in time” adaptive interventions, by applying machine learning to food, mood, and binge inputted data to predict high-risk times for binging and restricting. For example, based on individual data, artificial intelligence may identify a high risk of binge when a user has had prolonged social media use after 10 PM and may send notifications for relevant content and exercises to prevent binges, purging, or restriction. Recent research proposes that the collection of data needed for machine learning, such as eating behaviors, physical activity, sleep and visual attention, can be collected by sensor technologies used in modern smartwatches and smartphones [79]. The current literature proposes machine learning for ED treatment is a cost-effective and rapid treatment option [80].

Our findings highlight the importance of a highly personalized user experience, raising questions about the role and impact of cocreation in this context. The existing literature recognizes the value of cocreation in developing needs-based services [81], including digital interventions for mental health [42], as it ensures interventions are aligned with the needs and preferences of the target population. Subsequently, digital interventions designed using cocreation have improved engagement, acceptability, user-friendliness, and cultural sensitivity [81-83].

However, there is limited understanding on the direct effects of cocreation on improving digital interventions. Future work may use cocreation to involve end users in all stages of design and intervention development, a practice that is a core principle of cocreation but rarely practiced [84,85] and explore the impact of cocreation on increasing personalization and improving appropriateness of language.

Conclusions

Users reported positive experiences with digital interventions, valuing their flexibility, anonymity, and convenience. These tools improved their understanding of EDs, facilitated self-reflection, and promoted coping skills such as mindfulness during time of distress. Both peer and professional support were appreciated for building trust and empathy, enhancing user engagement.

Opinions varied across a range of features, such as food logging and user interface design. This shows the importance of personalization, allowing for customization of features based on individual preferences and triggers, which could significantly improve user engagement. However, it is crucial to ensure that digital interventions use components that are effective in ED treatment and are delivered in a way that is acceptable to the end user.

These insights provide clear direction for future codesign and development of digital interventions. Further involvement of end users from early research through to final testing will allow developers to create more engaging, personalized, and effective tools that better meet user needs, ultimately reducing dropout rates and closing the treatment gap for those with mild to moderate EDs.

Abstract

Background: Digital wearable devices, worn on or close to the body, have potential for passively detecting mental and physical health symptoms among people with severe mental illness (SMI); however, the roles of consumer-grade devices are not well understood.

Objective: This study aims to examine the utility of data from consumer-grade, digital, wearable devices (including smartphones or wrist-worn devices) for remotely monitoring or predicting changes in mental or physical health among adults with schizophrenia or bipolar disorder. Studies were included that passively collected physiological data (including sleep duration, heart rate, sleep and wake patterns, or physical activity) for at least 3 days. Research-grade actigraphy methods and physically obtrusive devices were excluded.

Methods: We conducted a systematic review of the following databases: Cochrane Central Register of Controlled Trials, Technology Assessment, AMED (Allied and Complementary Medicine), APA PsycINFO, Embase, MEDLINE(R), and IEEE XPlore. Searches were completed in May 2024. Results were synthesized narratively due to study heterogeneity and divided into the following phenotypes: physical activity, sleep and circadian rhythm, and heart rate.

Results: Overall, 23 studies were included that reported data from 12 distinct studies, mostly using smartphones and centered on relapse prevention. Only 1 study explicitly aimed to address physical health outcomes among people with SMI. In total, data were included from over 500 participants with SMI, predominantly from high-income countries. Most commonly, papers presented physical activity data (n=18), followed by sleep and circadian rhythm data (n=14) and heart rate data (n=6). The use of smartwatches to support data collection were reported by 8 papers; the rest used only smartphones. There was some evidence that lower levels of activity, higher heart rates, and later and irregular sleep onset times were associated with psychiatric diagnoses or poorer symptoms. However, heterogeneity in devices, measures, sampling and statistical approaches complicated interpretation.

Conclusions: Consumer-grade wearables show the ability to passively detect digital markers indicative of psychiatric symptoms or mental health status among people with SMI, but few are currently using these to address physical health inequalities. The digital phenotyping field in psychiatry would benefit from moving toward agreed standards regarding data descriptions and outcome measures and ensuring that valuable temporal data provided by wearables are fully exploited.

Introduction

Psychiatry, paralleling other health disciplines, has seen a rising interest in "digital phenotyping," the concept of leveraging streams of passively collected data captured by personal digital sensors and devices to infer, monitor, and predict different states of health and illness [1,2]. A seminal UK review identified "wearables"—that is, electronic sensing devices worn on or close to the body (eg, smartphones, watches, bracelets, or garments)—as a pivotal growth area set to transform 80% of patient care pathways by 2040 [3]. The momentum driving such developments has been fueled by a number of technological, scientific, and social factors including advances in mobile sensing technology, powerful machine learning algorithms, and the broad use of smartphones among the general population, including among those with severe mental illness (SMI) [4].

Within psychiatry, the notion of using wearables to predict and ultimately prevent relapse episodes, which are both emotionally and financially burdensome, has gained traction around the world [5]. Theoretically, low-cost personal devices could detect early signs of deteriorating mental state outside of the clinic via continuously monitoring of behaviors, such as activity, travel, conversation, and human-computer interaction, in a "passive" manner [1]. Such methods are distinguishable from digital interventions that rely on "active" user input such as periodic self-reporting of symptoms using ecological momentary assessment (EMA) methods. For example, increases in psychomotor agitation and social activity that are characteristic of oncoming manic episodes in bipolar disorder could theoretically be detected using data from accelerometers, GPS, and Bluetooth encounters [6], all of which could be collected without the need for active user input. Promising results from initial exploratory, qualitative, and feasibility studies [7-9] are spurring on substantial projects aimed at relapse prevention through the use of smartphones alone or supported by other wearable devices [10,11].

Meanwhile, in other chronic diseases [12-14] and in the general population [15], monitoring and promoting physical health appears to be a far more common use case for wearables. People with SMI have substantial, life-shortening physical health inequalities [16], yet physical health care has historically been under-resourced and overlooked in such populations [17]. Increasingly, a strong case is being made to introduce digital technologies as a low-cost, scalable way to monitor and improve physical health among people with SMI [16,18]. Ensuring people with SMI have access to new technologies and are not left behind in the "digital divide" is crucial to address health inequalities. Currently, however, it is not clear what studies have used wearables in particular to monitor physical, as well as mental, health in psychiatric settings.

Evidence regarding using wearables with non-SMI populations for physical health promotion may not necessarily be generalizable on multiple grounds, including utility, feasibility, and even safety. Default activity goals suitable for other populations may be unsuitable or unattainable for people with SMI, who often have lower rates of physical activity, increased rates of sedentary behavior, and higher rates of comorbid physical conditions [16]. Thus, as with other digital health behavior interventions, wearables may require tailoring to the particular needs of people with SMI [19]. Furthermore, there is a need to understand how remote monitoring itself may interact with mental health symptoms, whether positively or negatively. For example, concerns have been raised that remote monitoring may risk inducing distress or paranoia in people with schizophrenia [20,21].

Relatively recently, narrative, scoping, and systematic reviews (eg, [22-26]) have usefully examined findings from studies using wearables among people with mental illness. Of course, this is a fast-moving area that requires regular updating. Moreover, appreciation for the nuances between these reviews is important; indeed, on closer attention, there are numerous differences in review methods, device eligibility, outcomes, and populations studied, which carry implications for future research and clinical practice. In particular, we note there has been less attention toward reviewing physical health outcomes monitored by wearables among people with SMI, leaving a distinct knowledge gap. Furthermore, acknowledging the importance of scalability and sustained participant engagement has directed the focus of this review toward consumer-grade smartphones and wearable devices in individuals with SMI, for whom the roles of these widely used devices are not well understood.

Therefore, we aimed to conduct a systematic review to examine the utility of passively collected physiological data from *consumer-grade*, digital, wearable devices for remotely monitoring or predicting changes in *mental* or *physical health* among individuals with SMI, specifically schizophrenia or bipolar disorder. To the best of our knowledge, this is the first systematic review to focus on this specific combination of criteria, allowing us to explore the area in sufficient depth to generate useful insights. We explored the types of devices used, the varieties and combinations of data passively gathered, and the associations detected between different types of passively collected data and both mental and physical health outcomes in people with SMI. Thus, the findings will be useful to inform both future research and clinical initiatives aimed at implementing wearable technologies into mental health care.

Methods

Overview

This review was registered on the online review protocol database, PROSPERO (CRD42022382267). It was guided by

XSL•FO
RenderX

the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 statement for reporting systematic reviews [27]; a completed checklist is available (Multimedia Appendix 1).

Search Strategy

The searches were performed in May 2024 using the following databases: Cochrane Central Register of Controlled Trials, Technology Assessment, AMED (Allied and Complementary Medicine), APA PsycINFO, Embase, MEDLINE(R), IEEE XPlore.

The following combination of keyword search terms relevant to wearable technologies, mental illness, and health outcomes were used to find relevant papers: [psychosis OR psychoses OR psychotic OR schizophr* OR severe mental OR serious mental OR bipolar] AND [wearabl* OR smartphone OR smartwatch OR smart watch OR garmin OR fitbit OR apple watch OR withings OR oura OR passiv* collect* OR passive data OR device collected OR sensing data OR sensor OR sensors] AND [remote* OR relapse OR monitor* OR predict* OR machine learning].

The reference lists of all included papers were searched for additional studies. Only English language research papers were included in the review.

Eligibility Criteria

The eligibility criteria for this review are described in Table 1. Briefly, studies were deemed eligible for inclusion if they collected quantitative, passively collected data about at least one physiological measure of interest (eg, sleep, heart rate, or physical activity) using a commercially available, consumer-grade wearable or smartphone device from people with SMI and related the data to a health outcome.

Table 1. Eligibility criteria.

Domain	Criteria
Participants	Adults (mean age 18 years and over) with SMI[a]: at least 50% with a diagnosis of psychosis, schizophrenia, or bipolar disorder (as diagnosed using any recognized diagnostic criteria) OR possible to separate people with these diagnoses from the wider sample
Design	Observational studies, randomized controlled trials (RCTs), pilot studies, and feasibility studies, provided the study collected passive data using a consumer-grade, commercially available digital wearable device (including smartphones, watches, rings, or bracelets) in a relevant population for at least 3 days; studies involving invasive or obtrusive devices (eg, glasses, helmets) and studies using only research-grade actigraphy methods were excluded.
Measures and outcomes	Studies collected quantitative, passively collected data about at least one physiological measure of interest (sleep duration, heart rate, sedentary behavior, sleep and wake patterns, steps, physical activity) AND reported associations with at least one other measure of physical or mental health not measured by the device (eg, diagnosis, psychiatric symptoms, BMI).

[a]SMI: severe mental illness.

Consumer-grade devices were defined as products designed and marketed to the general public for personal use. Studies using devices designed for medical or research purposes without a commercial use (eg, actigraphy studies) or those using invasive or obtrusive devices (eg, glasses, helmets) were ineligible. We excluded studies that only collected data requiring "active" user input (eg, EMA methods, logging step counts manually). Studies that used wearable devices as a fitness intervention but did not report analyses of passively collected data were not eligible (eg, [18]). Studies that reported results on multivariate models without specific results pertaining to features of interest to this study were not included. Studies using only GPS as a measure of activity, without other physiological metrics that were capable of distinguishing physically active modes of travel (eg, walking versus being in a vehicle), were also excluded. Relationships between geolocation data and SMI symptoms have been effectively reviewed elsewhere [28]. Studies were only included if they reported relationships between passive data and another different health (physical or mental) outcome. Thus, we excluded purely methodological studies aimed at validating passively collected measures (eg, passively sensed sleep against gold standard polysomnography).

Study Selection Process

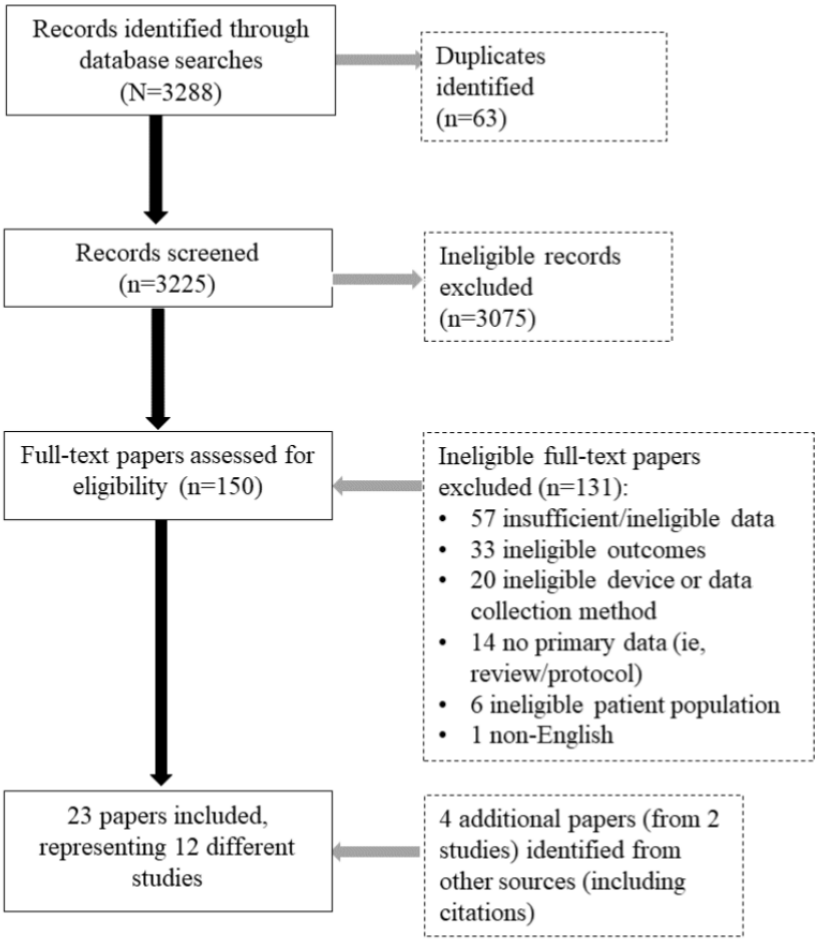
Titles, abstracts, authors, source, and date were imported for review into Covidence, where duplicate entries were removed prior to screening. All records were then initially screened by the lead author (LH); 15.2% (490/3229) of these records were selected on the basis of the final digit of their study import number in Covidence then independently reviewed by a second reviewer (AM). Inter-rater agreement at this stage was 98%. Reasons for exclusion at the title and abstract stage were not collected. Subsequently, at least 2 reviewers (LH plus AM or BR) independently reviewed the full texts of all short-listed papers. Inter-rater agreement on which studies to include at the full-text stage was 93%. Following full-text review, the lead author reviewed the reference lists of included papers for additional papers; the full texts of any papers she short-listed were referred for review by at least 1 other reviewer before reaching a decision about inclusion. Disagreements between reviewers regarding papers to include or exclude or reasons for exclusion were resolved via discussion.

Data Extraction and Synthesis

Data were extracted into a purposely designed proforma in Excel and included study setting (year, country, setting, design, total duration of study, and follow-up frequency), participant demographics (diagnosis, gender, inpatient or outpatient status) and baseline characteristics (total number, number of each group, mean age, diagnostic criteria, gender, ethnicity), device details (device make and model or app), measures of activity (measures, time points collected), measures of mental and

XSL•FO
RenderX

physical health (measures, time points collected), and eligible study outcomes. Due to the longitudinal nature of many of the studies, outcomes at all time points (eg, interim and on study completion) were considered eligible. Data pertaining to methods and outcomes were independently extracted by 2 reviewers (LH and AM), with any discrepancies resolved via discussion.



Meta-analysis was not appropriate due to the design of the studies and the heterogeneity of primary outcome measures reported. Outcomes were, therefore, synthesized narratively using commonly reported phenotypes (physical activity, heart rate, and sleep and circadian rhythm) to group results. Key results (for example, statistically significant associations or influential predictors included in final models) associated with mental health outcomes were also extracted and tabulated—in detail initially then summarized for clarity—organized using the aforementioned phenotypes. There were too few results to tabulate results for physical health outcomes.

Results

Overview

Overall, 3292 results were identified via database searches. Figure 1 summarizes the study selection process. We removed 63 duplicates, leaving 3229 records for screening. Following title and abstract screening, 150 full texts were reviewed for eligibility against the inclusion criteria. After this process, 131 papers were excluded. Additional searches of reference lists yielded 4 additional articles. The final number of papers included in the review was 23.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram.

Tables 2 and 3 describe the design and characteristics of the 23 selected papers, and Table 4 indicates which phenotypes were addressed by each paper, divided into physical activity, sleep and circadian rhythm, and heart rate. Table 5 summarizes the key results of the selected studies for studies reporting mental health outcomes, divided by phenotypes.

Table 2. Characteristics of included papers, including study name, aim, and location.

Study name and authors (year of publication)	Key aim	Location
Bipolar Illness Onset (BIO) study		
Melbye et al (2021) [29]	Investigated associations between automatically generated smartphone data and symptoms	Copenhagen, Denmark
Stanislaus et al (2020) [30,31]	Investigated associations between automatically generated smartphone data, diagnosis, and validated measures of (1) sleep [30] and (2) symptoms, activity, and functioning [31]	Copenhagen, Denmark
CrossCheck		
Buck et al (2019) [32]	Identified passively sensed indicators of persecutory ideation	New York, NY, US
He-Yueya et al (2020) [33]	Examined how behavioral stability features can be quantified and associations with symptoms	New York, NY, US
Lamichhane et al (2023) [34]	Used machine learning methods to predict relapse using passively sensed smartphone data	New York, NY, US
Wang et al (2016 [35], 2017 [36], 2020 [37])	Examined associations between passively sensed smartphone data and (1) self-reported symptoms [35], (2) total BPRS[a] scores [36], and (3) relapse [37]	New York, NY, US
e-Prevention		
Efthymiou et al (2023) [38]	Examined associations between passive data and changes in relapse states	Athens, Greece
Fekas et al (2023) [39]	Used survival analysis and machine learning models to predict risk of relapse	Athens, Greece
Kalisperakis et al (2023) [40]	Examined associations between digital phenotypes and changes in psychopathology	Athens, Greece
Zlatintsi et al (2022) [41]	Compared physiological and behavioral biomarkers between people with SMI[b] and healthy controls	Athens, Greece
Other		
Beiwinkel et al (2016) [42]	Examined relationships between symptoms, smartphone sensor data, and communication patterns	Lower Saxony, Germany
Cho et al (2019) [43]	Developed machine learning models to predict mood states using passively collected data	Seoul, Republic of Korea
Cohen et al (2023) [44]	Explored whether passive digital data could predict symptom change	Boston, MA, US; Bangalore and Bhopal, India
Henson et al (2020 [45], 2021 [46])	Used passively collected data to (1) explore social rhythm [45] and (2) compare anomaly rates and predictors of anomalies between patients and controls [46]	Boston, MA, US
Lahti et al (2021) [47]	Examined associations between device metrics and symptoms	Alabama, US
Martanto et al (2021) [48]	Examined associations between digital markers and symptoms	Singapore, Singapore
Osmani (2015) [49]	Investigated relationships between smartphone-sensed data and mood states	Tyrol, Austria
Shin et al (2016) [50]	Assessed the association between the severity of psychopathology and physical activity	Bugok, Republic of Korea
Song et al (2024) [51]	Examined causal relationships between circadian and sleep phase disturbances and mood symptoms	Daejeon, Republic of Korea

Table 3. Characteristics of included papers, including participants, duration, devices, and key variables.

Study authors (year of publication)	Sample size and diagnoses[a]	Follow-up duration	Devices	Passive data	Outcome measures
Beiwinkel et al (2016) [42]	13 with BD[b]	12 months	Smartphone (Android)	Device activity, % of day	YMRS[c], HAMD[d]
Buck et al (2019) [32]	62 with SZ[e]	12 months	Smartphone (Android)	Time (hours) sitting still, time (hours) moving on foot	Persecutory ideation (EMA[f])
Cho et al (2019) [43]	37 with BD and 18 with MDD[g]	2 years	Fitbit Charge HR	Daytime and bedtime steps; heart rate rhythm; sleep onset time, wake time, duration, and quality	Mood states, episodes
Cohen et al (2023) [44]	76 with SZ and 56 healthy controls	Interim analysis: mean 156 (SD 65) days	Smartphone (Android or iPhone)	Change points in sleep duration	PANSS[h], PHQ-9[i], GAD-7[j], SF-36[k], SFS[l], PSQI[m], WSS[n], BASIS-24[o], BACS[p]
Efthymiou et al (2023) [38]	19 with SZ and 10 with BD	Up to 2.5 years (mean 737 days)	Samsung Gear 3 + smartphone (Android)	Heart rate, HRV[q], sleep duration (hours), acceleration	Relapse
Fekas et al (2023) [39]	38 with SZ or BD and 26 healthy controls	Not clear	Samsung Gear 3 + smartphone (Android)	Heart rate, acceleration, gyroscope	Relapse
Henson et al (2020 [45], 2021 [46])	45 with SZ and 43 healthy controls [45]; 63 with SZ and 27 healthy controls [46]	3 months (interim analysis) [45]; 3-12 months (mean 126 days) [46]	Smartphone (own)	Circadian routine, weekend day routine [45]; monthly anomaly rates in sleep duration [46]	PHQ-9, GAD-7, self-reported mood (EMA) [45]; diagnosis, relapse (anomaly) [46]
He-Yueya et al (2020) [33]	61 with SZ	12 months	Smartphone (Android)	"Behavioral stability" in periods (minutes) spent being still, walking, cycling, and sleeping	Self-reported mood (EMA)
Kalisperakis et al (2023) [40]	20 with SZ and15 with BD	2-14 months	Samsung Gear 3 + smartphone (Android)	Monthly, per participant (mean and SD): total motor activity, heart rate averages, HRV, steps per minute, and sleep:wake ratio	PANSS
Lahti et al (2021) [47]	40 with SZ	4 months	Garmin vivofit + smartphone (Android)	Step count, walking time (seconds), sedentary time (seconds)	PANSS, BPRS[r], CGI[s], CDSS[t], PSQI, YMRS
Lamichhane et al (2023) [34]	63 with SZ	12 months	Smartphone (Android)	Average hourly total activity	Relapse
Martanto et al (2021) [48]	21 with SZ	1 week (interim analysis)	Fitbit Charge 3	Mean heart rate, mean HRV, steps, number of walks (>3 min), mean walk steps, mean walk duration (min), total duration (hours) of all sleep (light, deep, REM, total) events, mean sleep efficiency	PANSS, BNSS, CGI-S[u], CDSS, SOFAS[v]
Melbye et al (2021) [29]	40 with BD and 21 healthy controls	2 years	Smartphone (Android)	Step counts	HAMD, YMRS, IPAQ[w], FAST[x], self-reported mood and activity
Osmani (2015) [49]	12 with BD	12 weeks on average	Smartphone (Android)	Physical activity score	YMRS, HAMD
Shin et al (2016) [50]	61 with SZ	1 week	Fitbit Flex	Step counts	PANSS, BMI

Table 5. Summary of key results for studies reporting mental health outcomes, by diagnosis and passive data phenotype.

Passive data phenotype	Schizophrenia (SZ)	Bipolar disorder (BP)	Findings for SZ and BP
Physical activity	Higher step count: • Associated with less severe symptoms [47,48,50] • Achieved by healthy controls than people with SZ [41] • Not associated with symptom severity [40,47] Time spent walking: • In the morning associated with lower symptom severity [35] • In the evening associated with relapse [37] • Not associated with symptom severity [32,33,47] Changes in stillness positively associated with symptom severity [32,33,47]; stillness or sedentariness not associated with symptom severity [32,47]	Higher step count: • Positively correlated with mood [29] • Achieved by healthy controls than people with BD [31] • Not associated with symptom severity [29,31,40] • Not associated with BD in younger people [29] Timing of physical activity associated with psychiatric state [43,49]; time spent active not associated with symptom severity [42]	Larger variation in daytime movement behavior among people with SMI[a] [41]; lower frequency or quantity and variation in movement during sleep associated with SMI [41]; total motor activity not associated with symptom severity [40]
Heart rate	Heart rate associated with symptom severity [48]; HRV[b] associated with symptom severity [48]	Circadian rhythm of heart rate predicted mood state in bipolar disorder 1 and 2 [43]	Heart rate associated with symptom severity [40]; no association between sleep HRV (mean and variability) and symptoms [40]; increased variability in HRV features associated with SMI status [41]
Sleep and circadian rhythm	Sleep duration: • Associated with various psychosis symptoms [44] • Not associated with symptom severity [33,48] Later sleep onset and later waking times associated with poorer symptoms [35]; sleep efficiency not associated with symptom severity [48]; greater dysregulation in social rhythm (less routine) associated with higher symptom severity [45]	Sleep duration not associated with diagnostic status [30]; changes in sleep onset time predicted mood state [43]; causality between circadian phase disturbance (DLMO[c]) and mood symptoms in BD1 [51]	Higher mean and standard deviation of sleep:wake ratio compared with healthy controls [41]; increased mean sleep:wake ratio predicted increased negative, but not positive, symptoms [40]

[a]SMI: severe mental illness.

[b]HRV: heart rate variability.

[c]DLMO: dim light melatonin onset.

Study Types, Participants, Devices, and Data

The 23 papers covered 12 distinct research studies reporting on observational periods ranging from 1 week to 4 years. Most of the included studies can be broadly characterized as relapse prediction studies, with the long-term goal being to use passively collected data from wearable or smartphone devices as early warning systems to detect and prevent future episodes of mental illness. We found only 1 paper with a specific focus on physical health in people with SMI, which sought to evaluate daily activity levels using a wearable wristband [50].

Separate findings from the CrossCheck study were reported in 6 papers [32-37]; CrossCheck is a smartphone-based US study deploying passive and active EMA data collection methods to identify indicators of relapse among people with schizophrenia spectrum disorders. Other studies with multiple papers included in this review included the Danish Bipolar Illness Onset (BIO) study [29-31], which recruited patients with bipolar disorder plus unaffected relatives and healthy controls, and the Greek e-Prevention project [38-41]. Only 1 paper [44] included participants from a low or middle-income country, namely India.

A variety of measures were used to measure mental health outcomes including self-report rating scales of overall mood or individual symptoms (eg, persecutory ideation), often obtained via EMA methods; validated scales administered by clinicians, for example the Positive and Negative Syndrome Scale (PANSS; [52]), Young Mania Rating Scale [53], and Hamilton Depression Rating Scale [54]; and other outcomes or composite outcomes such as relapse.

Data only on participants with schizophrenia spectrum disorders were included in 12 papers, 7 papers only included participants with bipolar disorder, and 4 e-Prevention study papers included participants from both diagnostic groups. All papers described outpatient samples, except Shin and colleagues [50] who only recruited hospital inpatients and Song and colleagues [51] who recruited both outpatients and inpatients. Study sample sizes varied between 12 and 139 participants (including controls and diagnoses other than SMI). Some studies (eg, e-Prevention, CrossCheck) included only subsets of data for participants with valid data, for example using eligible Android devices or with sufficient data quality. After accounting for overlap between samples, we estimated that over 500 participants with SMI were included across the selected studies in total (using the largest

XSL•FO
RenderX

reported sample per diagnosis per study, estimated mean=49.4% female, 17 papers).

Papers predominantly reported on studies that used smartphones to support passive data collection and running a variety of study-specific (eg, CrossCheck), open-source (eg, Beiwe, MindLamp), and other apps (eg, Monsenso). With the exception of studies using open-source apps, papers were limited to reporting on patients using Android smartphones. The use of wrist-worn hardware to support passive data collection was reported in 8 papers [38,40,41,43,47,48,50,51]; the hardware specifically included the Samsung Gear 3 (used by the e-Prevention project), Garmin vivofit, and several Fitbit models (Fitbit Charge, Fitbit Charge HR, Fitbit flex).

Physical Activity

Physical activity was the most common metric presented in the selected studies, appearing in 18 of the 23 papers (Table 4). Physical activity was measured in a variety of ways. This included, most commonly, step counts [29,30,39-41,43,47,48,50]; the duration of time spent walking, being still, or being sedentary [32,33,35-37,47,48]; and other measures of total activity, such as linear acceleration [34,38,42,49]. The use of smartwatches to support data collection was reported by 8 papers [38-41,43,47,48,50]; the rest used smartphones only.

The evidence regarding the association between physical activity and symptom severity as measured by wearable devices was inconsistent (Table 5). The review found some evidence that increased overall daily physical activity, whether measured by steps or walking time, could be associated with improved mood in bipolar disorder [29] and less severe symptoms in schizophrenia [47,48]. For example, Martanto et al [48] reported multiple negative correlations between step counts and symptom severity using PANSS subscales.

Nonsignificant associations, however, were far more frequently reported between physical activity and symptoms across all diagnoses [29,31,32,40,42,47,50]. Studies were typically exploratory, testing multiple combinations of predictors and outcomes, with varying strategies for dealing with multiple testing. For example, Wang et al [36] developed a Brief Psychiatric Rating Scale score prediction model using passive sensing data in which 434 features were originally tested; however, none of the 18 features included in the final model addressed physical activity. Even where physical activity (eg, acceleration, gyroscope) data were included in relapse prediction models, some authors noted inconsistent [39] or weaker contributions to model performance relative to other modalities [34].

The detail of some studies may shed some light on the subtleties in the nature of the relationships between physical activity and symptoms among people with SMI. In particular, some results imply that timing of activity could be important in both schizophrenia and bipolar disorder. Three studies—1 on schizophrenia [35,37] and 2 on bipolar disorder [43,49]—found significant associations when activity was divided into time of day. For example, Wang and colleagues [35,37] found that walking in the morning was negatively associated with symptoms among people with schizophrenia, while evening walking was positively associated with symptoms. Similarly, steps taken at night made stronger contributions to mood episode prediction models among people with bipolar disorder than steps taken during the day [43]. Conversely, the absence of activity—or, at least, changes in activity—may also be important in the context of schizophrenia, at least. Although between-participant analyses showed that the duration of time spent sedentary or still was not a predictor of symptoms [32,47], some analyses from the CrossCheck study suggested that changes in stillness over time (within-participants) were indeed significant predictors [32,33].

Findings in terms of other health outcomes were limited. Lahti et al [47] found that activity data (walking time, sedentary time, and steps) predicted the sleep duration component (but not global score or other items) of the Pittsburgh Sleep Quality Index [55] among people with schizophrenia. Shin et al [50] found no significant correlation between daily activity (steps) and BMI among people with schizophrenia. Both studies that looked at levels of psychosocial functioning—1 with people with bipolar disorder [31], the other among people with schizophrenia [48]—found significant associations with step count.

Sleep and Circadian Rhythm

Measures relating to sleep or circadian rhythm were reported by 14 papers. Measures of sleep duration and sleep:wake ratio were most frequently cited, though some studies went into further detail citing metrics such as sleep efficiency, onset time, waking time, midpoint, and duration of sleep stages (eg, light, deep, and rapid eye movement [REM] sleep). The use of smartwatches to support data collection was reported by 6 papers [38,40,41,43,48,51].

No studies indicated that absolute sleep duration was significantly associated with symptom severity [30,48]; however, 1 study did find an increased sleep:wake ratio among people with SMI than for healthy controls [41]. Several papers did, however, report evidence that changes or irregularities in sleep patterns and circadian rhythm within participants over time were associated with psychiatric symptoms in both schizophrenia [44-46] and bipolar disorder [43,51].

Again, the addition of time-related data to sleep data appeared to yield some interesting associations. Wang et al [35] noted that waking up earlier was generally linked to more positive mental health states among people with schizophrenia, while going to bed later was linked with more negative states. In later papers from the CrossCheck study, however, sleep onset and offset features were less important relative to other features and were not selected in the final symptom and relapse prediction models [36,37]. A study with people with bipolar disorder found that regularity in sleep onset time ranked more highly relative to other features across various mood state prediction models, including sleep length [43]. Efthymiou et al [38] noted that adding day of the week information and temporal encoding data (the order of samples) to sleep duration data usefully contributed to psychosis relapse prediction models.

XSL•FO
RenderX

Research by Song et al [51] indicates that the subtle distinction between sleep and circadian phase disturbances (eg, light exposure patterns) may be important, at least for people with bipolar disorder. Using mathematical models and sleep midpoint data, they were able to estimate the timing of dim light melatonin onset, an important biomarker of circadian phase. They demonstrated causal relationships between circadian phase but not sleep phase, disturbances, and mood symptoms in people with type 1 bipolar disorder. Moreover, they postulated that sleep phase disturbance induced circadian phase disturbance, providing insights into causal pathways.

Heart Rate

Of the selected papers, 6 reported on heart rate data (Table 4), all of which used smartwatches [38-41,43,48]. Heart rate data types collected included mean heart rate (while awake and asleep), cyclical measures of heart rate indicative of circadian rhythm, various measures of heart rate variability (HRV; eg, means and standard deviations while awake and asleep), and heart rate rhythms over extended periods (eg, 48 hours).

Zlatintsi et al [41] looked at differences among people with SMI compared with healthy controls and found some signs of increased heart rate variability, particularly during wakefulness. Of the e-Prevention project papers, 2 reported that heart rate measures enhanced performance of relapse models [38,39].

The remaining studies looked at associations between heart rate features and psychiatric symptom severity. Two separate studies—1 with people with schizophrenia [48] and 1 with a mixed sample of people with SMI [40]—reported significant positive associations between mean heart rate and positive symptoms using the PANSS; however, neither of these studies found any associations between mean heart rate and negative symptoms. Significant inverse relationships were also found between HRV measures (mean and standard deviation) and negative symptoms [40,48]. Inclusion of BMI in models, however, nullified associations between mean HRV and negative symptoms in 1 study [40].

Finally, Cho and colleagues [43] found that various parameters indicative of heart rate circadian rhythms differed between people with bipolar disorder with higher and lower self-reported mood scores; subsequently, the average circadian rhythm of heart rate was identified as the most influential feature in mood state prediction models in type 1 but not type 2 bipolar disorder.

Discussion

Principal Findings

This review examined mental and physical health outcomes associated with passively collected physiological data in people with SMI in studies using consumer-grade wearable devices. We found 23 eligible papers reporting on 12 different studies, including data from over 500 participants with SMI, predominantly from high-income countries. Most of the selected studies collected physical activity data, followed by sleep and circadian rhythm data; a few studies used smartwatches to collect heart rate data.

The focus on mental health outcomes dominated the literature reviewed. There was a distinct evidence gap in terms of using passively collected wearables data to build a picture of physical health among people with SMI and to explore relationships with physical health indicators and outcomes such as blood pressure, BMI, and cardiorespiratory fitness. This presents a “missed opportunity” so far in the field, given that such technologies are typically designed and focused on physical health metrics and it is the heightened risk of physical diseases (rather than psychiatric relapse) that accounts for the majority of premature mortality in SMI populations [16]. Indeed, most eligible papers were from longitudinal cohort studies focused on relapse prevention. Although consumer-grade wearable devices have previously been used as physical health interventions among people with SMI [56], analyses of passively collected data relevant to profiling physical health have not necessarily been published. We found just 1 eligible study that explicitly addressed physical health and tracked participants for just 1 week [50]. Although relapse prevention is unquestionably an important goal, making better use of these unobtrusive and widely used devices to improve the physical health monitoring of people with SMI has been an underexplored avenue for addressing the key health inequalities that affect this population.

This review did find some evidence of digital markers indicating relationships between patterns of physiological metrics and psychiatric states or symptoms, largely in the manner expected: Lower levels of activity, higher and more variable heart rates, lower and more variable HRV, and later and irregular sleep onset times were associated with psychiatric diagnoses or poorer symptoms in some analyses. However, the heterogeneity in methods—including sampling, devices, measures, and statistical approaches—presents a complex picture when interpreting findings. Although we can conclude, on the basis of this review, that certain physiological metrics measurable by commercial devices likely have value for monitoring health, these are not necessarily always straightforward linear relationships; more evidence is needed before we can make conclusive statements about predictive utility in the context of individual psychiatric symptoms or diagnoses.

Implications for Future Digital Phenotyping Research

As others examining digital phenotyping more broadly have observed [22], studies used a wide variety of variables (or features) and combinations derived from different devices as predictors. One barrier to combining data sets and synthesizing findings on a greater scale may be that there is a lack of standards pertaining to research using wearable devices, including smartphones. Currently, for example, there is no consensus regarding how concepts such as “activity” should be measured in the context of digital phenotyping [31]. This means that different studies use different variables (eg, steps, walking time, or stillness) and different definitions of variables between studies. A degree of this is arguably to be expected: Different symptoms may require measurement in different conditions, and digital phenotyping in psychiatry is still in an “exploratory” phase. Nonetheless, it could preclude the types of evidence syntheses and meta-analyses required to advance the field. Other areas that may benefit from greater standardization either in study design or reporting include trial preregistration [57];

XSL•FO
RenderX

greater harmonization of data formats; and providing adequate descriptions of data, devices, and software (eg, versions and operating systems).

Nonetheless, despite the heterogeneity of studies, we were able to extract some useful general observations. We observed that some authors uncovered digital markers when incorporating more fine-grained temporal markers (eg, sleep onset time, daytime steps) into analyses [35,37]. Indeed, this would appear consistent with how symptoms can present in people with mental illnesses, such as experiencing morning fatigue or excessive nocturnal activity. It is thus possible that standard daily measures, such as daily steps or sleep duration, may be suitable for mass markets interested in wellness but overly coarse to enable the types of pattern detection crucial for research and clinical purposes. Collecting raw, unprocessed data may be optimal for retrospectively pooling data sets and creating sufficiently large sample sizes to allow novel analytical methods to be applied in future; however, this may not always be available for commercial devices. On this basis, we recommend future research use at least some form of epoch data (and other time or seasonality-related data) wherever available.

Furthermore, considering the trend for multimodal, data-driven approaches, the value of individual passively collected physiological data items may be best understood and maximized in the context of other variables—both within and between individuals. Considering patterns within individuals to understand routines and instability or anomalies in such patterns over time was a commonly tested approach among the selected studies [33,46]. This is consistent with the notion of individuals having individualized “relapse signatures” that precede relapse events [58]. Thus, future research should exploit the advantages of continuous monitoring offered by wearables and consider using methods and measures that attend to variability and not just symptom thresholds. This mirrors the findings of a recent review examining digital phenotyping in people with depression, which found associations between symptom severity and variability in sleep, affect, and psychomotor aspects of depression as captured by digital technologies [59].

We also found several papers using machine learning approaches to yield useful insights from complex, high-resolution data. Although we had to exclude some interesting machine learning papers included by other reviews [60] for lack of detail about features derived from passively collected physiological data, this general approach seems promising and an opportunity to build personalized models. Furthermore, although we focused on passively collected data in this review, actively collected, self-reported symptom data also clearly have value. Combining active and passive data collection may offer ways to combat disengagement and reduce missing data, which are well-recognized problems in digital psychiatry [61,62].

Although feasibility and acceptability outcomes were out of scope for this review, we note these are essential prerequisites for digital health interventions involving wearables. As with any digital intervention, care must be taken to ensure benefits outweigh potential harms. Study designs that give due attention to symptom monitoring and reactivity to digital methodologies may offer one way of guarding against unintended health effects. Although exacerbation of paranoia symptoms among people with schizophrenia has been one notable concern, studies of digital health interventions reporting on such outcomes have not yet found this to be a significant issue [20]. Specifically regarding the use of commercial devices, we also note potential challenges relating to data governance, privacy, and digital equity. Indeed, previous mental health data science initiatives have noted the need for transparent governance arrangements and sustained engagement of patients in research, a sentiment that we also echo [63]. We summarize our recommendations for future research using physiological data from consumer-grade wearables in Table 6.

XSL•FO
RenderX

Table 6. Recommendations for future research using physiological data from consumer-grade wearables in digital psychiatry.

Domain	Recommendations
Research topics	• Investigate the feasibility and acceptability of physical health monitoring in SMIa using passive data from consumer-grade wearables • Investigate the utility of passive data from consumer-grade wearables for physical health monitoring purposes in SMI and whether this mirrors relationships in other patient populations • Investigate relationships between heart rate data from consumer-grade wearables and mental health outcomes in people with SMI
Research methods	• Collect and use raw, unprocessed data wherever possible • Use at least some form of epoch data wherever available • Consider including measures of variability between and within individuals • Consider machine learning approaches to leverage multimodal wearable data and explore the use of personalized prediction models • Consider combining active and passive data collection to combat disengagement and reduce missing data • Consider whether consumer-grade or research-grade devices are the most suitable design choice for the study
Standardized reporting	• Include descriptions of devices, operating systems, and software versions, where available • Include definitions of activity (eg, total activity, walking) and other key outcome variables • Include adequate descriptions of sample characteristics including diagnosis and symptom severity • Describe results by diagnosis or provide justification for pooling results
Responsible research practices	• Encourage trial preregistration • Address inequalities in evidence resulting from under-representation of data from low and middle-income countries • Consider including measures to capture reactivity to digital methodologies • Consider whether raw data could be stored and made available for future research, subject to suitable ethics and governance arrangements • Involve patients and the public in research design to improve the relevance, transparency, and acceptability of research

[a]SMI: severe mental illness.

Limitations

This review was limited to consumer-grade wearables and physiological variables; thus, we excluded some well-cited studies using actigraphy, research-grade devices, and other passively sensed device-based measures (eg, GPS, call logs) to detect symptoms and relapse in people with SMI (eg, [64]). The decision to opt for a narrower focus was based on our interest in scalability of devices in routine clinical practice (hence, examining consumer-grade devices) and physical health promotion (hence, physiological sensing), offering a novel viewpoint. Our findings should be viewed in this context, acknowledging that consumer-grade wearables may be less accurate than research-grade devices; thus, the nature of the associations observed do not represent the full picture.

The studies that were included had some methodological limitations. In addition to the heterogeneity of passive data measures used, several studies were relatively small-scale or short in duration [48-50]. High levels of attrition were common, and monitoring duration varied. The majority of participants included in passive data analyses were Android phone users, and all except 1 study [44] recruited participants from high-income countries. Thus, sampling bias is potentially an issue. Similar problems have been noted by authors of previous reviews [25,60,65], and, based on our own findings, we join their calls for addressing evidence inequalities, greater optimization of methods, and standardized reporting. Caution should be exercised when generalizing results, especially given that, in several cases, multiple papers reported outcomes from overlapping samples. Although we tried to delineate outcomes within particular diagnoses and subtypes, this was not always possible where evidence was scarce or studies pooled results for people with SMI. Finally, although a thorough examination was beyond the scope of this paper, we recognize that a lack of common definitions for key measures such as relapse can be problematic [66] and could have affected the results.

Conclusions

This review shows that consumer-grade wearables are capable of detecting at least some digital markers indicative of psychiatric symptoms or mental health status among people with SMI, but more evidence is needed to demonstrate clinical utility in the context of particular diagnoses. Furthermore, our review identified a paucity of research examining the use of consumer-grade devices for physical health outcomes in people with SMI. Given that physical health is both the primary concern of such technologies and the leading cause of mortality in SMI, this represents a missed opportunity and further suggests this underserved population may be excluded from potential physical health improvements afforded by such devices. To advance this field, researchers should consider choice of predictors (features) and outcomes carefully, use temporal markers, and work toward agreeing on common measures to aid comparability and meta-analyses. Furthermore, those conducting future studies involving wearables should consider opportunities for physical health monitoring and promotion.

Abstract

Background: Digital mental health interventions (DMHIs) to monitor and improve the health of people with psychosis or bipolar disorder show promise; however, user engagement is variable, and integrated clinical use is low.

Objective: This prospectively registered systematic review examined barriers and facilitators of clinician and patient engagement with DMHIs, to inform implementation within real-world settings.

Methods: A systematic search of 7 databases identified empirical studies reporting qualitative or quantitative data about factors affecting staff or patient engagement with DMHIs aiming to monitor or improve the mental or physical health of people with psychosis or bipolar disorder. The Consolidated Framework for Implementation Research was used to synthesize data on barriers and facilitators, following a best-fit framework synthesis approach.

Results: The review included 175 papers (150 studies; 11,446 participants) describing randomized controlled trials; surveys; qualitative interviews; and usability, cohort, and case studies. Samples included people with schizophrenia spectrum psychosis (98/150, 65.3% of studies), bipolar disorder (62/150, 41.3% of studies), and clinicians (26/150, 17.3% of studies). Key facilitators were a strong recognition of DMHIs' relative advantages, a clear link between intervention focus and specific patient needs, a simple, low-effort digital interface, human-supported delivery, and device provision where needed. Although staff thought patients would lose, damage, or sell devices, reviewed studies found only 11% device loss. Barriers included intervention complexity, perceived risks, user motivation, discomfort with self-reflection, digital poverty, symptoms of psychosis, poor compatibility with existing clinical workflows, staff and patient fears that DMHIs would replace traditional face-to-face care, infrastructure limitations, and limited financial support for delivery.

Conclusions: Identified barriers and facilitators highlight key considerations for DMHI development and implementation. As to broader implications, sustainable business models are needed to ensure that evidence-based DMHIs are maintained and deployed.

Introduction

Background

The costs and burdens of schizophrenia spectrum psychosis and bipolar disorder are huge and often neglected in research [1,2]. Digital mental health interventions (DMHIs) can help people with psychosis or bipolar disorder monitor, manage, and improve their symptoms and health [3-6]. Although there is promising evidence of feasibility, acceptability, and efficacy [7-9], and widespread expectations that DMHIs will become core to health care [10], user uptake and engagement are highly variable [11], and integrated clinical use is low [12]. The challenges of implementing DMHIs in health care are well established; attempts to implement well-evidenced DMHIs for common mental health problems in the United States and United Kingdom health services have frequently failed due to lack of patient and provider engagement and difficulty integrating DMHIs into clinical care [13]. For example, while randomized controlled trials (RCTs) of computerized cognitive behavior therapy (cCBT) for depression have reported relatively high engagement (47% of participants completing all cCBT sessions [14]), pragmatic trials delivering cCBT in real-world settings report much lower engagement (16%-18% of participants completing all sessions; most participants completing 1 session only) [15]. Implementing DMHIs for people with psychosis or bipolar disorder, within secondary care mental health services (eg, community mental health teams), presents additional challenges (eg, high staff caseloads and reactive care in response to increased risk or crisis), which have been examined in this review.

Implementation science acknowledges that intervention effectiveness cannot guarantee uptake in services; uptake depends largely on contextual barriers and facilitators [16]. Examining such contextual factors is therefore crucial to improving uptake in real-world settings, allowing tailoring of interventions to maximize engagement, and informing development and testing of implementation strategies. Barriers and facilitators of engagement with DMHIs for common mental health problems (eg, depression or anxiety) were examined relatively recently [11], but the last systematic review of factors affecting DMHI implementation in samples with psychosis or bipolar disorder was 5 years ago [17]. This review provides a timely update on this rapidly developing literature by examining barriers and facilitators of patient and staff engagement with DMHIs for this group.

Using a best-fit framework synthesis approach [18,19], the Consolidated Framework for Implementation Research (CFIR) [20] guided this analysis, enabling consideration of user engagement barriers and facilitators in the context of the complex, multilevel systems within and surrounding health care [21]. In supplementary analyses, we also examined safety reporting within reviewed studies to explore whether perceived harms may be additional barriers to DMHI uptake and to further explore recent findings on safety reporting quality [22,23].

Objective

In summary, this review examines evidence from qualitative and quantitative studies regarding the barriers and facilitators of patient and staff engagement with DMHIs for psychosis or bipolar disorder. By synthesizing this information using CFIR, this review presents important findings about how to maximize engagement with such DMHIs, and ideal conditions for DMHI implementation in secondary mental health services.

Methods

Design

This systematic review follows PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses; see Multimedia Appendix 1 for PRISMA checklist) guidance [24], with eligibility criteria developed according to the PICOS (participants, interventions, comparators, outcomes, study design) framework. The review was registered with PROSPERO (main review: CRD42021282871; safety review: CRD42022306123).

Search Strategy and Selection Criteria

We conducted a PRISMA-compliant search of 7 databases using search terms relating to psychosis and bipolar disorder, DMHIs, and barriers, facilitators or implementation (see search terms and database list in Multimedia Appendix 2). Searches were restricted to peer-reviewed articles reporting on studies with human participants, published in English between January 2010 and October 2021. By restricting the search in this way, we were able to capture the period between the first studies of digital mental health tools being conducted (consistent with previous reviews [11,25]) and the COVID-19 pandemic. The search end date (1.5 years after the worldwide COVID-19 restrictions peaked [26]), allows for the lag from data collection to publication. The search retrieved very few papers reporting data gathered during or after the pandemic, suggesting this was a suitable watershed date. A future systematic review will examine studies from October 2021 onward.

Author EE combined, deduplicated, and screened the titles and abstracts of the search results; author AP independently screened a random selection (10%). Full-text of the remaining articles were independently screened against PICOS inclusion and exclusion criteria by authors EE and AP. Studies included and excluded by each researcher were compared, disagreements were resolved by consensus, and final reasons for all exclusions were recorded. Full inclusion and exclusion criteria are provided in Multimedia Appendix 2. In summary, the review included all published studies reporting qualitative or quantitative data on hypothetical or actual barriers or facilitators of patient or staff engagement with a DMHI aiming to monitor or improve the mental or physical health of adults with a bipolar or

XSL•FO
RenderX

schizophrenia spectrum diagnosis using a digital method (eg, smartphone app, SMS text messaging, website, or wearable).

Data Extraction

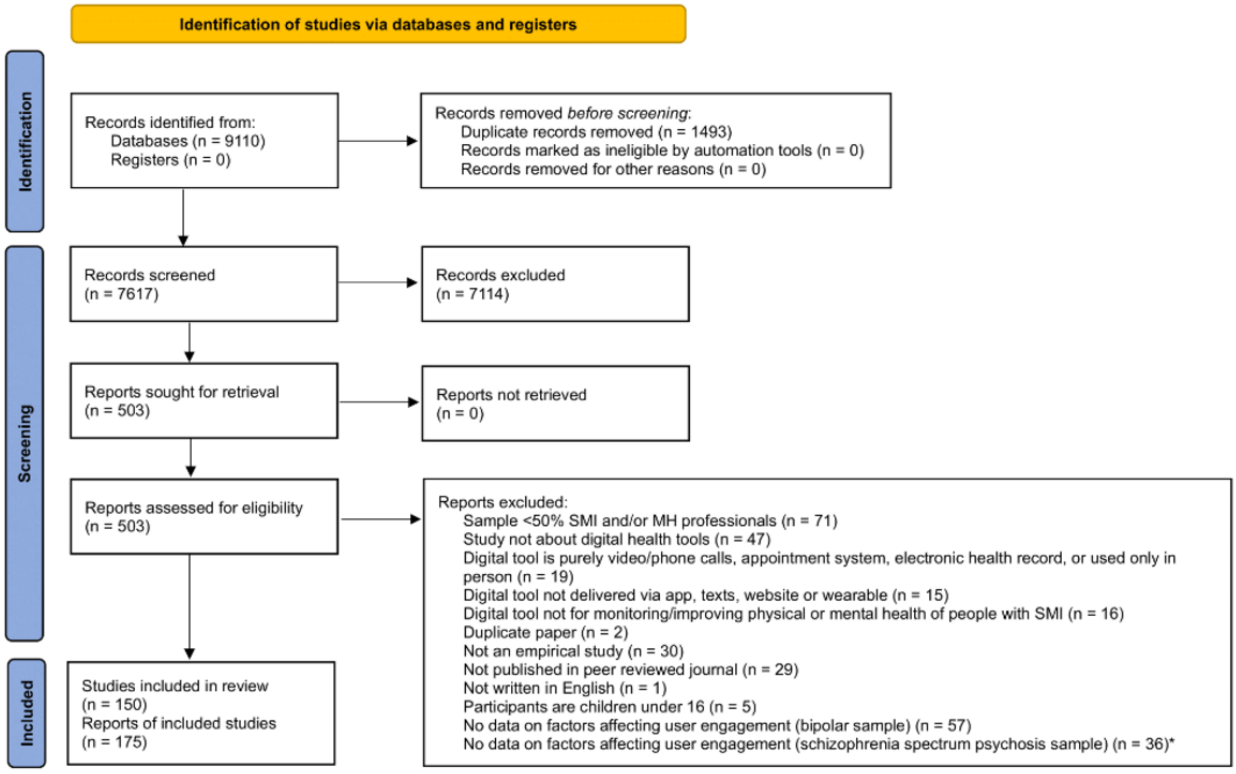
A data extraction form was used to extract relevant data: study metadata, design, DMHI details, and sample characteristics. Quantitative findings relating to barriers and facilitators of user engagement were extracted and imported into NVivo software (Lumivero) [27], as were the full results and discussion sections of qualitative studies. A second researcher checked all the extracted data. Study quality was assessed using the Mixed Methods Appraisal Tool [28]. In addition, from the main paper text and supplements of studies that tested the actual use of a DMHI, we extracted data on how adverse events (AEs) were monitored, classified (relatedness or severity), analyzed, reported, and discussed, and whether reporting followed the CONSORT (Consolidated Standards of Reporting Trials) harms checklist [29]. Given that the reporting of formal AE data is typically poor for DMHIs [22,23], we also extracted information about incidents that might be classifiable as AEs but were not described as such by the authors.

Data Analysis

Study characteristics, quality checks, and AE information were tabulated and summarized descriptively. A best-fit framework synthesis approach [18,19] was used to synthesize qualitative and quantitative data from all included studies to address the following research question: What are the barriers and facilitators of service user or staff engagement with DMHIs for people with psychosis or bipolar disorder? Generally, within a best-fit framework approach, relevant published frameworks, models, or theories are systematically identified, and key elements of these are integrated into an a priori coding framework for use in the review [19]. Primary studies are then deductively coded into the a priori coding framework, with data not fitting within the framework coded inductively. In this review, we were able to use a single existing implementation framework, the CFIR, as the a priori coding framework [20,30], followed by inductive coding. CFIR was developed using a comprehensive systematic review of the implementation science literature [20,30]. It is a meta-theoretical framework incorporating constructs from a wide range of existing implementation theories into a single comprehensive framework and is used by researchers and practitioners to identify barriers and facilitators of successful implementation and tailor their strategies accordingly. Thus, it is an appropriate choice of framework to guide the systematic evaluation of potential barriers and facilitators of user engagement with DMHIs in this review. CFIR has 5 major domains as provided in Textbox 1.

Textbox 1. Major domains of Consolidated Framework for Implementation Research.

- Innovation characteristics: features of the innovation or intervention being implemented, including its complexity, adaptability, design, and evidence base. For example, a smartphone app for monitoring symptoms of psychosis.
- Outer setting: the external context in which the organization is situated, including economic, political, legal, and social factors that may influence implementation. For example, a particular country or state.
- Inner setting: features of the organization in which the intervention is being implemented, including its culture, structure, resources, and readiness for change. For example, a secondary care mental health service.
- Individuals: characteristics of individuals involved in the implementation process, such as their knowledge, beliefs, and motivation. For example, patients with psychosis or bipolar disorder, and mental health staff.
- Implementation process: the implementation process itself, including planning, engaging, executing, and reflecting.



Results

Search Results

Our search retrieved 7617 records after deduplication (Figure 1); 503 underwent full-text review, of which 175 were included based on inclusion and exclusion criteria. A list of the excluded studies and their reasons for exclusion are provided in Table S1 in Multimedia Appendix 2. Studies that did not contain data on barriers or facilitators of DMHIs were excluded (psychosis samples n=36; bipolar samples n=57). However, to supplement findings regarding the potential harms of DMHIs, we examined AE reporting in the 36 studies of psychosis samples.
